The rise of Quakerism. There were meetings of the kind later associated with the Quakers before there was a group by that name. Small groups of Seekers gathered during the Puritan Revolution against Charles I to wait upon the Lord because they despaired of spiritual help either from the established Anglican Church or the existing Puritan bodies—Presbyterians, Congregationalists, and Baptists—through which most of them had already passed. To these Seekers came a band of preachers, mostly from the north of England, proclaiming the powers of direct contact with God. Fox and James Nayler were perhaps the most eminent of these, but Edward Burrough, William Dewsbury, and Richard Farnworth also were active. The cradle of the movement was Swarthmore (Swarthmoor) Hall in north-western Lancashire, which after 1652 became the centre of an evangelistic campaign by traveling ministers. Within

Persecution of Quakers

a decade perhaps 20,000 to 60,000 had been converted from all social classes except the aristocracy and totally unskilled labourers. Heaviest concentrations were in the north, Bristol, the counties around London, and London itself. Traveling Friends and Cromwellian soldiers brought Quakerism to the new English settlements in Ireland; Wales and especially Scotland were less affected.

The Puritan clergy, in England and New England, greeted the rise of Quakerism with the fury that an old left often reserves for a new. Friends' religious style was impulsive and nonideological; Quakers seemed to ignore the orthodox views of the Puritans and pervert their heterodox ones. Though most Friends had passed through varieties of Puritanism, they carried the emphasis on a direct relationship between the believer and God far beyond what Puritans deemed tolerable. The Restoration of Charles II in 1660 was only a change of persecutors for the Quakers, with their former tormentors now sharing some of their sufferings. From the Quaker Act of 1662 until the de facto toleration of James II in 1686 (*de jure* toleration came in the Toleration Act of 1689), Friends were hounded by penal laws for not swearing oaths, for not going to the services of the Church of England, for going to Quaker meetings, and for refusing tithes. Some 15,000 suffered under these laws, and almost 500 died in or shortly after being in prison, but they continued to grow in numbers until the turn of the century.

At the same time Quakers were converting and peopling America. In 1656 Quaker women preachers began work in Maryland and in the Massachusetts Bay Colony. The magistrates of Boston savagely persecuted the visitors and in 1659 and 1661 put four of them to death. Despite this, Quakerism took root in Massachusetts and flourished in Rhode Island, where Friends for a long time were in the majority. There were also many Friends in New Jersey, where English Quakers early secured a patent for settlement, and in North Carolina. Yearly meetings were established for New England (1661), Maryland (1672), Virginia (1673), Philadelphia (1681), New York (1695), and North Carolina (1698). The most famous Quaker colony was Pennsylvania, for which Charles II issued a charter to William Penn in 1681. Penn's "Holy Experiment" tested how far a state could be governed consistently with Friends' principles, especially pacifism and religious toleration. Toleration would allow colonists of other faiths to settle freely and perhaps become a majority; consistent pacifism would leave the colony without military defenses against enemies who might have been provoked by the other settlers. Penn, entangled in English affairs, spent little time in Pennsylvania and showed erratic judgment in selecting his non-Quaker deputies, who were almost always at odds with the Quaker-dominated legislature. Penn also went bankrupt through mismanagement; but the Quaker influence in Pennsylvania politics remained paramount until 1756, when legislators who were Friends could no longer find a saving formula allowing them to vote support for military operations against the French and Indians fighting settlers in western Pennsylvania. Voltaire's description of Penn's agreements with the Indians as the only treaties never sworn to and never violated was exaggerated; but Friends' relations with the Indians were more peaceful than those of other settlers.

The age of quietism. The achievement of religious toleration in the 1690s coincided with a quietist phase in Quakerism that lasted until the 19th century. Quietism is endemic within Quakerism and emerges whenever trust in the Inward Light is stressed to the exclusion of everything else. It suits a time when little outward activity is demanded and when the peculiar traditions of a group seem particularly worth emphasizing. In the 18th century Friends had gained most of their political objectives. Their special language and dress, originally justified as a witness for honesty, simplicity, and equality, became password and uniform of a group now 75 to 90 percent composed of second- and third-generation Quakers. Strict enforcement of rules prohibiting marriage without parents' consent or to nonmembers led to the disownment, according to one estimate, of a third of the English Friends who got married in the latter half of the 18th century. More were disowned

than converted, and since most members were the children of members, it is not surprising that Friends eventually came to recognize a category of "birthright" membership, which seemed to relax the expectation of conversion.

Seemingly self-absorbed in other ways, Friends in the age of quietism intensified their social concerns. English Friends were active in the campaign to end the slave trade, and American Friends, urged on by John Woolman and others, voluntarily emancipated all their own slaves between 1758 and 1800. Meetings, though slow to adopt this concern, pursued it thoroughly; in Rhode Island Stephen Hopkins, who was governor nine times, was disowned because he would not free his one slave.

The impact of evangelicalism. Cooperation with other Christians in the antislavery cause gradually led Friends out of their secluded religious life. They also came closer to other Protestants through the evangelical movement originally associated with John and Charles Wesley. Evangelical Friends were concerned with emphasizing the inerrancy and uniqueness of the Bible, the incarnation and atonement of Christ, and other characteristic Protestant doctrines which, although seldom denied outright by Friends, had tended to be subordinated to the quietistic emphasis on the Inward Light. In the early 19th century most leading English Friends were sympathetic to evangelical ideas, although they did not lose their unity with more traditional-minded Friends.

In the United States unity proved more difficult. Friends had gone west—from Virginia and North Carolina because of difficulties over slavery, but also from Pennsylvania. As new yearly meetings were formed—Ohio (1812), Indiana (1821), Iowa (1863), Kansas (1872), Oregon (1893), California (1895), and Nebraska (1908), among others—ties with the London Yearly Meeting, the "mother" meeting, became weaker, and no American yearly meeting had a predominant position. Leaders of the Philadelphia Yearly Meeting, mostly rich merchants with strong ties to England, were sympathetic to evangelicalism; but many poorer country Friends left the meeting, no longer feeling a unity with the beliefs of the Philadelphia ministers and elders or with the way they exercised their authority. Elias Hicks (1748–1830), whose name was applied to these separatists, placed extreme emphasis on the Inward Light; he wrote that it might be a good thing if God withdrew the Bible, since he could inspire worshipers to write new scriptures that would probably be better than the originals. Since the various American yearly meetings corresponded with one another, the Hicksite separation spread to other yearly meetings that had to decide to which portion of the Philadelphia Yearly Meeting to write. A pastoral visit to the United States (1837–40) by the leading English evangelical Friend, Joseph John Gurney (one of the few systematic theologians ever produced in the Society of Friends), led to a further separation when the evangelical or "Gurneyite" New England Yearly Meeting disowned John Wilbur, an orthodox quietist Friend.

Schism is often a sign of religious vitality, and so it proved then. Whether Hicksite, Wilburite, or Gurneyite, all branches of Quakerism began to show vigour unknown in their days of torpid unity. With more vital preaching, many converts not devoted to the inherited peculiarities of Quaker tradition joined Friends; to them it seemed more important to assure a saving ministry than to preserve the traditional mode of worship. There thus grew up, especially in the Midwest and Far West, "pastoral meetings" in which a paid minister assumed the functions of delivering a sermon and exercising pastoral care of members. Such meetings often called themselves "Friends' Churches"; congregational singing was a part of the service, which might have only a few moments of silence, and baptismal and marriage ceremonies were introduced. In doctrine, worship, and polity they were not unlike Congregational churches, though they remained faithful to Friends' social testimonies. Even in England, where such innovations were not introduced, Friends, under the influence of the evangelical revival, discontinued disownment for irregular marriages and curtailed the powers of elders and overseers, which had been a profoundly conservative force.

The 20th century. Friends in 1900 were divided into

Evangelical Friends

William Penn's "Holy Experiment"

Pastoral meetings

three groups. Yearly meetings of evangelical, or "orthodox," Friends were in fellowship with one another and with the London and Dublin yearly meetings. In the United States these Gurneyite meetings in 1902 formed the Five Years' Meeting (now the Friends United Meeting). The "conservative" American yearly meetings, in fellowship with one another, maintained traditional Quaker customs and mode of worship. The Hicksite yearly meetings, which formed the Friends General Conference in 1902, remained the most open to modern thought. During the century these divisions have been much softened. Theological distinctions have receded in importance, and the habit of cooperation in such agencies as the American Friends Service Committee has drawn Friends together.

The 20th century has also seen the extension of Quakerism to Africa and continental Europe. Quakerism took root in the Netherlands in the 17th century but died out in the mid-19th, as did groups in Congénies, France, and Bad Pyrmont, Germany. Quaker relief work in World War I and its aftermath produced new yearly meetings in Germany, The Netherlands, France, Sweden, and Switzerland, but numbers remain small.

The influence of Quakers. Quaker customs and the exclusion of Friends from many professions in England concentrated their secular achievements. Plainness meant that painting, music, and the theatre were proscribed. For a century trust in the Inward Light inhibited the foundation of colleges (though in the 19th century American Friends founded colleges like Earlham, Haverford, and Swarthmore; and individual Friends founded Bryn Mawr College, Cornell University, and Johns Hopkins University). Friends' schools emphasized science; the chemist John Dalton, the geneticist Francis Galton, the anthropologist E.B. Tylor, the astronomer Arthur Eddington, and Joseph Lister, discoverer of antiseptics, were Friends. In trade Friends were trusted and got customers; they trusted one another and extended credit; thus the many successful Quaker firms and banks, of which Barclay's and Lloyd's are the best known. Friends also pioneered in inventions, developing the puddling process for iron and the safety match and promoting the first English railroad line.

Disdaining formal education and a clerical intelligentsia, Friends, not surprisingly, often failed theologically (that is, could not solve some of the intellectual problems of their faith). But they would agree with the 19th-century Danish religious philosopher Søren Kierkegaard that "the highest of all is not to understand the highest but to act upon it."

TEACHINGS

The "public testimonies" of Friends from the very beginning included the plain speech and dress and refusal of tithes, oaths, and worldly courtesies. To these was added in a few years an explicit renunciation of participation in war; within the next century bankruptcy, marriage out of meeting, smuggling, and dealing in or owning slaves also became practices for which an unrepentant Friend would be disowned. These latter, especially those relating to slavery, became matters for discipline because a comparative minority of Friends persuaded the rest that they were inconsistent with Friends' principles.

But not all social concerns were corporate in this sense or were enforced by sanctions. Friends' relief work, for example, has usually arisen from an individual response to suffering, often as the result of war. From the time of the American Revolution Quakers have been active in ministering to refugees and victims of famine—so much so that the entire Society of Friends is sometimes taken for a philanthropic organization; yet this work, recognized in 1947 by the award of the Nobel Peace Prize to the American Friends Service Committee and the (British) Friends Service Council, has mobilized many non-Quakers and thus exemplifies the interaction between the Quaker conscience and the wider world.

Yet the Society of Friends is grounded in the experience of God, out of which philanthropic activities may flow. There have always been Friends whose concerns went well beyond what meetings were willing to adopt. Most Friends were not abolitionists before the American Civil War; they probably did not approve of the Underground Railroad

nor share the early feminist views of Lucretia Mott and Susan B. Anthony. (Most of the early suffragist leaders in America were Quakers.) The two American presidents of Quaker background were both Republicans: Herbert Hoover and Richard M. Nixon. Often the issue has been the relationship between private witness and public policy. Some Quaker pacifists make an absolute personal stand against war (for example, by refusing to register for selective service and thus forfeiting conscientious objectors' status); others are more willing to sacrifice absolute purity by working for an alleviation of international tensions even at the cost of less rigorous application of their principles.

WORSHIP AND ORGANIZATION

The Inward Light. Trust in the Inward Light is the distinctive theme of Quakerism. The Light should not be confused with conscience or reason; it is rather that of God in everyone, which allows human beings an immediate sense of God's presence and will for them. It thus informs conscience and redirects reason. The experience of hearkening to this inner Guide is mystical, but corporate and practical. Meetings to worship God and await his word (always open to anyone who wishes to come) are essential to Quaker faith and practice. Although the inward Seed can work in a solitary person, Friends do not meditate like monks, isolated in their cells. It is in the pregnant silence of the meeting of true waiters and worshipers that the Spirit speaks. Sometimes the meeting is too dull or worldly for any message to be heard, and sometimes there are altogether silent meetings. Although these are spiritually beneficial to the participants, ideally someone has reached a new understanding that demands to be proclaimed. He or she—for Friends have always given women equality in worship—speaks or prays and thus ministers to the meeting, which weighs this "testimony" by its own experiences of God. Friends historically have rejected a formal or salaried clergy as a "hiring ministry." If God can provide his own living testimony, the Bible and the learning necessary to read it can take a subordinate place, and creeds and outward sacraments can be dispensed with altogether. But despite their emphasis on silent waiting and their distrust of "creaturely" activity, Friends are no more habituated to passive than to solitary meditation. Often the "opening" of the Inward Light is a "concern" for the sufferings of others and a mandate laid upon the conscience to take action to alleviate that suffering. Such concerns typically are laid before a meeting and thoroughly considered; there must be a consensus for any corporate action. But slow as such action sometimes is, Friends have taken the lead in opposing slavery, brutality in prisons and insane asylums, oppression of women, militarism, and war.

Polity. Insofar as George Fox was the founder of Quakerism, he was so chiefly because of the system of meetings for church business that he established in the years immediately after 1667, which essentially stands today. Most important is the monthly meeting, which considers all applications for membership, in some localities manages Friends' properties, and acts on members' concerns. Generally, in the United States each congregation has a monthly meeting; in England and in some parts of the United States several meetings for worship combine in monthly meeting. Several monthly meetings form quarterly meetings, which are combined in yearly meetings.

This array is less hierarchical than it sounds. Any Friends can attend any meeting, which tries to remain open to the concerns or the service they can perform (much in the spirit of a meeting for worship). There is an official, the clerk, but the responsibility of the clerk is not to preside in a parliamentary manner but rather to feel for a "sense of the meeting," which draws together the thinking of the meeting to the point of action.

Though Friends have no ordination, they have always given a special place to Recorded Ministers (or Public Friends). Recorded Ministers are those whose testimony in local meetings has been officially recognized; they are free to "travel in the ministry" by visiting other meetings, should they be led to do so. Pastoral meetings maintain their Recorded Ministers, who also do much of the work

Clergy and sacraments

Recorded Ministers

of seeing to the relief of the poor, care of properties, and discipline of erring members. Ministers have usually had their own meetings together, and in most yearly meetings executive responsibility had been taken by a meeting like the Meeting for Sufferings in London (these are also called Representative meetings or committees or Permanent boards). London Meeting for Sufferings in the 17th century served as a political pressure group, lobbying Parliament for relief from persecution, coordinating legal strategy, and using the press for public appeals; in the 19th century they broadened their concerns to respond to sufferings everywhere.

Quakerism and world Christianity. The cause of schisms in the past—the tension between entire reliance on the Inward Light and the profession of orthodox Christian doctrines—remains unresolved. As it has divided Friends among themselves, it has also tended to separate them from other Christians. The London Yearly Meeting in 1940 declined to join the World Council of Churches out of uneasiness with its creedal basis, though some U.S. groups of Friends sent delegates to the first meeting of the council in 1948. Looked at in the context of Christendom as a whole, Friends offer a distinctive opportunity for spontaneity of worship, fellowship in mysticism, and proving mystical insight in labour for a suffering world. Many alienated from institutional Christianity have found this combination attractive; they may well feel more comfortable identifying themselves as Friends than as Protestants or even as Christians. This may make it more difficult for Quakerism to be subsumed into a reunited Christian church; but the faith of most Friends has always been that of Schweitzer in *The Quest of the Historical Jesus*: as “we do the work of Christ we shall come to know who he is.” (R.T.V.)

Methodists

Methodism began in the 18th century as a religious society that wished to reform the Church of England from within; by force of circumstance it became separate from its parent body and took on the characteristics of an autonomous church.

HISTORY

Origins. John Wesley, the founder of Methodism, was born in 1703. After ordination in the Church of England, he was elected a Fellow of Lincoln College at Oxford in 1726. In the following year he left Oxford temporarily to act as curate to his father, the rector of Epworth. Back in Oxford, to which his younger brother Charles had now come, he found himself a member and soon the leader of a group of earnest students pledged to frequent attendance at Holy Communion, serious study of the Bible, and regular visitation of the filthy Oxford prisons. The members of this group received the sobriquet of Methodists.

In 1735 both John and Charles Wesley set out for Georgia to be pastors to the colonists and missionaries (it was hoped) to the Indians, at the invitation of the founder of the colony, James Edward Oglethorpe. They were unsuccessful in their pastoral work and did no missionary work. The brothers returned to England conscious of their lack of genuine Christian faith. They looked for help from members of the Church of the Brethren, who were staying in England for a while before joining Moravian settlements in the American colonies; among these Peter Böhler was especially important. On May 24, 1738, John Wesley's *Journal* narrates that he “felt” his “heart strangely warmed” and continues, “I felt I did trust in Christ, Christ alone, for salvation; and an assurance was given me that He had taken away *my* sins, even *mine*, and saved *me* from the law of sin and death.” Charles Wesley had reported a similar experience a few days previously.

Some months later John Wesley was invited by his friend George Whitefield, also an Anglican clergyman who had undergone a “conversion experience,” to come to the city of Bristol and help to preach to the colliers of Kingswood Chase, just outside the city, where human conditions were at their lowest. Wesley came and found himself, much against his will, preaching in the open air. This enterprise

was the beginning of the Methodist Revival. Whitefield and Wesley at first worked together but later separated on doctrinal grounds: Whitefield believed in double predestination; Wesley regarded this as an erroneous doctrine and insisted that the love of God was universal.

Under the leadership at first of Whitefield and afterward of Wesley the movement rapidly gained ground among those who felt themselves neglected by the Church of England. Wesley differed from contemporary Anglicans not in doctrines but in emphases: he claimed to have reinstated the biblical doctrines that a man may be assured of his salvation and that, by the power of the Holy Spirit, he is capable of attaining perfect love for God and his fellows in this life. Wesley's helpers included only a few ordained clergymen and notably his brother Charles, who wrote more than 6,000 hymns to express the message of the Revival. In spite of Wesley's wish that the Methodist Society would never leave the Church of England, relations with Anglicans were often strained.

In 1784, when there was a shortage of ordained ministers in America after the Revolution, the Bishop of London refused to ordain a Methodist for the United States. Wesley, acting in an emergency and on biblical principles that allow (as he thought) a presbyter to ordain, ordained Thomas Coke as superintendent and two others as presbyters. In the same year, by a Deed of Declaration, he appointed a Conference of 100 men to govern the Society of Methodists after his death.

The definite break with the Church of England came in 1795, four years after Wesley's death. After this, English Methodism, with vigorous outposts in Ireland, Scotland, and Wales, rapidly developed as a church. But in order not to perpetuate the split from the Church of England, it was reluctant at first to ordain with the laying on of hands. Its system centred in the annual Conference (at first of ministers only, later thrown open to laypeople), which controlled all its affairs. The country was divided into districts and the districts into circuits, or groups of congregations. The ministers were appointed to the circuits, and each circuit was led by a superintendent, though much power remained in the hands of the local trustees.

This tightly knit system enabled the Wesleyan Methodist Church to grow rapidly throughout the 19th century, at the end of which it counted 450,000 members. The growth was largest in the expanding industrial areas. There their faith enabled Methodist workers, men and women, to endure economic hardship, while at the same time working for the alleviation of poverty. Because their faith encouraged them to live simply, their economic status tended to rise, with the unintended result that Wesleyan Methodism became a middle-class church that was not immune to the excessive stress on the individual in material and spiritual matters that marked the Victorian age.

At the same time the autocratic habits of some ministers in authority, notably Jabez Bunting, an outstanding but sometimes ruthless leader, alienated many of the more ardent and democratic spirits, and there was a series of schisms. The Methodist New Connexion broke off in 1797, the Primitive Methodists in 1811, the Bible Christians in 1815, and the United Methodist Free Churches in 1857.

The smaller Methodist groups were in closer contact with the working classes than the Wesleys and provided the leadership in early trade unionism to an extent disproportionate to their size. The Wesleys were at first conservative in politics but in the second half of the 19th century identified themselves more and more with the liberalism of William Gladstone.

A movement to reunite the Methodist groups began about the turn of the century and reached success in two stages. In 1907 the Methodist New Connexion, the Bible Christians, and the United Methodist Free Churches joined to form the United Methodist Church; and in 1932 the Wesleyan Methodist Church, the Primitive Methodist Church, and the United Methodist Church came together to form the Methodist Church.

The Methodist Church has shared with the other English churches in the numerical decline that began about 1910. This decline, together with changes in modern life and thought, roused it out of its Victorian complacency and

Break with
the Church
of England

John
Wesley's
conversion
experience

filled it with a desire to express Wesley's original ideals in a contemporary form. It continued to plan new attempts at evangelism. Its concern for education, shown especially in the development of Kingswood School (Wesley's foundation) and other boarding schools, as well as in the training of Christian teachers at Westminster and Southlands colleges, has not abated. Its strong social interest has expanded from preoccupation with total abstinence to a wide range of national and international issues, especially those connected with race, poverty, and peace.

Ecumenical efforts

The Methodist Church involved itself in the ecumenical movement when it began in 1910. Thereafter the church shared in all negotiations for church union. Relations with the Church of England improved so much by the 1960s that a plan for the reunion of the two churches (in two stages) was approved in principle by both in 1965. The final form of the plan was approved by the Methodist Church with a very large majority in 1969, but the Church of England did not muster a large enough majority to bring the plan into effect. The same thing happened in 1972.

Proposals for a "Covenant for Visible Unity," to include the United Reformed Church and the Moravian Church as well as the Methodists and the Anglicans, were put to the churches in 1982; once again the Anglican vote fell short, while the other churches were in favour. Most Methodists were grievously disappointed, but many threw themselves into projects in their own neighbourhood intended to realize locally the unity that was not possible nationally. In these projects Anglicans, United Reformed Church people, and sometimes Baptists and Roman Catholics, are taking part.

As a founder member of the British Council of Churches and the World Council of Churches, the Methodist Church has shared fully in the activities of these councils and provided many leaders. Official discussion with Roman Catholics on national and world levels has revealed a surprising degree of agreement while promoting tolerance and understanding of previously contentious issues.

Ordination of women

The first woman was ordained to "The Ministry of Word and Sacraments" in 1974. This was the climax of many years of discussion and controversy. It indicated a growing appreciation of the place of women in the life of the church. The theological objections had been carefully considered and rejected before the final step was taken.

Methodism in America. Methodism was taken to America by immigrants from Ireland who had been converted by John Wesley. Wesley also sent preachers, and by far the most successful of these was Francis Asbury, a blacksmith, who arrived in 1771 and covered vast distances. He adapted Wesley's principles to the needs both of the settled communities and of the frontier. Wesley took the side of the English government at the time of the Revolution, but Asbury aligned himself with the new American republic. Wesley sent the men whom he had ordained as presbyters, with Thomas Coke as superintendent, to help Asbury. The Methodist Episcopal Church was constituted in 1784 and regarded itself as autonomous. Asbury and Coke allowed themselves to be called bishops.

The next 50 years saw a remarkable advance led by the circuit riders who preached to the frontiersmen in simple terms. The slavery issue split the Methodist Church into two: the Methodist Episcopal Church and the Methodist Episcopal Church, South (organized in 1845). After the Civil War both churches increased rapidly and became gradually assimilated to the general pattern of American Protestantism. When it was clear that the old issues no longer divided them, they began to move together. But it was not until 1939 that they came together to form The Methodist Church. The Methodist Protestant Church, a smaller group, joined in the same union.

The church in the South lost its black members before and during the Civil War. At the time of the union the Central Jurisdiction was formed for all the black members wherever they lived; it existed alongside the other jurisdictions that were determined by geography. The Central Jurisdiction was abolished in 1968; and black Methodists are now integrated in the church.

The Central Jurisdiction

The originally German-speaking Evangelical United Brethren Church, itself a union of the Church of the

United Brethren in Christ and the Evangelical Church, was united with The Methodist Church in 1968 to form the United Methodist Church. Women were given limited clergy rights in 1924 and were accepted for full ordination in 1956.

Methodism in Canada. Methodism was extended to Canada by preachers from the United States and later reinforced by British Methodists. In 1874 The Methodist Church of Canada became autonomous; it went on to negotiate a union with other Canadian nonepiscopal churches to form The United Church of Canada in 1925.

TEACHINGS

Methodism is marked by an acceptance of the doctrines of historic Christianity; by an emphasis on those doctrines that indicate the power of the Holy Spirit to confirm the faith of the believer and transform his personal life; by insistence that the heart of religion lies in personal relationship with God; by simplicity of worship; by the partnership of ordained ministers and laity in the worship and administration of the church; by a concern for the underprivileged and the betterment of social conditions; and (at least in its British form) by the formation of small groups for mutual encouragement and edification.

All Methodist churches profess allegiance to the Scriptures as the supreme guide to faith and practice. They welcome the findings of modern biblical scholarship (except for the fundamentalist groups to be found within them). They accept the historic creeds and hold themselves to be in the tradition of the Protestant Reformation. Arguments about the virgin birth and the physical resurrection of Jesus do not greatly concern Methodists; they allow for differences of conviction on these points within the historic faith. They emphasize the teaching about Christian perfection, interpreted as "perfect love," which is associated with John Wesley, who held that every Christian should aspire to this by the help of the Holy Spirit.

Methodist churches assert the value of infant baptism and the need to receive regularly the sacrament of the Lord's Supper, in which they believe Christ to be truly present, though they have no precise definition of the manner of his presence. They believe themselves to be integral parts of the one, holy, catholic, and apostolic church, and their ministers to be true ministers of Word and sacrament in the church of God.

WORSHIP AND ORGANIZATION

Patterns of service. Methodist worship everywhere is partly liturgical, partly spontaneous. John Wesley regularly used the Anglican *Book of Common Prayer* and adapted it for use in the United States. He also conducted services that included extemporaneous prayer. His custom was continued in Britain. In the 20th century Anglican Morning Prayer gradually dropped out of Methodism, but Anglican Holy Communion continued until the Liturgical Movement impelled all churches, Roman Catholic and Protestant alike, to revise their liturgies. The *Methodist Service Book* (1975), written in a modern language, offers much opportunity for congregational participation. The Sunday Service, or Holy Communion, restores the traditional fourfold pattern—the offering of bread and wine, the thanksgiving, the breaking of the bread, and the sharing of the elements. Non-liturgical services, which constitute the majority, tend to be stereotyped although they claim to be spontaneous. Far more services are conducted by lay preachers than by ordained ministers.

In American Methodism services are rarely conducted by laypeople. The Liturgical Movement affected the *Book of Worship* (1965), the *Ordinal* (1980), and the *United Methodist Hymnal*, subtitled *The Book of United Methodist Worship* (1988), which is arranged to eliminate all traces of sexism.

Hymns are important in all branches of Methodism. Those of Charles Wesley are still dominant in British Methodism, but they are mingled with many contemporary hymns as well as hymns from other traditions. In *Hymns and Psalms* (1983) certain changes were made in order to eliminate sexist overtones. American books contain fewer hymns by Wesley.

Lay participation

Polity. In the churches of the British tradition the annual Conference is the supreme authority for doctrine, order, and practice. All ministers have parity of status, but special functions are exercised by the president and secretary of the Conference, the chairmen of districts, the secretaries of divisions, and superintendents. District affairs are regulated by Synods, Circuits by Circuit Meetings, local Societies by Church Councils. The American tradition is episcopal; the bishops are elected by the Jurisdictional Conferences, which, like the General Conference, meet every four years. Each diocese has an annual Conference and is divided into District Conferences, each with its superintendent. The dioceses are combined into five Jurisdictions that cover the nation. The circuit system is not developed. A minister is ordained first deacon, then elder.

In the United States the African Methodist Episcopal Zion Church and the African Methodist Episcopal Church antedate the explosion of the slavery question; the Colored (now "Christian") Methodist Episcopal Church was founded as a result of it. All three are exclusively black but follow the doctrine and organization of the United Methodist Church.

There are minority Methodist churches in most European countries. Those in Italy and Portugal are of English origin, that in Germany is of mixed English and American origin; the rest are all derived from American Methodism, though they exhibit many similarities in spirituality to the English type.

Missions. Thomas Coke began the missionary activities of British Methodism by his eloquence and ceaseless travels. The first area where missions took root was the West Indies; then came Sierra Leone and southern Africa. The Gold Coast, French West Africa, and Nigeria received missionaries not much later, though the climate in many parts of Africa took a toll of missionary lives.

In India converts were very few until about 1880, when a mass movement swept many thousand low-caste Indians in the south into the Methodist and other churches. In China missionary work had a checkered career, though there were mass movements there also. The last missionary left China in 1949. In Australia the Methodist Church began in 1815 and, like the Methodist Church in South Africa, became independent before the end of the 19th century. The movement toward autonomy became a flood after World War II; only a few small churches remain under the control of the Overseas Division of the church. Most of the autonomous churches negotiate for united churches in their countries; and the Church of South India, including Anglicans, Methodists, Congregationalists, and Presbyterians, has been in existence since 1947, and the Church of North India since 1970.

American Methodists have been equally enthusiastic for missionary activity, and their greater resources have carried them over still larger areas of the Earth's surface. North India, Mexico, and most of the other countries of Latin America, Cuba, Korea, Japan, Taiwan, and many parts of Africa possess Methodist churches of the American tradition. The movement toward autonomy took place more slowly in these areas than in the British sphere of influence. The General Conference of the United Methodist Church makes plans for combining fraternal relations among them with their newly found independence.

World Methodism. The two Methodist traditions diverged considerably for most of the 19th century but toward its end began to converge again. Ecumenical Methodist (since 1951 World Methodist) Conferences have been held regularly since 1888. The World Methodist Council represents some 80 churches.

Methodism in the world church. In Britain the Methodist Church is the largest of the Free Churches; it is not a nonconformist church but stands between nonconformity and Anglicanism, with affinities to both. In the United States it is closely aligned with the other non-Anglican Protestant denominations. (R.E.D.)

Disciples of Christ

There are three major bodies of the Disciples of Christ, all of which stem from a common source.

The Churches of Christ emphasize rigorous adherence to the New Testament as the model for Christian faith, practice, and fellowship. They reject ecclesiastical institutions other than the congregation, practice a dynamic evangelism based on a literal view of the Bible, and remain aloof from interdenominational activities.

The Christian Church (Disciples of Christ) affirms a free and voluntary covenantal relationship binding members, congregations, regions, and general units in one ecclesiastical body committed to a mission of witness and service. Recognizing its status as a denomination, it acknowledges the right of "dissent in love" and engages fully in the ecumenical venture.

The congregations loosely related in the Undenominational Fellowship of Christian Churches and Churches of Christ refused to enter such a "Christian Church." They earlier had refused to follow the Churches of Christ in rejecting musical instruments in worship and missionary organizations as a matter of biblical principle; they later repudiated the openness of their fellow Disciples toward biblical criticism, theological liberalism, ecumenical involvement through "official" channels, and development of denominational institutions.

In a larger sense Disciples of Christ includes sister churches in Australia and New Zealand, known locally as Churches of Christ, with origins largely independent of the United States. It also denotes churches in other lands resulting from the missionary efforts of all these bodies; most of these younger churches, as well as Churches of Christ in Great Britain, have entered united churches.

Originally Disciples blended the independence and pragmatism of the American frontier with an uncomplicated biblical faith that demanded restoration of the "ancient order" in the church. They repudiated "human creeds" and traditions as requirements for Christian fellowship, understood baptism as the immersion of believers only, and recognized no churchly authority beyond the congregation. This simple formula's typical "sectarianism" was combined with a strong catholic impulse: a plea for the union of all Christians, the regular celebration of the Lord's Supper in weekly worship, and the use of inclusive biblical names.

HISTORY

Origins. The movement emerged on the American frontier through various efforts to cut through the complexities of sectarian dogma and find a basis for Christian unity. Out of the Great Western Revival (1801) in Kentucky arose the short-lived Springfield Presbytery, which dissolved in 1804 so that its members might "go free" simply as Christians. Their leader, Barton W. Stone, championed revivalism, a simple biblical and non-creedal faith, and Christian union. In the upper Ohio Valley Presbyterian Thomas Campbell organized the Christian Association of Washington (Pennsylvania) in 1809 to plead for the "unity, peace, and purity" of the church. Soon its members formed the Brush Run Church and ordained his son Alexander, under whose leadership they accepted immersion of believers as the only scriptural form of baptism and entered the Redstone Baptist Association. Alexander Campbell rapidly gained influence as a reformer, winning fame as preacher, debater, editor (*Christian Baptist*), and champion of the new popular democracy. His colleague Walter Scott developed a reasonable, scriptural "plan of salvation." Its "positive," or objective, steps into the church (faith, repentance, baptism, remission of sins, gift of the Holy Spirit) attracted thousands who longed for religious security but had not experienced the emotional crisis and subjective assurance that characterized the prevailing revivalism.

By 1830 the regular Baptists and the reformers parted company, the latter terming themselves Disciples. Two years later Stone and many of his followers joined with them, though continuing to use the name Christians.

Alexander Campbell from 1830 on turned to constructive church craft. He founded *The Millennial Harbinger*, established Bethany College, then in Virginia (1840), and agitated unsuccessfully for a general church organization based on congregational representation. The first general

Stone
and the
Campbells

convention met at Cincinnati, Ohio, in 1849 and launched the American Christian Missionary Society as a "society of individuals" and not an ecclesiastical body. Similar cooperative organizations emerged in various states to support evangelists and to establish new churches. The Christian Woman's Board of Missions (1874) and the Foreign Christian Missionary Society (1875) initiated successful programs overseas, and other boards were soon founded to promote building loans for new churches, care for aged ministers, homes for orphans and the aged, temperance, and other causes. The Centennial Convention at Pittsburgh in 1909 claimed an attendance of 30,000; they had come to celebrate a century of triumph for the New Reformation, or Restoration Movement.

Controversy and separation. Meanwhile, schism had begun to sunder the ranks, yet without shaking the confidence of the Disciples in their plea for union. They had held together during the controversy over slavery and through the Civil War, when major American denominations had divided. In the succeeding era of bitterness, however, the Disciples also suffered schism. New developments in response to growing urbanization and sophistication brought two sharply divergent responses. The conservatives regarded such developments as unauthorized "innovations," while the progressives (pejoratively termed digressives) looked on them as permissible "expedients."

Discord first arose over the "society principle" involving general missionary work. Alexander Campbell's biblical view of the church had kept pushing him toward a general church organization, but he could never find a convincing biblical text to support his proposals. Frontier independence and pragmatic popular biblicism prevailed. The "society principle" seemed to its advocates a legitimate solution: entertaining no ecclesiastical pretensions as a secular corporation, the missionary society provided a means by which individual Disciples could work in voluntary cooperation. But the opponents saw in it a repudiation of the Bible as the determining rule of practice.

The introduction of musical instruments (reed organs) into Christian worship led to many local disputes. Other innovations added occasion for controversy—the infringement of the "one-man pastoral system" on the local ministry of elders, introduction of selected choirs, use of the title Reverend, and lesser issues.

In 1889 several rural churches in Illinois issued the Sand Creek Declaration, withdrawing fellowship from those practicing "innovations and corruptions." In 1904 a separate "preacher list" issued unofficially by some conservative leaders certified their preachers for discounts on railway tickets. The Federal Religious Census of 1906 acknowledged the separation between Churches of Christ and Disciples of Christ (who commonly used the name Christian Churches) even though many congregations did not decide which they were for some years.

The crucial issue centred on the manner of understanding biblical authority. Both conservatives and progressives accepted the New Testament as the only rule for the church. The conservatives, heavily concentrated in the South, applied a strict construction to Scripture; this required a specific New Testament precept to authorize any practice. The progressives tended toward a broader construction, accepting as expedient such measures as they found harmonious with Scripture or not in conflict with it.

Disciples in the 20th century. Disciples had experienced their most rapid growth in rural America. Their leaders responded to the passing of the frontier, the growth of cities, and the emergence of urban expectations. Whereas the Churches of Christ had opted for the practices established in the rural past, regarding them as biblical, the Disciples of Christ (progressives) were able to find some flexibility in the biblical rule. Nevertheless, rural and small-town Christian Churches predominated in numbers and membership even past mid-century, and the newer social and cultural influences did not affect all of them simultaneously.

Urban churches demanded full-time leadership, and Disciples gradually developed a professional ministry. In the first half of the century they worked hard to establish collegiate education as standard for ministers. As late as 1930 only 11 percent had graduate education, and the rapid

growth of theological seminaries did not come until after World War II. The expanding corps of educated leadership reworked the inherited formulas, introducing both ideas and practices that troubled the more traditional.

The cooperative organizations underwent notable changes. In 1917 the old general convention, a week-long series of annual meetings of the various societies, gave way to the International Convention (U.S. and Canada), to which all cooperative agencies were expected to submit reports for review and advice.

Meanwhile, a number of the agencies had combined in 1920 to form the United Christian Missionary Society. Ten years later most state and national agencies entered Unified Promotion, a cooperative program of fund raising, with voluntarily accepted restraints on independent campaigns, and with distribution on the basis of agreed allocations. Thus they gradually evolved, in effect, one general budget. From the start the United Society drew intense criticism for ecclesiasticism and theological liberalism. Opposition centred on reports of "Open Membership" in the China mission. (Open membership, increasingly practiced in the United States, meant reception of unimmersed Christians from other denominations.)

In 1927 traditional forces established the North American Christian Convention. Many churches gave their support to "independent" missionaries in large numbers, as well as to "independent" Bible colleges, youth camps, district meetings, Bible school curricula, various publications, and a directory of ministers—all of them explicitly denying official status—more or less parallel to the "cooperative" agencies. The power struggle focused on the placement of ministers and resulted, on the cooperative side, in enhancing the leadership of the state secretaries and creating the pressure for delegate conventions in the states.

The cooperative conventions (state and international) also became instruments of ecumenical participation, electing representatives to the old Federal Council of Churches (and to the succeeding National Council and the World Council of Churches) as well as to the state councils. Thus, for the sake of their original catholic commitment, the "cooperatives" accepted status as a denomination, a compromise that the independents rejected.

A growing sense of moral obligation toward the common cause led in 1950 to the formation of the Council of Agencies, which included all organizations reporting to the International Convention. Legally independent, they sought by consultation to avoid overlapping and to develop a common mind. From the council came a proposal for a Commission on Restructure, appointed by the convention in 1960. In 1967 the convention approved the commission's Provisional Design for the Christian Church (Disciples of Christ), ratified in the ensuing year by all 40 area conventions and 15 national agencies.

Beginning in 1968 the International Convention was replaced by the General Assembly, the state conventions by regional assemblies, and the old cooperative agencies by "general units" of the church. State secretaries became regional ministers, and the chief executive officer was named general minister and president. In 1977 the General Assembly removed the word Provisional from the title of the Design. Congregations retained full legal independence, but the system provided for corporate unity through decisions by representatives from congregations and regions.

Fear of infringement on congregational freedom and theological opposition to the doctrine of the church underlying restructure led to active opposition. Many independent congregations formally requested withdrawal of their names from the Yearbook of Christian Churches (Disciples of Christ), and a campaign led some cooperative churches to follow suit. From 1967 to 1969 the number of congregations listed dropped from 8,046 to 5,278.

Meanwhile, a self-appointed Chaplaincy Endorsement Commission for the Undenominational Fellowship of Christian Churches and Churches of Christ asked recognition by the U.S. government to represent those congregations that had elected "to continue as free, independent, and completely autonomous local churches" apart from the restructured Christian Church.

has sponsored mass meetings for fellowship and inspiration at five-year intervals. It attracts both cooperative and independent Disciples from America and from many nations but few from American Churches of Christ.

Churches of Christ in the 20th century. In 1906 the membership and leadership of the Churches of Christ were located mainly in the South, with heaviest concentrations in Tennessee and Texas. The reported membership of 159,658 apparently did not include all who accepted the general position of the Churches of Christ. In the ensuing half-century they grew into the largest of the three Disciples groups. The migration from the rural South to urban centres brought impressive membership gains in the North and the West—aided by a vigorous evangelism making intensive use of radio. Missionaries established churches in Asia, Africa, Latin America, and Europe, winning converts especially from Roman Catholicism. Many churches now forward their missionary funds to an agent for disbursement, while making certain that the actual appointment of missionaries remains the prerogative of congregational elders.

The churches' doctrine permits individual initiative in certain types of religious (not ecclesiastical) enterprises. A vigorous journalism has flourished for more than a century, the most influential papers being the *Gospel Advocate* (Nashville, Tenn.) and *Firm Foundation* (Austin, Texas). Benevolent homes provide care for children and the aged. A number of churches conduct Christian day schools, while private colleges offer Christian higher education and receive support from churches. A graduate school of religion at Harding College in Memphis, Tenn., offers a three-year Master of Theology degree.

Variations of conviction about specific practices (whether a single, "common" cup or many cups are to be used in communion) and doctrines (especially millennial ones about the perfect age of Christ's reign on earth) have produced sharp controversies and withdrawal of fellowship.

In the 1960s some leaders in the Churches of Christ set up informal forums or conferences on unity with members of the Christian Churches, both cooperative and independent. Although having no official status, these meetings provided opportunity for a limited but continuing ecumenical dialogue. Their doctrinal stance, in repudiation of ecclesiastical organization, prevents members of both the Churches of Christ and the Udenominational Fellowship of Christian Churches and Churches of Christ from official participation in general ecumenical gatherings.

TEACHINGS

Alexander Campbell summarized his theology in *The Christian System* (1835), the most influential book in shaping Disciples thought. In it he outlined a common-sense biblical doctrine against the complex theories of the schools and the sects. He emphasized reliance on the Bible and insisted on going to the sources. Relying on John Locke, "The Christian philosopher," Campbell perceived the grounds for Christian faith in historical events and objective evidence (recorded in Scripture) rather than in mysticism or subjective religious "experience." He therefore repudiated the Calvinist (and revivalist) concept of miraculous conversion and the similar concept of miraculous call to the ministry. Debates on these issues, as well as on the damnation of unbaptized infants, which Disciples denied, led them to think of themselves as anti-Calvinist.

The general framework of their thought nevertheless followed Reformed (Calvinist) lines, modified by the influence of British Independents (the originally Scottish Glasites—or Sandemanians—in practice a strictly New Testament sect, and the Congregationalists). Disciples shared the orthodox Protestant emphasis on the authority of Scripture. Their classic biblical position differs from that of other Protestants in being a product of the early 19th rather than of the 16th or 17th century.

Early Disciples understood their uniqueness to lie in the rigour, precision, and simplicity with which they set forth the biblical basis for the unity of all Christians. Campbell distinguished sharply between Old and New Covenants (Testaments), limiting to the latter any authority for "the original faith and order" of the church. Only explicit apostolic teaching or precedent belonged in the realm of faith,

of the essential; all else, however logical or helpful, fell in the area of opinion and consequently of Christian liberty. Thus they rejected creeds as tests of fellowship; they believed such tests usurped the sole authority of the New Testament and set forth demands not found there. The popular Disciples' bias against theology as a divisive preoccupation with human opinions—as well as Alexander Campbell's early protest against ecclesiastical institutions as unwarranted by Scripture and threatening to freedom—also was inferred from the New Testament.

WORSHIP AND ORGANIZATION

After fruitless attempts to derive a stated order of worship from the New Testament, Disciples settled into an informal but relatively stable pattern composed of hymns, extemporaneous prayers, Scripture, sermon, and breaking of bread. Except for its omission of the Decalogue, the public confession of sin, and the creed, it resembled classic Reformed (or Presbyterian) worship, especially in its austerity of spirit. In the second half of the 19th century it took over more of the mood of popular revivalism, which still prevails among Churches of Christ and the independent Christian Churches.

Because many churches in the 19th century had the services of a preacher only occasionally but regularly observed the Lord's Supper (communion) after the Bible School (Sunday School) hour, the breaking of bread came to precede the sermon, which was simply added on when a preacher was present. At the table two local elders presided, one offering a prayer of thanksgiving for the bread and the other for the cup. The minister now commonly presides, but the elders ordinarily offer the prayers.

Christian Worship: A Service Book (1953), a semiofficial manual for voluntary use, exerted wide influence in restoring and stabilizing the typical pattern, with an emphasis on use of scriptural sentences throughout. The influence of the Liturgical Movement brought greater use of responsive readings, litanies, and affirmations of faith, as well as closer accommodation to the historical pattern of the liturgy—all demonstrated in the 1987 "resource for Christian worship," *Thankful Praise*.

Campbell regarded immersion and "the breaking of bread" (i.e., baptism and communion) as ordinances of Christ. While the insistence on believer's baptism alone separated Disciples from the "paedobaptists" (those advocating baptism of children), weekly communion served as a universal element in their worship and tempered their rationalist bent. Despite their memorialist doctrine (that communion is a commemoration of Christ's Last Supper involving no miracle of transubstantiation), they understood the service as present communion with their Lord.

Campbell saw the biblically authorized ministry as that of elders and deacons, ordained by the congregations, and of evangelists, who served the church at large. Since the 1950s congregations have commonly elected women to diaconate and eldership, and Disciples have long ordained women as ministers. By the 1980s fully one-third of their seminarians were women.

The Design recognizes "the order of the ministry," consisting of ordained ministers and licensed ministers. Since restructure, the General Assembly has established policies and criteria for the order of ministry, which are interpreted and applied by regional commissions.

Internal differences. The divisions in the movement expressed varying attitudes toward Scripture as the norm of faith and practice: Churches of Christ construing it strictly, Disciples more loosely. Many who introduced organs in worship held the same view of biblical authority as those who refused to do so; their interpretation simply led to a different conclusion about the use of musical instruments in apostolic times. They provided the constituency for the "independent" Christian Churches, whereas Disciples tended to find more and more flexibility in the principle of expediency.

Beginning in the early 19th century as a revolution occurred in the scholarly understanding of the biblical documents and the nature of their authority, the Churches of Christ generally held steadfastly to older views of Scripture, as the independents also tended to do, while Disciples

Missionaries

Standards of apostolic teaching

Controversies in biblical interpretation

accepted the approach of critical scholarship. At the beginning of the 20th century, the most influential Disciples scholar was J.W. McGarvey, a champion of the traditional doctrines and view of the Bible and an opponent of the musical instrument in worship. Early in the century Herbert L. Willett, E.S. Ames, and C.C. Morrison led in a liberal reformulation of the plea, emphasizing a pragmatic and reasonable approach to faith, the repudiation of creeds, an openness to the scientific world view, and a commitment to Christian unity. Neoorthodoxy held less appeal for most Disciples, but William Robinson gained attention for his emphasis on biblical doctrine.

Recent trends. With the rapid growth of seminaries and religion faculties and extensive ecumenical involvement, Disciples enjoyed a theological renaissance in the 1950s. During the heyday of biblical theology some of them worked out a contemporary formulation of the tradition within the ecumenical context. A Panel of Scholars, appointed by two of the national agencies, published three volumes of papers in 1963 reflecting the new mood.

The institutional developments leading to restructuring were accompanied by a reformulation of the doctrine of the church. The founders had spoken of the Church of Christ as a local congregation; they recognized no other organization as a church. The new generation of Disciples could no longer deny the churchly character of the institutions that had been developed. The Design speaks of three manifestations of the Christian Church—congregational, regional, general (United States and Canada). The name that they adopted—the Christian Church (Disciples of Christ)—they found to have been dictated by their history. They saw that church manifesting itself organizationally “within the universal body of Christ” and committed to “responsible ecumenical relationships.” In 1962 Disciples entered the Consultation on Church Union and in 1985 an ecumenical partnership with the United Church of Christ. They gave a cordial reception to the World Council of Churches document *Baptism, Eucharist and Ministry* (1982), even while recognizing problems posed by their eldership for the emerging consensus.

In the immediate decades after restructure no major theological controversy arose. Resurgent Fundamentalism and Evangelicalism on the larger scene had little impact.

Social issues. On social questions Disciples have held positions characteristic of the American denominations of English background. With regard to the issue of slavery Campbell prevented schism by admitting that Scripture and civil law permitted slavery, though, as a matter of personal opinion, he favoured emancipation. During the Civil War a number of leading Disciples, especially in the Border States, espoused pacifism on biblical grounds.

Disciples representatives to the National Council of Churches and the World Council of Churches have supported those organizations' general stand on social issues. In the second half of the 20th century, though a moderate conservatism obtained at the grassroots, ministers, seminaries, general units, and General Assembly placed social issues high on their agenda, with vocal sympathy for liberation theology. In 1969 the General Assembly called for a 20 percent presence of ethnic minorities on church policy-making bodies, even though the combined number of Native American, black, Hispanic, and Asian-American Disciples fell well below that figure. (R.E.O.)

Unitarians and Universalists

Unitarians and Universalists, who have merged in the United States, are groups of religious liberals. In previous centuries they appealed for their views to Scripture interpreted by reason, but most contemporary Unitarians and Universalists base their religious beliefs on reason and experience.

Unitarianism as an organized religious movement emerged during the Reformation period in Poland, Transylvania, and England, and later in North America from the original New England Puritan churches. In each country Unitarian leaders sought to achieve a reformation that was completely in accordance with the Hebrew Scriptures and the New Testament; in particular, they found no

warrant for the doctrine of the Trinity accepted by other Christian churches.

Universalism as a religious movement developed from the influences of radical Pietism in the 18th century and dissent in the Baptist and Congregational churches from predestinarian views that only a small number, the elect, will be saved. Universalists argued that Scripture does not teach eternal torment in hell and with Origen, the 3rd century Alexandrian theologian, they affirmed a universal restoration of all to God.

HISTORY

Servetus and Socinus. In *De Trinitatis erroribus* (1531; “On the Errors of the Trinity”) and *Christianismi restitutio* (1553; “The Restitution of Christianity”) the Spanish physician and theologian Michael Servetus provided important stimulus for the emergence of Unitarianism. Servetus' execution for heresy in 1553 led Sebastian Castellio, a liberal humanist, to advocate religious toleration in *De haereticis* . . . (1554; Concerning Heretics”) and caused some Italian religious exiles, who were then in Switzerland, to move to Poland.

One of the most important of these Italian exiles was Faustus Socinus (1539–1604). His acquisition in 1562 of the papers of his uncle Laelius Socinus (1525–62), a theologian suspected of heterodox views, led him to adopt some of Laelius' proposals for the reformation of Christian doctrines and to become an anti-Trinitarian theologian. Laelius' commentary on the prologue to the Gospel According to John presented Christ as the revealer of God's new creation and denied Christ's preexistence. Faustus' own *Explicatio primae partis primi capituli Ioannis* (first edition published in Transylvania in 1567–68; “Explanation of the First Part of the First Chapter of John's Gospel”) and his manuscripts of 1578, *De Jesu Christo Servatore* (first published 1594; “On Jesus Christ, the Saviour”) and *De statu primi hominis ante lapsum* (1578; “On the State of the First Man Before the Fall”), were of subsequent influence, the first, particularly, in Transylvania and all three in Poland.

Unitarianism in Poland. Unitarianism appeared in Poland in incipient form in 1555 when Peter Gonesius, a Polish student, proclaimed views derived from Servetus at a Polish Reformed Church synod. Controversies that ensued with tritheists, ditheists, and those who affirmed the unity of God resulted in a schism in 1565 and the formation of the Minor Reformed Church of Poland (Polish Brethren). Gregory Paul, Marcin Czechowic, and Georg Schomann soon emerged as leaders of the new church. They were encouraged by Georgius Blandrata (1515–88), an Italian physician to the Polish-Italian bride of King John Sigismund, who aided the development of anti-Trinitarianism in Poland and Transylvania. In 1569 Racow was founded as the Polish Brethren's central community.

Faustus Socinus went to Poland in 1579. He rejected Anabaptist insistence on immersionist adult baptism and affirmed that Jesus Christ was a man whom God had resurrected and to whom he had given all power in heaven and earth over the church. Socinus emphasized the validity of prayer to Christ as an expression of honour and as a request for aid. Through his ability in theological debate he soon became the leader of the Polish Brethren, whose adherents were frequently referred to as Socinians.

After Socinus' death his followers published the *Racovian Catechism* (1605). The hostility of their opponents, however, caused the destruction of the Socinians' famous printing press and school at Racow (1632). In 1658 a legislative decree was enacted stating that by 1660 the Socinians must either become Roman Catholics, go into exile, or face execution. A few of these Polish exiles reached Kolozsvár, centre of the Transylvanian Unitarian movement, and some of their leaders moved to the Netherlands, where they continued the publication of Socinian books.

Transylvanian Unitarianism. Blandrata encouraged Ferenc Dávid (1510–79), a Transylvanian theologian, to deliver anti-Trinitarian sermons. Study at Wittenberg had led Dávid to convert from Roman Catholicism to Lutheranism. As superintendent of Transylvanian Lutheran churches Dávid had engaged in debates with Pe-

Laelius
Socinus

Ecumeni-
cal efforts

Ferenc
Dávid

ter Melius, leader of the Transylvanian Reformed Church, with the result that Dávid had joined the Reformed Church, of which he soon became superintendent. Cooperation between Dávid and Blandrata led to the publication of two Unitarian books, *De falsa et vera unius Dei Patri* (1567; "On the False and True Unity of God the Father, Son, and Holy Spirit") and *De regno Christi* . . . (1569; "On the Reign of Christ"), which showed the influences of Servetus and Laelius Socinus.

Biblical study and discussions with colleagues (e.g., with Jacobus Palaeologus) led Dávid to nonadorantism (denial that prayer should be addressed to Christ), which caused a serious crisis. In 1568 John Sigismund, Unitarian king of Transylvania, granted religious freedom to Catholics, Lutherans, the Reformed Church, and those who were soon to be called Unitarians, and in 1571 the Transylvanian Diet gave constitutional recognition to all four received religions. But Sigismund's successor, Stephen Báthory, forbade further innovations (changes in doctrine from beliefs held during Sigismund's reign). Dávid's non-adorantist innovation thus endangered the Unitarians' legal status. Blandrata sought to protect them by the arrest and trial of Dávid, who died in prison in 1579. This oldest Unitarian Church survives in Hungary and Romania.

English Unitarianism. John Biddle (1615–62), an English Socinian, whose knowledge of the Greek text of the New Testament convinced him that the doctrine of the Trinity was not of scriptural origin, published his Unitarian convictions in *Twelve Arguments Drawn out of Scripture* . . . (1647) and other works; English readers, moreover, were exposed to Unitarian views through Socinian books published in the Netherlands. Although the Toleration Act of 1689 excluded Unitarians, advocates of an Arian Christology (belief in Christ's preexistence as a subordinate, divine, created being) soon appeared within the Church of England and among Dissenters. This led some Anglicans to seek, without success, the rescinding of the requirement of subscription to the Anglican Thirty-nine Articles. Dissenting ministers, meeting in the Salters' Hall in London in 1719, separated into two groups, one insisting on adherence to confessional documents, the other requiring only agreement with Scripture. Of those in the second group, Presbyterians, General Baptists, and a few independents gradually moved during the 18th century with their congregations toward Unitarian views.

The first English Unitarian congregation, Essex Street Chapel, was founded in London in 1774 by Theophilus Lindsey, who previously had been an Anglican clergyman. The scientist and dissenting minister Joseph Priestley (1733–1804) influenced Unitarian ministers by his scriptural rationalism, materialist determinism, and emphasis on a humanitarian Christology. The scholar and theologian Thomas Belsham supported Priestley's emphasis on a humanitarian Christology and opposition to Arian views. The British and Foreign Unitarian Association was founded in 1825.

In the 19th century Parliament was persuaded to repeal some of the laws against nonconformity, which freed the Unitarians for a more active church life. English Unitarians, moreover, were greatly influenced by James Martineau (1805–1900), who, after studies in Germany, was led to a religious epistemology emphasizing intuition. In 1928 a union of the British and Foreign Unitarian Association with the National Conference (which included other Free Christian Churches) resulted in the founding of the General Assembly of Unitarian and Free Christian Churches. Unitarianism is also present in Wales, Scotland, and the Non-Subscribing Presbyterian Church of Ireland.

American Unitarianism. In the American colonies Congregationalist ministers influenced by Arian Christology and by Arminian theology, gradually moved in the 18th century toward Unitarian views. Conflicts with supporters of Jonathan Edwards' theological heritage resulted in the election at Harvard College of a liberal, Henry Ware, as Hollis Professor of Divinity in 1805. When the liberal Congregationalists were accused of agreeing with Belsham's strictly humanitarian Christology, the Unitarian clergyman William Ellery Channing defended them as Arians. Channing's 1819 sermon "Unitarian Christian-

ity," a manifesto, presented both a recognition that the liberals would have to separate from the Congregational Church and a coherent theology. In 1825 the American Unitarian Association (AUA), an association of individuals, was organized.

Channing's Arian Christology as well as his affirmations of the divine unity, the authority of Scripture rationally interpreted, and an optimistic view of human nature were dominant among early American Unitarians. His Lockean epistemology (modified by views of Scottish commonsense philosophers and the English Unitarian Richard Price), however, was challenged by such Transcendentalists as Ralph Waldo Emerson, in his "Divinity School Address" (1838), and Theodore Parker, in his sermon "The Transient and Permanent in Christianity" (1841), both of whom emphasized intuition and moral idealism. Parker's leadership in addressing issues of social reform, such as issues relating to the anti-slavery movement, made a lasting impact on Unitarians.

Although Transcendentalism divided the Unitarians, Henry Whitney Bellows, a prominent figure in Unitarianism after the Civil War, succeeded in organizing the National Conference of Unitarian Churches in 1865. A separatist Free Religious Association (FRA) was organized in 1867 by persons who, although holding a variety of views, were agreed in their opposition to the preamble of the National Conference's constitution, which was virtually a Christian creed. A Western Unitarian Conference, organized in 1852, also experienced a controversy over whether Unitarianism was to include persons whose views were not theistic and Christian. In 1894 a revision in the constitution of the National Conference enabled members of the FRA to rejoin the Conference. Later renamed the General Conference, it merged with the AUA in 1925.

In the 20th century religious humanism, the endeavour to reformulate liberal theology on strictly non-theistic grounds, emerged within Unitarianism, leading to a theist-humanist controversy. After such Unitarian ministers as John Dietrich and Curtis Reese signed the Humanist Manifesto (1933), religious humanism became the view of many Unitarians. A Commission of Appraisal (1934–36) recommended modifications in the structure and program of the AUA. Frederick May Eliot, chairman of the commission, was persuaded to become president of the AUA, and while in office he prepared the denomination for future growth. In the 1930s a critical movement emerged, largely in response to a general crisis of faith in liberal thought; its leader was James Luther Adams, whose writings contributed significantly to Unitarian theology and social thought. Of particular importance for Unitarianism today are his studies of voluntary associations and their implications (*On Being Human—Religiously*, 1976).

Early Universalism. Radical Pietism emerged in Germany under the leadership of Johann Wilhelm Petersen, who led groups of Philadelphian Pietists identifying themselves with the sixth church referred to in Revelation 3:7–13. A Philadelphian Society was organized in London in 1681 under Jane Leade, whose religious views were based on the thought of the German mystic Jakob Böhme and on her own visions and dreams. Convinced that Leade was correct in affirming a universal restoration (the ultimate reconciliation to God of all human beings, the devil, and his angels), Petersen gave her views scriptural foundations in his *Mystery of the Restitution of All Things* (1700–10), which included *The Everlasting Gospel*, a restorationist treatise by George Klein-Nicolai published under the pseudonym Paul Siegvölck. German Philadelphian Pietists took these and other works to Pennsylvania in the early 18th century, where George de Benneville (1703–93), a French Universalist who had gone to Pennsylvania in 1741, brought them into contact with other groups that affirmed universal salvation.

A different view of Universalism appeared in the work of the Welsh revivalist preacher James Rely (1720–78). In his *Union, or A Treatise of the Consanguinity and Affinity Between Christ and His Church* (1759) he presented scriptural texts for the view that universal salvation is assured. Christ's unity with all human beings and his acceptance of the guilt and endurance of the punishment

American

Association

James
Rely

for the sins of mankind ensured that among the elect for whom Christ had suffered was the entire human race. The English Methodist John Murray (1741–1815) unsuccessfully sought to refute Rely's views; instead he became convinced of their truth and took this theology to New England in 1770. His church at Gloucester, Mass. (1780), was the first American Universalist congregation.

Urged by George de Benneville to read *The Everlasting Gospel* and other Universalist works, Elhanan Winchester (1751–97), a Baptist minister, became converted to restorationist Universalism. He traveled to England, where he founded a Universalist Church in London in 1793 and wrote *The Universal Restoration . . .* (1794). He emphasized scriptural texts that affirmed the finite and remedial nature of punishment after death. Winchester subsequently continued his ministry in the United States.

American Universalism. Hosea Ballou (1771–1852) was the greatest 19th-century American Universalist leader. His *A Treatise on Atonement . . .* (1805) converted most Universalist ministers to a Unitarian view of God, an Arian Christology, and the view that, because sin is finite in nature and all of its effects will be experienced in this life, all of mankind will be saved after death. Ballou later abandoned his Arian belief in Christ's preexistence.

The Winchester Profession (1803), adopted by the General Convention of Universalists in the New England States at Winchester, N.H., was phrased in general terms to embrace differing Universalist views. In 1870, however, a resolution adopted by the General Convention required that the Winchester Profession be interpreted as requiring belief in the authority of Scripture and the lordship of Jesus Christ. This restriction was rescinded in 1899.

Ballou's theology was dominant during the first half of the 19th century, when Universalist ministers founded congregations in many states. Opposed to Ballou's theology, however, was a small group of ministers and laypersons, who left the denomination to form the Massachusetts Association of Universal Restorationists, which existed from 1831 to 1841. Although both factions believed that there would be no eternal punishment for sinners after death, the Massachusetts restorationists embraced the position that there would be a limited punishment followed by a general restoration to God. Adin Ballou (1803–90), a leading restorationist, was an outstanding advocate of the application of New Testament ethics to social issues. By the end of the 19th century most Universalists held restorationist views.

Clarence Skinner (1881–1949), dean of Crane Theological School, greatly influenced American Universalists by his emphasis on social issues and his reinterpretation of Universalism as referring not to salvation after death but to the unities and universals in human life (*A Religion for Greatness*, 1945). In 1935 the Universalists adopted a non-creedal Bond of Fellowship, which they revised in 1953. Clinton Lee Scott and Kenneth Patton affirmed religious humanism and emphasized drawing religious sustenance from the traditions of the world's great religions.

TEACHINGS

The Unitarian theologian Earl Morse Wilbur (1866–1956) advanced the thesis, now widely accepted, that the history of Unitarianism in Poland, Transylvania, England, and America gains unity from certain common themes. These themes are freedom of religious thought rather than required agreement with creeds or confessions, reliance not on tradition or external authority but on the use of reason in formulating religious beliefs, and tolerance of differing religious views and customs in worship and polity.

Unitarian Universalists are creedless and deny the authority of dogmas promulgated by church councils. Their teachings historically have included the unity of God, the humanity of Jesus, mankind's religious and ethical responsibility, and the possibility of attaining religious salvation through differing religious traditions. They emphasize the authority of the individual's religious conviction, the importance of religiously motivated action for social reform, democratic method in church governance, and reason and experience as appropriate bases for formulating religious beliefs. Their traditional concern for social issues has

caused Unitarian Universalists to give active support to the demands for equality of blacks, feminists, and other groups. Gains in equality for women within the Unitarian Universalist Association were significant, but its predominantly white, middle-class membership remains an issue.

Although the nonadorantist Unitarians in Romania and Hungary are firmly Christian, in England, the United States, and Canada, the beliefs of Unitarians range from Unitarian Christianity to religious humanism; there are also aspirations toward becoming a universal religion. Universalist teachings have changed also; whereas the restorationist theology that was dominant among American Universalists toward the end of the 19th century emphasized the salvation of all after death, many 20th-century Universalists affirm a naturalistic worldview and regard salvation as an aspect of present human experience.

WORSHIP AND ORGANIZATION

English and American Unitarian Universalist worship is predominantly thematic in emphasis and sermon-centred in form. It makes use of hymnals that have been revised to reflect changing religious interests; for example, today's hymns express themes of religious humanism. There also is some liturgical experimentation. Whereas baptism and frequent observance of the Lord's Supper characterize Hungarian and Romanian Unitarian worship, in England and the United States infants may be dedicated and observance of the Lord's Supper is rare, except among Unitarian Christians.

The American Unitarian Association and the Universalist Church of America merged in 1961 to form the Unitarian Universalist Association (UUA). The UUA's churches and fellowships are located primarily in the United States and Canada. (Canadian congregations are also members of the Canadian Unitarian Council.) The UUA is a member of the International Association for Religious Freedom, which was founded in 1900 as the International Association for Liberal Christianity and Religious Freedom (its name being changed in 1969 to reflect the inclusion of member-groups from non-Christian religious traditions).

English Unitarians and American Unitarian Universalists have congregational polity and emphasize the democratic process. Ministerial and lay delegates from congregations constitute the annual General Assembly, a legislative body. In Hungary and Romania a bishop and a lay president in each country supervise the Unitarian churches, which are governed by annual synods. (J.C.G.)

Protestantism (1961, reissued 1969), a study combining sources with narrative and interpretation; PAUL TILLICH, *The Protestant Era*, trans. from German (1948, reissued 1951), a collection of essays, one of which discusses the "end of the Protestant era"; CHARLES W. KEGLEY, *Protestantism in Transition* (1965), a theologian's survey of Protestant tendencies after the mid-20th century; ERNST TROELTSCH, *Protestantism and Progress: The Significance of Protestantism for the Rise of the Modern World* (1986; originally published in German, 2nd ed., 1911), a classic interpretation of Protestant contributions to modernity; MAX WEBER, *The Protestant Ethic and the Spirit of Capitalism* (1930, reissued 1985; originally published in German, 1904), a much debated study of the link between Protestantism and the rise of capitalism; JOHN A. HARDON, *The Protestant Churches of America*, rev. ed. (1969), a summary by a Roman Catholic of Protestant doctrinal positions; FREDERICK E. MAYER, *The Religious Bodies of America*, 4th ed. rev. by ARTHUR CARL PIEPKORN (1961), denomination-by-denomination study of doctrinal positions in American religious groups; ARTHUR CARL PIEPKORN, *Profiles in Belief: The Religious Bodies of the United States and Canada*, vol. 2, *Protestant Denominations* (1978), vol. 3, *Holiness and Pentecostal* (1979), and vol. 4, *Evangelical, Fundamentalist, and Other Christian Bodies* (1979), an extensive review of American Protestant bodies; WINTHROP S. HUDSON, *American Protestantism* (1961, reprinted 1972), a brief survey of Protestant history in America; JERALD C. BRAUER, *Protestantism in America: A Narrative History*, rev. ed. (1965, reprinted 1974), a presentation of the main themes of American Protestant history; ANDREW L. DRUMMOND, *Story of American Protestantism* (1949, reissued 1951), a British view of Protestant history in the United States; and MARTIN E. MARTY, *Righteous Empire: The Protestant Experience in America* (1970, reprinted 1977), written for the nation's bicentennial. Newsworthy developments in the Protestant Church are chronicled in *Christian Century* (weekly).

History: KENNETH SCOTT LATOURETTE, *A History of Christianity*, rev. ed., 2 vol. (1975), with useful bibliographies; and ÉMILE G. LÉONARD, *Histoire générale du protestantisme*, 3 vol. (1961–64)—vol. 1 has also appeared in English with the title, *A History of Protestantism* (1968). Additional references may be found in OWEN CHADWICK, *The History of the Church: A Select Bibliography*, 3rd ed. (1973).

For Puritanism, see WILLIAM HALLER, *The Rise of Puritanism: or, The Way to the New Jerusalem as Set Forth in Pulpit and Press from Thomas Cartwright to John Lilburne and John Milton, 1570–1643* (1938, reissued 1984); CHRISTOPHER HILL, *Society and Puritanism in Pre-Revolutionary England* (1964, reissued 1986); PATRICK COLLINSON, *The Elizabethan Puritan Movement* (1967); SAMUEL ELIOT MORISON, *The Intellectual Life of Colonial New England*, 2nd ed. (1956, reprinted 1980); and FRANCIS J. BREMER, *The Puritan Experiment: New England and Society from Bradford to Edwards* (1976). For Arminianism, see A.W. HARRISON, *The Beginnings of Arminianism to the Synod of Dort* (1926); and CARL BANGS, *Arminius: A Study in the Dutch Reformation*, 2nd ed. (1985). For Pietism, see KOPPEL S. PINSON, *Pietism as a Factor in the Rise of German Nationalism* (1934, reissued 1968); and F. ERNEST STOEFLER, *The Rise of Evangelical Pietism* (1965, reprinted 1971), and *German Pietism During the Eighteenth Century* (1973). For Protestant missionary expansion, see KENNETH SCOTT LATOURETTE, *A History of the Expansion of Christianity*, vol. 3–7 (1940–45); and STEPHEN NEILL, *A History of Christian Missions*, 2nd ed. rev. by OWEN CHADWICK (1986). For the 19th and 20th centuries, see KENNETH SCOTT LATOURETTE, *Christianity in a Revolutionary Age*, 5 vol. (1958–62, reissued 1973); STEPHEN NEILL (ed.), *Twentieth Century Christianity: A Survey of Modern Religious Trends by Leading Churchmen*, rev. ed. (1963); and DAVID B. BARRETT (ed.), *World Christian Encyclopedia: A Comparative Study of Churches and Religions in the Modern World, AD 1900–2000* (1982).

For American Protestantism, see H. SHELTON SMITH, ROBERT T. HANDY, and LEFFERTS A. LOETSCHER, *American Christianity: An Historical Interpretation with Representative Documents*, 2 vol. (1960–63), a general guide; E.S. GAUSTAD, *A Documentary History of Religion in America*, 2 vol. (1982–83), a comprehensive overview; WILLIAM WARREN SWEET, *The Story of Religion in America*, 2nd rev. ed. (1950); WINTHROP S. HUDSON, *American Protestantism* (1961, reprinted 1972); and R.T. HANDY, *A Christian America: Protestant Hopes and Historical Realities*, 2nd ed. rev. and enl. (1984), on cultural intentions. For the social Gospel, see C.H. HOPKINS, *The Rise of the Social Gospel in American Protestantism, 1865–1915* (1940, reprinted 1982). For churches under the Nazis, see J.S. CONWAY, *The Nazi Persecution of the Churches, 1933–45* (1968); and ARTHUR C. COCHRANE, *The Church's Confession Under Hitler*, 2nd ed. (1976), which accents resistance documents. For the ecumenical movement, see RUTH ROUSE and STEPHEN NEILL (eds.), *A His-*

tory of the Ecumenical Movement, 1517–1948, 3rd ed. (1986); and HAROLD E. FEY (ed.), *A History of the Ecumenical Movement, 1948–1968: The Ecumenical Advance*, 2nd ed. (1986). Research findings related to primarily American Protestant church history are published in *Church History* (quarterly).

Lutheran churches: CONRAD BERGENDOFF, *The Church of the Lutheran Reformation* (1967), a survey of Lutheranism, but especially useful for information on Lutheranism in the Scandinavian countries, in a very readable narrative with bibliography; and JAROSLAV PELIKAN, *From Luther to Kierkegaard: A Study in the History of Theology* (1950, reprinted 1963), a brief history of developments in Lutheran theology to the mid-19th century. JULIUS BODENSIECK (ed.), *The Encyclopedia of the Lutheran Church*, 3 vol. (1965), is the standard English reference work on Lutheranism, although articles vary from the scholarly to the propagandistic.

On Lutheranism in the United States, see SYDNEY E. AHLSTROM, "Theology in America: A Historical Survey," in JAMES WARD SMITH and A. LELAND JAMISON, *Religion in American Life*, vol. 1, *The Shaping of American Religion* (1961), pp. 232–321, a survey that sets Lutheran theology in the context of other developments; and ABDEL R. WENTZ, *A Basic History of Lutheranism in America*, rev. ed. (1964), a standard work on the major developments. E. CLIFFORD NELSON, *The Rise of World Lutheranism: An American Perspective* (1982), is a discussion of the cooperation among 20th-century Lutheran churches. E. CLIFFORD NELSON (ed.), *Lutherans in North America*, rev. ed. (1980), is a study on the various periods of American history.

Works on Lutheran teachings include THEODORE G. TAPPERT (ed. and trans.), *The Book of Concord: The Confessions of the Evangelical Lutheran Church* (1959, reprinted 1987), official translation; EDMUND SCHLINK, *Theology of the Lutheran Confessions* (1961, reissued 1975; originally published in German, 1940), a dialectical approach to Lutheran theology; WILHELM MAURER, *Historical Commentary on the Augsburg Confession* (1986; originally published in German, 2 vol., 1976–78), a thorough work on the basic Lutheran document; PAUL TILLICH, *Systematic Theology*, 3 vol. (1951–63, reprinted 1973), a systematics by the most original Lutheran theologian of the 20th century; and KARL FERDINAND MÜLLER and WALTER BLANKENBURG, *Leiturgia: Handbuch des evangelischen Gottesdienstes*, 5 vol. (1954–70), a historical and theological examination of the Lutheran service.

Reformed and Presbyterian churches: WILLIAM J. BOUWSMA, *John Calvin: A Sixteenth-Century Portrait* (1988), which places Calvin in his contemporary context; JOHN T. MCNEILL, *The History and Character of Calvinism* (1954, reissued 1973), a comprehensive treatment of the rise and development of Presbyterian and Reformed churches, with an excellent bibliography; JAMES HASTINGS NICHOLS, *Corporate Worship in the Reformed Tradition* (1968), an overview of the variety of forms developed in the Reformed tradition of the public worship of God; HEINRICH HEPPE, *Reformed Dogmatics Set Out and Illustrated from the Sources*, rev. and ed. by ERNST BIZER (1950, reprinted 1978; originally published in German, 1861), a work enabling the reader to get beyond Calvin's *Institutes* to some acquaintance with other Reformed theologians of the 16th and 17th centuries; ROBERT MCAFEE BROWN, *Theology in a New Key: Responding to Liberation Themes* (1978), and *Unexpected News: Reading the Bible with Third World Eyes* (1981), interpretations of Third World theology; JOHN H. LEITH, *An Introduction to Reformed Tradition: A Way of Being the Christian Community*, rev. ed. (1981); ARTHUR C. COCHRANE (ed.), *Reformed Confessions of the 16th Century* (1966), 12 classic confessions of the 16th century, with historical introductions; and THOMAS F. TORRANCE (ed. and trans.), *The School of Faith: The Catechisms of the Reformed Church* (1959), 10 catechisms of the 16th and 17th centuries. Useful periodicals include *Reformed World* (quarterly), published by the World Alliance of Reformed Churches (Presbyterian and Congregational), which reports on the life and work of Reformed and Presbyterian churches throughout the world; and *American Presbyterians: Journal of Presbyterian History* (quarterly), on all aspects of American Presbyterian history.

Anglican Communion: STEPHEN C. NEILL, *Anglicanism*, rev. ed. (1977), the most comprehensive treatment of Anglican history; JOHN R.H. MOORMAN, *A History of the Church in England*, 3rd ed. (1973, reissued 1980), the basic facts about Anglicanism's mother church; MARION J. HATCHETT, *Commentary on the American Prayer Book* (1981), a detailed examination of Anglican worship and its rationale; JAMES T. ADDISON, *The Episcopal Church in the United States, 1789–1931* (1951, reissued 1969), the most thorough treatment of American Anglicanism; and PAUL A. WELSBY, *A History of the Church of England, 1945–1980* (1984, reissued 1986), which explains recent changes in the Church of England. See also RAYMOND W. ALBRIGHT, *A History of the Protestant Episcopal Church* (1964), the standard story of American Episcopalianism.

Baptists: ROBERT G. TORBET, *A History of the Baptists*, 3rd ed. (1963, reprinted 1973), the most complete account of the Baptists; H. LEON MCBETH, *The Baptist Heritage* (1987), a comprehensive history of four centuries of Baptist witness; ALFRED C. UNDERWOOD, *A History of the English Baptists* (1947), which gives major attention to Baptist beginnings; JAMES E. WOOD, JR., *Baptists and the American Experience* (1976), a collection of essays; WINTHROP S. HUDSON, *Baptists in Transition: Individualism and Christian Responsibility* (1979); and ALBERT W. WARDIN, JR., *Baptist Atlas* (1980), international in scope. See also JAMES MELVIN WASHINGTON, *Frustrated Fellowship: The Black Baptist Quest for Social Power* (1986); and WILLIAM H. BRACKNEY (ed.), *Baptist Life and Thought, 1600–1980: A Source Book* (1983). NORMAN H. MARING and WINTHROP S. HUDSON, *A Baptist Manual of Polity and Practice* (1963), gives details of ecclesiastical organization. *Baptist History and Heritage* (quarterly) deals primarily with Southern Baptists.

Congregationalists: WILLISTON WALKER, *The Creeds and Platforms of Congregationalism* (1893, reprinted 1960); GEOFFREY F. NUTTALL, *Visible Saints: The Congregational Way, 1640–1660* (1957); RAYMOND P. STEARNS, *Congregationalism in the Dutch Netherlands: The Rise and Fall of the English Congregational Classis, 1621–1635* (1940); GAUIS GLENN ATKINS and FREDERICK L. FAGLEY, *History of American Congregationalism* (1942); WILLIAM WARREN SWEET, *Religion in Colonial America* (1942, reissued 1965); DOUGLAS HORTON, *Congregationalism: A Study in Church Polity* (1952), and *The United Church of Christ: Its Origins, Organization, and Role in the World Today* (1962); LOUIS H. GUNNEMANN, *The Shaping of the United Church of Christ: An Essay in the History of American Christianity* (1977), which looks at the merger of Congregationalism with the Evangelical and Reformed Church; R. TUDUR JONES, *Congregationalism in England, 1662–1962* (1962); and BROR WALAN, *Församlingstanken i Svenska missionsförbundet: en studie i de nyevangeliska rörelsens sprängning och Svenska missionsförbundets utveckling* (1964), a study of the Covenant Church of Sweden, with an English summary. Modern interpretative essays include DANIEL T. JENKINS, *Congregationalism: A Restatement* (1954); ERIK ROUTLEY, *English Religious Dissent* (1960); and NORMAN GOODALL (ed.), *Der Kongregationalismus* (1973).

Friends: Good introductions to Quakerism may be found in FRIENDS WORLD COMMITTEE FOR CONSULTATION, *Handbook of the Religious Society of Friends*, 5th ed. (1967); and in the interpretation by D. ELTON TRUEBLOOD, *The People Called Quakers* (1966, reissued 1971). The standard histories are WILLIAM CHARLES BRAITHWAITE, *The Beginnings of Quakerism*, 2nd ed. rev. by HENRY J. CADBURY (1955, reissued 1970), and a companion volume, *The Second Period of Quakerism*, 2nd ed. rev. by HENRY J. CADBURY (1961, reissued 1979); and RUFUS M. JONES, *The Quakers in the American Colonies* (1911, reissued 1966), and *The Later Periods of Quakerism*, 2 vol. (1921, reprinted 1970). More specialized works include ELIZABETH ISICHEI, *Victorian Quakers* (1970); RICHARD T. VANN, *The Social Development of English Quakerism, 1655–1755* (1969); JACK D. MARIETTA, *The Reformation of American Quakerism, 1748–1783* (1984); BARRY REAY, *The Quakers and the English Revolution* (1985); and MARY MAPLES DUNN and RICHARD S. DUNN (eds.), *The Papers of William Penn* (1981–), with 4 vol. published by 1987. The masterpiece of Quaker theology is ROBERT BARCLAY, *Apology for the True Christian Divinity* (1678, reissued 1967; originally published in Latin, 1676). WILLIAM CHARLES BRAITHWAITE, *Spiritual Guidance in the Experience of the Society of Friends* (1909, reissued 1941), best explains how Friends' polity should work. See also GLADYS WILSON, *Quaker Worship: An Introductory Historical Study of the English Friends' Meeting* (1952); and CLARENCE E. PICKETT, *For More Than Bread: An Autobiographical Account of Twenty-Two Years Work with the American Friends Service Committee* (1953). Quaker social thought on contemporary issues may be found in STELLA ALEXANDER (comp.), *Quaker Testimony Against Slavery and Racial Discrimination: An Anthology* (1958); and *Towards a Quaker View of Sex: An Essay*, rev. ed. (1964, reprinted 1976), published by the Friends Home Service Committee.

Methodists: GORDON RUPP, *Religion in England, 1688–1791* (1986), on the background and rise of Methodism; RUPERT DAVIES, GORDON RUPP, and A. RAYMOND GEORGE (eds.), *A History of the Methodist Church in Great Britain*, 4 vol. (1966–88), authoritative for history, doctrine, and missions; EMORY STEVENS BUCKE (ed.), *The History of American Methodism*, 3 vol. (1964), comprehensive and authoritative; RUPERT DAVIES, *Methodism*, 2nd rev. ed. (1985), a general survey, chiefly from the British point of view; UMPHREY LEE and WILLIAM WARREN SWEET, *A Short History of Methodism* (1956), concerned mainly with American Methodism; V.H.H. GREEN, *The Young Mr. Wesley* (1961, reissued 1963), a critical study of Wesley's Oxford days; MARTIN SCHMIDT, *John Wesley: A Theological*

Biography, 2 vol. in 3 (1962–73; originally published in German, 2 vol., 1953–66); RICHARD P. HEITZENRATER, *The Elusive Mr. Wesley*, 2 vol. (1984), with material by Wesley and by his contemporaries and biographers; A.C. OUTLER (ed.), *The Works of John Wesley*, vol. 1–4 (1984–87), a collection of his sermons; COLIN W. WILLIAMS, *John Wesley's Theology Today* (1960, reissued 1969), a systematic exposition; RUPERT DAVIES, *What Methodists Believe*, 2nd ed. (1988), Methodist beliefs in their ecumenical setting; GERALD F. MOEDE, *The Office of Bishop in Methodism* (1965), a history of constitutional developments in American Methodism; WADE C. BARCLAY, *History of Methodist Missions*, 4 vol. (1949–73), about American overseas missions; JOHN KENT, *The Age of Disunity* (1966), on division and reunion in British Methodism; BERNARD SEMMEL, *The Methodist Revolution* (1973), the social, economic, and political effect of Methodism on Britain; JOHN M. MOORE, *The Long Road to Methodist Union* (1943), on the reunion of American Methodism; and JOHN MUNSEY TURNER, *Conflict and Reconciliation: Studies in Methodism and Ecumenism in England, 1740–1982* (1985). See also METHODIST CHURCH (GREAT BRITAIN), *The Methodist Service Book* (1975), and *Hymns and Psalms* (1983), worship in British Methodism. Aspects of the church's history are discussed in *Methodist History* (quarterly).

Disciples of Christ: LEROY GARRETT, *The Stone-Campbell Movement: An Anecdotal History of Three Churches* (1981), which gives major attention to the 19th century; JAMES DEFOREST MURCH, *Christians Only: A History of the Restoration Movement* (1962), reflecting an independent viewpoint; and WILLIAM E. TUCKER and LESTER G. MCALLISTER, *Journey in Faith: A History of the Christian Church (Disciples of Christ)* (1975), centring on the cooperative stream. Biographical studies include WILLIAM GARRETT WEST, *Barton Warren Stone: Early American Advocate of Christian Unity* (1954); and LESTER G. MCALLISTER, *Thomas Campbell: Man of the Book* (1954). Beliefs, worship, and organization are treated in ALEXANDER CAMPBELL, *The Christian System, in Reference to the Union of Christians and a Restoration of Primitive Christianity as Plead in the Current Reformation*, 2nd ed. (1839, reprinted 1980), the classic summary of Campbell's theology; ROYAL HUMBERT (ed.), *A Compend of Alexander Campbell's Theology* (1961), with critical and historical commentary; KEITH WATKINS, *The Breaking of Bread: An Approach to Worship for the Christian Churches (Disciples of Christ)* (1966), a comprehensive, historical, and theological analysis; DAVID EDWIN HARRELL, JR., *A Social History of the Disciples of Christ*, 2 vol. (1966–73); and KENNETH LAWRENCE (ed.), *Classic Themes of Disciples Theology: Rethinking the Traditional Affirmations of the Christian Church (Disciples of Christ)* (1986). See also *Mid-Stream: An Ecumenical Journal* (quarterly).

Unitarians and Universalists: EARL MORSE WILBUR, *A History of Unitarianism*, 2 vol. (1945), which remains basic for understanding Unitarianism; C. GORDON BOLAM et al., *The English Presbyterians, from Elizabethan Puritanism to Modern Unitarianism* (1968); CONRAD WRIGHT, *The Beginnings of Unitarianism in America* (1955, reissued 1976), which portrays the 18th century; and CONRAD WRIGHT (ed.), *A Stream of Light: A Sesquicentennial History of American Unitarianism* (1975). RICHARD EDDY, *Universalism in America*, 3rd ed., 2 vol. (1891–94), still useful, has been followed by RUSSELL E. MILLER, *The Larger Hope*, vol. 1, *The First Century of the Universalist Church in America, 1770–1870* (1979), and vol. 2, *The Second Century of the Universalist Church in America, 1870–1970* (1985). ERNEST CASSARA (ed.), *Universalism in America: A Documentary History*, 2nd ed. (1984); and GEORGE HUNTSTON WILLIAMS, *American Universalism: A Bicentennial Historical Essay*, 2nd ed. (1976), are important supplements to Miller. DAVID ROBINSON, *The Unitarians and the Universalists* (1985), is a study of the merged denominations.

Evangelicals, Fundamentalists, and Pentecostals: LEONARD I. SWEET, *The Evangelical Tradition in America* (1984), which includes an extensive superior bibliography on all phases of the movements in the United States; WILLIAM G. MCLOUGHLIN (ed.), *The American Evangelicals, 1800–1900* (1968, reissued 1976), an anthology with a helpful introduction; GEORGE M. MARSDEN, *Fundamentalism and American Culture: The Shaping of Twentieth Century Evangelicalism, 1870–1925* (1980, reprinted 1982), the most important work on the subject; DEAN M. KELLEY, *Why Conservative Churches Are Growing: A Study in Sociology of Religion*, new ed. Protists

Protists are eukaryotic, predominantly microscopic organisms. They may share certain morphological and physiological characteristics with animals or plants, or both. The protists comprise what have traditionally been called protozoa, algae, and lower fungi.

From the time of Aristotle, near the end of the 4th century BC, until well after the middle of the 20th century, the entire biotic world was generally considered divisible into just two great kingdoms, the plants and the animals. The separation was based on the assumption that plants are pigmented (basically green), nonmotile (most commonly from being rooted in the soil), photosynthetic and therefore capable solely of self-contained (autotrophic) nutrition, and unique in possessing cellulosic walls around their cells. By contrast, animals are without photosynthetic pigments (colourless), actively motile, nutritionally phagotrophic (and therefore required to capture or absorb important nutrients), and without walls around their cells.

When microscopy arose as a science in its own right, botanists and zoologists discovered evidence of the vast diversity of life mostly invisible to the unaided eye. With rare exception, authorities of the time classified such microscopic forms as minute plants (called algae) and minute animals (called "first animals," or protozoa). Such taxonomic assignments went essentially unchallenged for many years, despite the fact that the great majority of these minute forms of life—not to mention certain macroscopic ones, various parasitic forms, and the entire group known as the fungi—did not possess the cardinal characteristics on which the "plants" and "animals" had been differentiated and thus had to be forced to fit into those kingdom categories.

An authority who took exception to the imposition of the plant and animal categories on the protists was the German zoologist Ernst Haeckel. In 1866 he proposed a third kingdom, the Protista, to embrace such "lower" organisms, but his conception failed to gain widespread support during his lifetime. Some 80–90 years later, Herbert F. Copeland, an American botanist, attempted a revival of the protist concept, but again without much success.

The basis for a major change in the systematics of these lower forms came through an advancement in the concept of the composition of the biotic world. About 1960, resurrecting and embellishing an idea originally conceived 20 years earlier by the French marine biologist Edouard Chatton but universally overlooked, R.Y. Stanier, C.B. Van Niel, and their colleagues formally proposed the division of all living things into two great groups, the prokaryotes and the eukaryotes. (Prokaryotes—bacteria and other Monera—are unicellular organisms that differ from eukaryotes in nuclear and morphological characteristics and are typically of much smaller size.) This organization was based on characteristics—such as the presence or absence of a true nucleus, the simplicity or complexity of the DNA (deoxyribonucleic acid) molecules constituting the chromosomes, and the presence or absence of intracellular membranes (and of specialized organelles apart from ribosomes) in the cytoplasm—that revealed a long phylogenetic separation of the two assemblages. The concept of "protists" originally embraced all the microorganisms in the biotic world. The entire assemblage thus included the protists as defined below plus the bacteria, the latter considered at that time to be lower protists. The great evolutionary boundary between the prokaryotes and the eukaryotes, however, has meant a major taxonomic boundary restricting the protists to eukaryotic microorganisms (but occasionally including relatively macroscopic organisms) and the bacteria to prokaryotic microorganisms.

During the 1970s and '80s, attention was redirected to the problem of possible high-level systematic subdivisions within the eukaryotes. The American biologists R.H.

Whittaker and Lynn Margulis, as well as others, became involved in such challenging questions. A major outcome was widespread support among botanists and zoologists for considering living organisms as constituting five separate kingdoms, four of which are placed in what may be thought of as the superkingdom Eukaryota (Protista, Plantae, Animalia, and Fungi); the fifth kingdom, Monera, constitutes the superkingdom Prokaryota.

This article discusses the kingdom Protista in general terms. For discussion of the differences and similarities among the four kingdoms of the superkingdom Eukaryota, as well as the Prokaryota, see BIOLOGICAL SCIENCES. For a generally more detailed treatment of the members of the Protista, see PROTOZOA and ALGAE.

GENERAL FEATURES

The protists include all unicellular organisms not included with the prokaryotes. Protists also embrace a number of forms of syncytial (coenocytic) or multicellular composition, generally manifest as filaments, colonies, coenobia (a type of colony with a fixed number of interconnected cells embedded in a common matrix before release from the parental colony), or thalli (a leaflike, multicellular structure or body composed primarily of a single undifferentiated tissue). Not all protists are microscopic. Some groups have large species indeed; for example, among the brown algal protists some forms may reach a length of 60 metres or more. A common range in body length, however, is 5 micrometres (0.002 inch) to 2 or 3 millimetres (0.07 or 0.1 inch); some parasitic forms (e.g., the malarial organisms) and a few free-living algal protists may have a diameter, or length, of only 1 micrometre. While members of many protistan groups are capable of motility, primarily by means of flagella, cilia, or pseudopodia, other groups (or certain members of the groups) may be nonmotile for most or part of the life cycle. Resting stages (spores or cysts) are common among many taxa, and modes of nutrition include photosynthesis, absorption, and ingestion. Some species exhibit both autotrophic and heterotrophic nutrition (see below *Form and function: Respiration and nutrition*). The great diversity shown in protist characteristics (Figures 1 and 2) supports the theories about the antiquity of the protists and of the ancestral role they play with respect to the other eukaryotic groups.

The architectural complexity of most protist cells is what sets them apart from the cells of plant and animal tissues. Not only are protists cells, they are also whole, complete, independent organisms, and they must compete and survive as such in the environments in which they live. Adaptations to particular habitats over eons of time have resulted in both intracellular and extracellular elaborations seldom, if ever, found at the cellular level in higher eukaryotic species. Internally, for example, complex rootlet

systems have evolved in association with the basal bodies, or kinetosomes (see below *Locomotion*), of many ciliates and flagellates, and nonhomologous endoskeletal and exoskeletal structures have developed in many protist taxa. Conspicuous food-storage bodies are often present, and pigment bodies apart from, or in addition to, chloroplasts are found in some species. In the cortex, just under the pellicle of some protists, extrusible bodies (extrusomes) of various types (e.g., trichocysts, haptocysts, toxicysts, and mucocysts) have evolved, with presumably nonhomologous functions, some of which are still unknown. Scales may appear on the outside of the body, and, in some groups, tentacles, suckers, hooks, spines, hairs, or other anchoring devices have evolved. Many species have an external covering sheath, which is a glycopolysaccharide surface coat sometimes known as the glycocalyx. Cyst or spore walls, stalks, loricae, and shells (or tests) are also common external features.

In terms of conventional classifications of the lower eukaryotes but considering the system used in this article, the major taxa treated here as protists include the algae, the protozoa, and the so-called lower, or zoosporic (motile), fungi.

Included are members from among the major conventional algal classes or divisions. Some are organized as phyla under the section heading chlorobionts—the chlorophytes sensu lato (chlorophyceans, charophyceans, micromonadophyceans, pleurostrophyceans, ulvophyceans) and the glaucophytes. Many of the algal heterokonts (chromophytes sensu lato) are organized under the heading chromobionts; these include the chrysophyceans, synurophyceans, haptophyceans, xanthophyceans, pedinellophyceans, bacillariophyceans (diatoms), and phaeophyceans (brown algae), as well as several other smaller algal groups. There are, in addition, four nonalgal protist taxa in the section chromobionts. Some members of the section euglenozoa—the euglenophytes (the remaining phyla being represented by the protozoan phylum Kinetoplastidea [the trypanosomatid/bodonid protozoans] and the two small protozoan phyla Pseudociliata and Hemimastigophorea)—and all members of the sections cryptomonads (Cryptophyta), rhodophytes (Rhodophyta, or red algae), and dinoflagellates (Pyrrhophyta, mostly dinoflagellates) are also conventionally classified as algae.

The protozoa included here are the members of the former conventional phyla (or subphyla) Sarcostomastigophora, Ciliophora, Sporozoa (or Apicomplexa), Microsporidia, and Myxosporidia. The zooflagellates sensu lato and the phytoflagellates, the latter embracing the mostly motile and/or phagotrophic algal groups among those listed in the preceding paragraph, were formerly, in more conventional classifications, placed at lower taxonomic levels. The zoomastigophorans comprised not only the so-called higher zooflagellates (mostly the symbiotic forms) but also the opalinids and the proteromonadeans of the section chromobionts, the taxonomically enigmatic choanoflagellates (phylum Choanomonadea), and the lower kinetoplastideans (the trypanosomes, class Trypanosomata, and relatives). Also included under the broad umbrella name of Sarcostomastigophora were the so-called rhizopod and actinopod Sarcodina taxa of sections X and XI—although the classification presented here also includes in those sections several groups formerly considered to be fungi—i.e., slime molds (Mycetozoa) and their presumed relatives.

Fungal groups that appear in the classification used in this article include the motile zoosporic groups, sometimes called the Oomycota and Hyphochytridiomycota (section chromobionts); the Chytridiomycetes, of the section chytrids (the latter group is not closely related to the former two); and Mycetozoa, or Myxomycetes, and its alleged relatives, which are found in the rhizopod sarcodine section.

The many groups of mostly microorganisms listed above are all interrelated to a degree. Not only are they not plants, animals, or fungi, but, despite the diverse characteristics they exhibit among themselves, they are evolutionarily, systematically, and taxonomically related by the common condition of being constructed solely on a cellular basis. They may show multicellularity as well as unicellularity, but never are they multitissued.

It should be emphasized that the protists cannot be divided perfectly into algae, protozoa, and fungi. This is principally because certain groups have been assigned historically to more than a single one of these three categories by zoologists, botanists, and mycologists. The rationale for past taxonomic decisions at such levels has not always been based solely on the presence or absence of chloroplasts; the situation is further complicated by the reliance of some pigmented species on the consumption of nutrients from the surrounding milieu (facultative phagotrophy) rather than on photosynthesis.

The following groups considered as phyla (or divisions) in this article have been treated—although not always uniformly and under a variety of names—as both algae and protozoa (usually as phytoflagellates) in many conventional taxonomic systems: some members of Chrysophyta, Haptophyta, Xanthophyta, Pedinellophyta, Eustigmatophyta, some members of Chlorophyta, some members of Micromonadophyta, some members of Pleurostrophyta, Glaucophyta, Euglenophyta, Cryptophyta, Dinoflagellata, Choanomonadea, and some members of Proteromonadea sensu lato.

"Conventional" classification

Problems in classification

Figure 2: Representative protists.

The phyla Mycetozoa, Dictyosteliidea, Acrasidea, Plasmodiophorea, and Labyrinthomorpha have been claimed as fungi by many mycologists and as protozoa by most zoologists. The three phyla of the zoosporic “lower fungi”—the Oomycota, Hyphochytridiomycota, and Chytridiomycetes—formerly embraced only by mycologists, are now widely considered to be true protists and not fungi.

FORM AND FUNCTION

Locomotion. One of the most striking features of many protist species is the presence of some type of locomotory organelle, easily visible under the light microscope. A few forms can move by gliding or floating, although the vast majority move by means of “whips” or small “hairs” known as flagella or cilia, respectively. (These organelles give their names to informal groups—flagellates and ciliates—of protists.) A lesser number of protists employ pseudopodia. These same organelles may be used in feeding as well.

Cilia and flagella are basically identical in structure and perhaps fundamentally in function as well. They are far more complex at the molecular level than they may seem to be when viewed solely by light microscopy. Cilia and flagella are also known among plants and animals, al-

though they are totally absent from the true fungi. These eukaryotic organelles are not to be confused with the locomotory structure of bacteria (the prokaryotic flagellum), which is a minute organelle composed of flagellin, not tubulin, as in the protists. The prokaryotic flagellum is intrinsically nonmotile (rather, it is moved by its basal part, which is embedded in the cell membrane); it is entirely extracellular, and it is neither homologous with (*i.e.*, does not have a common evolutionary origin) nor ancestral to the eukaryotic flagella.

Cilia and flagella consist of an inner cylindrical body known as the axoneme and an outer surrounding membrane, the latter continuous with the cell membrane. The axoneme itself is composed of nine outer pairs of longitudinal microtubules (microtubular fibres) and one inner pair. The nine outer pairs become triplets of microtubules below the surface of the cell; this structure, presumably anchoring the flagellum to the organism’s body, is known as the basal body or kinetosome. The membrane of the cilium or flagellum may appear to bear minute scales or hairs (mastigonemes) on its own outer surface, presumably functionally important to the organism and valuable as taxonomic characters. A fibrillar structure within the flagella, known as a paraflagellar, paraxial, or intraflagellar rod, may lie between the axoneme and the outer membrane of a flagellum; its function is not clear.

The distribution of these locomotory organelles over the cell varies among different taxonomic groups. Many of the algal protists are characteristically biflagellate, and in most instances both flagella originate near or at the anterior pole of the body. The presence, absence, or pattern of the mastigonemes may also differ between two flagella of the same species and among species belonging to separate taxa. Some of the parasitic zooflagellates have hundreds of long flagella, and the locomotion of some of these species is further aided by the presence of attached spirochetes (prokaryotes) undulating among the flagella.

Ciliated protists (phylum Ciliophora) show an even greater diversity in the number, distribution, and arrangement of cilia over the cell. In some groups, single cilia have, in effect, been replaced by compound ciliary organelles (*e.g.*, membranelles and cirri), which may be used effectively in locomotion and in feeding. Patterns are again associated with members of different taxa. While both ciliates and flagellates may have various rootlet systems associated with their locomotory organelles or with the basal bodies, or both, the organelles in the ciliates have developed a more complex and elaborate subpellicular infrastructure. Called the infraciliature, or kinetidal system, it lies principally in the outer, or cortical, layer of the ciliate’s body (only the outermost layer is called the pellicle) and serves primarily as a skeletal system for the organism. The system is composed of an array of single or paired kinetosomes with associated microtubules and microfibrils plus other specialized organelles (such as parasomal sacs, alveoli, contractile vacuole pores, and the cytoproct, or cell anus), which is unique among the protists. Variations are of great importance in the taxonomy and evolution of protists.

Typically, flagellates move through an aqueous medium by the undulatory motions of the flagella. The waves of movement are generated at the base of the flagellum. The direction and speed of propulsion and other elements of movement depend on a number of factors, including the viscosity of the medium, the size of the organism, the amplitude and length of the waves, the length and exact position of the flagella, and the kind and presence or absence of flagellar hairs. Some ciliates can move much more rapidly by virtue of having many though shorter, cilia beating in coordination with each other. The synchronized beat along the longitudinal ciliary rows produces what is known as a metachronal wave. Differences in details attest to the complexity of the overall process.

Flagella and cilia are also involved in sensory functioning, probably by means of their outer membranes which are known to contain, at the molecular level, as many as seven kinds of receptors. A variety of chemoreceptors can recognize minute changes in the medium surrounding the organism as well as cues from presumed mating partners that lead to sexual behaviour.

Taxonomic significance of cilia and flagella

Cilia and flagella

Pseudo-
podia

In comparison with flagella and cilia, pseudopodia seem rather simple. Pseudopodia are responsible for amoeboid movement, a type of locomotion particularly associated with members of the protist group traditionally called the Sarcodina. Such movement, however, is not exclusive to the amoebas; some flagellates, some sporozoa (apicomplexans), and even some cells of the other eukaryotic kingdoms demonstrate it. Pseudopodia, even more so than flagella and cilia, are widely used in phagotrophic feeding as well as in locomotion.

Three kinds of pseudopods (lobopodia, filopodia, and reticulopodia) are basically similar and are quite widespread among the rhizopod sarcodines, while the fourth type (axopodia) is totally different, more complex, and characteristic of certain specialized high-level taxa of the sarcodines under the designation actinopod sarcodines. The types, numbers, shapes, distribution, and actions of pseudopodia are important taxonomic considerations.

The lobopodium may be flattened or cylindrical (tubular). *Amoeba proteus* is probably the best-known protist possessing lobopodia. Although the mechanisms of amoeboid movement have long been a controversial topic, there is general agreement that contraction of the outer, nongranular layer of cytoplasm (the ectoplasm) causes the forward flow of the inner, granular layer of cytoplasm (the endoplasm) into the tip of a pseudopod, thus advancing the whole body of the organism. Actin and myosin microfilaments, adenosine triphosphate (ATP), calcium ions, and other factors are involved in various stages of this complex process (see PROTOZOA).

Other pseudopodia found among the rhizopod amoebas include the filopodia and the reticulopodia. The filopodia are hyaline, slender, and often branching structures in which contraction of microfilaments moves the organism's body along the substrate, even if it is bearing a relatively heavy test or shell. Reticulopodia are fine threads that may not only branch but also anastomose to form a dense network, which is particularly useful in entrapping prey. Microtubules are involved in the mechanism of movement, and the continued migration of an entire reticulum carries the cell in the same direction. The testaceous, or shell-bearing, amoebas possess either lobopodia or filopodia, and the often economically important foraminiferans bear reticulopodia—in fact, granuloreticulopodia, giving the name to the taxonomic class in which these rhizopod amoeboid protists are placed.

The actinopod sarcodines are characterized in large measure by the axopodium, the fourth and most distinct type of pseudopodium. Axopodia are composed of an outer layer of flowing cytoplasm that surrounds a central core containing a bundle of microtubules, which are cross-linked in specific patterns among different species. The outer cytoplasm may bear extrusible organelles used in capturing prey. Retraction of an axopod is quite rapid in some forms, although not in others; reextension is generally slow in all actinopods. The modes of movement of the axopodia often differ; for example, the marine pelagic taxopod *Sticholonche* (formerly considered to be a heliozoan) have axopodia that move like oars, even rotating in basal sockets reminiscent of oarlocks.

Respiration and nutrition. At the cellular level, the metabolic pathways known for protists are essentially no different from those found among cells and tissues of other eukaryotes. Thus, the plastids of algal protists function like the chloroplasts of plants with respect to photosynthesis, and, when present, the mitochondria function as the site where molecules are broken down to release chemical energy, carbon dioxide, and water. The basic difference between the unicellular protists and the tissue- and organ-dependent cells of other eukaryotes lies in the fact that the former are simultaneously cells and complete organisms. Such microorganisms, then, must carry out the life-sustaining functions that are generally served by organ systems within the complex multicellular or multitissued bodies of the other eukaryotes. Many such functions in the protists are dependent on relatively elaborate architectural adaptations in the cell. Phagotrophic feeding, for example, requires more complicated processes at the protist's cellular level, where no combination of tissues and cells is

available to carry out the ingestion, digestion, and egestion of particulate food matter. On the other hand, obtaining oxygen in the case of free-living, free-swimming protozoan protists is simpler than for multicellular eukaryotes because the process requires only the direct diffusion of oxygen from the surrounding medium.

Although most protists require oxygen (obligate aerobes), there are two main groups that may or must exhibit anaerobic metabolism: parasitic forms inhabiting sites without free oxygen and some bottom-dwelling (benthic) ciliates that live in the sulfide zone of certain marine and freshwater sediments. Mitochondria are not found in the cytoplasm of these anaerobes; rather, microbodies called hydrogenosomes or specialized symbiotic bacteria act as respiratory organelles.

The major modes of nutrition are autotrophy (involving plastids, photosynthesis, and the organism's manufacture of its own nutrients from the milieu) and heterotrophy (the taking in of nutrients). Obligate autotrophy, which requires only a few inorganic materials and light energy for survival and growth, is characteristic of algal protists (e.g., *Chlamydomonas*). Heterotrophy may occur as one of at least two types: phagotrophy, which is essentially the engulfment of particulate food, and osmotrophy, the taking in of dissolved nutrients from the medium, often by the method of pinocytosis. Phagotrophic heterotrophy is seen in many ciliates that seem to require live prey as organic sources of energy, carbon, nitrogen, vitamins, and growth factors. The food of free-living phagotrophic protists ranges from other protists to bacteria to plant and animal material, living or dead. Scavengers are numerous, especially among the ciliophorans; indeed, species of some groups prefer moribund prey. Organisms that can utilize either or both autotrophy and heterotrophy are said to exhibit mixotrophy. Many dinoflagellates, for example, exhibit mixotrophy, one of the reasons they are claimed taxonomically by both botanists and zoologists.

Feeding mechanisms and their use are diverse among protists. They include the capture of living prey by the use of encircling pseudopodial extensions (in certain rhizopods), the trapping of particles of food in water currents by filters formed of specialized compound buccal organelles (in ciliates), and the simple diffusion of dissolved organic material through the cell membrane, as well as the sucking out of the cytoplasm of certain host cells (as in many parasitic protists). In the case of many symbiotic protists, methods for survival, such as the invasion of the host and transfer to fresh hosts, have developed through long associations and often the coevolution of both partners.

Reproduction and life cycles. Cell division in protists, as in plant and animal cells, is not a simple process, although it may superficially appear to be so. The typical mode of reproduction in most of the major protistan taxa is asexual binary fission. The body of an individual protist is simply pinched into two parts or halves; the "parental" body disappears and is replaced by a pair of offspring or daughter nuclei, although the latter may need to mature somewhat to be recognizable as members of the parental species. The length of time for completion of the process of binary fission varies among groups of organisms and with environmental conditions, but it may be said to range from just a few hours in an optimal situation to many days under other circumstances. In some unicellular algal protists, reproduction occurs by fragmentation. Mitotic replications of the nuclear material presumably accompany or precede all divisions of the cytoplasm (cytokinesis) in protists.

Multiple fission also occurs among protists and is common in some parasitic species. The nucleus divides repeatedly to produce a number of daughter nuclei, which eventually become the nuclei of the progeny after repeated cellular divisions. There are several kinds of multiple fission, often correlated with phases or stages in the full life cycle of a given species. The number of offspring or filial products resulting from a multiple division (or very rapid succession of binary fissions) may vary from four to dozens or even hundreds, generally in a short period of time. Modes of such multiple fission range from budding, in which a daughter nucleus is produced and split

from the parent together with some of the surrounding cytoplasm, to sporogony (production of sporozoites by repeated divisions of a zygote) and schizogony (formation of multiple merozoites, as in malarial parasites). The latter two phenomena are characteristic of many sporozoan protists, which are obligate parasites of more advanced eukaryotes. Some multicellular algal protists reproduce via asexual spores, structures that are themselves often produced by a series of rapid fissions. The life cycles of two protist types as shown in Figures 3 and 4 illustrate many of these features of cell division.

Even under a light microscope, differences can be seen in the modes of division among diverse groups of protists. The flagellates, for example, exhibit a longitudinal, or mirror-image, type of fission (symmetrogeny). The ciliates, on the other hand, basically divide in a point-by-point correspondence of parts (homothetogeny), often seen as essentially transverse or perkinetal (across the kinetics, or ciliary rows). Most amoebas *sensu lato* exhibit, in effect, no clear-cut body symmetry or polarity, and thus their fission is basically simpler and falls into neither of the categories described above.

Sexual phenomena are known among the protists. The erroneous view that practically all protists reproduce asexually is explained by the fact that certain well-known organisms, such as species belonging to the genera *Euglena* and *Amoeba*, do not demonstrate sexuality. Even many of the unicellular species can, under appropriate conditions, form gametes (male and female sex cells, although sometimes multiple sexes are formed, which makes the terms "male" and "female" inappropriate), which fuse and give

rise to a new generation. In fact, sexual reproduction—that is, the union of one male and one female gamete (syngamy)—is the most common sexual phenomenon and occurs quite widely among the protists—for example, among various flagellate and sarcodine groups and among many parasitic phyla (e.g., in *Plasmodium*, a malaria-causing organism).

Conjugation, the second major kind of sexual phenomenon and one occurring in the ciliated protists, has genetic and evolutionary results identical to those of syngamy. The process involves the fusion of gametic nuclei rather than independent gamete cells. A zygotic, or fusion, nucleus, not a true zygote, is produced and undergoes a series of meiotic divisions to produce a number of haploid pronuclei; all but one of these pronuclei in each organism will disintegrate. The remaining pronuclei divide mitotically; one pronucleus from each organism is exchanged, and the new micronuclei and macronuclei of the next generation are formed. Following the exchange of the pronuclei and the subsequent formation of new micronuclei and macronuclei in each organism, a series of asexual fissions, accompanied by mitotic divisions of the new diploid micronuclei, occurs in each exconjugant line. The new polyploid macronuclei are distributed passively in the first of these divisions; in subsequent fission, the macronuclei duplicate themselves through a form of mitosis. This last stage constitutes the only reproduction involved in the process.

Conjugation, as described here, is essentially limited to the ciliates, and there is considerable variation in the manner in which it is exhibited among them. For example, the two ciliates themselves may be of noticeably different size (called macroconjugants and microconjugants), or the number of predivisions of the micronuclei may vary, as may the number of nuclear divisions that take place after the zygotic nucleus is formed. Furthermore, chemical signals (gamones) are given or exchanged before a pair of protists unite in conjugation. It is not known if these gamones should be considered as sex pheromones, reminiscent of those known in many animals (for example, certain insects), but they seem to serve the similar purpose of attracting or bringing together different mating types.

While conjugation may be considered a process of reciprocal fertilization, a parallel sexual phenomenon in ciliates, which takes place in single, unpaired individuals, may be considered a process of self-fertilization. In this type of fertilization, called autogamy, complete homozygosity is obtained in the lines derived from the single parent, and the species that seem to prefer this process are known as intensive inbreeders.

Figure 4: Life cycle of *Spirogyra*, a conjugating algal protist.

From L. Margulis et al., *Handbook of Protozoists* (1990), Jones and Bartlett, Boston, after Lee (1980)

Protist life cycles range from relatively simple ones that may involve only periodic binary fissions to very complex schemes that may contain asexual and sexual phases, encystment and excystment, and—in the case of many symbiotic and parasitic forms—an alternation of hosts. In the more complicated life cycles in particular, the morphology of the organism may be strikingly different (polymorphism) from phase to phase in the entire life cycle. Among certain ciliate groups in which a larval or migratory form (known as a swarmer) is produced by the parent, the offspring may demonstrate such a differing morphology that it might well be assigned taxonomically to an entirely different family, order, or even class.

Dormancy

Dormant stages in a life cycle are probably more common in algal protists than in protozoan protists. Such stages, somewhat analogous to hibernation in mammals, serve to preserve the species during unfavourable conditions, as in times of inadequate food supply or extreme temperatures. The occurrence of resistant cysts in the vegetative stage depends, therefore, on such environmental factors as season, temperature, light, water, and nutrient supply. The fertilized egg, or zygote, in a number of algal groups may also pass into a dormant stage (a zygospore). Temporary or long-lasting cysts may occur among other protist species as well. Many sporozoa and members of other totally parasitic phyla form a highly resistant stage—for example, the oocyst of the coccidians, which may survive for a long time in the fecal material of the host or in the soil. This cyst is the infective stage for the next host in the parasite's life cycle.

Some life cycles involve not only multiple hosts but also a vector—that is, a particular metazoan organism that can act as either an active or a passive carrier of the parasite to the next host. In malaria, for example, a mosquito is required to transfer the *Plasmodium* species to the next vertebrate host (Figure 5).

ECOLOGY

The distribution of protists is worldwide; as a group, these organisms are both cosmopolitan and ubiquitous. Every individual species, however, has preferred niches and microhabitats, and all protists are to some degree sensitive to changes in their surroundings. The availability of sufficient nutrients and water, as well as sunlight for photosynthetic forms, is, however, the only major factor restraining successful and heavy protist colonization of practically any habitat on Earth.

Free-living forms are particularly abundant in natural aquatic systems, such as ponds, streams, rivers, lakes, bays, seas, and oceans. Certain of these forms may occur at specific levels in the water column, or they may be bottom-dwellers (benthic). More specialized, sometimes human-made, habitats are also often well populated by both pigmented and nonpigmented members of various taxa. Such sites include thermal springs, briny pools, cave waters, snow and ice, beach sands and intertidal mud flats, bogs and marshes, swimming pools, and sewage treatment plants. Many are commonly found in various terrestrial habitats, such as soils, forest litter, desert sands, and the bark and leaves of trees. Cysts and spores may be recovered from considerable heights in the atmosphere, and some researchers claim that certain algal protists actually live, and perhaps reproduce, in air streams.

Fossilized forms are plentiful in the geologic record. They are found in strata of all ages, as far back, in the case of red alga fossils, as the Precambrian (1.9 billion years ago). Entire classes or even phyla of protists have left no record of their now extinct forms, making speculation about early phylogenetic and evolutionary relationships within the kingdom difficult to verify with the types of hard data available in the study of animal and plant evolution.

Symbiotic protists are as widespread as free-living forms, since they occur everywhere their hosts are to be found. Hundreds or even thousands of kinds of protists live as ectosymbionts or episymbionts, finding suitable niches with plants, fungi, vertebrate and invertebrate animals, or even other protists. Seldom are the hosts harmed; in fact, these often mobile substrates are actually used as a means of dispersal.

Endosymbionts include commensals, facultative parasites, and obligate parasites; the latter category embraces forms that have effects on their hosts ranging from mild discomfort to death. Protozoan and certainly nonphotosynthetic protists are implicated far more often in such associations than are algal forms. In a few protists, both cytoplasm and nuclei can be invaded by other protists, and intimate, mutually beneficial relationships between protistan hosts and protistan symbionts have been seen, such as foraminiferans or ciliates that nourish symbiotic algae in their cytoplasm. When higher eukaryotes are hosts to protists, all body cavities and organ systems are susceptible to invasion, although terrestrial plants bear relatively few such parasites. In animal hosts, the three principal areas serving as sites for endosymbiotic species are the coelom, the digestive tract and its associated organs, and the circulatory system.

The numbers of individuals in populations of many protists reach staggering figures. There are, on the average, tens of thousands of protists in a gram of arable soil, hundreds of thousands in the gut of a termite, millions in the rumen of a bovine mammal, billions in a tiny patch of floating plankton in the sea, and trillions in the bloodstream of a person infected with severe malaria. Fossil forms reach similar, if not greater, concentrations.

Some of the worst diseases of humans are caused by protists, primarily blood parasites. Malaria (caused by a protozoan protist of the phylum Sporozoa [Apicomplexa]), the various trypanosomiasis (one type is African sleeping sickness) and leishmaniasis (caused by tissue-invading flagellates), toxoplasmosis (caused by another sporozoan group), and amoebic dysentery (caused by sarcodine rhizopod species) are debilitating or fatal afflictions. Biomedical research still needs to be carried out to find ways of controlling and eradicating such diseases of humans.

Protist parasites infecting domesticated livestock, poultry, hatchery fishes, and other such food sources deplete

Endosymbionts

Figure 5: Life cycle of *Plasmodium vivax*, a protozoan that is parasitic in the blood of humans. Meiosis occurs when the diploid ookinete undergoes its first nuclear division, so that all stages in the life cycle other than the ookinete (zygote) are haploid.

supplies or render them unpalatable. The economic losses can be considerable. Certain free-living marine dinoflagellates are the causative agents of the so-called red tide outbreaks that occur periodically along coasts throughout the world; a toxin released by the blooming protists kills fishes in the area by the hundreds of tons. Other dinoflagellates produce a toxin that may be taken up by certain shellfish (bivalve mollusks) and which causes paralysis, even death, when the mollusk is eaten by humans. Some of the "lower" fungal protists have had significant effects on human history. One species was responsible for the great Irish potato blight of the mid-19th century, and later, another nearly ruined the entire French wine industry before a fungicide was developed to destroy it.

Benefits of protistan activities

Many protists provide humans with benefits, some more obvious than others. Because protists are located near the bottom of the food chain in nature (just above the bacteria), they serve a crucial role in sustaining the higher eukaryotes in fresh and marine waters. In addition to directly and indirectly supplying organic molecules (such as sugars) for other organisms, the pigmented (chlorophyll-containing) algal protists produce oxygen as a by-product of photosynthesis. Algae may supply up to half of the net global oxygen. Deposits of natural gas and crude oil are derived from fossilized populations of algal protists. Much of the nutrient turnover and mineral recycling in the oceans and seas comes from the activities of the heterotrophic (nonpigmented) flagellates and the ciliates living there, species that feed on the bacteria and other primary producers present in the same milieu. Seaweeds (e.g., brown algae) have long been used as fertilizers.

Several hundred species of algae are consumed as food, either directly or indirectly in prepared items. For example, alginates (extracted from brown algae) and agars (from red algae) occur in such foods as ice cream, candy bars, puddings, and pie fillings.

The calcareous test, or shell, of the foraminiferans is preservable and constitutes a major component of limestone rocks. Assemblages of certain of these protists, which are abundant and usually easily recognized, are known to have been deposited during various specific periods in the Earth's geologic history. Geologists in the petroleum industry study foraminiferan species present in samples of drilled cores in order to determine the age of different strata in the Earth's crust, thus making possible the identification of rich oil deposits. Before synthetic substitutes, blackboard chalk consisted mostly of calcium carbonate derived from the scales (coccoliths) of certain algal protists and from the tests of foraminiferans. Diatoms and some ciliate species are useful as indicators of water quality and therefore of the amount of pollution in natural aquatic systems and in sewage purification plants. Selected species of parasitic protozoans from among microsporidians (*Microspora*) may play a significant role as biological control organisms against certain insect predators of food plants.

Uses as laboratory models

Protists have been used as model cells in laboratory research, some of which is directed against major human diseases. The combination of characteristics that has made them superior to both prokaryotic cells and other eukaryotic cells includes their easy availability and maintenance, convenient size for handling in large numbers, short generation time, broad physiological adaptability, basic structural and functional similarity to the eukaryotic cells of animal organisms, and, most importantly for sophisticated work requiring purity of material and rigidity of controls, culturability (i.e., their successful growth axenically—free of other living organisms—and on chemically definable media). The culturability of some unicellular free-living protists has made them invaluable as assay organisms and pharmacological tools. Among those that have proven to be useful this way, the most important is the ciliate *Tetrahymena*, which serves as a superb model cell in investigations in cell and molecular biology. The value of such research in such biomedically important fields as cancer chemotherapy is potentially great.

EVOLUTION AND PALEOPROTISTOLOGY

Students of the evolution of most lines of plants and animals have relied heavily on the fossil records of their

forms to indicate ancestor-descendant relationships over time. In the case of most protist groups, extinct forms are rare or too scattered to be of much help in evolutionary studies. For certain major taxa, fossil forms are abundant, and such material is useful in an investigation of their probable interrelationships, but only at lower taxonomic levels within those groups themselves. Speculation about the possible degrees of phylogenetic closeness among the various phyla within the entire kingdom Protista is frustrated by the lack of appropriate fossil material. There are other ways and means of determining relationships, but these are also only partially helpful. The application of modern techniques of sequencing proteins and genes to problems of evolutionary protistology is offering invaluable assistance in these investigations.

Paleoprotistology, the study of extinct protists (i.e., of the parts that were capable of becoming fossilized: cell, cyst, or spore walls; internal or external skeletons of appropriate preservable materials; and scales, loricae, tests, or shells) has thrown light on the probable interrelationships of both fossil and contemporary forms within classes, orders, and genera and on the paleoecology of the geologic eras and periods in which the fossil forms once lived. In addition, it has provided valuable information on the antiquity of the groups being examined. Caution is necessary, however, since species with no hard parts left no fossil record, and the extinct forms that are studied may have been preceded by species that have left specimens not yet discovered.

The antiquity of several major groups of protists, however, has been quite well established. The rhodophytes (red algae) may have arisen as early as 1.9 billion years ago, in the Precambrian Era, although most of their fossils are from more recent geologic periods. The polycystine actinopods (classically known as the radiolarians) and various green algal protist lines also have origins in the late Precambrian (1.2 to 1.3 billion years ago). Foraminiferans, dinoflagellates, haptophytes, and some brown algae (phaeophytes) date to the middle of the Paleozoic Era (some 300 to 400 million years ago). Representatives of a number of protist taxa (including the ubiquitous diatoms) have been found as fossils from periods of the Mesozoic Era (100 to 200 million years ago).

A useful method of tackling the broad problems of possible phylogenetic interrelationships among diverse high-level protist taxa is the recognition of homologous (or presumed homologous) structures within representative forms from such groups. Electron microscopy has been important in comparative studies of this kind. Ultrastructural characteristics exhibited in common by groups seemingly as diverse as green euglenoid protists and the parasitic trypanosome "zooflagellates," for example, have caused major changes in the subkingdom systematics of the Protista. The principal features of high phylogenetic-information content are the microfibrillar and microtubular organelles associated with the basal bodies (kinetosomes) of all flagellated and ciliated protists; the mastigonemes, or flagellar "hairs," found on many flagella, especially of algal protists; the configuration of the cristae formed by the infolding of the inner membrane of mitochondria; the characteristics of plastids, including the number of surrounding membranes or envelopes; microtubular cytoskeletal systems not directly associated with cilia and flagella; extrusomes; and cell walls and walls and membranes of various spores, cysts, tests, and loricae.

Biochemical and physiological characteristics, sometimes directly related functionally to the anatomic ultrastructures mentioned above, include the exact nature of the pigments in those protists with plastids, of the storage products produced (food reserves), and of the cell walls or membranes enveloping the organism. Determination of the molecular structure or functions of such cytoplasmic inclusions as mitochondria, the Golgi apparatus, lysosomes, microbodies of diverse sorts, pseudopodia, spindle fibres (which function in mitosis and meiosis), and even miscellaneous vesicles, vacuoles, and membranes can throw light on group affinities. Comparing metabolic pathways can be valuable as well; for example, the choice of lysine biosynthesis differs among various protist taxa. Modes of nutrition are also investigated.

Paleo- protis- tology

The serial
endo-
symbiosis
theory

General ecological factors or characteristics have not played an important role in these studies. Specifically implicated in hypotheses of the origin of eukaryotic cells from prokaryotic ancestries (eukaryogenesis), however, is the phenomenon of endosymbiosis, which in a broad sense might be considered an ecological factor in the very early evolution of organisms destined to comprise the eukaryotic kingdoms. The serial endosymbiosis theory (or SET) offers one explanation of the origin of such cytoplasmic organelles as the mitochondria and plastids found in so many protists. According to SET, certain primitive prokaryotes were engulfed by other, different prokaryotes. The structures and functions of the first were ultimately incorporated into the second. The second form—now more highly evolved and presumably favoured by selection—could subsequently engulf, or be invaded by, still other types of primitive prokaryotes, acquiring from them additional, and different, structures and functions. Through its own internal evolution as well, this more complex organism eventually came to possess the characteristics recognizable as eukaryotic. This exogenous theory is to be contrasted with the endogenous hypothesis, which has held that all cellular organelles have been derived, in a long evolutionary process, from materials (especially membranes) already present in the (potential) eukaryotic cell.

Ribosomal RNA sequencing is a molecular technique that has had a major impact on conventional schemes of classification of the protists. It has, however, also strengthened or confirmed older systems that were based either on intuitive deductions or on the determination of ultrastructural homologies.

The protists are thought to have arisen from eubacterial (not archaeobacterial) prokaryotes, with symbiotic associations being involved in some way. The first, or "eoprotist," was probably a nonpigmented heterotrophic form. From within the vast array of protists there must have arisen the early members of the other eukaryotic kingdoms, as well as still additional protist groups. Numerous groups undoubtedly arose as evolutionary experiments, and many of these subsequently became extinct, generally leaving no fossil record. The protists are themselves likely someday to be subdivided into several separate kingdoms.

CLASSIFICATION

Macrosystems of protist classification. There are essentially three broad options with respect to treating protists within classification systems that embrace all living things. One is to recognize that a single kingdom, Protista, is evolutionarily and taxonomically justifiable, as is done in this article. Protists, by virtue of sharing many common characteristics, do seem to manifest an overall taxonomic unity or integrity of their own. Yet, if this approach is taken, a series of major problems remains: what is an acceptable definition of such an assemblage; exactly what does it include (*i.e.*, what are its boundaries); and what are the phylogenetic interrelationships of the high-level subgroups specifically included within it?

Alternative
schemes of
protistan
classifi-
cation

A popular alternative among evolutionary biologists is to consider the protists as only a structural grade of organization, a temporary state of transition in the evolution of the "higher" eukaryotic kingdoms from a prokaryote ancestry. While this view has appeal, it leaves confusion in its wake: if the protists belong to distinct taxonomic units at lower levels in the classificational hierarchy, then what phyla or kingdoms are to be identified for them at the top levels in the macrosystem? The fact that certain protists served as evolutionary "gap-bridgers" in eukaryogenesis and that others have played an ancestor-descendant role in the origin of plants, animals, and fungi by itself does not forbid the recognition of separate taxonomic distinctiveness for the protists as a group. Furthermore, many present-day protist taxa do not appear to have led anywhere evolutionarily.

The last of the three options proposes that there are more than four eukaryotic kingdoms and that the protists are scattered throughout them, sometimes sharing a particular kingdom with some plant, fungal, or animal groups. In this option, there is generally no specific kingdom bearing the name (or concept) Protista. For example, in the

late 1980s the biochemical cytologist Tom Cavalier-Smith argued, based on his interpretation of a number of facts mostly ultrastructural in nature, that within the Eukaryota there are six kingdoms: Archezoa, Protozoa, Chromista, Plantae, Fungi, and Animalia. The organisms treated as protists in this article appear in all his kingdoms except the Animalia, although only a few are in his Fungi. The huge and diverse group of heterokonts (mostly algal protists in this article) comprise the bulk of his Chromista; all the red and green algae are placed in his kingdom Plantae. Admittedly, the green algae, especially, are closely related to plants and are likely their direct progenitor group. Cavalier-Smith's kingdom Protozoa includes the typical nonpigmented, motile, heterotrophic protists long claimed by protozoologists, but not all such protozoa are included in his kingdom bearing that name. (For example, some are distributed among several other eukaryotic kingdoms, including what he has called Chromista and, especially, Archezoa, the latter containing groups considered in this article as the phyla Metamonadea, Karyoblastea, and Microsporidia.)

A scheme of classification is an effort to set up discrete units containing a great diversity of living organisms that have been evolving gradually over hundreds of millions of years, an evolution that does not necessarily show taxonomically convenient breaks in the succession of forms. The challenge is to recognize major lines of evolution within the diverse assemblage and to organize them into named groups and ranks with minimal violation of their probable phylogenetic interrelationships. The single greatest handicap to the successful production of an ideal macrosystem for the protists is the scarcity of unambiguous data about the comparative morphology, biochemistry, and molecular biology of practically any taxon of these lower eukaryotes above the level of genus or species. Problems arise when the same group or part of a particular taxon of organisms has been treated quite differently systematically at the higher levels by workers of different scientific backgrounds or training.

Application of a protist perspective, taxonomically mixing algal, protozoan, and fungal groups to the degree required by their phylogenetic interrelationships, would mean the dropping of such groups and their formal nomenclatural designations as "Protozoa," "Algae," "Phytomastigophora," "Zoomastigophora," "Sarcomastigophora," and the like.

The phyla and the classes listed in the following working high-level classification of the kingdom Protista are themselves grouped into sections, supraphyletic assemblages given only vernacular names because they do not have an official nomenclatural rank. This is done in order to indicate, in a general way, the supposed phylogenetic closeness of some protist taxa to others. Section I, for example, contains a dozen phyla sharing basic characteristics while also showing major differences that allow them to remain separate at the high level of phylum. It may be noted that one of these phyla has been claimed taxonomically as fungi in the past; three as protozoa only; four as algae only; and four, wholly or partially, as both—simultaneously—protozoa and algae. Only one section is composed solely of algae (the one containing only the unique rhodophytes); seven, all with nonpigmented members, are purely protozoan in nature; four contain mixtures of algal and protozoan phyla; and one contains protozoan and fungal groups (as indicated by their former classifications). It is this commingling of phyla formerly assigned to widely separated assemblages of organisms that makes impossible any recognition—at a formal taxonomic level—of distinct and discrete protozoan protists, algal protists, or fungal protists.

The order or the arrangement of the 16 sections below has no particular phylogenetic significance; in fact, a number of biologists today consider the most primitive protists to be members of Sections IX and X. Neighbouring sections may sometimes be closer phylogenetically than more distant ones, but not always (particularly in view of the vast ignorance of most intersectional affinities). In some publications, dinoflagellates and ciliates are postulated as being rather closely related; but, partly in an attempt to

Purpose of
classifi-
cation

keep (former) algal groups close together, the dinoflagellates, in the scheme below, are in Section VI, while the ciliates form Section XVI.

Diagnostic characterization. Eukaryotic organisms possessing, at most, one tissue—tissue being an aggregation of similar cells and their products forming a definite, specialized kind of structural material—protistan species are predominantly unicellular in organization and microscopic in size. The relatively few syncytial (coenocytic), coenobial, or multicellular forms, which generally appear as filaments, colonies, coenobia, or thalli, still do not exhibit a true multitissue organization in the active (vegetative) stage. Macroscopic sizes are attained by species of a few groups (notably the brown algae). There are no truly vascular protists. All eukaryotic modes of nutrition are shown by the kingdom, with both phototrophic and heterotrophic types being common. Cysts or spores occur widely. Motility is frequently exhibited, principally via flagella, cilia, or pseudopodia; in general, motility in at least one stage of the life cycle is more common among the protists than are completely nonmotile forms. Both intracellular and extracellular elaborations (such as the organelles and the skeleton) show considerable complexity in protists. The diversity that exists among the numerous characteristics of the group supports the hypothesis that protists were ancestral to the other three eukaryotic kingdoms. For example, the distribution of the protists is ubiquitous and cosmopolitan; they show all modes of nutrition, and some species may exhibit only aerobic respiration and others only anaerobic respiration; in aerobic groups, the mitochondrial cristae are tubular, vesicular, lamellar (flattened), or discoidal; and mitotic and meiotic mechanisms and types are diverse. The total number of acceptably described species, extinct and extant, may be estimated to reach at least 120,000, with another 80,000 (mostly fossil forms) on record but of questionable validity.

Annotated classification. In the following abbreviated classification, phyla are generally the only formal taxonomic categories presented. In selected sections, classes are also included, especially if they are an aid in relating the present classification to the older and more conventional schemes. Thus, a number of classes and many important orders, suborders, families, and so on are not mentioned at all. Some of the names used and several that are not shown here may occur at the same or lower taxonomic levels in the articles ALGAE and PROTOZOA. This does not necessarily mean that the classifications presented in these articles are contradictory. The protists are considered as a single integrated assemblage in this article, while the algal and protozoan protist types are treated in more detail in their respective articles. Differences, relatively minor though they are, between the classification presented here and those appearing in the articles ALGAE and PROTOZOA also reflect variations that arise from individual interpretations. Finally, it should be noted that “phylum” and “division” represent the same level of organization; the former is the zoological term, and the latter the botanical term.

Section I. Chromobionts (heterokonts or Chromophyta sensu lato). Predominantly golden-brown, yellow-green, and brown algae plus some lower fungal groups and 3 nonpigmented zooflagellate taxa; tubular mitochondrial cristae; pigmented moiety with chlorophylls *a*, *c*, and *d* and chloroplasts located within rough endoplasmic reticulum, tubular mastigonemes on anterior flagellum, and food reserves stored outside plastids; ubiquitous; more than 30,000 confirmed species described, about half of which are fossils, with a possible additional 50,000 to 70,000 recorded species.

PHYLUM HAPTOPHYTA (PRYMNESIOPHYTA)

PHYLUM XANTHOPHYTA

PHYLUM PEDINELLOPHYTA

PHYLUM CHLORARACHNIOPHYTA

PHYLUM EUSTIGMATOPHYTA

PHYLUM BACILLARIOPHYTA (diatoms)

PHYLUM PHAEOPHYTA (brown algae)

PHYLUM OOMYCOTA

PHYLUM HYPHOCYTRIDIOMYCOTA

PHYLUM PROTEROMONADEA

PHYLUM OPALINATA

Section II. Chlorobionts. Essentially the green algae; flattened mitochondrial cristae; chlorophylls *a* and *b* (except for glaucophytes); flagellates and nonflagellates; unicellular and multicellular cellulosic cell walls; starch stored within chloroplasts; flagella bear no tubular hairs; sometimes classified as plants because the ancestry of the kingdom Plantae is found in this group; 10,000 described species, only relatively few as fossils; additional desmid species may be considered questionable.

PHYLUM CHLOROPHYTA

PHYLUM CHAROPHYTA

PHYLUM MICROMONADOPHYTA

PHYLUM PLEURASTROPHYTA

PHYLUM ULVOPHYTA

PHYLUM GLAUCOPHYTA (controversial)

Section III. Euglenozoa. Discoidal mitochondrial cristae; large nuclear endosome; sheets of cortical microtubules under the pellicle; paraflagellar rods; cytochrome *c* and 5S rRNA homologies known for euglenoids and kinetoplastideans; euglenoid plastids enclosed in 3 membranes, no stored starch, and no cellulosic wall; kinetoplastideans with large DNA body in mitochondrion; approximately 1,600 acceptable species.

PHYLUM EUGLENOPHYTA

PHYLUM KINETOPLASTIDEA

Class Bodoninea

Class Trypanosomatea

PHYLUM PSEUDOCILIATEA

PHYLUM HEMIMASTIGOPHOREA

Section IV. Rhodophytes (red algae). Flattened mitochondrial cristae; no centrioles or basal bodies; no flagella; photosynthetic species with chlorophyll and accessory phycobilipigments that mask green colour; predominantly marine, filamentous forms; a few may reach lengths of 1 metre or more; 5,000 species described, 750 as fossils.

PHYLUM RHODOPHYTA

Section V. Cryptomonads. Algal protists; flattened mitochondrial cristae; chloroplasts contain chlorophylls *a* and *c* and some phycobilipigments; typically biflagellate and phagotrophic; a few species are nonpigmented; nucleomorph and ejectisomes (extrusomes) are unique to this group; approximately 200 species.

PHYLUM CRYPTOPHYTA

Section VI. Dinozoa. Predominantly biflagellates with flagella uniquely located, one essentially longitudinal and the other transverse; tubular mitochondrial cristae; photosynthetic species possess chlorophylls *a* and *c* as well as xanthophylls and carotenes; cortical alveoli present; nucleus contains condensed chromosomes; many also feed phagotrophically; of approximately 4,200 known species, half are fossil forms.

PHYLUM DINOFLAGELLATA (PYRRHOPHYTA)

Class Peridinea

Class Syndinea

Nonphotosynthetic; endosymbiotic; unique life cycles; low chromosome numbers; marine.

Section VII. Chytrids.

PHYLUM CHYTRIDIOMYCETES

Section VIII. Choanoflagellates.

PHYLUM CHOANOMONADEA

Section IX. Polymastigotes. Essentially the “higher zooflagellates”; nonpigmented; mostly endosymbiotic;

multiflagellated; mitochondria absent; hydrogenosomes, always present in cytoplasm, perform mitochondrial functions; anaerobes; unique organelles associated with the base of the flagellar apparatus; of 750–800 reported species, only 500–600 acceptable.

PHYLUM METAMONADEA

Class Retortamonadea

Class Diplomonadea

Class Oxymonadea

PHYLUM PARABASALIA

Class Trichomonadea

Class Hypermastiginea

Section X. Rhizopod sarcodines. Many possess nonaxopod pseudopodia in at least some stage of the life cycle, or a shuttle-type flow of cytoplasm is exhibited; tubular mitochondrial cristae; biflagellate stage is common in many species; pseudopodia are often employed in locomotion and holozoic feeding; some 44,000 described species, of which 85 percent are foraminiferans, with about 75 percent of the total represented by fossil forms.

PHYLUM KARYOBLASTEA

PHYLUM LOBOSEA

Rhizopod amoebas, including parasitic forms, plus amoeboflagellates and many testaceous amoebas.

PHYLUM LABYRINTHOMORPHA

Section XI. Actinopod sarcodines. All with axopodia; pseudopodia with microtubular cores; elaborate endoskeletal systems generally present; tubular mitochondrial cristae; complex central capsule characteristic of many; primarily marine; 11,000 to 12,000 reported species, more than half of which are extinct forms.

PHYLUM ACTINOPHRYIDEA

PHYLUM CENTROHELIDEA

PHYLUM GYMNOSPHERIDEA

PHYLUM DESMOTHORACIDEA

PHYLUM TAXOPODA

PHYLUM ACANTHARIA

PHYLUM POLYCYSTINA

PHYLUM PHAEODARIA

Section XII. Apicomplexans. Endosymbionts, mostly true parasites; unique apical complex of specialized organelles clearly visible only under the electron microscope; spores common in most life cycles; tubular mitochondrial cristae; host organisms are terrestrial, marine, and freshwater animals; often pathogenic; approximately 5,000 species.

PHYLUM SPOROZOA (APICOMPLEXA)

Class Gregarinidea

Class Coccidea

Class Hematozoa

Class Perkinsidea

Section XIII. Microsporidia. Minute intracellular parasites primarily of insects and fishes; resistant unicellular spores characterized by a single polar filament or tube; uninucleate or binucleate amoeboid sporoplasm emerges through the eversible tube on hatching of the spore in a new host, often developing into a syncytial plasmodial

stage; no plastids, mitochondria, or flagella; chitin in one of the spore walls; may be one of the most ancient of all protist assemblages; 800 described species.

PHYLUM MICROSPORIDIA (MICROSPORA)

Section XIV. Haplosporidia. Small endoparasites of cells and tissues of mostly certain marine invertebrates; spores structurally complex but without polar filaments or tubes; flagella not present; flattened mitochondrial cristae; infective sporoplasms contain unique and enigmatic haplosporosomes; about 25 described species.

PHYLUM HAPLOSPORIDIA (ASCETOSPORA)

Section XV. Myxozoa. Coelozoic or histozoic parasites of mainly cold-blooded vertebrates; one or more polar capsules within valved spores and exhibiting multinuclear plasmodial and multicellular developmental stages; polar capsules contain coiled, nonhollow polar filaments, which are not used for inoculation of sporoplasms into new hosts, but to anchor the organism in tissues to be infected; no flagella; flattened mitochondrial cristae; shell valves may be extensively drawn out and elaborately sculptured; at least 1,200 species.

PHYLUM MYXOSPORIDIA (MYXOSPORA)

PHYLUM PARAMYXIDIA

Section XVI. Ciliates. Dual nuclear apparatus; infraciliary or cortical system containing distinct microtubular and microfibrillar structures; exhibit conjugation; tubular mitochondrial cristae; pellicle contains many cilia and usually alveoli (organelles rarely found in other protists except dinoflagellates); homothetogenic binary fission; heterotrophic, mostly phagotrophic; functional, complex oral apparatuses; mostly free-living, some symbiotic; marine, soil, and freshwater habitats; classes distinguished on the basis of kinetid structure, 8,000 described species, some fossil forms.

PHYLUM CILIOPHORA

Class Karyorelictea

Class Spirotrichea (Polyhemenophorea)

Class Litostomatea

Class Prostomatea

Class Phyllopharyngea

Class Nassophorea

Class Oligohymenophorea

Class Colpodea

BIBLIOGRAPHY. Most modern works on protists are to be found in specialized biological journals, and very few books have appeared that are concerned with protists overall. To begin to understand "the protist perspective," the following publications are especially recommended for perusal: HERBERT F. COPELAND, *The Classification of Lower Organisms* (1956); JOHN O. CORLISS, "Progress in Protistology During the First Decade Following Reemergence of the Field as a Respectable Interdisciplinary Area in Modern Biological Research," *Progress in Protistology*, 1:11–64 (1986); LYNN MARGULIS *et al.* (eds.), *Handbook of Protozoists: The Structure, Cultivation, Habitats, and Life Histories of the Eukaryotic Microorganisms and Their Descendants Exclusive of Animals, Plants, and Fungi* (1990); MARK A. RAGAN and DAVID J. CHAPMAN, *A Biochemical Phylogeny of the Protists* (1978); MICHAEL A. SLEIGH, *Protozoa and Other Protists* (1989); F.J.R. TAYLOR, "Problems in the Development of an Explicit Hypothetical Phylogeny of the Lower Eukaryotes," *BioSystems*, 10(1/2):67–89 (1978); and R.H. WHITTAKER and LYNN MARGULIS, "Protist Classification and the Kingdoms of Organisms," *BioSystems*, 10(1/2):3–18 (1978).

Protozoa

The protozoa are a collection of single-celled eukaryotic (*i.e.*, possessing a well-defined nucleus) organisms. As such, they are among the simplest of all living organisms. Although they comprise a subkingdom in the kingdom Protista, protozoans are not necessarily related to one another. In biological terms, they are not a natural group but simply a collection of organisms. There are more than 65,000 described species, of which over half are fossil.

Protozoa are ubiquitous in most soils and in aquatic habitats from the South to the North poles. Most are invisible

to the naked eye. Many are symbionts of other organisms, and about one-third of the living species are parasites. The classification of protozoans requires regular revision because modern electron microscopy and new biochemical and genetic techniques provide an ever-increasing pool of knowledge about the relationships of various protistan species and groups, often showing previous assignments to be incorrect.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 313, and the *Index*.

GENERAL FEATURES

Free-living protozoan groups that inhabit soils and natural waters are extremely diverse, not only in their structure (Figure 1) but also in the manner in which they feed, reproduce, and move. Among the mainly free-living groups are the flagellates (Mastigophora). Their name derives from the whiplike structures, or flagella, that are used for movement and feeding. Each flagellate cell bears one or more of these organelles.

The flagellates exhibit the greatest diversity of nutrition among the protozoa. Many contain pigments also shared by plants, such as chlorophyll, which capture light energy during photosynthesis for the manufacture of carbohydrates and other complex nutrient substances. Thus they possess a plantlike nutrition and are called autotrophs (self-feeders). Other flagellates are colourless (*i.e.*, contain no photosynthetic pigments); they obtain their nutrients by feeding on algae, bacteria, and other protozoa. Such flagellates have an animal-like nutrition and are called heterotrophs. Some colourless flagellates have photosynthetic ecto- and endosymbionts—for example, *Oikomonas sycyanotica*, which carries cyanobacterial (blue-green algal) symbionts on its surface, and the dinoflagellate *Amphisolenia*, which contains endosymbiotic cyanobacteria. Some dinoflagellates, such as *Noctiluca* and *Gyrodinium*, may have other flagellates living within them as symbionts. Many autotrophic flagellates must also consume bacteria because photosynthesis alone is not sufficient. These flagellates and those with symbiotic algae exhibit a metabolism known as mixotrophy, in which heterotrophy and autotrophy are combined in a variety of ways and to different degrees. Thus, flagellates exhibit the complete nutritional spectrum, from totally plantlike nutrition to completely animal-like nutrition, with varying degrees of both.

In fact, nutrition is not taxonomically significant because many of the phytoflagellates (*i.e.*, the plantlike groups, or Phytomastigophorea) do not contain photosynthetic pigments but feed in a heterotrophic manner. The dinoflagellates are a good example: about one-half do not contain plant pigments, but they are classified as dinoflagellates because in every other respect they are like their coloured relatives. Moreover, even among the coloured dinoflagellates, many are mixotrophs.

While the majority of flagellates are free-living, some have evolved a parasitic way of life. These include the hemoflagellates (class Zoomastigophorea, order Kinetoplastida), so called because at some stage in their life

cycle they live in the blood of a vertebrate host. Several hemoflagellates cause disease, such as sleeping sickness and Chagas' disease.

The amoebas (phylum Sarcomastigophora, subphylum Sarcodina) are a diverse group of free-living protozoa that probably evolved from a number of different primitive protozoan ancestors. While they are often regarded as the simplest of protozoans, because many resemble a blob of protoplasm with no apparent organized shape, some members of the Sarcodina are actually extremely complex. The most sophisticated are the shell-bearing foraminiferans (superclass Rhizopoda, class Granuloreticulosea). There are two categories of amoebas: the naked amoebas, which lack skeletal structures, and those that possess a skeleton or shell of some type. Members of the Sarcodina move and feed by means of protoplasmic extrusions called pseudopodia (false feet). Pseudopodia vary in both structure and number among the different species. Some possess only one leading pseudopod, while others have a complex multibranched network of pseudopodia. Like the flagellates, the sarcodines also include some parasitic species among their number. A well-known example is *Entamoeba histolytica*, which causes amoebic dysentery in humans.

Amoebas

The most evolved and complex protozoans are the ciliates (phylum Ciliophora). The cell surface is covered with hundreds of hairlike structures, or cilia, arranged in ordered rows called kineties. The cilia beat in synchronized waves and thereby propel the organism through the water. Most ciliates possess a cell mouth (cytostome) through which food enters the cell. (Some flagellates also have cytostomes.) In some ciliates, the cilia around the cytostome have become specially modified into sheets called membranelles, which create a feeding current and act as a sieve to trap food particles. Other important ciliate characteristics include the possession of two types of nuclei (a large nucleus, or macronucleus, and one or more small nuclei, or micronuclei, occurring in each cell); sexual reproduction by conjugation; and asexual reproduction by binary fission in an equatorial, or transverse, plane.

A number of the protozoan phyla are exclusively parasitic, either in higher animals or, as in the phylum Labyrinthomorpha, on algae (although some members of this phylum feed saprotrophically on the surface of marine grasses and algae by secreting extracellular enzymes). The entirely parasitic phylum Apicomplexa is particularly important to humans because among its members are those

species responsible for causing such diseases as malaria and toxoplasmosis.

The major parasites causing pathological conditions in humans and other vertebrates are found in the apicomplexans and the two mainly free-living groups, the sarcostigophorans and the ciliophorans. This fact, coupled with the importance of free-living protozoa in ecological processes, means that more is known about these three groups, and this article, therefore, concentrates on the functioning and biology of these protozoans.

NATURAL HISTORY

Size range and diversity of structure. Protozoa range in diameter from a few thousandths of a millimetre to several millimetres. Because the subkingdom contains many unrelated or loosely related groups, there is enormous diversity in structure and form. Even within a single phylum, the variation in form can be considerable.

The flagellates range from a simple oval cell with one or more flagella to the structural sophistication of the collared flagellates (order Choanoflagellida). The collared flagellates lack photosynthetic pigments and are therefore colourless. They have a single flagellum surrounded by a delicate circular collar of fine pseudopodia on which they

trap food particles. In some marine species, the whole cell is enclosed in an elaborate, open latticelike basket formed from strands of silica. The dinoflagellates, half of which contain plant pigments and rely to a greater or lesser degree on photosynthesis, may be surrounded by a cell wall armour with a complicated pattern. In some species (e.g., *Ceratium*), long spines arise from the cell surface and aid in flotation. Dinoflagellates possess two flagella; one beats in a transverse plane around the equator of the cell while the other beats in a longitudinal plane. Many of the flagellates live in colonies. In *Volvox*, for example, hundreds of individual organisms are embedded in a gelatinous sphere.

The sarcodines also are extremely diverse. They have four types of pseudopodia—lobopodia, filopodia, axopodia, and reticulopodia. The simplest (lobopodia) are blunt extensions of the protoplasm, and the most complex (reticulopodia) form a complicated branching network. The simplest of the sarcodines, the naked amoebas (*Gymnamoebia*), have no defined shape and extend one or many pseudopodia. At the opposite extreme are the complex foraminifera, which live inside multichambered calcareous shells up to several millimetres in diameter. The pseudopodia (reticulopodia) of foraminiferans extend from the aperture of the largest chamber of the shell and form a complicated, sticky branching network. Other sarcodines, known commonly as radiolarians (class Polycystinea), form shells from silica; in some, the shell has so many holes that the structure resembles a sponge. Some of the most exquisite sarcodines are the sun protozoans, or heliozoans. Their radiating pseudopodia (axopodia), extend like spokes from the central body; microtubules support an outer layer of cytoplasm.

The ciliates are the most structurally homogeneous group, although even they have evolved considerable variation on the cilia-covered cell. In some species (e.g., the hypotrich *Euplotes*) the cilia are combined to form thick conical structures, called cirri, which the ciliate uses to crawl along surfaces, rather like little legs. In others the cilia virtually disappear from the main body of the cell, but the circle of cilia around the mouth becomes well developed (as in the oligotrich *Strombidium* and the tintinnid ciliates). The peritrich ciliates have developed stalks and attach to plants and animals as a means of dispersal. Many peritrichs (e.g., *Epistylis*) form branching colonies.

A group of ciliates, the suctorians, have completely lost their cilia in the adult phase. They have instead developed a stalk and many tentacles, which they use to capture passing prey, usually other ciliates. Because they cannot swim, they produce motile ciliated offspring, which settle elsewhere and then transform into the feeding stage, thus avoiding overcrowding.

Although the parasitic protozoa tend to be less structurally complex than free-living forms, considerable variation may occur during the course of their life cycles. *Plasmodium*, the malarial parasite that lives inside the liver and red blood cells of humans and the gut of its insect vector (the *Anopheles* mosquito), undergoes various changes in form through its asexual and sexual phases of development. Among the parasitic flagellates, the trypanosomes and their relatives (hemoflagellates), morphological variation occurs during the various stages of the life cycle in both the mammalian and insect host. Among species of *Leishmania*, which cause visceral leishmaniasis (kala-azar), cutaneous leishmaniasis (Oriental sore), and mucocutaneous leishmaniasis (espundia), two distinctly different forms occur. In humans, rounded, nonflagellated forms called amastigotes feed and divide inside macrophage cells in different regions of the body, while in the gut of the insect vector there occurs a flagellated form called a promastigote. Members of the genus *Trypanosoma*, which cause sleeping sickness and other diseases, have flagellated forms with different morphologies. At some stage in the life cycle, all assume the trypomastigote form—i.e., slender with part of the flagellum running over the body and attached to it by a finlike extension to form an undulating membrane. They may also occur as amastigote (stumpy flagella) or promastigote forms.

Distribution and abundance. Protozoa have colonized a wide array of aquatic and terrestrial habitats from the

Naked
amoebas

Habitats

Arctic and Antarctic to equatorial zones. In soils and bogs, ciliates, flagellates, and amoebas form part of a complex microbial community. They live in the moisture films surrounding soil particles, so that they are actually aquatic organisms, even though living in a terrestrial environment. Between 10,000 and 100,000 organisms per gram of soil may inhabit fertile land; the relative proportions of each group vary depending on soil type and latitude. In Antarctic soils, flagellates and testate (shell-dwelling) amoebas predominate, while in temperate woodland soils, ciliates are more numerous.

In the open waters of lakes, estuaries, and the sea, protozoa form an important component of the floating plant and animal community (plankton). They are often present in densities of tens of thousands per litre of water. During photosynthesis, flagellates carrying plant pigments transform the energy from the Sun into organic matter, which, along with many algal species, forms the base of the aquatic food chain. Most planktonic protozoa, however, feed on bacteria, algae, other protozoa, and small animals. The most common planktonic protozoa are the zooflagellates, ciliates—especially members of the oligotrichs and the tintinnids (which live inside small tubes, or loricae)—and the exclusively marine foraminiferans and radiolarians.

Although few data exist for oceanic depths, foraminiferans have been found at depths of 4,000 metres, and some protozoans have been observed around hydrothermal vents on the ocean floor.

Importance. Protozoa play important roles in the fertility of soils. By grazing on soil bacteria, they regulate bacterial populations and maintain them in a state of physiological youth—i.e., in the active growing phase. This enhances the rates at which bacteria decompose dead organic matter. Protozoa also excrete nitrogen and phosphorus, in the form of ammonium and orthophosphate, as products of their metabolism, and studies have shown that the presence of protozoa in soils enhances plant growth.

Role in
sewage
treatment

Protozoa play important roles in wastewater treatment processes, in both activated sludge and slow percolating filter plants. In both processes, after solid wastes are removed from the sewage, the remaining liquid is mixed with the final sludge product, aerated, and oxidized by aerobic microorganisms to consume the organic wastes suspended in the fluid. In the former process, aerobic ciliates consume aerobic bacteria, which have flocculated; in the latter process, substrates are steeped in microorganisms, such as fungi, algae, and bacteria, which provide food for oxidizing protozoa. In the final stages of both processes, solids settle out of the cleaned effluent in the settlement tank. Treatment plants with no ciliates and only small numbers of amoebas and flagellates produce turbid effluents containing high levels of bacteria and suspended solids. Good-quality, clean effluents are produced in the presence of large ciliated protozoan communities because they graze voraciously on dispersed bacteria and because they have the ability to flocculate suspended particulate matter and bacteria.

Protozoa probably play a similar role in polluted natural ecosystems. Indeed, there is evidence that, by feeding on oil-degrading bacteria, they increase bacterial growth in much the same way they enhance rates of decomposition in soils, thereby speeding up the breakdown of oil spillages.

Some radiolarians and foraminiferans harbour symbiotic algae that provide their protozoan hosts with a portion of the products of photosynthesis. The protozoans reciprocate by providing shelter and carbon and essential plant nutrients. Many ciliates contain endosymbiotic algae, and one species, *Mesodinium rubrum*, has formed such a successful relationship with its red-pigmented algal symbiont that it has lost the ability to feed and relies entirely on symbiosis for its livelihood. *Mesodinium* often forms dense, nontoxic red blooms (or red tides) when it reaches high densities in plankton. Among the ciliates with endosymbionts, *Mesodinium* is the only completely photosynthetic species. Other ciliates achieve photosynthesis in another way. Although they do not have symbiotic algae, they consume plantlike flagellates, sequester the organelles that contain the plant pigments, and use them for photo-

synthesis. Because the isolated plastids eventually age and die, they must be replaced continuously.

The impact of protozoan grazing on phytoplankton can be considerable. It has been estimated that at least half of the phytoplankton production in marine waters is consumed by protozoa. Like the soil protozoa, these planktonic protozoans excrete nitrogen and phosphorus at high rates. The protozoans are a fundamental component in recycling essential nutrients (nitrogen and phosphorus) to the phytoplankton.

Parasitic protozoa have invaded and successfully established themselves in hosts from practically every animal phylum, although it is about parasitic species of medical and agricultural importance that most is known. The trypanosomes, for example, cause a number of important diseases in humans. African sleeping sickness is produced by two subspecies of *Trypanosoma brucei*, namely, *T. brucei gambiense* and *T. brucei rhodesiense*. The life cycle of *T. brucei* has two hosts, humans and other mammals and the blood-sucking tsetse fly, which transmits the parasite between humans.

Parasitic
protozoa

Trypanosomes live in the blood plasma and the central nervous system of humans and have evolved an ingenious way of fooling the immune system of the host. Upon contact with a parasite, the immune system generates antibodies that recognize the specific chemical and physical nature of the parasite and actively neutralize it. Just as the host's immune system is beginning to win the battle against the parasite and the bulk of the population is being recognized and destroyed by host antibodies, the parasite is able to shed its glycoprotein coat, which is attached to the cell surface, and replace it with a coat containing different amino acid sequences. Thus, the parasite essentially changes its makeup. These alternate forms are known as antigenic variants, and it has been estimated that each species may have as many as 100 to 1,000 such variants. The host must produce a new set of antibodies against each new variant; in the meantime, the parasite has time in which to replenish its numbers. Ultimately, unless the disease is treated, the parasite wins the battle and the host dies. Such antigenic variation makes the development of an effective vaccine against certain parasitic protozoan diseases virtually impossible.

A close relative of *T. brucei*, *Trypanosoma cruzi*, causes Chagas' disease, or American trypanosomiasis. The vector hosts are bugs (*Rhodnius*) and other arthropods, such as lice and bedbugs. In humans the nonflagellated (amastigote) form of the parasite lives inside macrophage cells, the cells of the central nervous system, and muscle tissue, including the heart, where it grows and divides. Short trypomastigote flagellated forms periodically appear in the blood, where they are readily taken up by the bloodsucking vector hosts. These flagellated forms do not divide in the blood, reproduction occurring only in the amastigote intracellular forms.

Relatives of the trypanosomes, species of the genus *Leishmania*, cause a variety of diseases worldwide known as leishmaniasis. Like *T. cruzi*, these are intracellular parasites of the macrophage cells. The intermediate, or vector, hosts are a variety of sand fly species (*Phlebotominae*). In cutaneous leishmaniasis the infected macrophages remain localized at the site of the infection, causing an unsightly lesion, but in visceral leishmaniasis the infected macrophages are carried by the blood to the visceral organs. This latter disease is characterised by enlargement of the spleen and liver, leading to the distended abdomen that is typical of kala-azar. In mucocutaneous leishmaniasis the initial skin infection spreads to the mucous membranes of the face (the nose, mouth, and throat), producing a lesion that can cause the destruction of part of the face.

Malaria, which is caused by the protozoan *Plasmodium*, remains a serious disease despite both measures that can be taken to control and eradicate the mosquito vector host and the availability of an array of antimalarial drugs. The life cycle is fundamentally identical among the four species of *Plasmodium*, but the pathology of the disease varies in the frequency and severity of attacks and in the occurrence of relapses. Problems in controlling the disease include the development of resistance to insecticides by

Plas-
modium

the mosquito and the evolution of drug resistance by the parasite. Prophylactic drugs taken before and during a visit to areas where malaria is endemic may prevent the disease from forming in persons who have no natural resistance. Since antigenic variation does not appear to occur in *Plasmodium*, modern genetic engineering techniques offer promise of producing a vaccine.

The apicomplexan *Cryptosporidium* (class Coccidea) is a protozoan parasite of humans and other mammals that has become particularly prominent since the 1970s. It has a one-host life cycle and lives inside the cells lining the intestines and sometimes the lungs. *Cryptosporidium* carries out all the asexual reproductive stages typical of an apicomplexan (see below) inside a single host and is passed from host to host by a resistant cyst stage called an oocyst. The disease caused by the parasite is typified by severe diarrhea and vomiting. Although there is no drug treatment, most healthy people recover quickly. In persons who have impaired immune systems, such as AIDS patients, however, *Cryptosporidium* can cause serious infections.

FORM AND FUNCTION

The protozoan cell. The protozoan cell carries out all of the processes—including feeding, growth, reproduction, excretion, and movement—necessary to sustain and propagate life, although it does so at a somewhat simpler level than do multicellular organisms. The cell is enclosed in a unit membrane called the plasma membrane. Like all membranous structures in the eukaryotic cell, the plasma membrane is composed of protein and lipid molecules. The membrane is a barrier between the cytoplasm and the outside liquid environment. Some substances, such as oxygen, readily pass through the membrane by diffusion (passive transport), while others must be transported across at the expense of energy (active transport). Cilia and flagella arising from the cell are also sheathed in the cell membrane.

The cell also has internal membranes, which are not as thick as the plasma membrane. Among these are the endoplasmic reticulum, whose membranes separate out compartments of the cell, thereby allowing different conditions to be maintained in various parts—*e.g.*, separation of different substances. Enzymes are arranged on the surface of the endoplasmic reticulum; one such enzyme system catalyzes the activity of the ribosomes during protein synthesis. The Golgi apparatus is a cluster of flattened vesicles, or cisternae, associated with the endoplasmic reticulum. The vesicles are concerned with membrane maturation and the formation and storage of the products of cell synthesis, as, for example, in the formation of scales on the surface coat of some flagellates. The scales are formed within the Golgi and are transported by the vesicles to the plasma membrane, where they are incorporated onto the surface of the cell. The Golgi apparatus is well developed in flagellates, poorly seen in most ciliates, and absent from some amoebas.

All protozoa possess at least one nucleus, and many species are multinucleate. The genetic material DNA (deoxyribonucleic acid) is contained within the chromosomes of the nucleus. Each nucleus is bounded by two unit membranes through which pores provide a channel permitting the passage of molecules between the cytoplasm and the nucleoplasm. Most ciliates have two types of nuclei, micronuclei and macronuclei. Almost all protozoan cells contain at least one micronucleus, and many contain more than one. The macronucleus can be quite variable in shape, resembling in some species a string of beads or a horseshoe. It directs the normal functioning of the cell and usually disintegrates during sexual reproduction, to be reformed from the products of micronuclear division after the sexual phase is completed.

Almost all protozoa contain double-membrane mitochondria; the inner membrane forms fingerlike extensions (or cristae) into the mitochondrial interior, and the outer membrane forms the boundary of the organelle. Mitochondria are the sites of cellular respiration. Species that do not require oxygen (anaerobes), such as those that live in the intestinal tract of their hosts or those that occupy special anaerobic ecological niches, lack mito-

chondria. They have instead respiratory organelles called microbodies. These oblong or spherical membrane-bound organelles, about one to two micrometres in length, are believed to be the site of respiratory processes. They contain enzymes that oxidize pyruvate to acetate and carbon dioxide, resulting in the release of hydrogen sulphide under anaerobic conditions.

Photosynthetic pigments, when present, are housed in organelles called plastids. These also are bounded by at least two unit membranes. All plastids contain ribosomes and DNA of a type structurally similar to those of bacteria and other members of the kingdom Monera (prokaryotes). Ribosomes and DNA synthesize some of the protein and plastid RNAs of these protozoans independently from the synthesis carried out under the direction of the DNA of the macronucleus. Plastids are believed to have evolved from endosymbionts, and their structure and independent ability to produce proteins and RNA support this hypothesis.

Organisms that live in a liquid environment with a lower concentration of ions than is found in the interior of their cells—that is, a lower osmotic concentration—gradually gain water. If this remains unchecked, the cell swells and bursts. In protozoa the maintenance of the osmotic balance of the cell is achieved by the contractile vacuole. These membrane-bound organelles are situated close to the plasma membrane. They swell periodically and then suddenly contract and disappear, forcing their contents from the cell in repeated cycles. In the amoebas and the flagellates the contractile vacuole is formed when smaller vesicles combine with the main vacuole. In the ciliates the contractile vacuole is fed by a complex system of feeder canals, which are, in turn, fed by a complex of vesicles and fine tubules within the cytoplasm.

Heterotrophic protists have transitory food or digestive vacuoles. The number of these membrane-bound cell organelles depends on the feeding habits of the organism. Some species may have many, while others may contain only one or two at any one time. In ciliates the food vacuoles form at the base of the cytopharynx, while in species without a cell mouth the vacuoles form near the cell membrane at the site where food is ingested.

Within the cell, structural proteins of various types form the cytoskeleton (cell skeleton) and the locomotory appendages. They include microfilaments formed of a contractile protein also found in the muscles of animals (actin) and cylindrical microtubules formed from filaments of the protein tubulin. Microtubules are particularly important in the structural formation and functioning of cilia and flagella. Axopodia of certain flagellate species are supported by microtubules.

The protozoa exhibit diverse modes of locomotion across the various groups, but the modes of locomotion can be broadly divided into flagellar, ciliary, and amoeboid movement. Flagellar propulsion is employed by the flagellates and during some stages in the life cycles of certain sarcodines. The flagellum is a whiplike structure found not only in protozoans but in higher organisms as well (such as in sperm, the male reproductive cells of higher animals). The structure of all flagella is basically the same, consisting of a cylinder (axoneme) made up of a pair of central microtubules surrounded and joined by cross-bridges to a circle of nine pairs of microtubules. This “nine-plus-two” arrangement of the microtubules in the axoneme is surrounded by cytoplasm and ensheathed in cell membrane. The flagellum arises from the basal body, or kinetosome, within the cell.

The undulating motion of the flagellum is normally generated at its base. The waves move along the flagellum to produce a force on the water acting along the long axis of the organelle in the direction of the wave. The speed of movement is determined by the length of the flagellum and by the size of, and distance between, the waves it generates. Some species have hairs (mastigonemes) arising at right angles to the flagellum along its length, while other species have slender hairs called flimmer filaments. Either structure has the effect of altering the movement of water produced by undulations of the flagellum by reversing its flow toward the flagellar base.

Swimming speeds achieved by flagellates are relatively

vacuoles

Locomo-
tion

organelles

low. Ciliates have an increased number of beating flagella on the cell surface, thereby enabling greater power to be developed against viscous forces, for greater speeds. The structure of a cilium is identical to that of a flagellum, but the former is considerably shorter. Cilia are a type of flagellum arranged in closely aligned longitudinal rows called kineties. A complex system of fibres and microtubules arising from the basal bodies, or kinetosomes, of each cilium connects it to its neighbouring cilia in the kinety and to adjacent ciliary rows. In some species the body cilia may be reduced to specialized cirri, where the kinetosomes are not arranged in the usual rows but instead have a hexagonal pattern interlinked at several levels by fibres and microtubules.

The effective stroke of the cilium is usually planar, but in the recovery stroke the cilium sweeps out to the side, creating an overall beat with a three-dimensional pattern. The cilium performs work against the viscous force of the water during both the effective and the recovery strokes. To be effective, each cilium must beat in a coordinated manner with its neighbouring cilia. A synchronized beat is passed along a ciliary row by means of a hydrodynamic linkage between the cilia. During a beat, each cilium displaces a layer of surrounding water. Displaced water layers overlap between cilia and, as a consequence, interference occurs between the movements of adjacent cilia, creating a hydrodynamic linkage.

Amoeboid movement Amoeboid movement is characteristic of the sarcodines and some of the apicomplexans. It is achieved by pseudopodia and involves the flow of cytoplasm as extensions of the organism. The process is visible under the light microscope as a movement of granules within the organism. The basic locomotory organelle is the pseudopodium; the way in which movement is effected varies.

A variety of pseudopodial types are found among the naked and testate amoebas (Gymnamoebia and Testacalobosia, respectively). In some species, a single pseudopodium is extended at any one time; in others, numerous tubular pseudopodia are extended simultaneously. Some amoebas appear saclike throughout locomotion, and no pseudopodia are obvious. The numerous long, stiff protoplasmic extensions (axopodia) of heliozoans shorten and lengthen—the forward axopodia lengthen and become attached, while the posterior axopodia detach and retract—and the amoeba rolls slowly along. The foraminiferans move by extending slender pseudopodia (filopodia), which may be several millimetres long in some species. The extending filopodia branch and fuse with each other so that there is a complex, continuously changing network of pseudopodia pulling the organism along.

Various theories have been proposed to explain how pseudopodia effect movement. A widely accepted model suggests that the ectoplasm at the front of the pseudopod contracts; isometric tension is maintained on the endoplasm, while isotonic contraction in the rear ectoplasm increases pressure on the tail endoplasm to push it forward. In addition, the contractile protein actin and the force-generating enzyme myosin—which can release the energy carried by ATP (adenosine triphosphate) and is found in the muscle contraction system of higher animals—have been isolated from the cytoplasm of amoebas. During movement, the endoplasm moves toward the cell surface at the pseudopodial tip and then gels, while actin filaments polymerize to form a longitudinal network of endoplasm that interacts with myosin- and actin-binding proteins—some of which are attached to the plasma membrane—to create a contractile cytoskeleton. This contraction increases internal hydrostatic pressure, resulting in a flow of cytoplasm toward any area where the endoplasm can extend.

Respiration. Aerobic microorganisms are so small that they are able to obtain the oxygen they require for metabolism from the surrounding liquid medium by simple diffusion. The special pigments or structures required for the acquisition and transport of oxygen found in higher organisms are not required in the protozoa. The respiratory pigment hemoglobin has been found in some ciliates (e.g., *Tetrahymena*), but it does not function as an oxygen-carrying pigment as in humans.

Most species of free-living protozoa appear to be obligate aerobes; that is, they cannot survive without oxygen. As in the cells of higher organisms, their respiration is based on the oxidation of the six-carbon glucose molecule to single-carbon carbon dioxide molecules and water via the Embden-Meyerhof pathway, tricarboxylic acid cycle (Krebs cycle), and cytochrome systems, the last two metabolic processes taking place in the mitochondria. Within a single species, the rate of oxygen consumption varies in relation to such factors as temperature, the stage in the life cycle, and the cell's nutritional status (i.e., whether or not it is well fed).

Obligate anaerobes, in which metabolism must take place in the absence of oxygen, are rarely found among eukaryotic organisms. Some parasitic anaerobic species, however, live in the gastrointestinal tract of humans and other vertebrates or, in one ecological group of ciliates (e.g., *Metopus*, *Plagiopyla*, and *Caenomorpha*), are associated with sulfide-containing sediments. The latter have been found to lack cytochrome activity, and both anaerobes contain microbodies rather than typical protozoan mitochondria. Along with the microbodies, the sulfur protozoa also harbour endosymbiotic and ectosymbiotic bacteria, which may take the metabolic end products released by the ciliates and reutilize them for growth and energy-yielding processes. These ciliates are believed to have reverted from an aerobic metabolism to an anaerobic metabolism in order to exploit a specialized ecological niche rich in bacteria as a food source.

The type of microbodies of the anaerobic intestine-dwelling species, which are called hydrogenosomes, function as respiratory organelles. They possess enzymes that oxidize pyruvate to acetate and carbon dioxide. Under anaerobic conditions this also results in the release of hydrogen; when oxygen is present, the hydrogen combines with the oxygen to form water.

Certain parasitic protozoa that live in the blood, such as *Trypanosoma brucei*, have evolved a system of aerobic respiration that does not involve the mitochondria. The initial stages of glycolysis in the Embden-Meyerhof pathway are the same, but glucose, rather than being broken down completely to carbon dioxide and water, is broken down only to the three-carbon molecule pyruvic acid, which is then excreted. The subsequent stages (the tricarboxylic acid cycle and the cytochrome system), which usually take place in the mitochondria, do not occur; instead, the terminal respiration is mediated by an L- α -glycerophosphate oxidase-L- α -glycerophosphate dehydrogenase system located in small membrane-bound vesicles throughout the cytoplasm.

Metabolism and nutrition. The protozoa display a range of nutritional types, from the entirely plantlike photosynthetic (or autotrophic) nutrition to the totally animal-like (or heterotrophic) nutrition, in which bacteria, algae, other protozoa, and small animals like the crustacean copepods constitute the food source (Figure 2).

The coloured flagellates, or phytoflagellates (Phytomastigophorea), contain a variety of pigments that trap the Sun's radiant energy and use it to synthesize complex carbohydrates from carbon dioxide and water in the process of photosynthesis. Many coloured flagellates combine autotrophy with heterotrophy and are, strictly speaking, mixotrophs. Some members of the Euglenida, Cryptomonadida, and Volvocida, for example, are commonly called the acetate flagellates because their preferred food sources are acetates, simple fatty acids, and alcohols. In the presence of the correct nutrients, these flagellates are able to switch from carbohydrate-producing photosynthesis when light is available to heterotrophy on acetate and other substrates when it is not. Many planktonic marine and freshwater phytoflagellates also feed voraciously on bacteria. Indeed, in some lakes they may be the main consumers of bacteria suspended in the plankton. It is believed that this ingestion of bacteria (phagotrophy) provides the flagellates not only with an additional source of carbon to supplement what is gained by photosynthesis but also with phosphorus and nitrogen, which are often scarce in planktonic waters, and possibly with vitamins, all of which are essential to photosynthesis. Bacteria are

Aerobic
respiration

Nutritional
types

more efficient at taking up these nutrients because they have a higher surface-to-volume ratio than do the flagellates. Thus, one way for the flagellates to acquire essential nutrients is to consume the bacteria.

Heterotrophic protozoans (Zoomastigophorea, or zooflagellates) may take food into the cell at a specific point, such as the cytostome, at a particular region of the cell surface, or at any random point of entry. In the collared flagellates, for example, the collar and flagellum operate in feeding. The collar, composed of fine pseudopodia, surrounds the flagellum. The beating flagellum creates a water current, causing water to move through the collar. Particles of food in the current are trapped on the collar and are ingested by pseudopodia at its base. The ingested food is then enclosed in a membrane-bound digestive or food vacuole.

Filter
feeding

Figure 2: (Left) *Amoeba* engulfing a ciliate. (Right) *Euplotes patella* digesting algae; movement of cilia has started a whirlpool of algae at right.

Many ciliates are also filter feeders, creating water currents with special ciliary structures associated with the cytostome. The synchronized beating of these ciliary structures pushes a stream of water against a membranelle composed of cilia; the membranelle acts as a collecting sieve, where the food particles become trapped in the free spaces between the cilia. Using this mode of feeding, ciliates can shift considerable volumes of water in relation to their size. *Tetrahymena*, for example, can filter 3,000 to 30,000 times its own volume in one hour.

Other ciliates lack complex oral cilia and gather their food by other means. *Nassula* has a complex cytostome and cytopharynx supported by a basketlike cytopharyngeal structure composed of microtubules. This species ingests filamentous algae by grasping the filament, bending it like a hairpin, and drawing it into the cytopharynx, where it is broken up into fragments and enclosed in digestive vacuoles. Predatory ciliates such as *Didinium nasutum*, *Lacrymaria olor*, and *Dileptus anser* apprehend their prey with special structures called extrusomes. Among the various types of extrusomes are the toxicysts, which are found in the oral region and release toxins that paralyze the prey. The suctorians are ciliate predators that usually possess tentacles of two functional types, feeding tentacles and piercing tentacles; the latter trap and immobilize the prey, usually other ciliates that make chance contact with the outstretched tentacles of the suctorian. The cell contents of the prey are transported up through the feeding tentacles into the suctorian, where digestive vacuoles are formed. The transporting mechanism is mediated by a complex array of microtubules within the tentacle. A single suctorian can often feed on several prey at the same time, and frequently the prey are larger than the predator.

The sarcodines, all of which lack a cell mouth, or cytostome, also exhibit a diverse array of feeding mechanisms and diet. Some feed on filaments of cyanobacteria (blue-green algae)—which are composed of long chains of individual cells—by taking in the entire filament at any point on the cell surface and rolling it up into a coil inside a digestive vacuole. Others, such as the testate amoeba *Pon-*

tigulasia, pierce single cells in algal filaments and remove the contents. The radiolarians and foraminiferans trap a wide range of prey, including protozoans, algae, and small crustaceans, in their complex pseudopodial networks and then convey the food items to the main body of the cell for ingestion.

Parasitic protozoa feed in a variety of ways. Many live in the nutrient-rich medium of the body fluids—e.g., the blood or cells of their host. There they take in energy-rich fluids by pinocytosis, in which small amounts of the medium are pinched off into digestive vacuoles either at a specific site, such as the cytostome in ciliates or the flagellar pocket in trypanosomes, or along the surface of the cell in amoebas. Other parasitic protozoa engulf portions of the host tissue (phagocytosis) in much the same way that free-living amoebas feed. *Plasmodium*, for example, engulfs portions of the red blood cells or liver cells in which they live. The hemoglobin in the cytoplasm of the red blood cell is only partially digested by the parasite; the protein portion of the hemoglobin molecule is degraded to its constituent amino acids, but the iron-containing portion is converted into insoluble iron-containing hemozoin, which remains within the parasite's endosomes until discarded at the next division. This process removes free heme from the parasite cytoplasm, where it would otherwise prevent further metabolism within the parasite because it inhibits the actions of succinic dehydrogenase, an enzyme in the Krebs cycle.

Feeding in
parasitic
species

Whatever the mode of heterotrophic nutrition or diet, the food material is enclosed in food vacuoles, which are bounded by cell membrane. Digestive enzymes are poured into the newly formed vacuole from the surrounding cytoplasm. In the ciliate *Paramecium*, where the process has been researched in detail, it is known that the digestive vacuoles initially decrease in size and the enclosed particles aggregate. As digestion proceeds, the vacuole increases in size and the contents become progressively acidic, before gradually becoming alkaline near the end of the process. The products of digestion are then absorbed into the surrounding cytoplasm, and the waste material is ejected from the cell anus, or cytoproct. The length of the digestive cycle varies and depends on the species and the diet.

Paramecium contains a reservoir of membrane-forming material in discoid vesicles for the purpose of producing food vacuoles. The food vacuoles form at the cytopharynx when the cytopharyngeal membrane and the discoid vesicles fuse. At the cytoproct, where the vacuoles are broken down and the waste material of digestion is ejected, the membrane material is retrieved and returned to the cytopharynx. Thus, the pool of digestive vacuole membrane is continuously recycled within the cell.

While they seem to lack a sensory system, protozoans are capable of food selection. Many of the filter feeders apparently discriminate solely on the basis of size, dictated by the dimensions of the spaces in the membranelle acting as a sieve. Some filter-feeding ciliates, such as the tintinnids, however, are known to be selective and appear to be able to capture or reject items that arrive at the feeding membranelles in the feeding current. The large ciliate *Stentor*, for example, takes ciliates in preference to flagellates and algae, and discrimination increases as the animal becomes less hungry. Carnivorous species exercise distinct selectivity. Most suctorians feed exclusively on particular ciliate taxa. They are selective feeders and usually do not capture flagellates, sarcodines, or their own ciliated swimmers. Evidence suggests that a reaction between chemical compounds on the surface of the prey and the tentacle tip of the suctorian is responsible for feeding selectivity. Sarcodines also display feeding selectivity. *Amoeba proteus*, for example, selects the flagellate *Chilomonas paramecium* in preference to *Monas punctum*, even when the number of *Monas* in the medium is high. In this case, selection may be based on the digestibility of the prey; the latter is digested in 3½ hours, the former in 3 to 18 minutes.

Mixotrophy is a common phenomenon among free-living ciliates and sarcodines. Moreover, the degree of mixotrophy varies from complete reliance on the symbiotic algae or algae to transitory retention of the plastids of phytoflagellate prey with only a partial dependence on

photosynthesis to supplement the cell's energy balance. Some phytoflagellates (e.g. *Dinobryon* and *Ochromonas*), which are primarily autotrophic, also feed on bacteria and are consequently mixotrophic, but this represents a different kind of mixotrophy from that practiced by the fundamentally heterotrophic ciliates and sarcodines.

Symbiotic
algae

Many of the foraminiferans and radiolarians possess symbiotic algae. In some foraminiferans and radiolarians several different symbiotic species of algae may live within the protozoan cytoplasm. During the day, the endosymbionts are distributed in the pseudopodial network, but at night they are withdrawn close to the main body of the cell or into the shell. Many thousands of these algae may exist within a single protozoan, and a significant amount of the products of photosynthesis (e.g., glucose, alanine, maltose) are transferred from the algae to the protozoan. Indeed, in some circumstances, the protozoan can survive on this source of energy if deprived of food, although its growth may be impaired.

In another form of mixotrophy, the sarcodines and ciliates sequester the plastids of their phytoflagellate prey and use them for photosynthesis. The plastids do not replicate inside the protozoan as they do in the symbiotic algae and must be replaced continuously. The large marine ciliate *Tontonia appendiculariformis*, for example, may contain thousands of plastids that have been derived from a variety of flagellates; moreover, the ciliate appears to be selective in its choice of prey from which to derive plastids.

Reproduction and life cycles. Asexual reproduction is the most common means of replication by protozoans (Figure 3). The ability to undergo a sexual phase is confined to the ciliates, the apicomplexans, and restricted taxa among the flagellates and sarcodines. Moreover, sexual reproduction does not always result in an immediate increase in numbers but may simply be a means of exchanging genetic material between individuals of the same species (conjugation). Free-living protozoans normally only resort to sexual reproduction when environmental conditions become adverse, because this mode of reproduction enhances the fitness of the population and increases the chance of mutation. When food and other conditions are favourable, asexual reproduction is practiced.

Figure 3: Asexual reproductive patterns in protozoans.

Asexual reproduction in free-living species usually involves nuclear division and the division of the cell into two identical daughter cells of equal size by binary fission. In parasitic protozoa and some free-living species, multiple fission, resulting in the production of many offspring that may not resemble the parent cell, is normal. During the cycle of growth and division, the protozoan undergoes a series of identifiable phases: a division phase, a growth phase during which the cell increases substantially in size, a phase of DNA synthesis, and a phase of preparation for

division, which extends from the end of DNA synthesis until the initiation of division. The division of the cytoplasm is preceded by the division of the nucleus or nuclei.

The plane of division in protozoan cells varies among the different groups and is of taxonomic significance. The flagellates normally divide in a longitudinal plane. The usual process starts at the front end with the division of the flagella and the associated structures; simultaneously, the nucleus divides. The cytoplasm then splits from front to back into two identical daughter cells. The ciliates normally divide in an equatorial, or transverse, plane, thereby maintaining the correct number of ciliary rows, or kineties. The cell mouth and any specialized cilia around it are replicated in different ways among the various ciliate groups, depending on the complexity of the cytostome. The replication of the cytostome precedes the division of the cytoplasm. Some ciliates (e.g., *Colpoda*) divide within thin-walled reproductive cysts into two daughter ciliates, each of which then divides so that the cyst contains four progeny, which are released when the cyst wall ruptures.

Plane of
division

The sedentary suctorians do not reproduce by binary fission because the production of an identical, nonswimming offspring would rapidly lead to overcrowding. They instead produce single ciliated offspring called swimmers by a process called budding. Budding can occur endogenously, in which the bud forms within the parent and is ejected when mature, or exogenously, in which the swimmer is formed outside the parent. The swimmers swim away from the parent, settle on a substrate, lose their cilia, and develop feeding tentacles and an attaching stalk.

Naked amoebas (rhizopods) have no fixed plane of division but simply round up and divide into two basically equal halves. The testate amoebas (also rhizopods), which live in single-chambered shells, or tests, exude the daughter from the aperture of the shell. In species that have a shell formed from silica plates, the daughter contains the plates used to produce the shell but remains attached to the mother cell until the shell is fully formed, when the final severing of the cytoplasm between the individuals occurs. Some of the testate amoebas live inside proteinaceous shells. There, too, the new shell is secreted before binary fission is completed.

The foraminiferan and radiolarian sarcodines have evolved multiple fission. Both produce many flagellated swimmers, or zoospores. The common planktonic foraminiferan *Globigerinoides sacculifer*, for example, can produce 30,000 swimmers at one time. Each swimmer is about 5 micrometres (0.005 millimetre) long. In planktonic species the parent usually loses buoyancy and sinks by shedding spines and withdrawing the complicated pseudopodial network into the shell. The swimmers are produced in deep water and migrate upward as they mature. Each secretes a shell around itself, which is added to as the organism grows.

The foraminiferans are unusual among free-living protozoans in that a sexual phase is a regular part of the life cycle, alternating with an asexual phase. During the life cycle two types of swimmer are produced. One type, zoospores, have half the number of chromosomes of the parent (i.e., they are haploid); they grow until they become mature adults and can produce and release large numbers of gametic swimmers. These gametes are identical (isogamous) but are comparable to the eggs and sperm of higher organisms. The gametic swimmers fuse in pairs, thus restoring the full complement of chromosomes (i.e., they are diploid), and each individual grows, matures, and ultimately produces haploid zoospores.

Sexual reproduction among the flagellates is not widespread and can involve identical gametes (isogamy) or distinct male and female gametes (anisogamy). The female gametes are larger and are stationary, whereas the male gametes are smaller, produced in larger numbers, and motile.

Sexual reproduction among the ciliated protozoans takes the form of conjugation. The process does not result in an increase in numbers, but is a simple exchange of genetic material between two individual cells. Conjugation occurs only between compatible mating strains within a species, and each species may contain many mating strains. Before

Conjuga-
tion

conjugation occurs, special chemical signals, called gamones, are released by some ciliates. The gamones cause compatible mating strains to undergo processes that facilitate conjugation. In other ciliates, such as *Paramecium*, gamones are bound to the cell surface and elicit their responses when the ciliates make physical contact.

During conjugation, two ciliates line up side by side. The macronucleus, which plays no part in the process, disintegrates. A series of nuclear divisions of the micronuclei in each ciliate then ensues, including a meiosis, during which a number of haploid micronuclei are produced in both cells. All but one of these haploid micronuclei disintegrate. The remaining haploid micronucleus in each cell then divides through mitosis into two haploid nuclei (gamete nuclei). A bridge of cytoplasm forms between the two ciliates, and one gametic nucleus from each cell passes into the other cell. The two gametic nuclei in each cell unite, thus restoring the diploid number of chromosomes. The micronucleus undergoes two mitotic divisions to produce four micronuclei; two of these will form the new micronuclei of the cell and two are destined to become the macronucleus. Following the process of conjugation, normal binary fission proceeds. The number of macronuclei and micronuclei formed is dependent on the species and remains the same as the original number.

When no suitable mating partner is available, ciliates may undergo a form of conjugation called autogamy, in which all of the nuclear processes described above occur. But, because only one individual is involved, there is no exchange of gametic nuclei; instead, the two gametic nuclei within the cell unite to form the restored micronucleus.

Specialized sedentary suctorian ciliates practice a modified form of conjugation. The conjugating individuals differ in appearance. The macroconjugants resemble the normal feeding individuals, and the microconjugants resemble the swimmers, although smaller. When a microconjugant locates a macroconjugant, it enters and fuses with it. This is quite different from the temporary association between two cells that occurs in most ciliates.

As is common with other parasitic organisms, parasitic protozoans face the problem of how to disperse from one host to another. In order to increase the probability of finding more hosts, most parasitic protozoa reproduce in high numbers. A representative life cycle of a parasitic protozoan can be found in members of the parasitic phylum Apicomplexa. These protozoans have a complex life cycle that involves a series of stages characterized by episodes of asexual multiple division called schizogony. In the parasite *Plasmodium*, for example, this phase of the life cycle occurs in the liver and red blood cells of humans. The parasite (sporozoite) enters the host's cells and grows while feeding on the cell contents. It then undergoes a multiple asexual division (schizogony) into many individuals (merozoites). The host's cell wall ruptures, permitting each individual to invade a new red blood cell and repeat the process.

In certain merozoites a sexual cycle is eventually initiated inside the red blood cell, and male and female gametes are produced. The male gametes (microgametocytes) are small, while the female gametes (macrogametocytes) are larger. The life cycle continues if the gametocytes are taken up by a feeding female mosquito of the genus *Anopheles*. Only the gametocytes can infect the mosquito. Inside the mosquito's gut the haploid gametes fuse to form a diploid zygote, which then undergoes sporogony, a process of multiple divisions in which many sporozoites are produced. The sporozoites migrate to the salivary glands of the insect and are injected into a new host when the mosquito next feeds. They are carried by the blood to the liver, where they undergo their first schizogony inside liver cells, thereafter invading the red blood cells for repeated cycles of schizogony.

The parasitic flagellates reproduce entirely by asexual means and do not appear to have a sexual phase in their life cycles. There is, however, evidence of genetic exchange between certain subspecies of *Trypanosoma brucei*, although the process by which this occurs is not known.

Adaptations. For the most part, parasitic protozoans live in a fairly constant environment. Temperature fluctuates

very little, or not at all, inside the host, there is no risk of desiccation, and food is in constant supply. Free-living protists, on the other hand, face short- or long-term changes in temperature, acidity of the water, food supply, moisture, and light. Many protozoa respond to adverse environmental conditions by encysting. They secrete a thick, tough wall around themselves and effectively enter a quiescent state comparable to hibernation. The ability to form a resistant cyst is widespread among diverse protozoan groups and probably developed early in their evolutionary history. Resting cysts also are easily carried by the wind and form an important means of dispersal for species that live in the soil or are common in temporary ponds and pools. In climates with distinct cold seasons, the cyst may be an important phase in the annual life cycle.

The cyst wall is composed of a varying number of layers, the components of which are dependent on the species. During the encystment process, the protozoan cell undergoes a series of changes that considerably reduce the complexity of the organism. Flagellates and ciliates lose their flagella and cilia, the contractile vacuole and food vacuoles disappear, and the distribution of organelles within the cell may be reorganized. In some species, the cell volume reduces considerably. These changes are reversed during the process of excystment.

Certain of the tintinnid ciliates that live in the plankton of seas are programmed to break out of their cysts en masse at times of the year when the food supply is abundant. *Helicostomella subulata*, for example, excysts in June in temperate waters and becomes numerous from July through October. It encysts again in October, sinking to the sediments, where it remains until the following year. The cyst is a normal part of the annual life cycle, and even laboratory populations of this ciliate encyst at the same time as the natural population. This type of life strategy pattern has been demonstrated in several other ciliates and in sarcodines.

For soil-dwelling protozoa, the cyst is an important refuge when soil moisture disappears or when soil water becomes frozen. In soils that are subject to freezing and periodic short-term thawing, the protozoa rapidly excyst, feed, and reproduce and then encyst again when soil water becomes temporarily unavailable to them.

The cyst plays an important role in the life cycles of several parasitic protozoans that have a free-living dispersal stage, such as *Entamoeba histolytica* and *Cryptosporidium*. The cysts are excreted in the host's feces and survive in water or the soil. Humans are usually infected through drinking contaminated water or eating raw fruit and vegetables grown where human feces are used as fertilizer.

Some freshwater protozoans, especially the ciliates *Spirostomum*, *Loxodes*, and *Plagiopyla*, avoid unpleasant conditions, especially lack of oxygen, by abandoning their bottom-dwelling way of life and swimming upward to position themselves at a level where some oxygen is available but where they are not in direct competition with planktonic species. They remain there until oxygen again becomes available on the lake bottom, at which time they migrate downward.

The widespread occurrence of mixotrophy involving algal symbiosis and the retention and sequestration of the plastids of flagellate prey by planktonic ciliates and sarcodines is believed to be an adaptation to waters where food is limited. Ciliates that retain plastids appear to be far more common in waters where food is scarce than in productive waters. There appears to be an inverse relationship between this form of mixotrophy and the productivity of the waters.

EVOLUTION AND PALEONTOLOGY

Protists dominated life on Earth 1.5 billion years ago, giving rise eventually to multicellular organisms. While protozoa evolved early and have survived to the present day as unicellular organisms, they have undoubtedly undergone considerable evolutionary change. That many species must have become extinct as others appeared can be deduced from the limited fossil record. Extinct fossil foraminiferan species, for example, number around 34,000, while there are only about 4,000 described living species.

Encystment

Modified conjugation

Algal symbionts

Only a small number of protozoans have left fossil remains. The calcareous shells of the sarcodine foraminiferans and calcium-secreting flagellate coccolithophores, for example, have produced substantial geologic strata in the chalk formed during the Cretaceous Period (144 to 66.4 million years ago) and the well-developed foram-limestones of the Upper Paleozoic Era (570 to 245 million years ago), Early Cretaceous Period (144 to 97.5 million years ago), and Cenozoic Era (66.4 million years ago to the present). Another fossil-forming group includes the radiolarians, which date to late Precambrian times.

The most abundant and important fossil protozoans are the foraminiferans. This entirely marine group is extremely important as stratigraphic markers in oil exploration. Because species have appeared and then become extinct frequently during geologic history and because they have fairly wide geographic distribution, particularly planktonic species, their value is in showing distinct phases in geologic history and, with specific species, in typifying particular beds of rock or strata.

The poor fossil record of protozoans has hampered attempts at unraveling the complexities of their evolution. Modern biochemical and electron microscopy techniques, however, are providing evidence for new affinities between groups and are elucidating possible evolutionary pathways. Comparisons of flagellar structures, mitochondria, and nuclear and plastid characteristics in conjunction with ribosomal RNA (ribonucleic acid) sequences are revealing the relationships of various taxa.

The main protozoan groups seen today—the ciliates, flagellates, sarcodines, and apicomplexans—almost certainly separated early in geologic history from amoeboid and flagellate ancestors and represent independent ancestral branches of the protozoan evolutionary tree. The ancestral eukaryote organism is thought to have been an amoeboid creature that relied on anaerobic metabolism. The evolution of mitochondria (the centres of aerobic respiration in the cell) as organelles from endosymbiotic bacteria and the establishment of oxidative pathways allowed a more efficient cellular energy balance, which led the way to the evolution of an enormously diverse array of eukaryotic organisms. Some of the early amoeboid eukaryotes developed flagella to enhance their food-gathering abilities and to provide a more efficient mode of propulsion. The flagellates gradually evolved different ways of life, and their structures became modified accordingly. As phagotrophs that ingested bacteria for food, they came in some cases to establish symbiotic associations with photosynthetic species, and ultimately the endosymbionts became plastids within the cell. Some of the flagellates came to depend entirely on photosynthesis and to abandon heterotrophy completely, though many still retain both heterotrophic and autotrophic nutrition as mixotrophs. (Some present-day mixotrophs, however, may be only secondarily mixotrophic, having reestablished heterotrophy in conjunction with photosynthesis.)

A considerable number of protozoans became parasitic, a mode of life that evolved independently among the protozoa many times. Ciliates and sarcodines became symbionts in the intestinal tracts of both vertebrates and invertebrates as a result of surviving the digestive enzymes of the predator. (Most present-day parasites among these protists are intestinal parasites.) Once inside the intestine of the host, they multiplied and gradually, through mutation and selection, came to rely on the resistant cyst as a means of survival and dispersal, losing the ability to survive in a free-living feeding form. Some species subsequently started to invade the tissues of their host (e.g., *Entamoeba histolytica*), resulting in disease.

The process of parasitism probably arose several times among the parasitic flagellates. The trypanosomes, for example, evolved from free-living zooflagellates, which adapted to living in the alimentary canal of primitive invertebrates in Precambrian times (3.8 billion to 570 million years ago). They evolved with their hosts, becoming symbionts in a wide variety of invertebrates, including annelids, nematodes, and mollusks. It was in the insects, however, that they underwent their most extensive evolutionary explosion into two stocks. At this stage they were

transmitted from insect to insect by resistant cysts passed in the feces and ingested by subsequent hosts. When insects developed the habit of sucking vertebrate blood as an energy source, which is believed to have occurred about 40 million years ago, the protozoan symbionts that lived in the gut entered the blood of vertebrates, probably as feces left by the insect were rubbed into the wound. The blood provided a rich environment for the flagellates and thus evolved the two-host life cycles seen today in the *Leishmania* and *Trypanosoma* groups.

The apicomplexans, which also inhabit the blood of vertebrates at some stage in their life cycle, probably evolved from a basal primitive stock seen today as the gregarines, which are parasites of invertebrates. They gave rise to a group of parasitic organisms of which the Coccidia, with a one-host life cycle, are primitive survivors. At first these protozoans lived in the guts of their vertebrate host, but they gradually began invading host tissues and eventually became adapted to spending part of their life cycle in the bloodstream. There they were taken up by blood-feeding insects, and an insect vector host became incorporated into the life cycle. Associated modifications in the reproductive pattern, as seen in *Plasmodium*, which belongs to the Haemosporina, also occurred. This series of events appears to have happened at least twice in the evolution of apicomplexan life cycles.

CLASSIFICATION

General principles. Until the 1970s the general view was that the protozoans were animals, and as such they were placed in the animal kingdom as the phylum Protozoa. Under this system of classification, zoologists placed the coloured flagellates in the phylum Protozoa despite their obvious plant affinities. Botanists, on the other hand, classified the same organisms as algae, which were regarded as plants. Protozoans are now regarded as a phylum or subkingdom of the kingdom Protista (sometimes called the Protoctista), which also includes the algae. The Society of Protozoologists, which periodically reviews the systematics of the group, favours the subkingdom level for the Protozoa.

Protozoan systematics remains a subject of debate and change. Protozoans comprise a large, unwieldy assemblage, and assignments of species to particular taxa change as new biochemical techniques and electron microscopy studies provide more details on the affinities of various species. The subkingdom Protozoa essentially represents a level of organization—that is, single-celled eukaryote organisms—and does not necessarily indicate single major branches of an evolutionary tree comparable with the kingdoms Plantae or Animalia. Thus, while affinities between some of the groups exist, this is not the case with all the phyla within the subkingdom. Moreover, certain groups (e.g., the Sarcodina or amoebas) are considered by some researchers to have had many different ancestors and lineages (polyphyletic). The Labyrinthomorpha, Myxozoa, and Microspora have no clear affinities either with one another or with other protozoan groups; they are placed in Protozoa until more information is available.

Diagnostic features. The subkingdom Protozoa has been reviewed and divided by a committee of the Society of Protozoologists into six phyla. A major review was undertaken in 1980 by a committee headed by N.D. Levine, and a series of changes have been made subsequently as outlined in a major work on protozoan systematics published by the society in 1985. The six phyla include the Sarcomastigophora (flagellates and amoebas), the Ciliophora (ciliates), and the entirely parasitic Apicomplexa, all of which are discussed in this article. At least some of these groups show affinities in having common amoeboid or flagellate ancestors early in their evolutionary history. The remaining three phyla are totally unrelated to one another and to the phyla discussed here.

In this assemblage of organisms, the only common feature is a single-celled level of organization. Such a situation invariably means that within the whole group there are considerable differences in structure physiology, life mode, and life cycles.

In addition, the classification of protists generally contin-

Develop-
ment of
flagella

Two stocks
of parasites

ues to be debated, and a standard outline of the kingdom has not been established. The differences between the classification of protozoa given below and that given in the article PROTISTS reflect taxonomic variations that arise from individual interpretations.

Annotated classification.

PHYLUM SARCOMASTIGOPHORA

All have one type of nucleus, though some may be multinucleate; Foraminiferida may show nuclear dimorphism similar to that seen in ciliates; sexual reproduction is not widespread; flagella or pseudopodia, and in some species both, occur at one or another stage in the life cycle.

Subphylum Mastigophora

At least 1, and often many, flagella as feeding and locomotory organelles; binary fission resulting in 2 identical daughter cells is the usual mode of asexual reproduction (symmetrogenic binary fission); sexual reproduction occurs in some groups.

Class Phytomastigophorea. Typically possess chloroplasts, with a range of photosynthetic pigments; some members lack chloroplasts but have an evident relationship to the pigmented forms; all free-living, solitary or colonial; typical species include the green species *Volvox* (which belongs to the order Volvocida) and *Euglena* (of the order Euglenida) and the colourless species *Peranema* (Euglenida) and *Noctiluca* (a dinoflagellate from the order Dinoflagellida).

Class Zoomastigophorea. Colourless flagellates; heterotrophic nutrition; binary fission; some groups, such as the collared flagellates, produce flagellated swimmers; both free-living and parasitic species; includes many free-living groups, among which are the collared flagellates (Choanoflagellida) and the amoeboid flagellates, having both amoeboid and flagellated forms in the life cycle (Cercomonadida), and various parasitic orders and families; includes *Trypanosoma brucei gambiense* and *Trypanosoma cruzi* (both of the order Kinetoplastida).

Subphylum Opalinata

Previously classified with the ciliates because of their outward appearance in being covered with rows of cilia; their kinetosomes differ from those of the ciliates; they have only 1 type of nucleus, whereas the ciliates have 2 nuclear types; they lack a cytostome; most divide by symmetrogenic binary fission; asexual and sexual phases of reproduction alternate in the life cycle; all members commensals in the alimentary tracts of amphibians.

Subphylum Sarcodina

Not necessarily closely related; pseudopodia of varying types for locomotion and feeding; most are free-living and divide by binary fission; sexual reproduction is not widespread but does occur in some groups, such as the foraminiferans; some groups are naked; others have shells, or tests, formed from calcium, silica, or protein; others have a structured internal cytoskeleton.

Superclass Rhizopoda

Includes all species that use different types of pseudopodia for movement (filopodia, lobopodia, and reticulopodia), such as naked amoebas (Gymnamoebia), testate forms (Testacealobosia), the foraminiferans (Granuloreticulosea), and some parasitic forms, but not forms that use axopodia.

Superclass Actinopoda

Radial stiffened axopods with a central rod composed of microtubules; many have mineral material incorporated into the cytoskeleton; mostly marine, many planktonic; includes Polycystinea (radiolarians, e.g., *Hexacontium*), Heliozoa (the heliozoans, or sun protozoans, e.g., *Actinosphaerium eichhorni*), Acantharea (e.g., *Acanthochiasma rubescens*), and Phaeodarea (e.g., *Planktonella atlantica*).

PHYLUM LABYRINTHOMORPHA

An ectoplasmic network of spindle-shaped or spherical non-amoeboid cells; in some, amoeboid cells move within the network by gliding, using a unique cell-surface organelle associated with the ectoplasmic network; produce zoospores; saprozoic or parasitic on algae; mostly in marine and brackish waters.

PHYLUM APICOMPLEXA

Previously called Sporozoa; parasitic in both vertebrates and invertebrates; vesicular nucleus; lack flagella or cilia, except in the flagellated microgamete stage; usually a sexual phase in the life cycle with male and female gametes; schizogony and sporogony are features of the life cycle, and cysts are often present at some stage in species with one-host cycles; typical species include *Plasmodium falciparum*, *Toxoplasma gondii*, *Cryptosporidium*, and *Eimeria* species.

PHYLUM MICROSPORA

Not analogous with any other protozoan group; include intracellular parasites of a wide variety of animals; produce spores at some stage in their life cycle, and all active stages develop in

the host's tissues, specifically in the cytoplasm; invasive stage is the sporoplasm, a tiny uninucleate or binucleate structure only 1 micrometre in diameter; both schizogony and sporogony occur in the life cycle; a typical species is *Pleistophora typicalis*.

PHYLUM MYXOZOA

Parasites of the tissues and organ cavities of cold-blooded vertebrates, especially fish, and annelid worms; spore producers; typical species is *Myxidium giardi*.

PHYLUM CILIOPHORA

Each cell usually has at least 1 macronucleus and 1 or more micronuclei; most have a cytostome; all cilia arranged in an ordered fashion at some time in the life cycle; divide by homothetogenic binary fission, but some sedentary forms produce swimmers during asexual reproduction; sexual reproduction is universal in ciliates and normally involves conjugation between 2 cells; more than 7,000 described species, of which the majority are free-living.

Subphylum Postciliodesmatophora

Class Karyorelictea. Long, wormlike ciliates that may be extremely contractile; in some, 1 of the surfaces may be devoid of cilia; 2 to many macronuclei; includes 4 orders; representative genera include *Protocruzia*, *Trachelonema*, *Loxodes*, and *Geleia*.

Class Spirotrichea. Conspicuous right and left oral or preoral ciliature; cytostome may be deep or shallow, and some species live inside loricae (tubes secreted by themselves or an agglomerate of material); lorica may be attached to a substrate; 3 subclasses, Heterotrichia, Choreotrichia (including the loricate tintinnid ciliates and the oligotrichs), and Stichotrichia.

Subphylum Rhabdophora

Class Prostomatea. Cytostome apical to subapical, with a shallow cytostomal cavity; oral kinetids may be tangential to the perimeter of the oral area; includes *Coleps* and *Tiarina*.

Class Litostomatea. Simple oral ciliature may have oral toxicysts; includes *Dileptus* and *Lacrymaria*.

Subphylum Cyrtophora

Class Phyllopharyngea. Where the feeding stage is sessile, the dispersal stage has simple ciliature; includes suctorians, which lack cilia in the trophic stage and feed via tentacles, and the chonotrichs, which are usually sessile ectosymbionts of crustaceans.

Class Nassophorea. Often well-developed oral/cytopharyngeal zones; typical genera are *Nassula*, *Paramecium*, *Frontonia*, and hypotrichs, such as *Euplotes*.

Class Oligohymenophorea. Complex oral cilia distinct from the body cilia; oral cavity may be deep, with ciliary structures extending into it; includes *Tetrahymena* and *Vorticella*.

Class Colpodea. Some inhabit gelatinous sheaths (*Mycetothrix tuamotuensis*); includes *Woodruffia* and *Colpoda*.

BIBLIOGRAPHY. JOHN J. LEE, SEYMOUR H. HUTNER, and EUGENE C. BOVEE (eds.), *An Illustrated Guide to the Protozoa* (1985), includes sections on the different groups, with many excellent illustrations. MICHAEL A. SLEIGH, *Protozoa and Other Protists* (1989), covers the features and physiology of the major groups, with a section on symbiosis and ecology, and is well illustrated. Coverage of the ecology and physiology of ciliates, sarcodines, and flagellates may be found in JOHANNA LAYBOURN-PARRY, *A Functional Biology of Free-Living Protozoa* (1984); and TOM FENCHEL, *The Ecology of Protozoa* (1987). RICHARD R. KUDO, *Protozoology*, 5th ed. (1966, reissued 1971), although slightly out-of-date, is nonetheless a useful book covering the major groups in detail. MICHAEL LEVANDOWSKY and SEYMOUR H. HUTNER (eds.), *Biochemistry and Physiology of Protozoa*, 2nd ed., 4 vol. (1979–81), contains articles on all aspects of protozoan physiology and biochemistry, including structure, locomotion, metabolism, mating behaviour, and immunology of parasitic protozoan diseases. J.P. KREIER and J.R. BAKER, *Parasitic Protozoa* (1987), is an easy-to-read overview covering physiology, biochemistry, and life cycles. R.S. PHILLIPS, *Malaria* (1983), a small, easy-to-read book, discusses pathology, immunology, and control methods. JOHN R. HAYNES, *Foraminifera* (1981), covers the fossil record and the importance of these sarcodines, with many illustrations. O. ROGER ANDERSON, *Radiolaria* (1983), covers the biology of this marine group. F.J.R. TAYLOR (ed.), *The Biology of Dinoflagellates* (1987), contains articles on the physiology and other aspects of these flagellates. LYNDA J. GOFF (ed.), *Algal Symbiosis* (1983), contains articles on endosymbionts of some protozoans and their role. JOHN O. CORLISS, *The Ciliated Protozoa: Characterization, Classification, and Guide to the Literature*, 2nd ed. (1979), is a specialized text providing further references. LYNN MARGULIS, *Symbiosis and Cell Evolution: Life and Its Environment on the Early Earth* (1981), is an interesting text on the evolution of cellular structures. (J.E.M.L.-P.)

Psychological Tests and Measurement

The word “test” refers to any means (often formally contrived) used to elicit responses to which human behaviour in other contexts can be related. When intended to predict relatively distant future behaviour (e.g., success in school), such a device is called an aptitude test. When used to evaluate the individual’s present academic or vocational skill, it may be called an achievement test. In such settings as guidance offices, mental-health clinics, and psychiatric hospitals, tests of ability and personality may be helpful in the diagnosis and detection of troublesome behaviour. Industry and government alike have been prodigious users of tests for selecting workers. Research workers often rely on tests to translate theoretical concepts (e.g., intelligence) into experimentally useful measures.

For coverage of related topics in the *Micropædia* and *Macropædia*, see the *Propædia*, section 434, and the *Index*.

GENERAL PROBLEMS OF MEASUREMENT IN PSYCHOLOGY

Physical things are perceived through their properties or attributes. A mother may directly sense the property called temperature by feeling her infant’s forehead. Yet she cannot directly observe colicky feelings or share the infant’s personal experience of hunger. She must infer such unobservable private sensations from hearing her baby cry or gurgle; from seeing him flail his arms, or frown, or smile. In the same way, much of what is called measurement must be made by inference. Thus, a mother suspecting her child is feverish may use a thermometer, in which case she ascertains his temperature by looking at the thermometer, rather than by directly touching his head.

Indeed, measurement by inference is particularly characteristic of psychology. Such abstract properties or attributes as intelligence or introversion never are directly measured but must be inferred from observable behaviour. The inference may be fairly direct or quite indirect. If persons respond intelligently (e.g., by reasoning correctly) on an ability test, it can be safely inferred that they possess intelligence to some degree. In contrast, people’s capacity to make associations or connections, especially unusual ones, between things or ideas presented in a test can be used as the basis for inferring creativity, although producing a creative product requires other attributes, including motivation, opportunity, and technical skill.

Types of measurement scales. To measure any property or activity is to assign it a unique position along a numerical scale. When numbers are used merely to identify individuals or classes (as on the backs of athletes on a football team), they constitute a nominal scale. When a set of numbers reflects only the relative order of things (e.g., pleasantness-unpleasantness of odours), it constitutes an ordinal scale. An interval scale has equal units and an arbitrarily assigned zero point; one such scale, for ex-

ample, is the Fahrenheit temperature scale. Ratio scales not only provide equal units but also have absolute zero points; examples include measures of weight and distance.

Although there have been ingenious attempts to establish psychological scales with absolute zero points, psychologists usually are content with approximations to interval scales; ordinal scales often are used as well.

Primary characteristics of methods or instruments. The primary requirement of a test is validity—traditionally defined as the degree to which a test actually measures whatever it purports to measure. A test is reliable to the extent that it measures consistently, but reliability is of no consequence if a test lacks validity. Since the person who draws inferences from a test must determine how well it serves his purposes, the estimation of validity inescapably requires judgment. Depending on the criteria of judgment employed, tests exhibit a number of different kinds of validity.

Empirical validity (also called statistical or predictive validity) describes how closely scores on a test correspond (correlate) with behaviour as measured in other contexts. Students’ scores on a test of academic aptitude, for example, may be compared with their school grades (a commonly used criterion). To the degree that the two measures statistically correspond, the test empirically predicts the criterion of performance in school. Predictive validity has its most important application in aptitude testing (e.g., in screening applicants for work, in academic placement, in assigning military personnel to different duties).

Alternatively, a test may be inspected simply to see if its content seems appropriate to its intended purpose. Such content validation is widely employed in measuring academic achievement but with recognition of the inevitable role of judgment. Thus, a geometry test exhibits content (or curricular) validity when experts (e.g., teachers) believe that it adequately samples the school curriculum for that topic. Interpreted broadly, content covers desired skills (such as computational ability) as well as points of information in the case of achievement tests. Face validity (a crude kind of content validity) reflects the acceptability of a test to such people as students, parents, employers, and government officials. A test that looks valid is desirable, but face validity without some more basic validity is nothing more than window dressing.

In personality testing, judgments of test content tend to be especially untrustworthy, and dependable external criteria are rare. One may, for example, assume that a man who perspires excessively feels anxious. Yet his feelings of anxiety, if any, are not directly observable. Any assumed trait (anxiety, for example) that is held to underlie observable behaviour is called a construct. Since the construct itself is not directly measurable, the adequacy of any test as a measure of anxiety can be gauged only indirectly; e.g., through evidence for its construct validity.

A test exhibits construct validity when low scorers and high scorers are found to respond differently to everyday experiences or to experimental procedures. A test presumed to measure anxiety, for example, would give evidence of construct validity if those with high scores (“high anxiety”) can be shown to learn less efficiently than do those with lower scores. The rationale is that there are several propositions associated with the concept of anxiety: anxious people are likely to learn less efficiently, especially if uncertain about their capacity to learn; they are likely to overlook things they should attend to in carrying out a task; they are apt to be under strain and hence feel fatigued. (But anxious people may be young or old, intelligent or unintelligent.) If people with high scores

Validity

	<p>on a test of anxiety show such proposed signs of anxiety, that is, if a test of anxiety has the expected relationships with other measurements as given in these propositions, the test is viewed as having construct validity.</p>	
Reliability	<p>Test reliability is affected by scoring accuracy, adequacy of content sampling, and the stability of the trait being measured. Scorer reliability refers to the consistency with which different people who score the same test agree. For a test with a definite answer key, scorer reliability is of negligible concern. When the subject responds with his own words, handwriting, and organization of subject matter, however, the preconceptions of different raters produce different scores for the same test from one rater to another; that is, the test shows scorer (or rater) unreliability. In the absence of an objective scoring key, a scorer's evaluation may differ from one time to another and from those of equally respected evaluators. Other things being equal, tests that permit objective scoring are preferred.</p> <p>Reliability also depends on the representativeness with which tests sample the content to be tested. If scores on items of a test that sample a particular universe of content designed to be reasonably homogeneous (e.g., vocabulary) correlate highly with those on another set of items selected from the same universe of content, the test has high content reliability. But if the universe of content is highly diverse in that it samples different factors (say, verbal reasoning and facility with numbers), the test may have high content reliability but low internal consistency.</p> <p>For most purposes, the performance of a subject on the same test from day to day should be consistent. When such scores do tend to remain stable over time, the test exhibits temporal reliability. Fluctuations of scores may arise from instability of a trait; for example, the test taker may be happier one day than the next. Or temporal unreliability may reflect injudicious test construction.</p>	Response sets
Reliability estimates	<p>Included among the major methods through which test reliability estimates are made is the comparable-forms technique, in which the scores of a group of people on one form of a test are compared with the scores they earn on another form. Theoretically, the comparable-forms approach may reflect scorer, content, and temporal reliability. This ideally demands that each form of the test be constructed by different but equally competent persons and that the forms be given at different times and evaluated by a second rater (unless an objective key is fixed).</p> <p>In the test-retest method, scores of the same group of people from two administrations of the same test are correlated. If the time interval between administrations is too short, memory may unduly enhance the correlation. Or some people, for example, may look up words they missed on the first administration of a vocabulary test and thus be able to raise their scores the second time around. Too long an interval can result in different effects for each person due to different rates of forgetting or learning. Except for very easy speed tests (e.g., in which a person's score depends on how quickly he is able to do simple addition), this method may give misleading estimates of reliability.</p> <p>Internal-consistency methods of estimating reliability require only one administration of a single form of a test. One method entails obtaining scores on separate halves of the test, usually the odd-numbered and the even-numbered items. The degree of correspondence (which is expressed numerically as a correlation coefficient) between scores on these half-tests permits estimation of the reliability of the test (at full length) by means of a statistical correction.</p> <p>This is computed by the use of the Spearman-Brown prophecy formula (for estimating the increased reliability expected to result from increase in test length). More commonly used is a generalization of this stepped-up, split-half reliability estimate, one of the Kuder-Richardson formulas. This formula provides an average of estimates that would result from all possible ways of dividing a test into halves.</p> <p>Other characteristics. A test that takes too long to administer is useless for most routine applications. What constitutes a reasonable period of testing time, however, depends in part on the decisions to be made from the test. Each test should be accompanied by a practicable and economically feasible scoring scheme, one scorable by machine or by quickly trained personnel being preferred.</p>	Weber's law
<p>TYPES OF INSTRUMENTS AND METHODS</p> <p><i>Psychophysical scales and psychometric, or psychological, scales.</i> The concept of an absolute threshold (the lowest intensity at which a sensory stimulus, such as sound waves, is perceived) is traceable to the German philosopher Johann Friedrich Herbart. The German physiologist Ernst Heinrich Weber later observed that the smallest discernible difference of intensity is proportional to the initial stimulus intensity. Weber found, for example, that, while people could just notice the difference after a slight change in the weight of a 10-gram object, they needed a larger change before they could just detect a difference from a 100-gram weight. This finding, known as Weber's law, is expressed more technically in the statement that the perceived (subjective) intensity varies mathematically as the logarithm of the physical (objective) intensity of the stimulus.</p> <p>In traditional psychophysical scaling methods, a set of standard stimuli (such as weights) that can be ordered according to some physical property is related to sensory judgments made by experimental subjects. By the method of average error, for example, subjects are given a standard stimulus and then made to adjust a variable stimulus until they believe it is equal to the standard. The mean (average) of a number of judgments is obtained. This method and many variations have been used to study such experiences as visual illusions, tactual intensities, and auditory pitch.</p> <p>Psychological (psychometric) scaling methods are an outgrowth of the psychophysical tradition just described. Although their purpose is to locate stimuli on a linear (straight-line) scale, no quantitative physical values (e.g., loudness or weight) for stimuli are involved. The linear scale may represent an individual's attitude toward a social institution, his judgment of the quality of an artistic product, the degree to which he exhibits a personality characteristic, or his preference for different foods. Psychological scales thus are used for having a person rate his own characteristics as well as those of other individuals in terms of such attributes, for example, as leadership potential or initiative. In addition to locating individuals on a scale, psychological scaling can also be used to scale objects and various kinds of characteristics: finding where different foods fall on a group's preference scale; or determining the relative positions of various job characteristics in the view of those holding that job. Reported degrees of similarities between pairs of objects are used to identify scales or dimensions on which people perceive the objects.</p> <p>The American psychologist L.L. Thurstone offered a number of theoretical-statistical contributions that are widely used as rationales for constructing psychometric scales. One scaling technique (comparative judgment) is based empirically on choices made by people between members of any series of paired stimuli. Statistical treatment to provide numerical estimates of the subjective (perceived) distances between members of every pair of stimuli yields a psychometric scale. Whether or not these computed scale values are consistent with the observed comparative judgments can be tested empirically.</p>		

Equal-
appearing
intervals

Another of Thurstone's psychometric scaling techniques (equal-appearing intervals) has been widely used in attitude measurement. In this method judges sort statements reflecting such things as varying degrees of emotional intensity, for example, into what they perceive to be equally spaced categories; the average (median) category assignments are used to define scale values numerically. Subsequent users of such a scale are scored according to the average scale values of the statements to which they subscribe. Another psychologist, Louis Guttman, developed a method that requires no prior group of judges, depends on intensive analysis of scale items, and yields comparable results. Quite commonly used is the type of scale developed by Rensis Likert in which perhaps five choices ranging from strongly in favour to strongly opposed are provided for each statement, the alternatives being scored from one to five. A more general technique (successive intervals) does not depend on the assumption that judges perceive interval size accurately. The widely used graphic rating scale presents an arbitrary continuum with preassigned guides for the rater (*e.g.*, adjectives such as superior, average, and inferior).

Tests versus inventories. The term "test" most frequently refers to devices for measuring abilities or qualities for which there are authoritative right and wrong answers. Such a test may be contrasted with a personality inventory, for which it is often claimed that there are no right or wrong answers. At any rate, in taking what often is called a test, the subjects are instructed to do their best; in completing an inventory, they are instructed to represent their typical reactions. A distinction also has been made that in responding to an inventory the subjects control the appraisal, whereas in a test they do not. If a test is more broadly regarded as a set of stimulus situations that elicit responses from which inferences can be drawn, however, then an inventory is, according to this definition, a variety of test.

Free-response versus limited-response tests. Free-response tests entail few restraints on the form or content of response, whereas limited-response tests restrict responses to one of a smaller number presented (*e.g.*, true-false). An essay test tends toward one extreme (free response), while a so-called fully objective test is at the other extreme (limited response).

Essay and
objective
tests

Response to an essay question is not completely unlimited, however, since the answer should bear on the question. The free-response test does give practice in writing, and, when an evaluator is proficient in judging written expression, his comments on the test may aid the individual to improve his writing style. All too often, however, writing ability unfortunately affects the evaluator's judgment of how well the test taker understands content, and this tends to reduce test reliability. Another source of unreliability for essay tests is found in their limited sampling of content, as contrasted with the broader coverage that is possible with objective tests. Often both the scorer and the content reliability of essay tests can be improved, but such attempts are costly.

The objective test, which minimizes scorer unreliability, is best typified by the multiple-choice form, in which the subject is required to select one from two or (preferably) more responses to a test item. Matching items that have a common set of alternatives are of this form. The true-false test question is a special multiple-choice form that may tend to arouse antagonism because of variable standards of truth or falsity.

The more general multiple-choice item is more acceptable when it is specified only that the best answer be selected; it is flexible, has high scorer reliability, and is not limited to simple factual knowledge. The ingenious test constructor can use multiple-choice items to test such functions as generalization, application of principles, and the ability to educate unfamiliar relationships.

Forced-
choice
items

Some personality tests are presented in a forced-choice format. They may, for example, force the person to choose one of two favourable words or phrases (*e.g.*, intelligent-handsome) as more descriptive of himself or one of two unfavourable terms as less descriptive (*e.g.*, stupid-ugly). Marking one choice yields a gain in score on some trait

but may also preclude credit on another trait. This technique is intended to eliminate any effects from subjects' attempts to present themselves in a socially desirable light; it is not fully successful, however, because what is highly desirable for one person may be less desirable for another.

The forced-choice technique for self-appraisals is exemplified in a widely used interest inventory. Forced-choice ratings were introduced for evaluation of one military officer by another during World War II. They were an effort to avoid the preponderance of high ratings typically obtained with ordinary rating scales. Raters tend to give those being rated the benefit of any doubt, especially when they are fellow workers. Also, supervisors or teachers may give unduly favourable ratings because they believe good performance of subordinates or students reflects well on themselves.

Falling between free- and limited-response tests is a type that requires a short answer, perhaps a single word or a number, for each item. When the required response is to fit into a blank in a sentence, the test is called a completion test. This type of test is susceptible to scorer unreliability.

A personality test to which a subject responds by interpreting a picture or by telling a story it suggests resembles an essay test except that responses ordinarily are oral. A personality inventory that requires the subject to indicate whether or not a descriptive phrase applies to him is of the limited-response type. A sentence-completion personality test that asks the subject to complete statements such as "I worry because . . ." is akin to the short-answer and completion types.

Verbal versus performance tests. A verbal (or symbol) test poses questions to which the subject supplies symbolic answers (in words or in other symbols, such as numbers). In performance tests, the subject actually executes some motor activity; for example, he assembles mechanical objects. Either the quality of performance as it takes place or its results may be rated.

The verbal test, permitting group administration, requiring no special equipment, and often being scorable by relatively unskilled evaluators, tends to be more practical than the performance test. Both types of devices also have counterparts in personality measurement, in which verbal tests as well as behaviour ratings are used.

Written (group) versus oral (individual) tests. The oral test is administered to one person at a time, but written tests can be given simultaneously to a number of subjects. Oral tests of achievement, being uneconomical and prone to content and scorer unreliability, have been supplanted by written tests; notable exceptions include the testing of illiterates and the anachronistic oral examinations to which candidates for graduate degrees are liable.

Proponents of individually administered intelligence tests (*e.g.*, the Stanford-Binet) state that such face-to-face testing optimizes rapport and motivation, even among literate adult subjects. Oral tests of general aptitude remain popular, though numerous written group tests have been designed for the same purpose.

The interview may provide a personality measurement and, especially when it is standardized as to wording and order of questions and with a key for coding answers, may amount to an individual oral test. Used in public opinion surveys, such interviews are carefully designed to avoid the effects of interviewer bias and to be comprehensible to a highly heterogeneous sample of respondents.

Interviews
as tests

Appraisal by others versus self-appraisal. In responding to personality inventories and rating scales, a person presumably reveals what he thinks he is like; that is, he appraises himself. Other instruments may reflect what one person thinks of another. Because self-appraisal often lacks objectivity, appraisal by another individual is common in such things as ratings for promotions. Ordinary tests of ability clearly involve evaluation of one person by another, although the subject's self-evaluation may intrude; for example, he may lack confidence to the point where he does not try to do his best.

Projective tests. The stimuli (*e.g.*, inkblots) in a projective test are intentionally made ambiguous and open to different interpretations in the expectation that each sub-

ject will project his own unique (idiosyncratic) reactions in his answers. Techniques for evaluating such responses range from the intuitive impressions of the rater to complex, coded schemes for scoring and interpretation that require extensive manuals; some projective tests are objectively scorable.

Speed tests versus power tests. A pure speed test is homogeneous in content (e.g., a simple clerical checking test), the tasks being so easy that with unlimited time all but the most incompetent of subjects could deal with them successfully. The time allowed for testing is so short, however, that even the ablest subject is not expected to finish. A useful score is the number of correct answers made in a fixed time. In contrast, a power test (e.g., a general vocabulary test) contains items that vary in difficulty to the point that no subject is expected to get all items right even with unlimited time. In practice, a definite but ample time is set for power tests.

Speed tests are suitable for testing visual perception, numerical facility, and other abilities related to vocational success. Tests of psychomotor abilities (e.g., eye-hand coordination) often involve speed. Power tests tend to be more relevant to such purposes as the evaluation of academic achievement, for which the highest level of difficulty at which a person can succeed is of greater interest than his speed on easy tasks.

In general, tests reflect unknown combinations of the effects of speed and power; many consist of items that vary considerably in difficulty, and the time allowed is too limited to allow a large proportion of subjects to attempt all items.

Teacher-made versus standardized tests. A distinction between teacher-made tests and standardized tests is often made in relation to tests used to assess academic achievement. Ordinarily, teachers do not attempt to construct tests of general or special aptitude or of personality traits. Teacher-made tests tend instead to be geared to narrow segments of curricular content (e.g., a sixth-grade geography test). Standardized tests with carefully defined procedures for administration and scoring to ensure uniformity can achieve broader goals. General principles of test construction and such considerations as reliability and validity apply to both types of test.

Special measurement techniques. Sociodrama and psychodrama were originally developed as psychotherapeutic techniques. In sociodrama, group members participate in unrehearsed drama to illuminate a general problem. Psychodrama centres on one individual in the group whose unique personal problem provides the theme. Related research techniques (e.g., the sociometric test) can offer insight into interpersonal relationships. Individuals may be asked to specify members of a group whom they prefer as leader, playmate, or coworker. The choices made can then be charted in a sociogram, from which cliques or socially isolated individuals may be identified at a glance.

Research psychologists have grasped the sociometric approach as a means of measuring group cohesiveness and studying individual reactions to groups. The degree to which any group member chooses or is chosen beyond chance expectation may be calculated, and mathematical techniques may be used to determine the complex links among group members. Sociogram-choice scores have been useful in predicting such criteria as individual productivity in factory work and combat effectiveness.

DEVELOPMENT OF STANDARDIZED TESTS

Test content. Item development. Once the need for a test has been established, a plan to define its content may be prepared. For achievement tests, the test plan may also indicate thinking skills to be evaluated. Detailed content headings can be immediately suggestive of test items. It is helpful if the plan specifies weights to be allotted to different topics, as well as the desired average score and the spread of item difficulties. Whether or not such an outline is made, the test constructor clearly must understand the purpose of the test, the universe of content to be sampled, and the forms of the items to be used.

Tryouts and item analysis. A set of test questions is first administered to a small group of people deemed to

be representative of the population for which the final test is intended. The trial run is planned to provide a check on instructions for administering and taking the test and for intended time allowances, and it can also reveal ambiguities in the test content. After adjustments, surviving items are administered to a larger, ostensibly representative group. The resulting data permit computation of a difficulty index for each item (often taken as the percentage of the subjects who respond correctly) and of an item-test or item-subtest discrimination index (e.g., a coefficient of correlation specifying the relationship of each item with total test score or subtest score).

If it is feasible to do so, measures of the relation of each item to independent criteria (e.g., grades earned in school) are obtained to provide item validation. Items that are too easy or too difficult are discarded; those within a desired range of difficulty are identified. If internal consistency is sought, items that are found to be unrelated to either a total score or an appropriate subtest score are ruled out, and items that are related to available external criterion measures are identified. Those items that show the most efficiency in predicting an external criterion (highest validity) usually are preferred over those that contribute only to internal consistency (reliability).

Estimates of reliability for the entire set of items, as well as for those to be retained, commonly are calculated. If the reliability estimate is deemed to be too low, items may be added. Each alternative in multiple-choice items also may be examined statistically. Weak incorrect alternatives can be replaced, and those that are unduly attractive to higher scoring subjects may be modified.

Cross validation. Item-selection procedures are subject to chance errors in sampling test subjects, and statistical values obtained in pretesting are usually checked (cross validated) with one or more additional samples of subjects. Typically, it is found that cross-validation values tend to shrink for many of the items that emerged as best in the original data, and further items may be found to warrant discard. Measures of correlation between total test score and scores from other, better known tests are often sought by test users.

Differential weighting. Some test items may appear to deserve extra, positive weight; some answers in multiple-choice items, though keyed as wrong, seem better than others in that they attract people who earn high scores generally. The bulk of theoretical logic and empirical evidence, nonetheless, suggests that unit weights for selected items and zero weights for discarded items and dichotomous (right versus wrong) scoring for multiple-choice items serve almost as effectively as more complicated scoring. Painstaking efforts to weight items generally are not worth the trouble.

Negative weight for wrong answers is usually avoided as presenting undue complication. In multiple-choice items, the number of answers a subject knows, in contrast to the number he gets right (which will include some lucky guesses), can be estimated by formula. But such an average correction overpenalizes the unlucky and underpenalizes the lucky. If the instruction is not to guess, it is variously interpreted by persons of different temperament; those who decide to guess despite the ban are often helped by partial knowledge and tend to do better.

A responsible tactic is to try to reduce these differences by directing subjects to respond to every question, even if they must guess. Such instructions, however, are inappropriate for some competitive speed tests, since candidates who mark items very rapidly and with no attention to accuracy excel if speed is the only basis for scoring; that is, if wrong answers are not penalized.

Test norms. Test norms consist of data that make it possible to determine the relative standing of an individual who has taken a test. By itself, a subject's raw score (e.g., the number of answers that agree with the scoring key) has little meaning. Almost always, a test score must be interpreted as indicating the subject's position relative to others in some group. Norms provide a basis for comparing the individual with a group.

Numerical values called centiles (or percentiles) serve as the basis for one widely applicable system of norms. From

Item

Socio-
drama
and
psycho-
drama

Centiles

a distribution of a group's raw scores the percentage of subjects falling below any given raw score can be found. Any raw score can then be interpreted relative to the performance of the reference (or normative) group—eighth-graders, five-year-olds, institutional inmates, job applicants. The centile rank corresponding to each raw score, therefore, shows the percentage of subjects who scored below that point. Thus, 25 percent of the normative group earn scores lower than the 25th centile; and an average called the median corresponds to the 50th centile.

Another class of norm system (standard scores) is based on how far each raw score falls above or below an average score, the arithmetic mean. One resulting type of standard score, symbolized as z , is positive (e.g., +1.69 or +2.43) for a raw score above the mean and negative for a raw score below the mean. Negative and fractional values can, however, be avoided in practice by using other types of standard scores obtained by multiplying z scores by an arbitrarily selected constant (say, 10) and by adding another constant (say, 50, which changes the z score mean of zero to a new mean of 50). Such changes of constants do not alter the essential characteristics of the underlying set of z scores.

The French psychologist Alfred Binet, in pioneering the development of tests of intelligence, listed test items along a normative scale on the basis of the chronological age (actual age in years and months) of groups of children that passed them. A mental-age score (e.g., seven) was assigned to each subject, indicating the chronological age (e.g., seven years old) in the reference sample for which his raw score was the mean. But mental age is not a direct index of brightness; a mental age of seven in a 10-year-old is different from the same mental age in a four-year-old.

To correct for this, a later development was a form of IQ (intelligence quotient), computed as the ratio of the subject's mental age to his chronological age, multiplied by 100. (Thus, the IQ made it easy to tell if a child was bright or dull for his age.)

Deviation
IQ

Ratio IQs for younger age groups exhibit means close to 100 and spreads of roughly 45 points above and below 100. The classical ratio IQ has been largely supplanted by the deviation IQ, mainly because the spread around the average has not been uniform due to different ranges of item difficulty at different age levels. The deviation IQ, a type of standard score, has a mean of 100 and a standard deviation of 16 for each age level. Practice with the Stanford-Binet test reflects the finding that average performance on the test does not increase beyond age 18. Therefore, the chronological age of any individual older than 18 is taken as 18 for the purpose of determining IQ.

The Stanford-Binet has been largely supplanted by several tests developed by the American psychologist David Wechsler between the late 1930s and the early 1960s. These tests have subtests for several capacities, some verbal and some operational, each subtest having its own norms. After constructing tests for adults, Wechsler developed tests for older and for younger children.

ASSESSING TEST STRUCTURE

Factor analysis. Factor analysis is a method of assessment frequently used for the systematic analysis of intellectual ability and other test domains, such as personality measures. Just after the turn of the 20th century the British psychologist Charles E. Spearman systematically explored positive intercorrelations between measures of apparently different abilities to provide evidence that much of the variability in scores that children earn on tests of intelligence depends on one general underlying factor, which he called g . In addition he believed that each test contained an s factor specific to it alone. In the United States, Thurstone developed a statistical technique called multiple-factor analysis, with which he was able to demonstrate, in a set of tests of intelligence, that there were primary mental abilities, such as verbal comprehension, numerical computation, spatial orientation, and general reasoning. Although later work has supported the differentiation between these abilities, no definitive taxonomy of abilities

has become established. One element in the problem is the finding that each such ability can be shown to be composed of narrower factors.

The first computational methods in factor analysis have been supplanted by mathematically more elegant, computer-generated solutions. While earlier techniques were primarily exploratory, the Swedish statistician Karl Gustav Jöreskog and others have developed procedures that permit the researcher to test hypotheses about the structure in a set of data.

Rooted in extensive applications of factor analysis, a structure-of-intellect model developed by the American psychologist Joy Paul Guilford posited a very large number of factors of intelligence. Guilford envisaged three intersecting dimensions corresponding respectively to four kinds of test content, five kinds of intellectual operation, and six kinds of product. Each of the 120 cells in the cube thus generated was hypothesized to represent a separate ability, each constituting a distinct factor of intellect. Educational and vocational counselors usually prefer a substantially smaller number of scores than the 120 implied by this model.

Factor analysis has also been widely used outside the realm of intelligence, especially to seek the structure of personality as reflected in ratings by oneself and by others. Although there is even less consensus here than for intelligence, a number of studies suggest that four prevalent factors can be approximately labeled, namely, conformity, extroversion, anxiety, and dependability.

Profile analysis. With the fractionation of tests (e.g., to yield scores measuring separate factors or clusters), new concern has arisen for interpreting differences among scores measuring the underlying variables, however conceived. Scores of an individual on several such measures can be plotted graphically as a profile; for direct comparability, all raw scores may be expressed in terms of standard scores that have equal means and variabilities. The difference between any pair of scores that have less than perfect reliability tends to be less reliable than either, and fluctuations in the graph should be interpreted cautiously. Nevertheless, various features of an individual's profile may be examined, such as scatter (fluctuation from one measure to another) and relative level of performance on different measures. (The particular shape of the graph, it should be noted, partly depends upon the arbitrary order in which measures are listed.) One may also statistically express the degree of similarity between any two profiles. Such statistical measures of pattern similarity permit quantitative comparison of profiles for different persons, of profiles of the same individual's performance at different times, of individual with group profiles, or of one group profile with another. Comparison of an individual's profile with similar graphs representing the means for various occupational groups, for example, is useful for vocational guidance or personnel selection.

Factors of
intelligence

Public Administration

Public administration, traditionally defined, denotes the implementation of government policies. Today public administration is often regarded as including also some responsibility for determining the policies and programs of governments. Specifically, it is the planning, organizing, directing, coordinating, and controlling of government operations.

Public administration is a feature of all nations, whatever their system of government. Within nations public administration is practiced at the central, intermediate, and local levels. Indeed, the relationships between different levels of government within a single nation constitute a growing problem of public administration.

In most of the world the establishment of highly trained administrative, executive, or directive classes has made public administration a distinct profession. The body of public administrators is usually called the civil service. In the United States and a few other countries, the elitist class connotation traditionally attached to the civil service has been either consciously abandoned or avoided, with the result that professional recognition has come slowly and only partially.

Traditionally the civil service is contrasted with other bodies serving the state full time, such as the military, the judiciary, and the police. Specialized services, sometimes referred to as scientific or professional civil services, provide technical rather than general administrative support. Traditionally, in most countries, a distinction is also made between the home civil service and those persons engaged abroad on diplomatic duties. A civil servant, therefore, is one of a body of persons who are directly employed in the administration of the internal affairs of the state and whose role and status are not political, ministerial, military, or constabulary.

In most countries the civil service does not include local government or public corporations, such as, in the United Kingdom, the National Coal Board. In some countries, however—particularly those unitary states in which provincial administration is part of the central government—some provincial staffs are civil servants. In the United States, all levels of government have their own civil services, federal, state, and local, and a civil service is specifically that part of governmental service entered by examination and offering permanent tenure.

Certain characteristics are common to all civil services. Senior civil servants are regarded as the professional advisers

to those who formulate state policy. In some countries entry requirements for a career in the higher civil service stress qualifications in technical fields such as accounting, economics, medicine, and engineering. In other countries legal training is deemed appropriate, and in others no specific technical or academic discipline is required among candidates for senior posts. Whatever their precise qualifications, senior civil servants are professional in the sense that their experience of public affairs is thought to provide them with the knowledge of the limits within which state policy can be made effective and of the probable administrative results of different courses of action. Civil servants in every country are expected to advise, warn, and assist those responsible for state policy and, when this has been decided, to provide the organization for implementing it. The responsibility for policy decisions lies with the political members of the executive (those members who have been elected or appointed to give political direction to government and, customarily, career civil servants). By custom, civil servants are protected from public blame or censure for their advice. The acts of their administration may, however, be subject to special judicial controls from which no member of the executive can defend them.

Civil services are organized upon standard hierarchical lines, in which a command structure rises pyramid-fashion from the lowest offices to the highest. This command implies obedience to the lawful orders of a superior, and in order to maintain this system the hierarchy of offices is marked by fixed positions, with well-defined duties, specific powers, and salaries and privileges objectively assessed. In some countries there may be direct appointment to higher office of persons not previously employed by the service, but even then a recognized system of internal promotion emphasizes the nature of the hierarchical pyramid.

This article discusses the growth of public administration through history as well as its development under different political systems. Special attention is paid to the problems of administrative law and bureaucratic structure. For discussion of a subject integral to public administration, see GOVERNMENT FINANCE. For further discussion of the various regimes under which public administration operates, see POLITICAL SYSTEMS.

History

EARLY SYSTEMS

Public administration has ancient origins. In antiquity the Egyptians and Greeks organized public affairs by office,

and the principal officeholders were regarded as being principally responsible for administering justice, maintaining law and order, and providing plenty. The Romans developed a more sophisticated system under their empire, creating distinct administrative hierarchies for justice,

military affairs, finance and taxation, foreign affairs, and internal affairs, each with its own principal officers of state. An elaborate administrative structure, later imitated by the Roman Catholic Church, covered the entire empire, with a hierarchy of officers reporting back through their superiors to the emperor. This sophisticated structure disappeared after the fall of the Roman Empire in western Europe in the 5th century, but many of its practices continued in the Byzantine Empire in the east, where civil service rule was reflected in the pejorative use of the word Byzantinism.

Medieval
Europe

Early European administrative structures developed from the royal households of the medieval period. Until the end of the 12th century official duties within the royal households were ill-defined, frequently with multiple holders of the same post. Exceptions were the better-defined positions of butler (responsible for the provision of wine), steward (responsible for feasting arrangements), chamberlain (often charged with receiving and paying out money kept in the royal sleeping chamber), and chancellor (usually a priest with responsibilities for writing and applying the seal in the monarch's name). With the 13th century a separation began between the purely domestic functions of the royal household and the functions connected with governing the state. The older household posts tended to disappear, become sinecures, or decline in importance. The office of chancellor, which had always been concerned with matters of state, survived to become the most important link between the old court offices and modern ministries, and the development of the modern treasury or finance ministry can be traced back to the chamberlain's office in the royal household.

From the middle of the 13th century three institutions began to emerge as the major bodies for handling affairs of state: the high court (evolving primarily from the chancellery), the exchequer, and the collegial royal council. In England and France, however, it was not until the early 14th century that such bodies emerged. In Brandenburg, which was governed by an elector (a prince with a right to elect the Holy Roman emperor) and which later formed the basis of the Prussian state, they became distinct entities only at the beginning of the 17th century.

Apart from justice and treasury departments, which originated in old court offices, modern ministerial structures in Europe developed out of the royal councils, which were powerful bodies of nobles appointed by the monarch. From the division of labour within these bodies the monarchs' secretaries, initially given low status within a council, emerged as perhaps the first professional civil servants in Europe in the modern sense. The proximity of the secretaries to the monarch gave them more knowledge of royal intentions, and their relative permanence gave them greater expertise in particular matters of state than could be found among the more transient nobles on the council. They were also assisted by staffs. The secretaries grew in importance in the 15th and 16th centuries as they became more or less full members of the council.

The distribution of functions among secretaries was initially based upon geography. In England this geographical allocation—with, for example, a secretary of the North and a secretary of the South—persisted until 1782, when the offices of home and foreign secretary were created. In France a more complex allocation of territorial responsibilities among secretaries of state had begun to give way to functional responsibilities by the end of the ancien régime in 1789.

Chinese
civil service

The civil service in China was undoubtedly the longest lasting in history; it was first organized, along with a centralized administration, during the Han dynasty (206 BC–AD 220) and improved under the T'ang (618–907) and Sung (960–1279). The administration was organized so well that the pattern stood until 1912. During the Sung dynasty there developed the full use of civil service examinations. Candidates were subjected to successive elimination through written tests on three levels, more than a hundred persons beginning the ordeal for each one who emerged successful. Although there was strong emphasis on the Chinese Classics (because knowledge of the Classics was thought to form the virtues of a good citizen), there was

also an effort to devise objective and meaningful tests for practical qualities, and there were always long contentions over subject matter and testing methods. To preserve the anonymity of the candidate and to ensure fairness in grading, examination papers were copied by clerks, examinees were identified by number only, and three examiners read each paper. Higher officials were privileged to nominate junior relatives for admission to the bureaucracy, but the great stress on examination grades in promotion, the use of annual merit ratings, and the practice of recruiting many lower officials from the ranks of the clerical service ensured a considerable freedom of opportunity.

MODERN DEVELOPMENTS

Prussia. The foundations of modern public administration in Europe were laid in Prussia in the late 17th and 18th centuries. The electors of Brandenburg (who from 1701 were the kings of Prussia) considered a rigidly centralized government a means of ensuring stability and furthering dynastic objectives. Their principal effort was devoted in the first instance to the suppression of the autonomy of the cities and to the elimination of the feudal privileges of the aristocracy. Civil servants were therefore appointed by the central government to administer the provinces, where the management of crown lands and the organization of the military system were combined in a *Kriegs-und-Domänen-kammer* ("Office of War and Crown Lands"). Subordinate to these offices were the *Steuerräte* ("tax councillors"), who controlled the administration of the municipalities and communes. These officials were all appointed by the central government and were responsible to it. At the apex of the new machinery of government was the sovereign.

Military
functions
of the
Prussian
bureau-
cracy

This centralized system was strengthened by creating a special corps of civil servants. In the beginning these civil servants—in a real sense servants of the crown—were sent out from Berlin to deal with such purely military matters as recruiting, billeting, and victualing the troops, but in the course of time they extended their supervision to civil matters as well. By 1713 there were clearly recognizable administrative units dealing in civil affairs and staffed by crown civil servants.

Special ordinances in 1722 and 1748 regulated recruitment to the civil service. Senior officials were required to propose to the king the names of candidates suitable for appointment to the higher posts, while the adjutant general proposed noncommissioned officers suitable for subordinate administrative posts. Further steps were taken throughout the 18th century to regularize the system of recruitment, promotion, and internal organization. All of these matters were brought together in a single General Code promulgated in 1794. The merit system of appointment covered all types of posts, and the general principle laid down was that "special laws and instructions determine the appointing authority to different civil service rank, their qualifications, and the preliminary examinations required from different branches and different ranks." Entry to the higher civil service required a university degree in cameralistics, which, though strictly speaking the science of public finance, included also the study of administrative law, police administration, estate management, and agricultural economics. After the degree course, candidates for the higher civil service spent a further period of supervised practical training in various branches of the administration, at the end of which they underwent a further oral and written examination. The basic principles of modern civil services are to be found in this General Code.

France. A fundamental change in the status of the civil servant came about as a result of the French Revolution of 1789. The fall of the ancien régime and the creation of a republic meant that the civil servant was seen as the servant no longer of the king but rather of the state—even though rule by a king or emperor was soon brought back and continued in France for nearly another century. The civil servant became an instrument of public power, not the agent of a person. This depersonalization of the state encouraged a rapid growth in the field of public law concerned with the organization, duties, and rights of "the

public power," of which civil servants were the principal component. To the ordered structure of the Prussian bureaucracy there began to be added the logical development of administrative law.

Innovations under Napoleon I

This bureaucratization was greatly fostered by Napoleon I, who built up a new civil service marked not only by some of the features of military organization but also by the principles of rationality, logic, and universality that were the inheritance of the Enlightenment. There was a clear chain of command and a firmly established hierarchy of officials, with duties clearly apportioned between authorities. Authority was depersonalized and went to the office and not the official—although Napoleon insisted that each official should be responsible for action taken in the name of his office. France was divided into new territorial units: *départements*, *arrondissements*, and *communes*. In each of these, state civil servants had a general responsibility for maintaining public order, health, and morality. They were all linked in a chain to the national Ministry of the Interior. A special school, the *École Polytechnique*, was set up to provide the state with technical specialists in both the military and the civil fields—particularly in general administration. In the field of general administration, the *Conseil d'État* ("Council of State"), descended from the old *Conseil du Roi* ("Council of the King"), imposed an intellectual as well as a judicial authority over the rest of the civil service; as the first major European administrative court, it became the creator of a new type of administrative jurisprudence. The prestige of the new French administrative organization and the logical arrangement of its internal structure prompted many other European countries to copy its principal features. And the expansion of the French Empire spread many of its features across the world.

In France under the Third Republic (1870–1940) there developed, however, considerable political interference in some branches of the civil service; and much of its vitality was diminished as its bureaucratic practices tended to become unwieldy and its personnel lethargic. Not until 1946 was the system reformed—which involved overhauling the administrative structure of the central government, centralizing personnel selection, creating a special ministry for civil service affairs, and setting up a special school, the *École Nationale d'Administration*, for the training of senior civil servants. This school in particular has attracted worldwide attention for its ability to instill in its graduates both specialist and generalist skills.

British civil service in India

The British Empire. The first attempts by Great Britain to create efficient administrative machinery arose from its commitment to govern India and to avoid in that country the periodic scandals that marked some of the rule of the East India Company. Robert Clive, appointed governor of Bengal for the second time in 1764, introduced a code of practice that prohibited servants of the company from trading on their own account or accepting gifts from native traders. Subsequent governors strengthened the ban, compensating for the loss of benefits by substantially increasing salaries, introducing promotion by seniority, and reorganizing the higher echelons of administration. Recruitment was carried on by the company in London, and after 1813 entrants to the civil service had to study the history, language, and laws of India for a period of four terms at Haileybury College, England, and to obtain a certificate of good conduct before taking up their posts. As a result of advocacy by Thomas Macaulay, secretary to the board of control, examination rather than patronage was adopted as a recruitment method. New rules from 1833 stipulated that four candidates had to be nominated for each vacancy and that they were to compete with one another in "an examination in such branches of knowledge and by such examinations as the Board of the Company shall direct."

Foundation of the modern civil service in Britain

There was further criticism of the way India was run, however, and in 1853 another legislative reform of the administration was proposed. The experience of the Indian Civil Service influenced the foundation of the modern civil service in the United Kingdom. A report was published in 1854 on the organization of the Permanent Civil Service in Britain. Its principal author, Sir Charles Trevelyan,

had acquired a reputation for searching out corruption in the Indian Civil Service during 14 years of service there. The report of 1854 recommended the abolition of patronage and recruitment by open competitive examination. It further recommended (1) the establishment of an autonomous semijudicial body of civil service commissioners to ensure the proper administration of recruitment to official posts, (2) the division of the work of the civil service into intellectual and routine work, the two sets of offices to have separate forms of recruitment, and (3) the selection of higher civil servants more decidedly on the basis of general intellectual attainment than specialized knowledge. The Civil Service Commission was established in 1855, and during the next 30 years patronage was gradually eliminated. The two original classes were increased to four, and some specialized branches were amalgamated to become the Scientific Civil Service. The new civil service managed to attract to its senior levels highly capable, discreet, and self-effacing university graduates. Graduates of Oxford and Cambridge became—and remain to the present—especially prominent in the ranks of senior civil servants in Britain.

The United States. In the United States patronage remained the norm for considerably longer than in Britain. From the early days of the federation two principles were firmly held. First, there was antipathy to the notion of a cadre of permanent civil servants; President Jackson clearly dismissed this notion of a highly professional caste when he said, in 1829, that "the duties of all public officers are . . . so plain and simple that men of intelligence may readily qualify themselves for their performance." As a consequence, he said, "I can not but believe that more is lost by the long continuance of men in office than is generally to be gained by their experience. No one man has any more intrinsic right to official station than another." The second principle—that as far as possible public office should be elective—followed more or less automatically. But because this principle could not be practically applied to the subordinate levels of administration, there developed the "spoils system," in which public office became a perquisite of political victory, being widely used to reward political support. This system was susceptible to persistent, blatant, and ultimately unacceptable degrees of inefficiency, corruption, and partisanship. These particular faults were strongly felt after the Civil War (1861–65), during the period of rapid economic and social development. Under considerable pressure, the federal government accepted a restricted principle of entry by competitive open examination, and in 1883 the U.S. Civil Service Commission was established to control entry to office in the federal service. The work of the commission was mainly restricted to the lower grades of employment, and it was not until the first 20 years of the 20th century that the merit system of recruitment was expanded to cover half the posts in the federal service. After that period the commission's control gradually increased, mainly over the lower, middle, and managerial offices in the federal service. After 1978 the functions of the commission were divided between the Office of Personnel Management and the Merit Systems Protection Board. Principal policymaking posts, numbering some 2,000, remain outside the jurisdiction of these two bodies, being filled instead by presidential nomination.

The development of civil service in U.S. local government varied among states, counties, and cities. The adoption of a merit system can usually be dated from the early 20th century, during the reform period of the muckrakers. In some states the merit system became well established, with a central personnel office that included a civil service commission or board similar to the federal model. At the other extreme there was simply a central personnel office headed by a single personnel director with no advisory board. At the municipal level, by the mid-20th century, most large cities in the United States had developed some sort of merit system; in smaller cities, however, merit systems were correspondingly less common. In the counties, the majority of which were rural and had relatively few public employees, formally established merit systems were rare.

The U.S. Civil Service Commission

The Soviet Union. In Russia the Revolution of 1917 swept away the tsarist civil service. The Communist Party at first held that a strong administrative organization was bound to damage the revolution by dampening spontaneity and other revolutionary virtues. But it soon became clear that a regime dedicated to social engineering, economic planning, and world revolution needed trained administrators. The party fell back, albeit reluctantly, upon the expertise of the more reliable tsarist civil servants. It did, however, surround the new civil service with elaborate controls in an attempt to ensure that its members remained loyal to party directives.

As the Communist Party itself became bureaucratized and as the more enthusiastic revolutionary leaders were eliminated, special industrial academies were set up for party members who had shown administrative talent. With the First Five-Year Plan (1928–32) the status of civil servants was improved, and their conditions of service were made less rigid, even though the party never relaxed its tight system of control over all branches of the state apparatus. In 1935 the State Commission on the Civil Service was created and attached to the Commissariat of Finance with responsibility for ensuring general control of personnel practice. This commission laid down formal patterns of administrative structure, reformed existing bureaucratic practices, fixed levels of staffing, standardized systems of job classification, and eliminated unnecessary functions and staff. The inspectorate of the Ministry of Finance ensured that the commission's general policies were carried out in the ministries. The commission itself remained under the close supervision of the Council of People's Commissars to ensure that it complied with party directives, and the commission's members were appointed directly by the council.

The Soviet commission, unlike those in such countries as Great Britain and the United States, was given no jurisdiction over the recruitment of civil servants, which remained the function of the ministries and agencies. The highest administrative and technical staff members were recruited by each ministry. Each branch of industry and administration had its own training schools, from which it selected qualified students with satisfactory records. On appointment, the student was bonded for a minimum of three years and liable to criminal proceedings if he refused or subsequently relinquished his assignment. At the lower levels of administration, recruitment and job placement were the responsibility of the Commissariat of Labour Reserves.

The Communist Party made determined attempts to recruit higher civil servants as party members. These drives, which followed periodically after the 1930s, went a long way toward transforming the party itself into an administrative and managerial elite and uniting the party and the state administration. It is now generally believed that the highest levels of the civil service constitute an influential apparatus and power centre in their own right. The internal structure of the civil service, moreover, has been fashioned along classic French and German lines; and titles, ranks, insignia, and uniforms have officially appeared in various parts of the public services.

China. The People's Republic of China also illustrates the conflict between revolutionary suspicion of bureaucracy and the need to construct strong administrative machinery in order to attain revolutionary goals. China's long tradition of bureaucracy remained important even after the Communist Party came to power in 1949. Within a decade the weight of the administration had already led, according to party dogma, to a gap between the elite and the masses and also to excessive stratification among the ruling bureaucrats, or cadres, themselves. There was not only a distinction between "old cadres" and "new cadres," depending on nothing more substantial than the date of an official's entry into the revolutionary movement, but also a complex system of job evaluation that divided the civil service into 24 grades, each with its own rank, salary scales, and distinctions. The number of ratings represented very considerable differences of power, prestige, and prerogatives and produced psychological barriers between the highest and lowest grades at least as great and as

conspicuous as between the cadres and the masses. These distinctions and discrepancies were widely attacked during the Cultural Revolution of the 1960s and '70s, but they remained deeply ingrained in the administrative structure.

Japan. Until the 17th century, Japan under the shogunate was administered by a military establishment made up of vassals and enfeoffed nobles. After the 1630s a civil bureaucracy developed and began to assume a more important role than the military. Appointment within the bureaucracy was based upon family rank, and officials were loyal primarily to the feudal lord. It was not until after Matthew C. Perry sailed four U.S. warships into Uraga Harbour in 1853, thus forcibly ending more than two centuries of Japan's isolation from the rest of the world, that the Japanese bureaucracy moved away from feudal rank as the basis of appointments, establishing in its place loyalty to the emperor rather than to feudal lords. Merit appointments were made on a modest scale immediately after Japan was opened to the West, yet it was not until the 1880s, during the Meiji Restoration, that a modern civil service was created on the basis of job security, career paths, and entry by open competition. Tokyo University law graduates tended to dominate this new civil service. Personal allegiance to the emperor was reflected in the status of Japanese civil servants as "Emperor's Officials."

After World War II the Allied occupation authorities directed the passage of a Japanese law guaranteeing that all public officials should be servants of the people rather than of the emperor. The National Public Service Law of 1947 set up an independent National Personnel Authority to administer recruitment, promotion, conditions of employment, standards of performance, and job classification for the new civil service. Technically the emperor himself became a civil servant, and detailed regulations brought within the scope of the new law all civil servants from labourers to the prime minister. Civil servants were classified into two groups, the regular service and a special service. Civil servants in the former category entered the service by competitive examination on a standard contract with tenure. The special service included elected officials and political appointees and covered such officials as members of the Diet (legislature), judges, members of the audit boards, and ambassadors.

Although in theory the sovereign people have an inalienable right to choose and dismiss all public officials—who are constitutionally described as "servants of the whole community"—both tradition and political practice have allowed the civil service in Japan to retain and consolidate its old position in government. The idealization of the scholar-bureaucrat (a Confucian tradition borrowed from China) makes the civil service an independent power centre. Political struggles in the Diet have led to constantly changing ministries, and individual ministers rarely stay at a post long enough to establish firm control of their administration. As in many democratic countries with volatile political systems, administrative control has tended to pass to senior civil servants.

Developing nations. Less-developed countries have had to face the opposite problem with their civil services. After World War II many such countries became independent before they had developed effective administrative structures or bodies of trained civil servants. Few of the colonial powers had trained indigenous administrators sufficiently. The British left a viable administrative structure in India and a partly Indianized civil service, but the newly independent Pakistan had few experienced civil servants. The Belgians left the Congo without any trained administrative or technical staff, and for some years there was near anarchy.

Even when they inherited reasonably efficient administrative organizations, the newly independent countries' politicians frequently proved incapable of fulfilling their supporters' expectations. Civil servants from the old colonial powers who remained behind often found radical policies and new masters uncongenial. The resulting exodus of many such civil servants worsened matters, for indigenous civil servants were seldom an adequate substitute.

The lack of qualified personnel sometimes led to not only a reduction in efficiency but also a decline in admin-

istrative morality. Nepotism, tribalism, and corruption as well as inefficiency in the civil service were difficulties often added to the other trials of independence. In many countries the incapacity of the civil service was a factor leading to military rule, as were the political failings of the elected leaders. Military regimes have frequently been the last resort of a country where the civil power has failed to cope with the problems of independence. Consequently, the United Nations (UN), in conjunction with the governments of advanced countries, began to develop training programs for civil servants from underdeveloped countries. The first request came from Latin America, which led to the founding of a school of public administration in Brazil, followed in 1953 by an Advanced School of Public Administration for Central America. Various other international organizations, including the Organisation for Economic Co-operation and Development and the World Bank, supported institutions for the training of administrators in the less-developed countries. Such institutions included the Arab Planning Institute in Kuwait, the Arab Organization of Administrative Sciences in Jordan, and the Inter-American School of Public Administration in Brazil. Civil servants from the less-developed nations also studied administration at such places as the Institute of Social Studies in The Hague, Neth., the Institute of Local Government Studies in Birmingham, Eng., and the International Institute of Public Administration in Paris.

After the 1970s the international agencies gave less help toward training, on the assumption—often unrealized—that the less-developed nations would take on greater responsibility themselves. Training also tended to be generalist and academic, leading to acute shortages of trained administrators in specialized fields such as finance and planning. However, organizations such as the British Council began in the early 1980s to remedy some of these deficiencies. (B.Ch./E.C.P.)

Principles of public administration

THE CLASSICAL DEFINITION

Throughout the 20th century the study and practice of public administration has been essentially pragmatic and normative rather than theoretical and value free. This may explain why public administration, unlike some social sciences, developed without much concern about an encompassing theory. Not until the mid-20th century and the dissemination of the German sociologist Max Weber's theory of bureaucracy was there much interest in a theory of public administration. Most recent bureaucratic theory, however, has been addressed to the private sector, and there has been little effort to relate organizational to political theory.

A prominent principle of public administration has been economy and efficiency, that is, the provision of public services at the minimum cost. This has usually been the stated objective of administrative reform. Despite growing concern about other kinds of values, such as responsiveness to public needs, justice and equal treatment, and citizen involvement in government decisions, efficiency continues to be a major goal.

Classical
principles
of organi-
zation

In its concern with efficiency and improvement, public administration has focused frequently on questions of formal organization. It is generally held that administrative ills can be at least partly corrected by reorganization. Many organizational principles originated with the military, a few from private business. They include, for example: (1) organizing departments, ministries, and agencies on the basis of common or closely related purposes, (2) grouping like activities in single units, (3) equating responsibility with authority, (4) ensuring unity of command (only one supervisor for each group of employees), (5) limiting the number of subordinates reporting to a single supervisor, (6) differentiating line (operating or end-purpose) activities from staff (advisory, consultative, or support) activities, (7) employing the principle of management by exception (only the unusual problem or case is brought to the top), and (8) having a clear-cut chain of command downward and of responsibility upward.

Some critics have maintained that these and other prin-

ciples of public administration are useful only as rough criteria for given organizational situations. They believe that organizational problems differ and that the applicability of rules to various situations also differs. Nonetheless, and despite much more sophisticated analyses of organizational behaviour in recent decades, such principles as those enumerated above continue to carry force.

Public administration has also laid stress upon personnel. In most countries administrative reform has involved civil service reform. Historically, the direction has been toward "meritocracy"—the best individual for each job, competitive examinations for entry, and selection and promotion on the basis of merit. Attention has increasingly been given to factors other than intellectual merit, including personal attitudes, incentives, personality, personal relationships, and collective bargaining.

In addition, the budget has developed as a principal tool in planning future programs, deciding priorities, managing current programs, linking executive with legislature, and developing control and accountability. The contest for control over budgets, particularly in the Western world, began centuries ago and at times was the main relationship between monarchs and their subjects. The modern executive budget system in which the executive recommends, the legislature appropriates, and the executive oversees expenditures originated in 19th-century Britain. In the United States during the 20th century, the budget became the principal vehicle for legislative surveillance of administration, executive control of departments, and departmental control of subordinate programs. It has been assuming a similar role in many of the developing countries of the world.

RECENT INTERPRETATIONS

The classical approach to public administration described above probably reached its fullest development in the United States during the 1930s, although since that time, through educational and training programs, technical assistance, and the work of international organizations, it has also become standard doctrine in many countries. However, some of its elements have been resisted by governments with British or continental-legal perspectives, and even during the 1930s it was being challenged from several quarters. Since that time study of the subject has greatly developed. It has also become somewhat confused as a result of certain inconsistencies in approach.

The orthodox doctrine rested on the premise that administration was simply the implementation of public policies determined by others. According to this view, administrators should seek maximum efficiency but should be otherwise neutral about values and goals. During the Great Depression of the 1930s, and even more so during World War II, however, it became increasingly evident that many new policies originated within the administration, that policy and value judgments were implicit in most significant administrative decisions, that many administrative officials worked on nothing except policy, and that, insofar as public policies were controversial, such work inevitably involved administrators in politics. The supposed independence of administration from policy and politics was seen to be illusory. Since the 1930s there has thus been increasing concern with policy formation and the development of techniques to improve policy decisions. Although the concept of a value-free, neutral administration is regarded by many as no longer tenable, no fully satisfactory substitute has been offered. How to ensure that responsible and responsive policy decisions are made by career administrators, and how to coordinate their work with the policies of politically elected or appointive officials, remain key preoccupations, especially in democratic states.

It was with governmental efforts to combat the Depression that new informational devices were introduced, including national income accounting and the scrutiny of gross national product as a major index of economic health. The applied techniques of fiscal and monetary policy have become established specializations of public administration. Economists occupy key posts in the administrations of most nations, and many other adminis-

tion

trators must have at least elementary knowledge of the economic implications of government operations. France, Sweden and other Scandinavian nations, Great Britain, and the United States were among the leaders in developing economic planning techniques. Such planning has become a dominating concern of public administration in many of the developing countries.

As economic and social intervention by governments has increased, the limitations of "incrementalism" as a public administration practice have become increasingly apparent. Incrementalism is the tendency of government to tinker with policies rather than to question the value of continuing them. A number of techniques have been introduced to make decisions more rational. One such technique, widely applied, is cost-benefit analysis. This involves identifying, quantifying, and comparing the costs and benefits of alternative proposals. Another, less successful, technique was the Planning, Programming, and Budgeting System (PPBS), introduced into the U.S. Department of Defense in 1961 and extended to the federal budget in 1965. According to PPBS, the objectives of government programs were to be identified, and then alternative means of achieving these objectives were to be compared according to their costs and benefits. In practice, PPBS made little difference in federal budgeting, partly because the objectives of governmental programs were difficult to specify and partly because comprehensive evaluation took too long. PPBS was abandoned in 1971, and similar attempts, such as Management by Objectives and Zero-Base Budgeting, both introduced in the 1970s, were equally short-lived and ineffective. Comparable schemes in western Europe, such as the method called "rationalization of budgetary choice" introduced into France in the late 1960s and the so-called Programme Analysis and Review in Great Britain in the 1970s, were likewise unsuccessful.

Difficulty
of meas-
uring social
costs and
benefits

Quantitative economic measurement is useful up to a certain point, but the value of human life, of freedom from sickness and pain, of safety on the streets, of clean air, and of opportunity for achievement are hardly measurable in monetary terms. Public administration has thus increasingly concerned itself with developing better social indicators, quantitative and qualitative—that is, better indexes of the effects of public programs and new techniques of social analysis.

Another development has been an increasing emphasis on human relations. This originated in the 1930s when what became known as the Hawthorne research, involving the workers and management of an industrial plant near Chicago, brought out the importance to productivity of social or informal organization, good communications, individual and group behaviour, and attitudes (as distinct from aptitudes).

Awareness of the importance of human relations influenced the conduct of public administration. Many shibboleths of administration (hierarchy, directive leadership, set duties, treatment of employees as impersonal "units" of production, and monetary incentives) were challenged.

By the late 1930s the human relations approach had developed into a concept known as "organization development." Its primary goal was to change the attitudes, values, and structures of organizations so that they could meet new demands. Trained consultants, usually from outside the organization, undertook intensive interviewing of senior and junior staff, and sensitivity training and confrontation meetings were also held. Unlike the rationalistic PPBS approach, organization development stressed the identification of personal with organizational goals, the "self-actualization" of workers and managers, effective interpersonal communication, and broad participation in decision making. Its direct use within governmental agencies has been limited and has not always been successful, but it has had considerable indirect influence upon administrators.

Another modern movement in public administration has been the greater participation of citizens in government. It was stimulated during the 1950s and '60s by a growing feeling that governments were not responding to the needs of their citizens, particularly minority groups and

the poor. A variety of experiments to involve citizens or their representatives in making governmental decisions were begun in the 1960s. These involved the delegation of decision making from central to local offices and, at the local level, the sharing of authority with citizen groups.

From the early 1970s increasing analysis of the way government policies affected the public resulted in a concept called the "public policy approach" to administration. This examines to what extent each stage in devising and executing a policy affects the overall shape and impact of the policy. According to the concept, the way a problem is conceived in the first place influences the range of remedies considered. The nature of the decision-making process may determine whether a course of action is merely incremental or truly radical. Indeed, it has been argued that the nature of the decision-making process shapes the outcome of the decision itself, particularly when the process is dominated by a powerful interest group. Moreover, the willingness of the government to evaluate programs, and modify them if necessary, affects the outcome. Many supporters of the public policy approach regard the concept as an important tool for constructing a body of knowledge on which recommendations can be based.

Until World War II there was relatively little exchange among nations of ideas about public administration. As early as 1910, however, a professional organization, which eventually became the International Institute of Administrative Sciences (IIAS), had been established. At first its membership consisted principally of scholars and practitioners of administrative law in the countries of continental Europe. By the late 1980s the IIAS had a membership drawn from some 70 countries. Its triennial congresses have covered all aspects of the field.

Since World War II international interest in administrative systems has grown, precipitated by the necessity of cooperation during the war, by the formation of international organizations, by the occupation of conquered nations and the administration of economic recovery programs for Europe and the Far East, and by aid programs for developing countries. One by-product of aid programs was a renewed appreciation of how crucial effective administration is to national development. It has also become apparent how parochial and culture-bound styles of public administration have often remained within individual countries.

Another effect of this international communication and sharing of experiences has been the realization that development is not exclusive to the so-called underdeveloped countries. All countries have continued to develop, and public administration has increasingly been perceived as the administration of planned change in societies that themselves have undergone rapid change, not all of it planned. Government has no longer been merely the keeper of the peace and the provider of basic services; in the postindustrial era government has become a principal innovator, a determinant of social and economic priorities, and an entrepreneur on a major scale. On virtually every significant problem or challenge—from unemployment to clean air—people have looked to the government for solutions or assistance. The tasks of planning, organizing, coordinating, managing, and evaluating modern government have likewise become awesome in both dimension and importance.

EDUCATION AND TRAINING

European universities have traditionally produced administrative lawyers for their governments, but legal skills alone are hardly adequate for handling contemporary problems. U.S. universities began graduate programs in the early years of the 20th century, and by the late 1980s there were more than 300 university programs in public administration. Nevertheless, very few of the scientists and other specialists who become administrators in their fields attend such programs.

Training programs have particularly flourished since World War II, many of them with government help. Some are attached to universities. In establishing the École Nationale d'Administration as one of its civil service reforms of 1946–47, France provided an extensive course for re-

trators

cruits to the higher civil service. It was not until 1969 that Britain established a Civil Service College under the new Civil Service Department. In the United States the government established a variety of educational and training programs during the 1960s, including the Federal Executive Institute and the Executive Seminar Centers. Many less-advanced countries have since established centres for the training of public administrators. (F.C.M./E.C.P.)

Organization of civil service

APPOINTMENT

In earlier times, when civil servants were part of the king's household, they were literally the monarch's personal servants. As the powers of monarchs and princes declined and as, in some countries, their sovereignty was denied them, appointment became a matter of personal choice by ministers and heads of departments. The influence senior civil servants may wield over policy and the need for them to work in close harmony with ministers induce all governments to insist on complete freedom of choice in appointments, even when, as in Great Britain, the freedom is rarely invoked. In some countries, notably the United States, senior advisers usually are replaced whenever a new administration takes office.

In Europe in the 19th century, appointment and promotion frequently depended on personal or political favour, but tenure was common in the lower and middle ranks once an appointment had been made.

Dependency on a superior's favour led civil servants to ally themselves with liberal public opinion, which was critical of the waste and corruption involved in political patronage. Pressure for reform led to official formulations of basic qualifications for different posts; appointments and promotions boards were established within each department to prevent or obstruct overt political favouritism and nepotism; and salary scales were introduced for different grades to provide a civil servant with increments for good service while still holding the same post. In many countries civil service commissions were set up to ensure impartiality in selection procedures and to lay down broad principles for personnel management in the civil service. Recruitment in many European countries corresponded to the national educational systems: the highest class of civil servants entered service after graduation from a university, the executive class after full completion of secondary school, the clerical class after the intermediate school examination. The manual workers in the service were mainly recruited from persons of mature age who had left school after primary education or, in such countries as France and Germany, from military veterans. As public administration became more complex in the 20th century, specialized categories of civil servants were created to bring into the service doctors, scientists, architects, naval constructors, statisticians, lawyers, and so on. In several countries the establishment of these special classes caused some difficulties because their salary scales had to be linked with those of competing professional groups outside the service. The distinction between foreign service and home service personnel has sometimes caused difficulty because of inadequate liaison between overseas representatives and the makers of foreign policy at home. In the United States, the Rogers Act of 1924 unified the overseas service itself, but the civil servants of the State Department in Washington, D.C., continued to be regarded as part of the federal civil service.

The posts that fall under the rules of the U.S. merit system are not grouped into a small number of general classes but have individual job specifications and entry qualifications. Although designed to select entrants with special knowledge or skills for individual posts, this system has been criticized for failing to make the best use of the talent available to the government. In 1978 the Senior Executive Service was created to achieve more effective promotion and deployment.

All countries base appointments on some kind of competition. In some countries great emphasis is placed on formal written examinations supplemented by interviews. Such is the situation in France, where entry into the higher civil

service is channeled through specialist schools, or *grandes écoles*, of which the École Nationale d'Administration and the École Polytechnique are the most important. In Great Britain, traditionally one of the great advocates of entry by formal examination, the Civil Service Commission relies more on informal tests and a series of interviews and observations and tends to measure the candidate's intellectual competence by the quality of his university degree. The conventional written examination is dispensed with also in such European countries as Finland, Switzerland, The Netherlands, and Portugal, as well as the West German *Länder*, or states. In the *Länder* the qualifications and references of all candidates are compared, whereupon the most eligible are interviewed by a departmental board. Candidates are expected to have completed a lengthy program of academic work for professional qualification and a period of subsequent training in a variety of public institutions under official supervision. If successful in their interviews, candidates are recommended to the minister, who makes appointments to higher grade posts, or to the heads of department, who handle the middle and lower categories. On the face of it, this method offers fewer guarantees of impartiality than does the formal written examination, but a civil service career is less attractive now than formerly and the civil service has to compete, usually at lower salaries, with business and the professions for the best available talent. In Sweden a constitutional provision requires that nearly all public documents (including the proceedings of authorities that make appointments) be open for public inspection, thus providing a check upon corruption or favouritism.

Most federal and culturally diverse countries try to ensure an equitable distribution of posts among their constituent elements. In Switzerland the federal authorities try to maintain a balance of posts not only between the cantons but also between the political parties, religions, and languages. The federal civil service in West Germany draws on the public service officers in the *Länder*, and some degree of proportional representation is attempted. There was considerable pressure in Canada in the 1970s to ensure a more equitable distribution of federal civil service posts between the English- and French-speaking populations. It is also clear that many African states are compelled to recognize regional and tribal origins in their appointments to the civil service.

CONDITIONS OF SERVICE

The forerunners of civil servants, being members of the royal household, had duties but no rights. The first attempts to formalize methods of appointment and conditions of service were among the administrative innovations introduced in Prussia in the 18th century. Elsewhere attempts were frustrated by political and public objections. Increased formal regulation of conditions of service came about when civil servants organized themselves into professional groups, sometimes barely distinguishable from trade unions. The fact that civil servants are agents of the public power, providing services on which law, order, and public health depend, has raised the question whether they should be permitted to strike; if they cannot lawfully strike, they are deprived of the main weapon in pressing for improvements in their conditions of service. Thus, there have developed special arrangements for reviewing conditions of service periodically and for settling contentious issues. In particular, it has been necessary to have a properly recognized system for regulating conduct and discipline. In the United Kingdom, traditional standards are supplemented or revised to accord with recommendations from periodic commissions of enquiry, which pay special attention to official conduct in relation to political activities and business dealings. In France and West Germany these codes of conduct have been based mainly upon the rules of administrative law and the jurisprudence of administrative courts, although certain civil service rights and duties are specified in constitutional law. In other countries, particularly in the United States and India, conduct and discipline are regulated by administrative rules and codes promulgated by executive order after discussion and enquiry.

Reaction
against
patronage

Competitive
examinations

The need
for codes
of conduct

The standards placed upon a civil servant's conduct are partly those to be expected of any loyal, competent, and obedient employee and partly those enjoined upon a public employee. Ideally, the civil servant should be above any suspicion of partiality and should not let personal sympathies, loyalties, or interests affect the performance of duties; for example, a civil servant is obliged to be circumspect in private financial dealings. As a general rule, a civil servant is not allowed to engage directly or indirectly in any trade or business and may engage in social or charitable organizations only if these have no connection with official duties. There are always strict limits on a civil servant's right to lend or borrow money, and they are prohibited from accepting gifts.

Political
involvement
of civil
servants

There are different attitudes about the extent to which civil servants may engage in political activities. One view is that a civil servant has the same constitutional rights as other citizens and that it is therefore unconstitutional to attempt to limit those rights other than by the common law. The opposing view is that since civil servants are engaged in the unique function of national government, their integrity and loyalty to their political masters might be affected by active participation in political affairs, and public confidence in their impartiality could be shaken. Broadly speaking, those countries that traditionally expect civil servants to behave with complete impartiality and to conform to ministerial policy with energy and good will, whether they agree with the policy or not, expect all civil servants to behave with circumspection in political affairs. The United Kingdom has a total ban on its senior civil servants engaging in any form of political activity. The prohibition becomes progressively less strict, however, for the medium and lower grades of the service.

Another group of countries, including France and West Germany, have deemed policy and administration to be so intimately connected that all top posts are filled at the discretion of the government of the day; thus, civil servants are allowed greater scope in political activities. They are nevertheless expected to act with greater discretion and public decorum than private citizens, and an excess of power or an abuse of office for political purposes renders a civil servant instantly liable both to statutory regulations and to severe internal disciplinary proceedings.

Unions
of civil
servants

Traditionally, governments have been hostile toward civil service unions, and in the past repressive laws made strike action unlawful. Strikes nevertheless occurred, and governments eventually adopted an attitude of open encouragement toward trade unionism. Most governments accept, in theory at least, that the state should be a model employer. It follows that if the state genuinely pursues a policy of discussion and negotiation with civil servants and attempts properly to fulfill agreements with them, it should in return be freed from the threat of strike action. Mindful that the withdrawal of civil servants from some public services would lead to chaos, many governments have found it prudent to establish permanent channels for negotiating such matters as salaries and discipline. Organizations representing the staff and a management side of senior officials representing the state mirror the employer-employee relationship of private industry, although a higher percentage of public- than private-sector employees are members of unions. The United Kingdom was the first country to establish negotiating machinery for civil servants. Following a report in 1917, organizations known as Whitley Councils were set up, consisting of equal numbers of medium and lower staff on the one hand and directing and supervisory staffs on the other. These councils operate within the ministries, and a National Whitley Council performs central advisory functions for the government. They have no powers of decision, however, only of recommendation, because governments are never prepared to surrender their ultimate responsibility for determining the public interest. The councils have done a good deal to provide a sense of common purpose and joint responsibility within the civil service as a whole, although pay restraints from the early 1970s generated great friction between civil service unions and government.

In France each department has a comparable consultative body, but its work is broader in scope in that it can

scrutinize recruitment, personnel records, promotions, and disciplinary procedures. There is also a national council, presided over by the prime minister or a specially nominated minister for civil service affairs, which is concerned with general personnel policy, conditions of service, and coordination of departmental committees.

Until after World War II, the commonly accepted view in the United States was that expressed by President Calvin Coolidge: "There is no right to strike against the public safety by anybody, anywhere, at any time." Although federal employees are still forbidden to strike, a rule illustrated by the dismissal of striking air traffic controllers in 1981, consultation has increased, and in many federal departments appeals committees comprising departmental heads and one or more members of the Merit Systems Protection Board may now hear appeals from civil servants against decisions adversely affecting their careers. These committees are also consulted on general matters of departmental interest, such as job classifications, pension schemes, promotion policies, and office procedures.

PATTERNS OF CONTROL

The expansion of public services, as well as the development of permanent civil service career structures, raised fears that civil services were becoming autonomous powers in their own right, no longer subject to the traditional forms of control. This view is associated with the sociologists Max Weber, who criticized the bureaucracy of imperial Germany, and Robert Michels, who formulated the "iron law of oligarchy." Michels' law suggested that every organization with a permanent staff produces an oligarchy running the organization according to the interests and values of the bureaucratic group. In addition, the growing complexity of modern government has greatly augmented the informal power of senior civil servants who act as advisers to ministers. This is particularly the case in countries (usually the more democratic ones) where ministries frequently change hands.

In the 19th century civil services were normally restricted to maintaining law and order and minor economic regulations such as those concerning weights and measures and factory laws. The subordination of civil servants to their political masters and their political masters' responsibility to the courts and legislatures seemed to provide an adequate safeguard against arbitrary administrative actions. But in some countries, notably Germany, France, and Austria, civil services became endowed with much greater authority, operating as part of the police power. This caused concern because civil servants were exempt from normal legal processes when performing their official functions. In response, special administrative courts were set up to which private citizens or corporations could appeal against administrative acts. Jurisdiction was limited, however, and redress was frequently slow. The courts themselves remained specialized institutions of the executive rather than normal parts of the judiciary.

Sweden provided a marked contrast. Before the constitution of 1809 the executive power had been absolute. Afterward, not only did it become subject to control by the legislature, but this control also was reinforced by the creation of a special post of ombudsman (see below *Ombudsman*).

World War I brought increased governmental activity almost everywhere. The area in which administrative discretion could be exercised grew; civil servants became as much adjudicators as administrators, and their influence upon economic life increased. By World War II the state had become, even in many conservative countries, an economic regulator, an industrial producer of overwhelming importance, and a conciliator between competing interests. In all of these matters civil servants were the effective agents of the state.

In the United States, Congress created an institution to counter the threatened increase in civil service power. As far back as the late 19th century Congress, when legislating for new areas of government, assigned powers to agencies or commissions, specifying their powers, competence, and composition and freeing them from direct presidential control. In this way large areas of government escaped the

U.S.
regulatory
agencies

control of the executive branch of government, including the federal civil service. These independent regulatory agencies have covered major economic fields and have included the Interstate Commerce Commission, the Federal Communications Commission, the Tennessee Valley Authority, and the Nuclear Regulatory Commission. This policy has laid Congress open to the charge that it has created a headless fourth branch of government, but it has successfully prevented the emergence of a monolithic federal civil service.

To counter charges that the U.S. civil service was encroaching on the powers of the judiciary, the Administrative Procedure Act of 1946 laid down detailed provisions to safeguard citizens' rights where the administration had powers of adjudication. These rights included the right to ample previous notice of proceedings, the right to submit evidence, the right to have independent hearing officers (to the exclusion of investigating or prosecuting officers), and the right to a decision based solely on testimony and papers actually entered in the proceedings.

Other democratic countries have been concerned about the growing powers of the civil service and about whether traditional forms of judicial and ministerial control are adequate. Many European countries have modeled their instruments of administrative jurisdiction and jurisprudence on the French Conseil d'État. In the United Kingdom the creation of a special administrative jurisdiction of this kind has been opposed by both parliamentary and judicial opinion, but it was because of mounting criticism of civil service immunity from detailed control that Parliament created the special office of parliamentary commissioner, or ombudsman. Public access to the office is by way of a member of Parliament, and the commissioner is excluded from inquiring into matters of policy, local government authorities, or lower judicial bodies.

Special problems of control have arisen in Communist countries, where the main preoccupation of the regime, which is under the direct control of the Communist Party, has been to ensure the civil service's continual loyalty. Impartiality and objectivity in the administrative machine's dealings with the public are not of such high priority as in pluralist societies. A body of administrative procedure has been built up, but this has always been subordinated to the directives of the party leadership. Communist countries have also had to establish new ways of judging performance, since the state monopoly of political power and means of production ensures that traditional incentives and yardsticks cannot be applied.

Yet in their own way, Communist countries have elaborate controls. In the Soviet Union all ministries have a special section staffed by, and responsible to, operatives from the Ministry of Internal Affairs. This section provides security control over the ordinary civil servants, and its personnel are not part of that ministry's official structure. The Communist Party maintains further control through the party apparatus, and it closely supervises senior appointments.

Communist planning, financial, and personnel controls of a technical kind resemble those in democratic countries, but in the Soviet Union there are two additional special supervisory agencies. The Commission of State Control is responsible for vigilance over state property and administration. Its departments parallel the different branches of state administration and maintain audits of their work. Its officers have the right of access to all administrative records and can issue directives to other institutions. They have powers to prosecute civil servants for criminal offenses, and they can apply a formidable range of disciplinary measures to civil servants, either by direct action or through the responsible minister.

The second agency of control arose because of the difficulty of reconciling disputes between production units and their controlling ministries in an economy that lacks the traditional forms of market discipline and cannot rely upon an enforceable law of contract. A special system of compulsory arbitration operates through the State Arbitration Tribunal (known as Gosarbitrazh) under the Council of Ministers and through arbitration tribunals responsible to the councils of ministers in each of the republics. It

settles all disputes concerning contracts, quality of goods, and other property disputes between various state enterprises. The system is staffed by civil servants charged with enforcing "contractual and plan discipline," but it is supported by technical experts qualified in economic and industrial matters. (B.Ch./E.C.P.)

INTERNATIONAL CIVIL SERVICE

The elements of an international civil service first appeared in the Universal Postal Union (established 1874–75). Some four and a half decades later the League of Nations and the International Labour Organization (ILO) were founded. They required a staff of almost 600 experts and subordinate personnel, which took the form of a true international civil service. It drew mainly on British, French, and Swiss personnel, but more than 40 states contributed members in order to spread recruitment as widely as possible. There were no formal methods of selection for the higher personnel; the secretary general of the League used personal contacts. The staff fell into three divisions: administrative, supervisory and clerical, and custodial. The history of the League shows that, at any rate as far as a secretariat was concerned, a broad measure of international loyalty could be achieved. The staff of the ILO was maintained after the League's disbandment in 1946.

Until World War II the League of Nations was the only major international organization of its kind. Since then, international organizations have multiplied, and compared with most of them the League had a small staff. The postwar organizations include the United Nations, the Organization of American States, the Council for Mutual Economic Assistance, the European Communities (EC), and the Organisation for Economic Co-operation and Development. By the mid-1980s there were nearly 20,000 smaller bodies, ranging from the Nordic Council to small research institutes.

International organizations have evolved into two types. In the first—an example of which is the EC—a genuinely supranational civil service exists; its members have a career structure within the organization and can identify with it. In the second (e.g., the UN), officials undertake a particular job for a limited period and seldom develop a career within the organization. In the EC the civil service is divided into four major grades, recruitment to the service usually being through competitive examination. After recruitment a period of training follows. Each agency within the UN operates its own recruitment system. By far the majority of senior appointees assigned to the UN at any one time have served there for less than 15 years.

In both types of international organization, there is a danger that officials will promote the interests of their own country to the detriment of internationalism. In the UN a quota system operates by which each country is allocated a number of appointments in proportion to its UN budget contribution. As a result, some national governments are in a strong position to influence recruitment. In contrast, the statutes governing the EC's civil service forbid quotas, but an unofficial system has developed whereby a relatively high proportion of senior officials are from the more populous states. Such practices risk sacrificing meritocracy to nationalism.

Some countries do expect their nationals working at the UN to promote national interests. But the quota system—and this is one of the arguments for it—leads to administrators from at least the more prosperous countries competing with fellow nationals rather than with colleagues from other countries. Moreover, it is unlikely that decisions, whether biased or not, will be made in the bureaucracy alone. And since officials' national origins are no secret, partiality is fairly difficult to conceal. (E.B./E.C.P.)

Administrative law

Administrative law is the legal framework within which public administration is carried out. It derives from the need to create and develop a system of public administration under law, a concept that may be compared with the much older notion of justice under law. Since administra-

Communist controls over the civil service

Two types of international civil service

The
regulation
of public
administra-
tion

tion involves the exercise of power by the executive arm of government, administrative law is of constitutional and political, as well as juridical, importance.

There is no universally accepted definition of administrative law, but rationally it may be held to cover the organization, powers, duties, and functions of public authorities of all kinds engaged in administration; their relations with one another and with citizens and non-governmental bodies; legal methods of controlling public administration; and the rights and liabilities of officials. Administrative law is to a large extent complemented by constitutional law, and the line between them is hard to draw. The organization of a national legislature, the structure of the courts, the characteristics of a cabinet, and the role of the head of state are generally regarded as matters of constitutional law, whereas the substantive and procedural provisions relating to central and local governments and judicial review of administration are reckoned matters of administrative law. But some matters, such as the responsibility of ministers, cannot be exclusively assigned to either administrative or constitutional law. Some French and American jurists regard administrative law as including parts of constitutional law.

The law relating to public health, education, housing, and other public services could logically be regarded as part of the corpus of administrative law; but because of its sheer bulk it is usually considered ancillary.

DEFINING PRINCIPLES

One of the principal objects of administrative law is to ensure efficient, economical, and just administration. A system of administrative law that impedes or frustrates administration would clearly be bad, and so, too, would be a system that results in injustice to the individual. But to judge whether administrative law helps or hinders effective administration or works in such a way as to deny justice to the individual involves an examination of the ends that public administration is supposed to serve, as well as the means that it employs.

In this connection only the broadest generalities can be attempted. It can be asserted that all states, irrespective of their economic and political system or of their stage of development, are seeking to achieve a high rate of economic growth and a higher average income per person. They are all pursuing the goals of modernization, urbanization, and industrialization. They are all trying to provide the major social services, especially education and public health, at as high a standard as possible. The level of popular expectation is much higher than in former ages. The government is expected not only to maintain order but also to achieve progress. There is a widespread belief that wise and well-directed government action can abolish poverty, prevent severe unemployment, raise the standard of living of the nation, and bring about rapid social development. People in all countries are far more aware than their forefathers were of the impact of government on their daily lives and of its potential for good and evil.

The growth in the functions of the state is to be found in the more-developed and in the less-developed countries; in both old and new states; in democratic, authoritarian, and totalitarian regimes; in the Communist countries of eastern Europe and in the mixed economies of the West. The movement is far from having reached its zenith. With each addition to the functions of the state, additional powers have been acquired by the administrative organs concerned, which may be central ministries, local, provincial, or regional governments, or special agencies created for a particular purpose.

Distinctions between public administration and private action. Activities such as traffic control, fire-protection services, policing, smoke abatement, the construction or repair of highways, the provision of currency, town and country planning, and the collection of customs and excise duties are usually carried out by governments, whose executive organs are assumed to represent the collective will of the community and to be acting for the common good. It is for this reason that they are given powers not normally conferred on private persons. They may be authorized to infringe citizens' property rights and restrict

their freedom of action in many different ways, ranging from the quarantining of infectious persons to the instituting of criminal proceedings for nonpayment of taxes. To take another example, the postal laws of many countries favour the post office at the expense of the customer in a way unknown where common carriers are concerned. Again, a public authority involved in slum clearance or housing construction tends to be in a much stronger legal position than a private developer.

The result of the distinction between public administration and private action is that administrative law is quite different from private law regulating the actions, interests, and obligations of private persons. Civil servants do not generally serve under a contract of employment but have a special status. Taxes are not debts, nor are they governed by the law relating to the recovery of debts by private persons. In addition, relations between one executive organ and another, and between an executive organ and the public, are usually regulated by compulsory or permissive powers conferred upon the executive organs by the legislature.

The law regulating the internal aspects of administration (*e.g.*, relations between the government and its officials, a local authority and its committees, or a central department and a local authority) differs from that covering external relations (those between the administration and private persons or interests). In practice, internal and external aspects are often linked, and legal provisions of both kinds exist side by side in the same statute. Thus, a law dealing with education may modify the administrative organization of the education service and also regulate the relations between parents and the school authorities.

Another distinction exists between a command addressed by legislation to the citizen, requiring him to act or to refrain from acting in a certain way, and a direction addressed to the administrative authorities. When an administrative act takes the form of an unconditional command addressed to the citizen, a fine or penalty is usually attached for failure to comply. In some countries the enforcement is entrusted to the criminal courts, which can review the administrative act; in others the administrative act itself must be challenged in an administrative court.

The need for legal safeguards over public administration. Statutory directions addressed to the executive authorities may impose absolute duties, or they may confer discretionary powers authorizing a specified action in certain circumstances. Such legislation may give general directions for such activities as factory inspection, slum clearance, or town planning. The statute lays down the conditions under which it is lawful for the administration to act and confers on the authorities the appropriate powers, many of which involve a large element of discretion. Here the executive is not confined merely to carrying out the directions of the legislature; often it also shares in the lawmaking process by being empowered to issue regulations or ordinances dealing with matters not regulated by the statute. This may be regarded either as part of the ordinary process by which the legislature delegates its powers or as an inevitable feature of modern government, given that many matters are too technical, detailed, or subject to frequent change to be included in the main body of legislation—legislation being less easy to change than regulations.

Whatever the source of the executive's rule-making power, safeguards against misuse are necessary. For instance, the regulation must not exceed the delegated powers; its provisions must conform with the aims of the parent statute; prior consultation with interests likely to be affected should take place whenever practicable; and the regulations must not contravene relevant constitutional rules and legal standards. In some countries regulations are scrutinized by a type of watchdog known as the council of state before they come into force; in others, by the parliamentary assembly; and in yet others, by the ordinary courts.

In most countries the executive arm of government possesses certain powers not derived from legislation, customary law, or a written constitution. In the United Kingdom there are prerogative powers of the crown, nearly all of which are now exercised by ministers and which concern

Internal
and
external
aspects of
administra-
tive law

Prob-
lems of
executive
power

such matters as making treaties, declaring war and peace, pardoning criminals, issuing passports, and conferring honours. In Italy, France, Belgium, and other continental European countries, certain acts concerning the higher interests of the state are recognized as *actes de gouvernement* and are thereby immune from control by any court or administrative tribunal. In the German Empire (1871–1918) the principle that an administrative act carried its own legal validity was accepted at the end of the 19th century by leading jurists. This led to the doctrine that administration was only loosely bound to the law. The doctrine was rejected in the Federal Republic of Germany (1949), however, and efforts were made to reduce the area in which the executive was free to act outside administrative law.

Bureaucracy and the role of administrative law. An inevitable consequence of the expansion of governmental functions has been the rise of bureaucracy. The number of officials of all kinds has greatly increased, and so too have the material resources allocated to their activities, while their powers have been enlarged in scope and depth. The rise of bureaucracy has occurred in countries ruled by all types of government, including the Communist countries, the dictatorships and Fascist regimes, and the political democracies. It is as conspicuous in the new states of Africa and Asia as among the highly developed countries of western Europe or North America. A large, strong, and well-trained civil service is essential in a modern state, irrespective of the political character of its regime or the nature of its economy.

Fear of the maladies that tend to afflict bureaucracy has produced a considerable volume of protest in some countries; and, even in those where opposition to the government or the party in power is not permitted, criticism and exposure of bureaucratic maladministration are generally encouraged.

Bureaucratic maladies are of different kinds. They include an overdevotion of officials to precedent, remoteness from the rest of the community, inaccessibility, arrogance in dealing with the general public, ineffective organization, waste of labour, procrastination, an excessive sense of self-importance, indifference to the feelings or convenience of citizens, an obsession with the binding authority of departmental decisions, inflexibility, abuse of power, and reluctance to admit error. Many of these defects can be prevented or cured by the application of good management techniques and by the careful training of personnel. A whole range of techniques is available for this purpose, including effective public relations, work-study programs, organization and management, operational research, and social surveys.

Administrative law is valuable in controlling the bureaucracy. Under liberal-democratic systems of government, political and judicial control of administration are regarded as complementary, but distinct. The former is concerned with questions of policy and the responsibility of the executive for administration and expenditure. The latter is concerned with inquiring into particular cases of complaint. Administrative law does not include the control of policy by ministers or the head of state. Under Communist regimes, however, this distinction rarely exists. The control exercised by an elected council or a presidium over a similar body at the next lower level of government is regarded as a form of legal control over administration. Internal methods of control are also regarded as falling within the ambit of administrative law. These include an appeal from the decision of an official within the same organization or an appeal to a higher administrative unit. A distinctive feature of Communist countries is that there is no definition of the powers of governmental organs at different levels. They are all assumed to be unlimited in scope but always subject to an equally unlimited right of intervention and restraint by the corresponding organ at the next higher level of government. This contrasts with the explicit definition of powers at each level of government that is found in the Western-type democracies. The admixture of political and legal control results in administrative law having a loose and imprecise meaning in Communist countries.

JUDICIAL REVIEW OF ADMINISTRATION

Judicial review of administration is, in a sense, the heart of administrative law. It is certainly the most appropriate method of inquiring into the legal competence of a public authority. The aspects of an official decision or an administrative act that may be scrutinized by the judicial process are the competence of the public authority, the extent of a public authority's legal powers, the adequacy and fairness of the procedure, the evidence considered in arriving at the administrative decision and the motives underlying it, and the nature and scope of the discretionary power. An administrative act or decision can be invalidated on any of these grounds if the reviewing court or tribunal has a sufficiently wide jurisdiction. There is also the question of responsibility for damage caused by the public authority in the performance of its functions. Judicial review is less effective as a method of inquiring into the wisdom, expediency, or reasonableness of administrative acts, and courts and tribunals are unwilling to substitute their own decisions for that of the responsible authority.

Judicial review of administration varies internationally. Sweden and France, for instance, have gone as far as subjecting the exercise of all discretionary powers, other than those relating to foreign affairs and defense, to judicial review and potential limitation. Elsewhere, a preoccupation with procedure results in judicial review deciding only whether the correct procedure was observed rather than examining the substance of the decision.

It is of course impractical to subject every administrative act or decision to investigation, for this would entail unacceptable delay. The complainant must, therefore, always make out a *prima facie* case that maladministration has occurred.

Judicial review cannot compel the state to act in a particular way because the courts concerned cannot impose sanctions on the government, which itself controls the use of force. Such remedies as an injunction, an order for specific performance, or an order for *mandamus* will not lie against the central government. These inhibitions, however, are of less practical importance than might be supposed. Nevertheless, nearly all governments (even revolutionary ones) are eager to proclaim the lawfulness of the regime and seldom disregard the decisions of an authorized court or tribunal.

In judicial review of administration at a national level, a country's history, politics, and constitutional theory all play their part. There are, broadly, three major systems: the common-law model; the French, or council of state, model; and the procurator model.

The common-law system. Origins. The common-law system originated in England in the Middle Ages. In the 17th century relations between the courts and the executive developed into a constitutional struggle between the Stuart kings and the judges over the judges' right to decide questions affecting the royal power and even to pronounce an independent judgment in cases in which the king had an interest. Francis Bacon, in his essay *Of Judicature* (written in 1612), put forth the royalist point of view when he declared that the judges should be "lions, but yet lions under the throne." "It is a happy thing in a state," he wrote, "when kings and states do often consult with judges; and again, when judges do often consult with the king and state: the one, when there is matter of law intervenient in business of state; the other, when there is some consideration of state intervenient in matter of law." The subordination of the judicature to the royal will was strongly resisted by Chief Justice Sir Edward Coke, Bacon's great rival, who refused to comply with James I's wishes in a number of cases in which the royal prerogative was involved. The King harangued the judges more than once on their duty to respect the royal prerogative and power.

In the constitutional conflict that took place a generation later, the judges and the lawyers made common cause with Parliament against Charles I, and eventually the independence of the judges was established. Henceforth there was to be one system of law to which all would owe obedience. As a result, the executive possessed no inherent powers other than those subject to the rule of law inasmuch as legislation now had to emanate from the crown

Distinction
between
political
and legal
control

Independence
of the
judiciary

in Parliament. In addition, the judges were expected to protect the subject against the executive. A more intangible consequence was the belief that "government" and "law" were often thought to be opposed to one another. The earlier conflict between crown and judges survived to become an antagonism between the legal profession and the executive, particularly the civil service.

These developments established the principle that the executive should never interfere with the judiciary in the exercise of its functions. This was, indeed, almost the only strict application in England of the doctrine of the separation of powers. On the other hand, it was regarded as right and proper that the judiciary should interfere with the executive whenever a minister or a department was shown to have acted illegally. In this way the concept of the rule of law came gradually to be identified with the idea that the judges, in ordinary legal proceedings in the ordinary courts, could pronounce upon the lawfulness of the activities of the executive. Any attempt to divide the seamless web of the law, any suggestion of a distinction between public and private law, appeared destructive of the law's universality and its power to keep the executive within bounds.

American
checks and
balances

The principle that all public authorities are liable to have the lawfulness of their acts and decisions tested in the ordinary courts was applied everywhere the common law prevailed, including the United States, despite the much stricter interpretation given by the Founding Fathers there to the doctrine of the separation of powers—a doctrine embodied in the federal and state constitutions. A complete separation of powers was not considered feasible by the framers of the Constitution, and they therefore introduced checks and balances, whereby each of the three branches of government would be prevented from growing too powerful by the countervailing power of the others. This actually strengthened the power of the courts to review the actions of the executive. Elsewhere in the common-law world, the extended role of the courts in reviewing administration was adopted without any public debate concerning the separation of powers or the need to protect liberty by a system of checks and balances. This absence of an explicitly defined role for courts led, in the early post-World War II years in Britain, to real fears that the courts would be unable or unwilling to question the expanded powers of governmental bodies.

British
admin-
istrative
tribunals

Modification of the common-law system. The common-law system has been extensively modified in the course of the 20th century. Until recently it did not correspond to the realities of the situation in Britain because, prior to the Crown Proceedings Act, 1947, it was not possible to sue ministers and their departments in tort; government ministers in Britain are considered ministers of the crown, and an ancient legal doctrine holds that "the king can do no wrong." Moreover, the development of state-provided social services has been accompanied by the creation of a large number of administrative tribunals to determine disputes between a government department and a citizen. The jurisdiction of these tribunals is of a specialized and narrowly circumscribed character and relates to such functions as social insurance and social assistance, the National Health Service, rent control, assessment of property for local taxation, the compulsory acquisition of land by public authorities, and the registration of children's homes. Since 1958 a permanent Council on Tribunals appointed by the lord chancellor has exercised a general supervision over about 40 tribunal systems, but they remain an unsystematic and uncoordinated movement. However, they provide a method of administrative adjudication far cheaper, more informal, and more rapid than that offered by the courts; the members are persons possessing special knowledge and experience of the subject dealt with; they do not have to follow the strict and complex rules of evidence that prevail in the courts; and it is possible to introduce new social standards and moral considerations to guide their decisions. These tribunals have won general approval for the quality and impartiality of their work. An appeal on a question of law lies in most instances from the decision of an administrative tribunal to the High Court of Justice. There is still no comprehensive administrative jurisdiction

in Britain permitting judicial review over the whole field of executive action and decision.

In Australia a similar movement took place with the growth of a large number of administrative tribunals that regulate many different spheres of public administration, such as industrial conditions; the award of pensions, allowances, and other state grants; town planning; censorship of films; fair rents; the licensing of occupations calling for special skills or public responsibility; trade, transport, and marketing; the assessment of national taxes, local taxes, or duties; the protection of industrial design, patents, and copyrights; and compensation for interference with private-property rights in the public interest. As in Britain, the growth of these tribunals has been sporadic, and no attempt has been made to introduce a systematic or comprehensive administrative jurisdiction. A similar situation has developed in other Commonwealth countries.

In the United States the courts review administration much more comprehensively than in Britain. Nevertheless, much adjudication is now performed by public authorities other than the courts of law. The movement toward administrative tribunals began with the Interstate Commerce Act (1887), establishing the Interstate Commerce Commission to regulate railways and other carriers. This law introduced a new type of federal agency, outside the framework of the executive departments and largely independent of the president. Other regulatory commissions followed: the Federal Trade Commission, the Federal Communications Commission, the Securities and Exchange Commission, the National Labor Relations Board, and the Occupational Safety and Health Administration. These bodies have had administrative, legislative, and judicial functions delegated to them by Congress, and the doctrine of the separation of powers can no longer be successfully invoked to challenge the constitutionality of such legislation. The regulatory commissions are often described by American jurists as administrative tribunals.

American
regulatory
commis-
sions

Thus, in the United States, as in other parts of the Anglo-American common-law world, the concept of the exclusive exercise by the ordinary courts of all judicial powers and of the absence of special administrative tribunals has been substantially modified by these developments.

The council of state system. The French system. In France the separation of powers was given a place of honour in the Declaration of the Rights of Man and of the Citizen (1789). In the French view, however, if a court were permitted to review an administrative act or decision, it would contravene the separation of powers as much as if the executive could override the decision of a court. Just as an appeal from a court lies to a higher court, the reasoning goes, so an appeal from an administrative authority should lie to a higher administrative authority. Only thus would the true separation of powers be observed.

Herein lies the explanation of administrative law as a system of law separate from the body of law administered in the courts. A law of August 1790 declared that the judiciary was distinct from and would always remain separated from the executive. It forbade judges, on pain of dismissal, to interfere in any way with the work of administrative bodies. In October 1790 a second law stated that under no circumstances should claims to annul acts of administrative bodies fall within the jurisdiction of the courts. Such claims should be brought before the king as head of the general administration.

French
conception
of separa-
tion of
powers

The Conseil du Roi of the ancien régime, with its functions as legal adviser and administrative court, is generally considered to be the precursor of the Conseil d'État. The basic structure of the Conseil d'État was laid down by Napoleon, however. Among the functions accorded to it by the constitution of the year VIII (December 1799) was that of adjudicating in conflicts that might arise between the administration and the courts. It was also empowered to adjudicate any matters previously left to the minister's discretion that ought to be the subject of judicial decision. In 1806 a decree created a Judicial Committee of the Conseil to examine applications and report thereon to the General Assembly of the Conseil. These enactments laid the foundation of an administrative jurisdiction that was not clearly established until May 24, 1872, when a

law delegated to the Conseil d'État the judicial power to make binding decisions and recognized the Conseil as the court in which claims against the administration should be brought.

The Conseil d'État is and always has been part of the administration. It has for long had the task of giving legal advice to the government on bills, regulations, decrees, and administrative questions. It is this that long led foreign jurists into believing that, when sitting as a court, its decisions would inevitably be biased in favour of the executive. Nothing could be further from the truth, and today the Conseil is universally recognized as an independent court that provides French citizens with exceptionally good protection against maladministration. Suits that are directed against the French administration are heard in the Section du Contentieux, or Judicial Division, the successor of the Judicial Committee after restructuring in 1872.

French
system of
adminis-
trative
courts

The Conseil d'État is the final authority in administrative disputes. Owing to the immense volume of work falling on it, the former prefectural councils, which served as administrative courts subordinate to the Conseil d'État, were transformed in 1953 into administrative tribunals of first instance, and the professional qualifications and career prospects of their members were improved. The great majority of cases go before these tribunals, and the Conseil d'État is the court of first and last instance only in those rare cases when it is specially designated for that purpose.

If difficulty or doubt arises as to whether a case falls within the administrative jurisdiction or that of the ordinary courts, the question is resolved by the Tribunal des Conflits. This is a court specially established for the purpose, consisting of five judges from the Cour de Cassation (the highest civil court) and five from the Conseil d'État. The minister of justice, in his capacity as keeper of the seals (*garde des sceaux*), may sometimes preside and cast a tie-breaking vote.

Several other countries have followed France in establishing councils of state. Among them are Italy, Greece, Belgium, Spain, Turkey, Portugal, and Egypt. It must be stated, however, that in no other country has a council of state acquired such high status, powers, authority, or prestige as in France.

The German system. Germany traditionally has had no council of state, but West Germany does have a fully articulated system of special administrative courts. In the states, or *Länder*, there are lower administrative courts and superior administrative courts, and for the federation there is the Federal Administrative Court, which acts mainly as a court of appeals from the superior administrative courts in the *Länder* and even from the lower administrative courts in certain circumstances. The Federal Administrative Court serves also as a court of first and last instance in disputes not involving questions of constitutionality between the federation and the *Länder* or between two or more *Länder*; it hears petitions by the federal Cabinet on declarations that an association is prohibited under the Basic Law of the Federal Republic, petitions against the federation in matters concerning the diplomatic or consular service, and cases concerning the business of the Federal Intelligence Service.

German
system of
administra-
tive and
civil juris-
dictions

A *Land* administrative court possesses jurisdiction concerning the acts of the *Länder* administrative authorities and also complaints against officers of the federal government located in the *Länder*. Some of the highest federal organs are exempt from the *Länder* courts. Few cases go beyond the *Länder* supreme administrative courts.

Recourse to an administrative court is available for public law disputes unless the matter has been assigned to another court by federal legislation. (Public law governs the relationship between the state and executive in the exercise of their governmental authority and the individual—insofar as the relationship is not commercial.) The Administrative Courts Code holds that property claims arising from services for the common good and restitution claims arising from violation of duties under public law shall be heard by the ordinary courts. In other words, the German system is complicated by the rule that only the ordinary civil courts can award damages against an official or the executive arm of government. Hence the distinction

between the ordinary courts and the administrative courts depends on the remedy sought and not on the subject matter of the dispute or the nature of the parties. The jurisdiction of the administrative courts in West Germany is thus less comprehensive and clear-cut than in France.

The procurator system. The third system for ensuring administrative legality is the Procuracy, an institution founded in Russia by Peter the Great in 1722, who intended it to be the "eye of the tsar." Catherine II issued a directive in 1764 stating that the procurator general and his staff were to supervise the execution of the laws in the provinces, ensure justice, and prevent abuses. This was designated general supervision. In 1864, however, the Procuracy was relieved of its responsibility for supervising administration, its functions being confined to judicial matters, such as acting as public prosecutor in all criminal cases and conducting them on behalf of the government and the law.

The Procuracy was abolished in November 1917 but revived in 1922. The Soviet constitution charges the procurator general with the general duty of supervising the observance of the law by all ministries and institutions subordinate to them as well as by individual officials and citizens. The procurator general is appointed by the Supreme Soviet for five years. He appoints subordinate procurators at all administrative levels, from union republic to district and town.

The functions actually performed by the procurator have undergone many fluctuations and vicissitudes since 1922. The role as a public prosecutor has continued, but it has been exercised mainly to enforce party policies or programs on recalcitrant citizens rather than to punish public officers or authorities for breaches of the law. Sometimes the task of general supervision has been emphasized; at other times it has been abandoned in favour of more urgent tasks, as in World War II. The present position of the Procuracy is laid down in a union law of May 24, 1955, and a decree of the Presidium of the Supreme Soviet made on April 7, 1956.

The procurator is not the president of a court or a tribunal but a watchdog of legality. His organization comprises a department for general supervision; a bureau of investigation for the supervision of preliminary inquiries in criminal matters; a department for the supervision of investigations carried out by the KGB (Committee for State Security); departments to supervise criminal and civil proceedings in the courts; a department to supervise prisons, compulsory-labour centres, and the like; and departments for statistics, administration, and research.

General supervision is defined by Soviet writers on administrative law as meaning supervision by the procurators over legality in administration. Procurators are expected to see that the laws are strictly observed, to oppose their violation by anyone whatsoever, to protect the citizens, and to ensure that they fulfill their duties. The law of May 24, 1955, requires the Procuracy to ensure that the regulations or decisions issued by ministries, departments, their subordinate establishments and enterprises, and co-operative and other public organizations strictly conform to the constitution and laws of the Soviet Union and the republics as well as to the decrees of the Council of Ministers of the Soviet Union and the republics. They are also to ensure strict execution of the laws by officials and citizens. The procurator is concerned solely with the legality of administrative action.

Since the mid-1960s observers have detected a change in the role of the procurator from the handling of complaints by citizens against government bodies to the handling of "economic" complaints (e.g., violations such as filing fraudulent plan fulfillment records) and the monitoring of economic performance. The decline in the number of individual citizens' grievances handled by the Procuracy, as well as the economic and coercive purposes for which it has been used, make direct analogy between the procurator and an ombudsman misleading.

Since the Procuracy is not a court, it cannot make a binding decision. This point was emphasized by Article 58 of the 1977 constitution, giving citizens the right to take complaints against administrative actions to the courts.

Disci-
plinary
functions
of the
Soviet
procurator

The normal procedure (apart from cases of dereliction involving a criminal prosecution) is for the procurator to protest against any illegality that he may detect or that is brought to his notice or to initiate disciplinary action against an erring official. Every citizen has a right to lodge a complaint with the procurator, and denunciation and exposure of bureaucratic abuses are officially encouraged by the Communist Party. The fact that the Procuracy cannot make a binding decision does not necessarily prevent it from being an effective organ for securing administration according to law. Neither the French Conseil d'État nor the courts in any country can enforce judgments against the central government, but this does not prevent the decisions of the Conseil or declaratory judgments of the courts from being observed almost as a matter of course.

The other Communist regimes of eastern Europe have established procuracies based on the Soviet model. In Poland an additional institution to maintain administrative legality is the Supreme Chamber of Control, which is independent of the government and subordinate only to the legislature and the Council of State, a political body quite different from the French model. The functions of the Supreme Chamber of Control involve exercising general supervision over public administration, taking into account legality, economy, and opportuneness.

THE OMBUDSMAN

The ombudsman is a part of the system of administrative law for scrutinizing the work of the executive. He is the appointee not of the executive but of the legislature. The ombudsman enjoys a large measure of independence and personal responsibility and is primarily a guardian of correct behaviour. His function is to safeguard the interests of citizens by ensuring administration according to law, discovering instances of maladministration, and eliminating defects in administration. Methods of enforcement include bringing pressure to bear on the responsible authority, publicizing a refusal to rectify injustice or a defective administrative practice, bringing the matter to the attention of the legislature, and instigating a criminal prosecution or disciplinary action.

When Sweden created the office of ombudsman in the constitution of 1809, the holder of that office was occupied with civil affairs and was appointed by the legislature. He was independent of both executive and judiciary and had full powers to inquire into the details of any administrative or executive act and into certain judicial activities if reported to him by individuals as an abuse of rights. He had effective authority to prosecute civil servants and other public officials—including, on occasion, ministers themselves.

The Swedish ombudsman's responsibility now comprises civil affairs, including the judicature, the police, prisons, and the public administration, both central and local, but excluding ministers and the monarch. He can act as a public prosecutor (although he does not often do so); as a receiver of complaints from aggrieved citizens; or as an inspector of such institutions as jails, mental hospitals, homes for delinquent children, and retreats for alcoholics to discover if they are being administered in accordance with the law.

The institution of ombudsman was first adopted in other Scandinavian countries and then—especially from the 1960s—in many countries throughout the world, including New Zealand (1962), the United Kingdom (1967), Israel (1971), Portugal (1976), The Netherlands (1981), and Spain (1981). Australia, the United States, and Canada have ombudsmen at the state or provincial level, and in the United States several cities have municipal ombudsmen. In Britain there is an ombudsman to investigate complaints against local government, the National Health Service, and administration in Northern Ireland, in addition to the ombudsman operating at the national level. Some specialized ombudsmen have been appointed in the United States to safeguard the rights of prisoners to medical treatment. In Israel the police have an office of public complaints, and there is a military ombudsman; there is also a state controller, who issues annual reports on executive procedures.

There is no doubt about the value of the ombudsman in the states in which the institution has been established. Part of the ombudsman's usefulness lies in his ability to reassure citizens who believe they have been unjustly treated that careful inquiry into their complaints shows their suspicions to be groundless. In most countries the ombudsman has little positive power other than the right to inspect and to demand the fullest information. But he may recommend a particular interpretation of, or a particular change in, the law. He can also recommend that the government pay compensation to a complainant.

ADMINISTRATIVE PROCEDURE

An orderly procedure, besides being efficient, allows responsibility to be fixed on a particular officer or body at each stage of the administrative process. It can safeguard the rights of citizens and protect the executive against the criticism of having acted in an arbitrary manner. It can ensure regularity and consistency in the handling of individual cases. Much depends, however, on the quality and purpose of the procedural requirements. Most countries possess only an uncoded mass of administrative law prescribing procedure. Much of it is to be found in the laws and regulations governing particular functions of government, such as taxation, public health, education, and town planning.

Rules of administrative procedure cover such matters as the setting of administrative machinery in motion; methods for lodging appeals; the rights of interested persons; the time limits that must be observed; the conditions to be satisfied by objectors; and the right of legal representation. The leading treatise on U.S. administrative law devotes many chapters to such procedural topics as rule making, requirement of opportunity to cross-examine and rebut, adjudication procedure, examiners, bias, evidence, official notice, findings, reasons, and opinions.

Some countries have a general code of administrative procedure embodied in legislation. Among them are Austria, Czechoslovakia, Poland, Yugoslavia, Spain, and the United States. The Yugoslav law regulating the general administrative procedure is lengthy, containing 393 sections. It enacts that all state organs must proceed according to this law whenever, applying rules directly, they decide in administrative affairs on the rights, obligations, or legal interests of individuals, corporate bodies, or other parties. The law deals in great detail with the right of appeal to a higher administrative body or, exceptionally, to another agency at the same level of government. Appeals from a people's committee go to the corresponding committee at the next higher level, while appeals from an assembly go before the next higher assembly. Each enactment is expressed in clear and precise language.

In addition to an appeal to the next higher level of authority in the administrative hierarchy, the Yugoslav code of procedure provides for an appeal on a question of law to the courts. Judicial control of the legality of administrative actions is vested in the supreme courts of the various republics, which have separate divisions to hear administrative litigation. The intention is that decisions on the merits of administrative acts will normally be dealt with by the administrative hierarchy, since they are experts in public administration and are familiar with its tasks and needs, while the legal aspects will normally be decided on appeal to the courts. Only in exceptional cases will the Supreme Court have power to consider the merit of the act.

In the common-law systems, the doctrine of natural justice influences administrative procedure in two ways: (1) that a person may not be judge of his own cause, and (2) that a person shall not be dealt with to his material disadvantage, whether of person or property, or removed from or disqualified for office, without being given adequate notice of what is alleged against him and an opportunity to defend himself.

An indirect result of the second principle is the public hearing, widely used by government departments (and in the United States by regulatory commissions) in deciding matters involving individual or corporate rights. In the United Kingdom a public inquiry is now a com-

Scope of procedural rules

Procedure in common-law systems

Independence of the Swedish ombudsman

mon means of handling appeals to the Department of the Environment against the decisions of local authorities in such matters as planning applications and compulsory purchase of land.

In 1957 the Franks Committee was appointed by the British lord chancellor to study administrative tribunals and such procedures as the holding of a public inquiry. The committee declared that the work of administrative tribunals and of public inquiries should be characterized by openness, fairness, and impartiality, and their report applied these aims in great detail. Its recommendations were largely accepted and resulted in the Tribunals and Enquiries Act of 1958. (W.A.R./E.C.P.)

BIBLIOGRAPHY. The most comprehensive treatment of administration is ANDREW DUNSIRE, *Administration: The Word and the Science* (1973, reprinted 1981). Included among the classics in the field are FREDERICK WINSLOW TAYLOR, *The Principles of Scientific Management* (1911), available in numerous later editions; HENRI FAYOL, *General and Industrial Management*, rev. ed. (1984; originally published in French, 1917); and MAX WEBER, *Economy and Society: An Outline of Interpretive Sociology*, edited by GUENTHER ROTH and CLAUS WITTICH, 2 vol. (1978; originally published in German, 4th rev. ed., 1956). MARSHALL W. MEYER, *Change in Public Bureaucracies* (1979), is an important quantitative study of the process of change; and E.N. GLADDEN, *A History of Public Administration*, 2 vol. (1972), is an informative survey of developments from the 11th century to the present day. For further study, useful information can be found in JAY M. SHAFRITZ, *The Facts on File Dictionary of Public Administration* (1985); and also in ROBERT D. MIEWALD, *The Bureaucratic State: An Annotated Bibliography* (1984).

The traditional approach to public administration and its principles are set forth in LUTHER H. GULICK and L. URWICK (eds.), *Papers on the Science of Administration* (1937, reprinted 1987); and L. URWICK, *The Elements of Administration*, 2nd ed. (1947). Challenges to the principles, as well as efforts to build a theory of decision making as central to administration, appear in CHESTER I. BARNARD, *The Functions of the Executive* (1938, reprinted 1979); HERBERT A. SIMON, *Administrative Behaviour: A Study of Decision-Making Processes in Administrative Organization*, 2nd ed. (1957, reissued 1965); and HERBERT A. SIMON, DONALD W. SMITHBURG, and VICTOR A. THOMPSON, *Public Administration* (1950, reprinted 1971). A thoughtful review of the evolution of public administration in its relation to society is provided in DWIGHT WALDO, *The Administrative State: A Study of the Political Theory of American Public Administration*, 2nd ed. (1984). A challenge to the traditional dichotomy between policy and administration is expressed cogently in various works of PAUL H. APPLEBY, most notably in his *Policy and Administration* (1949, reprinted 1975). Later developments of similar views are found in DAVID B. TRUMAN, *The Governmental Process: Political Interests and Public Opinion*, 2nd ed. (1971); EMMETTE S. REDFORD, *Democracy in the Administrative State* (1969); and HAROLD SEIDMAN and ROBERT GILMOUR, *Politics, Position and Power: From the Positive to the Regulatory State*, 4th ed. (1986). The nature and role of cost-benefit analysis is discussed in PETER SELF, *Econocrats and the Policy Process: The Politics and Philosophy of Cost-Benefit Analysis* (1975). The incremental approach to decision making is set out in CHARLES E. LINDBLOM, *The Intelligence of Democracy: Decision Making Through Mutual Adjustment* (1965); the problems involved in applying techniques such as PPBS and Programme Analysis and Review are discussed in AARON WILDAVSKY, *The Politics of the Budgetary Process*, 4th ed. (1984); and ANDREW GRAY and WILLIAM I. JENKINS, *Administrative Politics in British Government* (1985). The prophet of the human relations movement was Mary Parker Follett, some of whose writings are published in *Dynamic Administration: The Collected Papers of Mary Parker Follett*, new ed., edited by ELLIOT M. FOX and L. URWICK (1973, reissued 1982). The derivative movement, now called organization development, is treated in CHRIS ARGYRIS, *Integrating the Individual and the Organization* (1964); RENSIS LIKERT, *New Patterns of Management* (1961, reprinted 1987); and WARREN G. BENNIS, *Organization Development: Its Nature, Origins, and Prospects* (1969). A wide-ranging discussion of issues in policy analysis is provided in BRIAN W. HOGWOOD and LEWIS A. GUNN, *Policy Analysis for the Real World* (1984). A growing literature has developed since World War II in case studies of actual administrative experience. Pioneered and led by the American Inter-University Case Program, the use of cases has spread to many other countries. An example of the use of cases in comparative analysis is FREDERICK C. MOSHER (ed.), *Governmental Reorganizations: Cases and Commentary* (1967). JOHN E. ROUSE, JR., *Public Administration in American Society: A*

Guide to Information Sources (1980), is a comprehensive annotated bibliography.

On the administrative systems of different countries, see BRIAN CHAPMAN, *The Profession of Government: The Public Service in Europe* (1959, reprinted 1980); F.F. RIDLEY (ed.), *Specialists and Generalists: A Comparative Study of the Professional Civil Servant at Home and Abroad* (1968); FRED W. RIGGS, *Administration in Developing Countries: The Theory of Prismatic Society* (1964); MORROE BERGER, *Bureaucracy and Society in Modern Egypt: A Study of the Higher Civil Service* (1957, reissued 1969); and JOSEPH LA PALOMBARA (ed.), *Bureaucracy and Political Development*, 2nd ed. (1967).

There are few general comparative studies on civil services. The important comparative works in the prewar period are HERMAN FINER, *Theory and Practice of Modern Government*, rev. ed. (1949, reprinted with a new introduction, 1970); ERNEST BARKER, *The Development of Public Services in Western Europe, 1660-1930* (1944, reissued 1966); LEONARD D. WHITE (ed.), *The Civil Service in the Modern State* (1930), and *The Civil Service Abroad: Great Britain, Canada, France, Germany* (1935). The postwar comparative studies include POUL MEYER, *The Administrative Organization: A Comparative Study of the Organization of Public Administration* (1957); EDWARD C. PAGE, *Political Authority and Bureaucratic Power: A Comparative Analysis* (1985); and B. GUY PETERS, *The Politics of Bureaucracy*, 2nd ed. (1984). For a wider discussion of public employment, including local and regional government officials and employees in public enterprises and health services, as well as a survey of the growth in public employment since the middle of the 19th century, see RICHARD ROSE *et al.*, *Public Employment in Western Nations* (1985). For a comparative public policy analysis, see ARNOLD J. HEIDENHEIMER, HUGH HECLLO, and CAROLYN TEICH ADAMS, *Comparative Public Policy: The Politics of Social Choice in Europe and America*, 2nd ed. (1983). Two classic works that established the modern theory of the relations between civil servants and the state are RUDOLF GNEIST, *Der Rechtsstaat* (1872); and LEON DUGUIT, *Law in the Modern State* (1919, reprinted 1970; originally published in French, 1913).

European countries with long traditions of civil service government have very considerable bibliographies on various aspects of public administration. Useful surveys of the administrative systems of the larger European nations are found in F.F. RIDLEY (ed.), *Government and Administration in Western Europe* (1979). The special aspect of control of the civil service is dealt with in CHARLES E. FREEDEMAN, *The Conseil d'Etat in Modern France* (1961; reprinted 1968). The political background to the struggle for civil servants' rights may be traced through PIERRE D'HUGUES, *La Guerre des fonctionnaires* (1912).

The overall pattern of the federal civil service and administration in the United States is dealt with in EDWARD S. CORWIN, *The President: Office and Powers, 1787-1957: History and Analysis of Practice and Opinion*, 5th rev. ed. (1984); and MARVER H. BERNSTEIN, *The Job of the Federal Executive* (1958, reprinted 1986). The special problem of the U.S. diplomatic service is the subject of a special enquiry presented in the COMMITTEE ON FOREIGN AFFAIRS PERSONNEL, *Personnel for the New Diplomacy: Report* (1962). The relations between the civil service and Congress are studied in depth in JOSEPH P. HARRIS, *Congressional Control of Administration* (1964, reprinted 1980). LAURENCE E. LYNN, JR., *Managing the Public's Business: The Job of the Government Executive* (1981); HUGH HECLLO, *A Government of Strangers: Executive Politics in Washington* (1977); and HERBERT KAUFMAN, *The Administrative Behavior of Federal Bureau Chiefs* (1981), focus on the difficulties experienced by appointed executives in managing their agencies.

General studies on the organization of executive power in Communist countries include H. GORDON SKILLING, *The Governments of Communist East Europe* (1966); and GHITA IONESCU, *The Politics of the European Communist States* (1967). A detailed study of the organization of authority in the Soviet Union may be found in MICHEL TATU, *Power in the Kremlin* (1969, originally published in French, 1967); this is contrasted with Chinese theory and practice in DONALD W. TREADGOLD (ed.), *Soviet and Chinese Communism: Similarities and Differences* (1967). The internal organization and structure of government in China itself may be found in FRANZ SCHURMANN, *Ideology and Organization in Communist China*, 2nd ed. (1968); and A. DOAK BARNETT, *Cadres, Bureaucracy, and Political Power in Communist China* (1967). See also HARRY HARDING, *Organizing China: The Problem of Bureaucracy, 1949-1976* (1981).

The special problems of civil services in new states are outlined in KENNETH YOUNGER, *The Public Service in New States: A Study in Some Trained Manpower Problems* (1960, reprinted 1974); and in A.L. ADU, *The Civil Service in New African States* (1965), which can be compared with the same author's *Civil Service in Commonwealth Africa: Development and Transition*

(1969). Interesting comparative, theoretical, and institutional studies on a broad front are found in RALPH BRAIBANTI (ed.), *Asian Bureaucratic Systems Emergent from the British Imperial Tradition* (1966); JOHN D. MONTGOMERY and WILLIAM J. SIFFIN (eds.), *Approaches to Development: Politics, Administration and Change* (1966); FERREL HEADY, *Public Administration: Comparative Perspective*, 3rd rev. ed. (1984); and JOSEPH LA PALOMBARA (ed.), *Bureaucracy and Political Development*, 2nd ed. (1963). Useful descriptions of the civil services of the European Communities and the United Nations can be found in CHARLES DEBBASCH (ed.), *La Politique de choix des fonctionnaires dans les pays européens* (1981).

There are no works covering the whole subject of administrative law in its differing forms in many countries. For the present system in the United Kingdom, see H.W.R. WADE, *Administrative Law*, 5th ed. (1982); DAVID FOULKES, *Administrative Law*, 6th ed. (1986); S.A. DE SMITH, *De Smith's Judicial Review of Administrative Action*, 4th ed., edited by J.M. EVANS (1980); and J.F. GARNER and B.L. JONES, *Garner's Administrative Law*, 6th ed. (1985). WILLIAM A. ROBSON, *Justice and Administrative Law: A Study of the British Constitution*, 3rd ed. (1951, reprinted 1970), is a standard work on the rise and purpose of administrative tribunals. PHILIP NORTON, *The Constitution in Flux* (1982), contains a useful introductory overview of the system of grievance redress in the United Kingdom. The leading work on American administrative law is KENNETH CULP DAVIS, *Administrative Law Treatise*, 2nd ed., 5 vol. (1978-84). The complex question of the control of administrative discretion in the United States is examined by KENNETH CULP DAVIS, *Discretionary Justice: A Preliminary Inquiry* (1969, reprinted 1980). A readable account of the American system may be found in BERNARD SCHWARTZ, *An Introduction to American Administrative Law*, 2nd ed. (1962). See also WALTER GELLHORN et al., *Administrative Law: Cases and Comments*, 8th ed. (1987). The French system is appraised in C.J. HAMSON, *Executive Discretion and Judicial Control: An Aspect of the French Conseil d'État* (1954,

reprinted 1979); a reliable description of its principles is contained in L. NEVILLE BROWN and J.F. GARNER, *French Administrative Law*, 3rd ed. (1983). A comparison between the Anglo-American system and the French is given in BERNARD SCHWARTZ, *French Administrative Law and the Common-Law World* (1954). Leading treatises by eminent French jurists are GEORGES VEDEL and PIERRE DELVOLVÉ, *Droit administratif*, 9th ed. (1984); MARCEL WALINE, *Droit administratif*, 9th ed. (1963); and M. LONG, P. WEIL, and G. BRAIBANT, *Les Grands Arrêts de la jurisprudence administrative*, 8th ed. (1984). For Australia, see HARRY WHITMORE, *Principles of Australian Administrative Law*, 5th ed. (1980). On West Germany, ERNST FORSTHOFF, *Lehrbuch des Verwaltungsrechts*, 10th rev. ed. (1973); and HANS J. WOLFF and OTTO BACHOF, *Verwaltungsrecht*, 3 vol. in various editions (1978), are reliable works. The procuracy can be studied in GLEN G. MORGAN, *Soviet Administrative Legality: The Role of the Attorney General's Office* (1962); LEON BOIM and GLENN G. MORGAN, *The Soviet Procuracy Protests, 1937-1973: A Collection of Translations* (1978); GORDON B. SMITH, *The Soviet Procuracy and the Supervision of Administration* (1978); and more briefly in LEONARD SCHAPIRO, *The Government and Politics of the Soviet Union*, new rev. ed. (1978). Wide-ranging books on the ombudsman are a symposium edited by DONALD C. ROWAT, *The Ombudsman: Citizen's Defender*, 2nd ed. (1968), and his *Ombudsman Plan: The Worldwide Spread of an Idea*, 2nd rev. ed. (1985); WALTER GELLHORN, *Ombudsmen and Others: Citizens' Protectors in Nine Countries* (1966), and *When Americans Complain: Governmental Grievance Procedures* (1966); and GERALD E. CAIDEN (ed.), *International Handbook of the Ombudsman*, 2 vol. (1983). An excellent work on Scandinavia is NILS HERLITZ, *Elements of Nordic Public Law*, (1969; originally published in Swedish, 1959). The only accessible text in English of the Yugoslav procedural code is BORISLAV T. BLAGOJEVIĆ (ed.), *Law on General Administrative Procedure*, (1969; originally published in Croatian, 4th ed., 1968).

(F.C.M./B.Ch./W.A.R./E.C.P.)

Public Opinion

There are many difficulties in the way of defining public opinion, the most important of which are discussed below. A simple definition is that public opinion is an aggregate of the individual views, attitudes, and beliefs about a particular topic, expressed by a significant proportion of a community.

This article is divided into the following sections:

Historical background	310
Ancient times	
Middle Ages	
Early modern times	
Current conceptions of public opinion	
The formation and change of public opinion	312
Formation of attitudes

Interest groups	
Opinion leaders	
Complex influences	
Public opinion and government	313
Public-opinion polling	314
Methodology of opinion polling	
Criticisms and justifications of opinion surveys	
Bibliography	316

HISTORICAL BACKGROUND

Ancient times. Although the term public opinion was not used until the 18th century, phenomena that closely resembled public opinion seem to have occurred in many historical epochs. One of the oldest written records from ancient Egypt, a poem entitled "The Dispute with His Soul of One Who Is Tired of Life," refers to an upheaval that apparently involved a complete reorientation of mass opinion:

To whom shall I speak today?
People are greedy . . .
Gentleness of spirit has perished.
All the people are impudent . . .
People laugh at crimes of him who before
Would have enraged the righteous . . .
There are no just men.
The earth has been given over to evil doers.

Similar references to popular attitudes can be found in the histories of Babylonia and Assyria. The prophets of ancient Israel sometimes justified the policies of the government to the people and sometimes appealed to the people to oppose the government. In both cases they were concerned with swaying opinion. And in classical Greece it was observed by many that everything depended on the people, and the people were dependent on the word. Wealth, fame, and respect all could be given or taken away by persuading the populace.

Wide dissemination of news, which is usually necessary for the formation of public opinion, could be observed in classical Rome. Much of this took place through person-to-person channels. When the Roman statesman Cicero was in Cilicia in the year 51 bc, he asked his friend Caelius to keep him informed of what was happening in the capital. Caelius promised to do so: "If anything important of a political nature should occur . . . I will diligently describe to you its origin, the general opinion about it, and the prospects of future action that it opens up." Rome also had its wall newspapers, composed by Roman officials and posted in public places to inform the public about acts of the government and principal local events.

Middle Ages. During the Middle Ages in western Europe, the masses were encased in a rural, traditional society in which most activities and attitudes were dictated by a person's station in life; but phenomena much like

public opinion could be observed among the religious, intellectual, and political elite. Religious disputations, the struggle between popes and the Holy Roman Empire, and the dynastic ambitions of princes all involved efforts to persuade, to create a following, and to line up the opinions of those who counted. In 1191 the English bishop William of Ely was attacked by his political opponents for hiring troubadours to extol his merits in public places, so that "people spoke of him as though his equal did not exist on earth." The propaganda battle between emperors and popes was waged largely through sermons, but handwritten literature also played a part.

From the end of the 13th century, the ranks of those who could be drawn into controversy regarding current affairs grew steadily. There was an increasing spread of education among the lay population. The rise of humanism in Italy saw the emergence of a group of writers and publicists whose services were eagerly sought by the princes who were consolidating national states. Some of these writers were used as advisers and diplomats; others were employed as publicists because of their ability to sway opinion. Such a one was the Italian Pietro Aretino (1492–1556), of whom it was said that he knew how to defame, to threaten, and to flatter better than all others and whose services were sought by both Charles V of Spain and Francis I of France. The Italian political philosopher Niccolò Machiavelli, a contemporary of Aretino, wrote that princes should not ignore popular opinion, particularly in regard to such matters as the distribution of offices.

The invention of printing from movable type in the 15th century and the Protestant Reformation in the 16th increased still further the numbers of people able to form opinions on contemporary issues. Martin Luther broke with the humanists by abandoning the use of classical Latin, intelligible only to the educated, and turned directly to the masses. "I will gladly leave to others the honour of doing great things," he wrote, "and will not be ashamed of preaching and writing in German for the unschooled layman." Luther's Ninety-five Theses, which were printed against his will and widely spread throughout Europe, were of a theological nature, but he also wrote on such subjects as the war against the Turks, the Peasants' Revolt, and the evils of usury. His vigorous expressions and the counterblasts from his many opponents, both lay and clerical, led to the formation of larger and larger groups holding opinions on important matters of the day.

Extensive attempts to create and influence public opinion were made during the Thirty Years' War (1618–48). A flood of propaganda tracts, many illustrated with woodcuts, emanated from both sides. Opinions were also swayed by means of speeches, sermons, and face-to-face discussions. Not surprisingly, both civil and religious authorities attempted to control the dissemination of unwelcome ideas by increasingly strict censorship. Pope Paul IV had the first Index of Prohibited Books drawn up in 1559. Charles IX of France decreed in 1563 that nothing could be printed without the special permission of the king.

More quietly, but more significantly, newspapers and news services were developing. Rudimentary private news services had been maintained by political authorities and wealthy merchants ever since classical times, but they were not available to the public. By 1500, however, it was possible to buy specialized news sheets in many of the principal cities of Europe. One of these, printed in 1514 or 1515, contains an extract of a merchant's letter telling of the Portuguese discovery of Brazil. The first regularly printed newspapers appeared in about 1600 and multiplied rapidly thereafter, although they were frequently bedeviled by censorship regulations. Regular postal services, started in France in 1464 and in the Austrian Empire in 1490, facilitated the spread of information enormously.

opinion

Bourses as sources of informed opinion

Early modern times. The great news centres of early modern times were the financial exchanges. With the introduction of a paid civil service and the employment of paid soldiers in the place of vassals, princes found it necessary to borrow money. The bankers, in turn, had to know a great deal about the credit of the princes, the state of their political fortunes, and their reputations with their subjects. All kinds of political and economic information flowed to the money-lending centres at Antwerp, Lyon, and Nürnberg, and this information gave rise to generally held opinions in the banking community. The *ditta di borsa*—the opinion on the bourse—is often referred to in documents of the period. Queen Elizabeth of England was regarded as especially well informed because Sir Thomas Gresham, the finance agent of the English crown, kept in constant touch with the Antwerp bourse.

Significantly, it was another financial official who first popularized the term public opinion in modern times. Jacques Necker, who was the finance minister of Louis XVI on the eve of the French Revolution, noted repeatedly in his writings that public credit depended upon the opinions of holders and buyers of government securities about the viability of the royal administration. He, too, was vitally concerned with the *ditta di borsa*. But he also remarked on the power of public opinion in other areas. "This public opinion," Necker wrote, "strengthens or weakens all human institutions." As he saw it, public opinion should be taken into account in political undertakings. Necker was not, however, concerned with the opinions of all Frenchmen. For him, the people who collectively shaped public opinion were those who could read and write, who lived in cities, who kept up with the day's news, and who had money to buy government securities—or in short, the bourgeoisie.

A public opinion that extended beyond the middle classes and embraced the urban masses took shape during the French Revolution. Observers of the Revolution were mystified, and often terrified, by this new phenomenon of public opinion, which seemed able to sweep aside the entrenched institutions of the time: the monarchy, the church, and the feudal system. Thinkers of the late 18th and early 19th centuries advanced a variety of definitions as to what public opinion actually was. One of the most detailed descriptions was given in 1799 by the German poet Christoph Wieland, who closely followed the stormy events in France and the rest of western Europe:

I, for my part, understand by it an opinion that gradually takes root among a whole people, especially among those who have the most influence when they work together as a group. In this way it wins the upper hand to such an extent that one meets it everywhere. It is an opinion that without being noticed takes possession of most heads, and even in situations where it does not dare to express itself out loud can be recognized by a louder and louder muffled murmur. It then requires only some small opening that will allow it air, and it will break out with force. Then it can change all nations in a brief time and give whole parts of the world a new configuration.

A German philosopher of the time, Christian Garve, gave much more emphasis to the rational component:

Public opinion as interpreted . . . by those French writers who are clearest on the subject is the agreement of many or of the majority of the citizens of a state with respect to judgments which every single individual has arrived at as a result of his own reflection or of his practical knowledge of a given matter.

The English philosopher Jeremy Bentham, who advanced the first detailed discussion of public opinion in English, was troubled by the difficulty of defining it and advised that the term be employed only in deference to common usage.

Current conceptions of public opinion. In spite of voluminous discussions of the subject, scholars still do not agree on a definition of public opinion. Members of a roundtable of the American Political Science Association that met in 1925 divided into three groups: those who did not believe that there was such a thing as public opinion; those who accepted its existence but doubted their ability to define it precisely; and those who could offer a definition. This last group could not, however, agree on the definition to be adopted. Although few scholars now

question the existence of such a phenomenon as public opinion, differences in defining it have persisted to the present day.

These differences stem in part from the varying perspectives with which scholars have approached the study of public opinion and in part from the fact that the phenomenon is still not completely understood. Political scientists and some historians have tended to emphasize public opinion's role in the governmental process, paying particular attention to its influence on government policy. Some political scientists have regarded public opinion as equivalent to the national will. In this sense, there can be only one public opinion on an issue at any one time.

Sociologists usually give more emphasis to public opinion as a product of social interaction and communication. According to the sociological view, there can be no public opinion without communication among members of the public who are interested in a given issue. A large number of persons may hold quite similar views, but these will not coalesce into public opinion as long as each person remains ignorant of the opinions of the others. Communication may take place by means of the mass media of the press, radio, and television or through face-to-face discussions. Either way, people learn how others think about a given issue and may take the opinions of others into account in making up their own minds.

Sociologists suggest that there may be many different public opinions existing on a given issue at the same time. One body of opinion may be dominant or may be reflected in governmental policy, but this does not mean that other organized bodies of opinion do not exist. The sociological approach also sees the public-opinion phenomenon as extending to areas that are of little or no concern to government. Thus, fads and fashions are appropriate subject matter for students of public opinion, as are public attitudes toward movie stars or corporations.

It is often the case that opinions expressed in public may differ from those expressed in private and that only the former contribute to public opinion. Similarly, some attitudes—even though widely shared—may not be expressed at all. Thus, in a totalitarian state, a great many people may be opposed to the government but may fear to express their attitudes even to their families and friends. In such cases, an antigovernment public opinion fails to develop.

Private opinions, if expressed in public, may become a basis for public opinions. Until the 1930s, for example, there was an unwritten prohibition in the United States against discussions of venereal disease, although many individuals had private opinions about it. Then, when the subject began to be treated in the mass media and public opinion researchers began to ask questions about it, opinions that had formerly been private were expressed in public, and sentiment in favour of government action to stamp out venereal disease developed.

Some public-opinion survey specialists have preferred a definition that links public opinion directly to their polling procedures. Public opinion is therefore defined as being identical to what people's responses to a survey questionnaire would be. Other similar definitions have been to the effect that public opinion is whatever is discovered by public-opinion polls. This definition, while widely used in practice, has the disadvantage of implying that public opinion does not exist in places and times in which there are no opinion polls. A more generally applicable approach that embodies much the same reasoning is that public opinion on any matter may be conceived as the hypothetical result of some imaginary survey or vote.

Those who are primarily engaged in the manipulation of public opinion, notably professional politicians and public relations men, rarely stop to define it. The American journalist and political scientist Walter Lippmann has observed that there has been a tendency in democracies to make a mystery out of public opinion but that "there have been skilled organizers of opinion who understood the mystery well enough to create majorities on election day." (*Public Opinion*, 1922.) Public relations practitioners have concerned themselves less with public opinion in general than with the opinions of specified "publics" that may affect the fortunes of a client: employees, stockholders,

Sociological conceptions of public opinion

government officials, suppliers, and potential buyers, for example. Both politicians and public relations men are interested in influencing behaviour and thus in determining any attitudes and opinions that may affect that behaviour, whatever they may be called.

Nearly all scholars and manipulators of public opinion, regardless of the way they may define it, agree that at least four factors are involved in public opinion: there must be an issue; there must be a significant number of individuals who express opinions on the issue; there must be some kind of a consensus among at least some of these opinions; and this consensus must directly or indirectly exert influence.

THE FORMATION AND CHANGE OF PUBLIC OPINION

The democratic system itself defines a number of issues on which citizens are under pressure to form opinions. They are called upon to decide among various candidates in elections and, on occasion, to vote on constitutional amendments and various other propositions. Almost any matter on which the executive or legislature has to decide may become a public issue if a significant number of persons wish to make it one. The attitudes of these persons are often stimulated or reinforced by outside agencies—a crusading newspaper, a pressure group, or a governmental agency or official. Even matters that are not within the purview of any governmental agency may become public issues. No agency, for example, has the authority to determine how many children a family may have or how long a man's hair should be, but discussion on these subjects has at times been sufficiently intense to generate widespread opinion about them.

Formation of attitudes. Once a public issue is identified, a certain number of people will begin to form attitudes about it. If the attitude is expressed to others by sufficient numbers of people, a public opinion on the topic begins to emerge. Not all people develop attitudes on public issues; some may not be interested, and others simply may not hear about them. The attitudes that are formed may be held for various reasons. Thus, four men may all be opposed to higher property taxes but for very different reasons. One man may not be against higher taxes in principle, but he opposes them because he is having trouble paying the mortgage on his house. This attitude serves an adjustment, or utilitarian, function in that it helps its holder to accommodate the immediate financial situation in which he finds himself. A second man may fight the tax because he does not want a certain social group, such as the poor or the unemployed, to derive any benefit from tax revenues. Such an attitude may be the result of a psychological insecurity, of a desire to keep the poor "in their place" in order to bolster his own sense of superiority toward underprivileged groups. For such a person, the attitude serves an ego-defensive function. A third man may resist the tax increase because he believes that governmental activities should be severely restricted. His attitude has a value-expressive function in that it reflects his overall philosophy. A fourth man opposes the increased tax because he is familiar with instances of governmental waste and is convinced that all necessary services could be rendered if officials spent the already available funds more rationally. His attitude is thus determined by knowledge or experience in that it is a reflection of what he has learned in the past. A fifth man, of course, might fight the tax for all four reasons. A seemingly homogeneous body of public opinion may thus be composed of individual opinions that are rooted in very different interests and values. If an attitude does not serve a function such as one of the above, it is unlikely to be formed: an attitude must be useful in some way to the person who holds it.

How many people will actually form opinions on a given issue, as well as what sort of opinions they form, depends partly on their own preexisting knowledge, attitudes, and values; partly on the personal situations in which they find themselves; and partly on a number of environmental factors. As far as preexisting knowledge and attitudes are concerned, it is often surprising to discover how many people are not informed about major issues and therefore have no attitudes toward them. In 1964, for instance, one

in four Americans did not know that the government in China was Communist, and about the same proportion at any given time is ignorant of any major issue of public policy. Substantially the same situation has been found to exist in western European countries, and ignorance is probably even more widespread in nations with lower levels of education. Values are of considerable importance in determining whether people will form opinions on a particular topic. If people feel that their moral principles or personal philosophies are involved in an issue, they are more likely to take a favourable or opposing stand.

Immediate environmental factors. Environmental factors play an extremely important part in the formation of attitudes and opinions. Most pervasive is the influence of the immediate social environment: family, friends, neighbourhood, place of work, church, or school. People usually adjust their attitudes to conform with those that are most prevalent in the social groups to which they belong. If a person who considers himself a liberal is surrounded in his home or at his place of work by people who profess conservatism, he is more likely to switch his vote than is a liberal whose family and friends share his political views. Similarly, it was found in World War II that men transferred from one unit to another often adjusted their opinions to conform more closely with those in the unit to which they were transferred.

The mass media. The press, radio, and television are usually less important than the immediate social environment when it comes to the formation of attitudes, but they are still significant. They focus the attention on certain personalities and issues, and many people subsequently form opinions about these issues. Government officials have noted that their mail from the public tends to "follow the headlines"; whatever is featured in the press at a particular moment is likely to be the subject that most people write about. The mass media can also activate and reinforce latent attitudes. Political attitudes, for example, are likely to be activated and reinforced just before an election. Voters who may have only a mild preference for one party or candidate before the election campaign starts are often worked up by the mass media to a point where they not only take the trouble to vote but may contribute money or help a party organization in some other way.

The mass media play another extremely important role in letting individuals know what other people think and in giving leaders large audiences. In this way they make it possible for public opinion to include a large number of individuals and to spread over wider geographic areas. It appears in fact that in some European countries the growth of broadcasting, and especially television, has affected the operation of the parliamentary system. Before television, national elections were seen largely as contests between a number of candidates or parties for parliamentary seats. More recently, elections in such countries as West Germany and Great Britain have appeared more as a personal struggle between the leaders of the principal parties concerned, since these leaders were featured on television and came to personify their parties. Television in France and the United States has been regarded as a powerful force strengthening the presidential system, since the president can easily appeal to a national audience over the heads of elected legislative representatives.

Even when the mass media are thinly spread, as in developing countries or in nations where the media are strictly controlled, word of mouth can sometimes perform the same functions as the press and broadcasting, although on a more limited scale. In developing countries, it is common for those who are literate to read from newspapers to those who are not, or for large numbers of persons to gather around the one village radio. Word of mouth in the marketplace or neighbourhood then carries the information farther. In countries where important news is suppressed by the government, a great deal of information is transmitted by rumour. Word of mouth thus helps public opinion to form in developing countries and encourages "underground" opinion in totalitarian countries, even though these processes are slower and usually involve fewer people than in countries where the media network is dense and uncontrolled.

The influence of mass media

Elements involved in the formation of attitudes

The role of
pressure
groups

Interest groups. Pressure groups, or interest groups, also play an important part in the formation and spread of public opinion on issues of relevance to themselves. These groups may be concerned with political, economic, or ideological issues and often work through the mass media as well as by word of mouth in trying to influence attitudes. Some of the larger or more affluent interest groups in the United States, western Europe, and elsewhere make use of advertising and public relations to influence opinion. During the late 1960s and early 1970s, for example, hundreds of thousands of dollars were spent in the United States on advertising by opponents and proponents of U.S. policy in Southeast Asia, and lesser amounts were devoted to interest group advertising on other public issues. In Britain, much advertising space was purchased by opponents of Britain's proposed entry into the Common Market.

Opinion leaders. Opinion leaders play a major role in defining important issues and in influencing individual opinions regarding them. Political leaders, in particular, can turn a hitherto relatively unknown problem into a national issue if they decide to call attention to it. One of the ways in which opinion leaders rally opinion and smooth out the differences among those who are in basic agreement on a subject is by coining or popularizing symbols or slogans: Sir Winston Churchill popularized the phrase Cold War, and the Allies in World War I were fighting "a war to end all wars." Slogans are perhaps among the most useful tools that are available to the political leader. Once enunciated, symbols and slogans are frequently kept alive and communicated to large audiences by the mass media and may become the cornerstone of public opinion on any given issue.

Opinion leaders are not confined only to prominent figures in public life. There are likely to be persons in every social group to whom others in the immediate environment look for guidance on certain subjects. Thus, one person may be thought of by those in his own social group as especially qualified in the realm of local politics, another as a reliable guide in foreign affairs, and a third as an expert when it comes to buying a house. These local opinion leaders are generally unknown outside their own circle of friends and acquaintances, but their cumulative influence in the formation of public opinion is substantial.

Complex influences. Although a person's psychological makeup, his personal circumstances, and external factors such as pressure groups and opinion leaders all play a role in the formation of opinions, it is still not known exactly how public opinion on an issue takes shape. Many aspects of the public opinion process have yet to be explored. The same is true with regard to changes in public opinion. Some of these can be accounted for by changing events and circumstances, but others are more difficult to explain. It is known that public opinion on some subjects tends to follow events. Public attitudes toward other nations, for example, seem to depend largely on the relations between the governments of the two nations. Hostile attitudes do not cause poor relations; they are the result of them. People presumably change their attitudes when these attitudes do not correspond with their perception of prevailing circumstances and hence are not useful as guides to action. It is also frequently the case that an issue ceases to be important and simply fades from public attention, while new issues arise as the basis for new bodies of opinion. There are still, nevertheless, major changes in public opinion that are difficult to explain. During the second half of the 20th century in many parts of the world, attitudes toward religion, family, sex, international relations, social welfare, and the economy have undergone major shifts. There have been important issues claiming public attention in all these areas, but the changes in public opinion are difficult to relate to any major event or even to any complex of events.

PUBLIC OPINION AND GOVERNMENT

Many early thinkers saw public opinion as a powerful force that rulers must learn how to control. The 18th-century French philosopher Jean-Jacques Rousseau believed that all laws were based upon it but that this did not necessarily diminish the powers of government. It was Rousseau's opinion that "Whoever makes it his business to give laws

to a people must know how to sway opinions and through them govern the passions of men." The 19th-century German philosopher G.W.F. Hegel described public opinion as containing both truth and falsehood together and added that it was the task of the great man to distinguish the one from the other. Jeremy Bentham saw the greatest difficulty of the legislator as being "in conciliating the public opinion, in correcting it when erroneous, and in giving it that bent which shall be most favourable to produce obedience to his mandates."

At the same time, Bentham and some other thinkers believed that public opinion was a useful check on the authority of rulers. Bentham demanded that all official acts be given publicity, so that an enlightened public opinion could pass on them, as would a tribunal: "To the pernicious exercise of the power of government it is the only check." The British jurist and historian James Bryce, writing a century later, maintained that if government was based on popular consent, this would give a nation great stability and strength: "It has no need to fear discussion and agitation. It can bend all its resources to the accomplishment of its collective ends." Bryce did not, however, believe that mass opinion could or should dominate details of governmental policy, since most people did not have the leisure or inclination to arrive at a position on every question. Rather, the masses would set the general tone for policy, their sentiments leading them to take a stand on the side of justice, honour, and peace.

Those who worked to advance international understanding were particularly likely to invoke the power of public opinion. Both Bentham's "Plan for an Universal and Perpetual Peace" (1789) and Immanuel Kant's proposals in his essay "On Perpetual Peace" (1795) were based on the belief that public opinion is peace loving and that international peace can be sustained by it. Those who advocated establishment of the League of Nations after World War I also looked to world public opinion as the principal force that would sustain the League. Drafters of the charter of the United Nations Educational, Scientific and Cultural Organization (UNESCO) apparently had somewhat the same idea, noting that because the origins of war were to be found in the minds of the masses of men it was in the minds of men that the defenses of peace should be constructed.

Some scholars, while acknowledging the power of public opinion, warned that it could be a dangerous force. The 19th-century French writer Alexis de Tocqueville was concerned about the possible "tyranny of the majority" if government was in fact to be an expression of mass attitudes. Many other writers have expressed concern, often in a more extreme form, about the dangers of allowing government policy to be influenced too much by public opinion, which may well be uninformed, unthinking, and unstable. But whether public opinion is regarded as a constructive or a baneful force in a democracy, there are few politicians who are prepared to deny in public that government should follow public opinion.

In recent years, political scientists have been less concerned with what part public opinion should play in a democratic polity and have given more attention to establishing what part it does play in actuality. From the examination of numerous histories of policy formation, it is clear that no sweeping generalization can be made that will hold in all cases. The role of public opinion appears to vary from issue to issue, and the way it asserts itself differs from one democracy to another. The safest generalization that can be made is that public opinion does not influence the details of most policies but that it does set limits within which the policymaker must operate. That is, public officials will usually seek to satisfy a widespread demand, or will at least take it into account in their deliberations, and they will also try to avoid decisions that they believe will fly in the face of popular opinion. In addition, it has been observed that the relation between public opinion and public policy is two-way; policy influences opinion, as well as the reverse, and there is usually at least an initial tendency for the public to accept a decision once it is made. Public opinion seems to be particularly effective in influencing policymaking at the local level,

Public
opinion
as a
safeguard
against
abuse of
authority

An
assessment
of the
significance
of public
opinion

as officials appear to feel themselves constrained to yield to popular pressures for better roads, better schools, or more hospitals.

Public opinion at the national level seems to play a more limited role—partly because of the inability of most people to understand the complexities of most issues faced by government and partly because of the growth of executive power and the development of large governmental bureaucracies that serve as screens between the policy-maker and the public. Representative government itself also tends to limit the power of public opinion to influence specific decisions, since ordinarily the public is given the choice only of approving or disapproving the election of a given official.

PUBLIC-OPINION POLLING

Public-opinion polling can provide a fairly exact analysis of the distribution of opinions on almost any issue within a given population. Assuming that the proper questions are asked, polling can also reveal something about the intensity with which opinions are held, about the reasons for these opinions, and about whether or not the issues have been discussed with others. Polling does not usually reveal whether or not the people holding an opinion can be thought of as constituting a cohesive group, and it is unlikely to provide very much information about the elites who may have played an important part in developing the opinion. But in spite of these deficiencies, polling is a valuable tool for estimating the state of public opinion on almost any subject.

Origins of
opinion
research

Opinion research developed from market research. Early market researchers picked small samples of the population and used these to obtain information on such questions as how many people read a given magazine or listen to the radio and what the public likes and dislikes in regard to various consumer goods. About 1930, both commercial researchers and scholars began to experiment with the use of these market research techniques to obtain information on opinions about political issues. In 1935 the U.S. statistician George Gallup began conducting nationwide surveys of opinions on current political and social issues in the United States. One of the first questions asked by the Gallup Poll (its full name is the American Institute of Public Opinion) was “are Federal expenditures for relief and recovery too great, too little, or about right?” To this, 60 percent of the sample replied that they were too great, only 9 percent thought they were too little, and 31 percent regarded them as about right.

From the 1930s on, the spread of opinion polls conducted by both commercial and academic practitioners continued at an accelerated pace in the United States and, to a more limited extent, elsewhere. In 1937, the *Public Opinion Quarterly*, which later became the official organ of the American Association for Public Opinion Research, began publication. State and local polls, some sponsored by newspapers, were started in many parts of the country, and opinion research centres were organized at several universities. Before and during World War II, opinion polls were extensively used by U.S. government agencies, notably the Department of Agriculture, the Treasury Department, and the War Department.

At the same time, opinion research was increasingly used in other parts of the world. Several affiliates of the American Institute of Public Opinion were organized in Europe and Australia in the late 1930s, and following World War II polling organizations appeared in numerous countries of Europe, Asia, and Latin America.

Polls have been successful in forecasting election results in nearly every case in which they have been used for this purpose. The two most notable failures were in the United States in 1948, when nearly all polls forecast a Republican victory and the Democrats won by a narrow margin, and in Great Britain in 1970, when all but one of the major polls predicted a Labour Party victory and the Conservative Party achieved a majority. In both cases the major polls did not show large deviations from the actual results but nevertheless picked the wrong winner. Professional opinion researchers point out that predicting elections will always be chancy because of the possibility

of last-minute shifts and turnout problems; nevertheless, their record has been good over the years.

Although popular attention has been focussed on polls taken before major elections, most polling is devoted to other subjects, and university-based opinion researchers usually do not make election forecasts at all. Support for opinion studies comes largely from public agencies, foundations, and commercial firms, which are interested in such questions as how well people feel that their health, educational, and other needs are satisfied; how such problems as racial prejudice and drug addiction can be attacked; or how well a given industry is meeting public demands. Polls that are regularly published in newspapers or magazines usually have to do with some lively social issue—and elections are included only as one of many subjects of interest.

Methodology of opinion polling. The principal steps in opinion polling are the following: defining the “universe,” choosing a sample, framing a questionnaire, interviewing persons in the sample, tabulating the results, and analyzing or interpreting the results.

Universe is the term used to denote whatever body of people is being studied. This is not always easy to define precisely. If, for example, one is making a study of college-student opinion, it is necessary to decide whether the universe should include full-time students only or whether it should include those who are not candidates for established degrees. The way in which these questions are answered will have an important bearing on the outcome of the survey and possibly on its usefulness.

Once the universe has been carefully defined a sample of the universe has to be picked. If possible, a “probability sample” should be chosen. Ideally, the best way to do this would be to assign a number to each person in the universe—or write his name on a slip of paper—place all the numbered or named slips in a container, mix thoroughly, and then pick a sample without looking at the names or numbers. In this way, each slip will have the same probability of being chosen. If each person is numbered, the same effect can be achieved by using tables of random numbers, which can often be purchased in book form. The random numbers are matched up with the numbered members of the universe, until a sample of the desired size is drawn. The numbering procedure is often not practicable, but a few universes are already assigned numbers—all the workers in a given factory, for instance, or all members of the armed forces. It is not surprising that some of the most reliable opinion surveys have been conducted by the military.

Another method, not quite so reliable statistically, is to include every “*n*th” member of the universe in the sample. Thus, if one wishes to study the attitudes of the subscribers to a certain magazine and the magazine has 10,000 subscribers, one could take every 10th name from the subscription list and end up with a sample of 1,000.

Neither of these methods is likely to be useful when the universe consists of a large population that has not been numbered and when the names of members of the universe are not listed in a card file somewhere. This is the situation that was faced by market and opinion researchers when they first started conducting large-scale surveys. They therefore adopted the simpler device of picking a “quota sample.” In quota sampling, an effort is made to match up the characteristics of the sample with those of the universe, so that a small replica of the universe is achieved. If one knows, possibly on the basis of the most recent census, that there are 51 women to every 49 men in the universe, then the sample should reflect these proportions. The same principle should be applied with respect to age, income, education, occupation, religious preference, national origin, area of residence, and indeed every characteristic that might be relevant to the range of opinions being studied. Each interviewer is told the characteristics of the people that he must locate and interview.

Most survey organizations prior to 1948 used quota samples, and some still do. The British organization that correctly forecast the outcome of the 1970 parliamentary election used a quota sample, but it is, nevertheless, a risky technique. In many countries census data are poor

Quota
sampling

or nonexistent. Even when there are reliable census data, some characteristics that may affect the opinions being studied cannot be taken into account. It is not known, for example, how many vegetarians there are in most populations or how many extroverts and introverts. Yet these characteristics may be related to opinions on certain subjects. Statisticians point out that in a quota sample it is impossible to give each member of the universe a known chance of being selected, and one cannot therefore calculate the range of error in the results that could be due to chance. In this type of sample, furthermore, interviewers have to use their judgment in selecting respondents, and their standards may vary. The great advantage of a quota sample is that it is rather inexpensive to design and interview. By contrast, selecting and interviewing a probability sample from a large population can be very expensive.

How large a sample should be depends on the precision that is desired. For many purposes, a sample of a few hundred is adequate—if it is properly chosen. A magazine, for instance, might poll a random sample of 200 of its subscribers and find that 18 percent wanted more fiction and 62 percent wanted more articles on current social issues. Even if each of these figures were wrong by as much as 10 percentage points, the poll would probably still be of value since it would give fairly accurate information about the way the subscribers ranked the types of content. An election poll, on the other hand, would have to be much more accurate than this, since leading candidates often split the vote rather evenly. For most purposes, a national sample of about 1,500 cases is adequate unless it is desired to make comparisons among rather small subgroups in the population or to compare one small group with a much larger one. In such cases a larger sample is required in order that a significant number of members of the minority group may be included.

Allowances
for chance
and errors

There are no hard-and-fast rules for interpreting poll results, since there are many possible sources for bias or error. Nevertheless, for a well-conducted poll the following "rule of thumb" allowances for error are helpful. When any group of people is compared with another and the sample size of the smaller group is about 100, the difference between the percentages based on the two groups should be greater than 14 if this difference is to be regarded as significant. If the smaller group is larger than 100, the allowance for error caused by chance decreases approximately as follows: for a group comprising 200 cases, allow 10 percentage points; for 400 cases, allow 7 percentage points; for 800, allow 5; for 1,000, allow 4; for 2,000, allow 3. Thus, if a national sample survey shows that 27 percent of college students favour a volunteer army, while 35 percent of adults who are not in college do, and there are only 200 students in the sample, the difference between the two groups may well be due to chance. If the difference were greater than 10 percentage points, then it is much more likely that the opinions of students actually differ from those who are not in college. Similar allowances have to be made when election polls are interpreted. The larger the sample and the larger the difference between the number of preferences expressed for each candidate, the greater the certainty with which the election result can be predicted.

Even larger variations than those due to chance may be caused by the way the questions are worded. If one poll asks "Are you in favour of increasing government aid to higher education?" while another poll asks "Are you in favour of the president's (or premier's) recommendation that government aid to higher education be increased?" the second question is likely to receive many more affirmative answers than the first. Similarly, the distribution of replies will often vary if an alternative is stated. The question might be phrased: "Are you in favour of increasing government aid to higher education, or do you think enough tax money is being spent on higher education now?" In this form, it is probable that the question would receive fewer affirmative responses than if only the first half were used. As a rule, relatively slight changes in question wording do not cause great variations in response when people hold very strong opinions, but if their opinions are not firm then slight differences may sway them one way

or another. Opinion researchers therefore frequently ask exactly the same question over a period of years. In this way, the results from an earlier survey can more safely be compared with the results from a later one.

Questionnaire construction, as with sampling, requires a high degree of skill. The question must be clear to people of varying educational levels and backgrounds. Questions must not embarrass respondents. They must be arranged in a logical order and so on. Even experienced researchers find it necessary to pretest their questionnaires. They send out interviewers to interview a small sample with the preliminary questions, and they may revise these questions to ensure that they are unambiguous and are actually obtaining the information sought.

Poll questions may be of the "forced-choice" or "free-answer" type. In the former, a respondent is asked to reply "yes" or "no" or else may be given a list of prepared alternatives. Even so, many respondents are likely to reply "don't know" or to prefer an alternative that the researcher had not listed in advance. A free-answer question allows the respondent to state his opinion in his own words. For instance, "What do you think are the most important problems facing the country today?"

Interviewing is also a skilled operation. An inexperienced interviewer may bias a respondent's answer by the way he asks a question. He may antagonize some respondents so that they refuse to go on with the interview. He may not record the replies to free-answer questions accurately, or he may not be sufficiently persistent in locating designated respondents. Most large polling organizations give interviewers special training before they are sent out on surveys or else contract with an interviewing service that has trained and experienced interviewers available. A good sample and a well-tested questionnaire are not sufficient to guarantee an accurate survey if interviewing is slipshod.

Tabulation is usually done by machine. To simplify this process, most questionnaires are "precoded," which is to say that numbers appear beside each question and each possible response. The answers given by respondents can thus be translated rapidly into a numerical form that can be used in a computer. In the case of free-answer questions, responses must usually be grouped into categories, each of which is also assigned a number. How the categories are defined may make a large difference in the way the results are presented. If a respondent mentions narcotics addiction as a major problem facing the country, for instance, this answer might be coded as a health problem or a crime problem or might be grouped with other replies dealing with drug abuse or alcoholism.

The final steps in a survey are the analysis and presentation of results. Some reports present only what are termed marginals—the proportion of respondents giving certain answers to each question. If 40 percent favour one candidate, 50 percent another, and 10 percent are undecided, these figures are marginals. Usually, however, a number of cross tabulations are also given. These may show, for instance, that Candidate A's support comes disproportionately from Jewish groups, and Candidate B's, from Irish groups. Sometimes a cross tabulation will substantially change the meaning of survey results. A poll may seem to show that one candidate is the favourite of black voters and another of white voters. But if the preferences of poor respondents and well-to-do respondents are analyzed separately, it may turn out that Candidate A is actually supported by most poor people and Candidate B by most well-to-do people. The most important factor in determining voting intention may thus not be whether a respondent is white or black but whether he is well-to-do or poor.

In judging the overall reliability of a survey, it is advisable to scrutinize at least eight factors: (1) the identity of the sponsor and the past record of reliability of the organization conducting the poll; (2) the exact wording of the questions used; (3) the care with which the population sampled has been defined; (4) the size of the sample and the method by which it was chosen; (5) the "completion rate," or proportion of the sample that actually responded (this is especially important in mail polls, in which frequently fewer than half of those in the sample respond); (6) the degree to which particular results are based on

Importance
of careful

viewing

Assessing
a survey's
reliability

the whole sample or on small parts of it; (7) the way in which the interviewing was done (whether by telephone, mail, or face-to-face); and (8) the time that the survey was taken (intervening events frequently make people change their opinions).

Criticisms and justifications of opinion surveys. There have been many criticisms of public-opinion polling. Among these are that people are asked to give opinions on matters about which they are not competent to judge, that polling interferes with the democratic process, and that survey research causes annoyance and invasion of privacy.

It is often pointed out that most members of the public are not familiar with the details of complex policies such as those governing tariffs or missile defense systems. Therefore, it is argued, opinion researchers should not ask questions about such subjects. The results at best could be meaningless and at worst misleading, since respondents may be reluctant to admit that they are ignorant. Critics also refer to the fact that many people hold inconsistent opinions, as shown by the polls themselves. The same person may favour larger government expenditures and at the same time be opposed to higher taxes.

Poll takers usually acknowledge that these problems exist but maintain that they can be overcome by careful survey procedures and by proper interpretation of results. It is common for surveys to include "filter" questions, which help to separate those who are familiar with an issue from those who are not. Thus, the interviewer might first inquire: "Have you heard or read about the government's policy on the tariff?" Then the interviewer would ask only those who answered "yes" whether they were or were not in favour of the policy advocated by the government. Sometimes polls include factual questions that help to assess knowledge, such as "Can you tell me how the veto power in the United Nations Security Council works?" Furthermore, argue the researchers, if people are ignorant, or if they hold inconsistent opinions, this should be known. It is not possible to raise the level of information if areas of ignorance or inconsistency are not identified.

Critics allege also that election polls create a "bandwagon effect"—that people want to be on the winning side and therefore switch their votes to the candidates whom the polls show to be ahead. They complain that surveys undermine representative democracy, since issues should be decided by elected representatives on the basis of the best judgment and expert testimony—not on the basis of popularity contests. They point out that some well-qualified candidates may decide not to run for office because the polls indicate that they have little chance of winning and that a candidate who is far behind in the polls has difficulty in raising funds for campaign expenditures since few contributors want to waste money on a lost cause. Other candidates find out from polls what the public wants and merely pander to popular preferences rather than run on their convictions about what is best for the country.

Those engaged in election research usually concede that polls may dissuade some candidates and also may inhibit campaign contributions. But they also point out that candidates and contributors would have to make their decisions on some basis anyway. If there were no polls, other and less accurate methods would be used to test public sentiment; columnists and political pundits would still make forecasts. As far as the bandwagon effect is concerned, careful studies have failed to show that it exists.

An abuse that is recognized by both critics and poll takers is the practice of leaking to the press partial or distorted results from private polls. A politician may contract privately with a research organization and may then release only results for those areas in which he is ahead, or he may release old results without stating the time when the poll was taken, or he may conceal the fact that a very small sample was used and that the results may have a large margin of error.

Finally, critics aver that the proliferation of opinion polls and market research surveys places an unfair burden on the public. People may be asked to respond to questionnaires that take an hour or more of their time. Pollers may tie up their telephones or occupy their doorsteps for long periods, sometimes asking questions about private matters that are not suitable subjects for public inquiry. But insofar as public resistance to polling is concerned, researchers point out that the "refusal" rate in most surveys is rather low. Most people, in fact, seem to enjoy answering the questions. They also note that, with the use of small samples, it is unlikely that any one individual will be approached very often.

Legislation to deal with these and other problems of poll taking has been proposed in the United States, Britain, and a number of other countries; however, little legislation has been adopted. Survey researchers maintain that such abuses as exist should be dealt with by the profession and by educating the public to evaluate and criticize poll results, rather than by government regulation.

BIBLIOGRAPHY. There is no adequate history of public opinion in English. The best account is WILHELM BAUER, *Die öffentliche Meinung in der Weltgeschichte* (1929); see also HANS SPEIER, "Historical Development of Public Opinion," *American Journal of Sociology*, 55:376-388 (Jan. 1950); and P.A. PALMER, "The Concept of Public Opinion in Political Theory," in *Essays in History and Political Theory in Honor of Charles Howard McIlwain* (1936). General texts include: HARWOOD L. CHILDS, *Public Opinion* (1965); BERNARD C. HENNESSEY, *Public Opinion*, 4th ed. (1981); WILLIAM ALBIG, *Modern Public Opinion* (1956); NORMAN J. POWELL, *Anatomy of Public Opinion* (1951); and LEONARD W. DOOB, *Public Opinion and Propaganda*, 2nd ed. (1966). Classic treatments of public opinion include: JAMES BRYCE, *The American Commonwealth*, vol. 2 (1888); A. LAWRENCE LOWELL, *Public Opinion and Popular Government*, rev. ed. (1926, reprinted 1969); A.V. DICEY, *Lectures on the Relation of Law and Public Opinion in England During the Nineteenth Century* (1914, reissued 1981); and WALTER LIPPMANN, *Public Opinion* (1922, reissued 1976). Historical approaches to the study of public opinion are explored in a special issue of the *Public Opinion Quarterly*, vol. 31, no. 4 (Winter 1967-68).

The nature and patterns of formation of public opinion in the United States are dealt with in G.A. ALMOND, *The American People and Foreign Policy* (1950, reprinted 1977); and in GLADYS E. LANG and KURT LANG, *The Battle for Public Opinion: The President, the Press, and the Polls During Watergate* (1983). Excellent use of poll data is made in V.O. KEY, JR., *Public Opinion and American Democracy* (1961). STANLEY KELLEY, JR., *Professional Public Relations and Political Power* (1956), presents fascinating case histories of the manipulation of public opinion. Principal election studies, which reveal a great deal about public opinion, include: PAUL F. LAZARSFELD, B. BERELSON, and H. GAUDET, *The People's Choice* (1944; 3rd ed., 1968); B. BERELSON, PAUL F. LAZARSFELD, and W.H. MCPHEE, *Voting* (1954); ANGUS CAMPBELL et al., *The American Voter* (1960, reprinted 1980); HAROLD MENDELSON and GARRETT J. O'KEEFE, *The People Choose a President: Influences on Voter Decision Making* (1976); and THOMAS E. PATTERSON, *The Mass Media Election: How Americans Choose Their President* (1980). Diffusion of information and opinion leadership is discussed in ELIHU KATZ and PAUL F. LAZARSFELD, *Personal Influence* (1955). An analysis of the process by which public opinion is formed, based largely on surveys conducted in West Germany, is ELISABETH NOELLE-NEUMANN, *The Spiral of Silence* (1984). Two excellent expositions of sampling method are FREDERICK F. STEPHAN and P.J. MCCARTHY, *Sampling Opinions* (1958, reprinted 1974); and MORRIS H. HANSEN, W.N. HURWITZ, and W.G. MADOW, *Sample Survey Methods and Theory*, 2 vol. (1953). Detailed treatments of the conduct of surveys may be found in HERBERT H. HYMAN, *Interviewing in Social Research* (1954, reissued 1975), and *Survey Design and Analysis* (1955). M. KENT JENNINGS, *Generations and Politics* (1981), studies the effect of political socialization on behavioral and attitudinal change; JAMES B. LEMERT, *Does Mass Communication Change Public Opinion After All?* (1981), is a thorough analysis of the effect of mass media on opinion and the nonelectoral effect of public opinion on policymakers.

bandwagon
effect

Public Works

The concept of public works—government-sponsored fixed works constructed for public utility, convenience, or enjoyment—is one of the oldest elements of civilization. Networks of waterways and roads were the lifelines of the ancient empires. Modern public works are indispensable to industry, commerce, and even health and provide citizens with facilities and improvements unavailable or unaffordable through the private sector.

ROADS AND HIGHWAYS

The terms road and highway define those travelled ways on which wheeled vehicles, carriage animals, and men on foot have moved throughout recorded history. The most ancient name for these arteries of travel seems to be the antecedent of the modern "way." Way stems from the Middle English *wey*, which in turn branches from the Latin *veho* ("I carry"), derived from the Sanskrit *vah* ("carry," "go," or "move"). The word highway goes back to the elevated Roman roads that had a mound or hill formed by earth from the side ditches thrown toward the centre, thus "high" "way." The more recent road derived from the Anglo-Saxon *rad* ("to ride") and the Middle English *rode* or *rade* ("a riding or mounted journey"). In modern usage highway refers to a rural travelled way as contrasted with the urban "street" derived from the Latin *strata via* ("a way paved with stones"). The word road is more generally used today to describe lesser travelled ways in rural areas, primarily those carrying small amounts of traffic or being of minor importance. In more recent years the terms freeway, expressway, and motorway and similar terms in other languages (*autobahn*, *autostrada*) have come into use to describe highways in both urban and rural areas for which there is full control of access. On these facilities points of entrance and exit for traffic are limited and strictly controlled.

This article is concerned with the development of major road and highway systems of the world. It reviews the major elements of highway building from financing to final construction and including the activities essential to the operation and maintenance of the system.

History

ROADS OF ANTIQUITY

The first road builders probably practiced their art in southwestern Asia in the area bounded by the Black and Caspian seas, the Mediterranean Sea, and the Persian Gulf. People migrated east, west, north, and south from this area; presumably in their earliest travels they recognized the necessity of improving their paths and trails to facilitate the movement of their draft animals; this made the beginnings of trade possible. The first artificial roadways may have been constructed by levelling the high ground, filling the hollows, and transferring earth from the edges of the pathway to the centre, thus forming side ditches and providing for drainage.

Wheeled vehicles were probably first developed in a broad, roughly trapezoidal area with its longer base extending from north of the Black Sea to the Caspian and its shorter base the northern end of the Persian Gulf, with Lake Van in eastern Asia Minor as the centre. The earliest wheeled vehicles have been found within 600 miles (966 km) of the lake. The oldest archaeological evidence indicates that the wheeled vehicle came into existence somewhat earlier than 3000 BC. The earliest of these were probably two-wheeled wooden carts built by the Sumerians in the forested regions south of the Caucasus and Taurus mountains. Four-wheeled vehicles with draft poles recently found north of the Caucasus Mountains in the U.S.S.R. date from about 2400 BC. The wheeled vehicle apparently was taken westward into Europe by people who travelled up the Danube River and north to the Balkans where there is evidence for wheeled vehicles going back beyond 2000 BC (see TRANSPORTATION: *Pre-industrial transportation*).

During the Bronze Age, the development of agriculture and trade, facilitated by the domestication of the horse, marked the beginning of civilization. Trade required better roads. The first serious road builders probably were the Mesopotamians, who developed a travel route from the Babylonian Empire west and southwest to Egypt. Processional roads (700–600 BC) connecting the temples and palaces (Figure 1A) of the ancient cities of Assur, Babylon, and Tall al-Asmar were paved roadways in which burnt brick and stone were lain in bituminous mortar.

Such roads, while they did not serve the normal needs of caravan traffic, may have been the forerunners of the Roman system.

The oldest road. The modern highway systems are a natural outgrowth of the ancient road systems. The earliest long-distance road, in use from approximately 3500 to 300 BC was the Persian Royal Road, which began at Susa

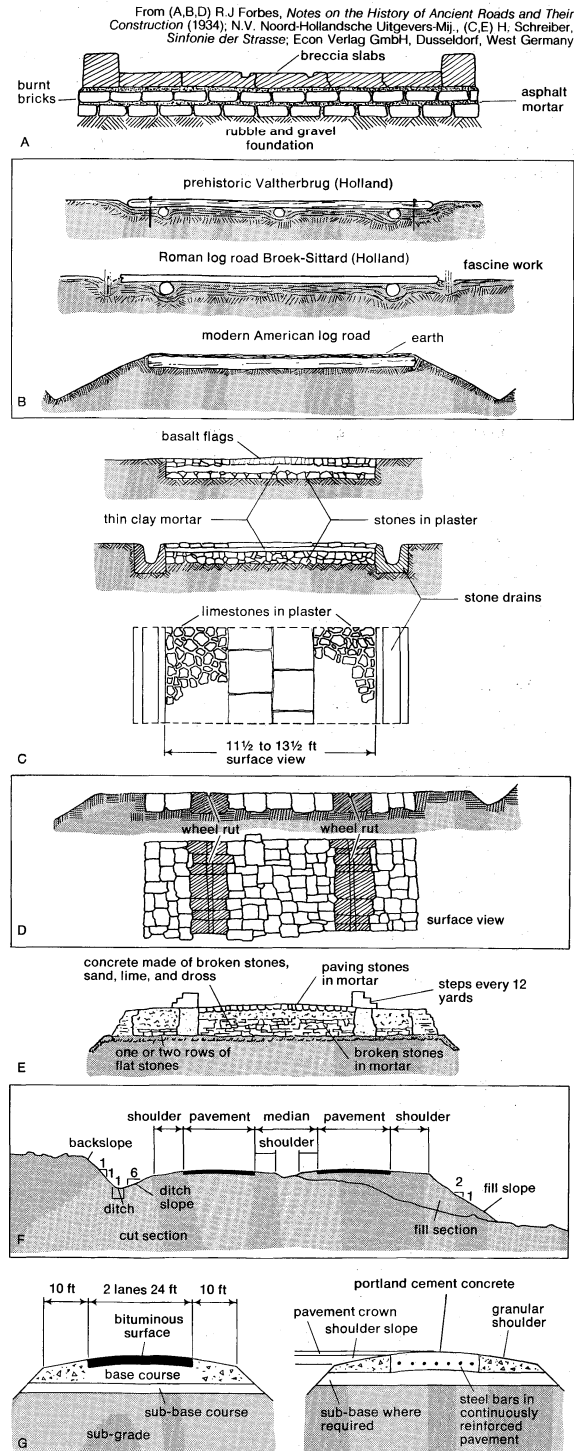

Figure 1: Cross sections of representative ancient and modern road and highway constructions (see text).

The role of trade in growth of roads

near the Persian Gulf, wound northwestward to Arbela and thence westward through Nineveh to Harran, a major road junction and caravan centre. The main road then continued northwestward to Samosata (modern Samsat) where it crossed the Euphrates River, and westward to Boğazköy, the capital of the Hittite kings. From there travellers journeyed westward to Ancyra (modern Ankara) and Sardis where the road divided to twin termini at Smyrna and Ephesus. A branch went south from Harran through Palmyra, Damascus, Tyre, and Jerusalem to Memphis (Cairo) and another went westward from Harran to Tarsus, thence south to Caesarea and Tyre. From Susa an alternate route went westward to Ur and thence north through Babylon and Assur to Nineveh. From Boğazköy one could travel northward to the Black Sea. The overland distance from Susa to Smyrna was 1,775 miles (2,857 kilometres), and Herodotus, writing in about 475 BC, put the time for the journey at 93 days.

"Amber Routes" of Europe. The earliest roads in Europe were the "Amber Routes" probably used between 1900 and 300 BC by Etruscan and Greek traders to transport amber and tin from the north of Europe to points on the Mediterranean and Adriatic. Four routes have been identified, the first from modern Hamburg southwestward by dual routes through Cologne and Frankfurt to Lyon and Marseille. The second also passed from Hamburg south to Passau on the Danube and then through the Brenner Pass to Venice. The third began at Samland on the East Prussian Coast (where amber is still found), crossed the Vistula River at Thorn, and thence continued southeastward through the Moravian Gate to Aquileia on the Adriatic. The fourth, the Baltic-Pontus road, followed the main eastern rivers, the Vistula, Saw, Sereth, Prut, Bug, and Dnieper. While these were not roads in the modern sense, they were improved at river crossings and over the mountain passes. In the same time period, evidence indicates, log roads (Figure 1B) were constructed extensively in northern Europe (modern The Netherlands, Germany, Poland, Latvia, Sweden, and White Russia) to carry traffic across wet and swampy areas. These roads were constructed by laying two or three strings of logs in the direction of the road on a bed of branches and boughs up to 20 feet (6 metres) wide and covering them with transverse logs 9 to 12 feet (2.7–3.6 metres) in length laid side by side. In the best log roads, every fifth or sixth log was fastened to the underlying subsoil with pegs. There is evidence that the older log roads were built prior to 1500 BC. The roads were maintained in a level state by covering with sand and gravel or sod, and the Romans used side ditches to reduce the moisture content and increase the carrying capacity.

Imperial roads of China. The ancient road system of China, which paralleled in time the Royal Road, was a substantial and remarkable system. The Imperial roads played the same role in southeastern Asia as the Roman roads in Europe and Asia Minor. Many of the Chinese roads were wide, well built, and surfaced with stone; rivers were crossed by bridges or well-managed ferries; steep mountains were traversed by stone-paved stairways with broad treads and low steps. The Imperial road system, about 2,000 miles (3,200 kilometres) in total length, radiated from Sianfu, Nanking, and Ch'eng-tu. Except for short periods of time, however, the roads of China were not adequately maintained and fell into disrepair; it was said that in China a road was good for seven years and then bad for 4,000 years. Chinese roads differed markedly from the Roman roads in their crookedness, particularly in hilly areas.

Early roads of Malta and Crete. Unique "rut" roads were built on the island of Malta probably about 2000 to 1500 BC. These consisted of two V-shaped grooves about 4½ feet (1.35 metres) apart cut into the coral sandstone of the island. The roads apparently were traversed by carts, drawn by human power, with the wheels running in the grooves. During the Minoan civilization on the island of Crete (3000 to 1100 BC), a road (Figure 1C) was built from Gortyna on the south coast over the mountains at an elevation of about 4,300 feet (1,300 metres) to Knossos on the north coast. Constructed of layers of stone, the

roadway took account of the necessity of drainage by a crown throughout its length and even gutters along certain sections. The pavement was about 12 feet (3.6 metres) wide and the central portion consisted of two rows of basalt slabs two inches (50 millimetres) thick. The centre of the roadway seems to have been used for foot traffic and the edges for animals and carts. Guard houses were located at frequent intervals along the road.

India. The Indus civilization in Sindh, Baluchistan, and the Punjab probably flourished in the period 3250–2750 BC. Excavations indicate that the cities of this civilization paved their major streets with burned bricks cemented with bitumen. Great attention was devoted to drainage. The houses had drain pipes that carried the water to a street drain in the centre of the street, two to four feet (about a metre) deep and covered with slabs or bricks.

Evidence from archaeological and historical sources indicates that by AD 75 several methods of road construction were known in India. These included the brick pavement, the stone slab pavement, a kind of concrete as a foundation course or as an actual road surface, and the principles of grouting (filling crevices) with gypsum, lime, or bituminous mortar. Street paving seems to have been common in the towns in India at the beginning of the Christian era and the principles of drainage were well known. The crowning of the roadway and the use of ditches and gutters was common in the towns. Northern and western India in the period 300 to 150 BC had a network of well-built roads. The rulers of the Maurya Empire (4th century BC), which stretched from the Indus to the Brahmaputra and from the Himalayas to the Vindhya Range, generally recognized that the unity of a great empire depended on the quality of their roads. The Great Royal Road of the Mauryans began at the Himalayan border, ran through Taxila (near modern Rawalpindi), crossed the five streams of the Punjab, and continued by way of Jumna to Prayag (now Allahabad). A "Ministry of Public Works" was responsible for construction, marking, and maintenance of the roads and rest houses and for the smooth running of the many ferries that carried the Royal Road across the wide rivers.

Egypt and Greece. Although Herodotus credits the Egyptians with building the first roads to provide a solid track upon which to haul the immense limestone blocks used in the pyramids, archaeological evidence indicates that road-building technology travelled southwest from Asia toward Egypt. The wheel arrived in Egypt at the relatively late date of about 1600 BC. There is little evidence of street surfacing in ancient Egyptian towns, though there is evidence of the use of paved processional roads leading to the temples. The ancient travel routes of Egypt ran from Thebes and Coptos on the central Nile east to the Red Sea and from Memphis (Cairo) across the land bridge to Asia Minor.

The early Greeks depended primarily on sea travel. There is evidence of the building of special roads for religious purposes and transport about 800 BC, but there is little evidence of substantial road building for travel and transport prior to the Roman system. The Greeks built a few ceremonial, or "sacred," roads, paved with shaped stone and containing wheel ruts (Figure 1D) about 55 inches (1.4 metres) apart, very similar to those built in Malta at a much earlier date.

Roman roads. The first scientific road builders were the Romans. By the peak of the Empire the Romans had built nearly 53,000 miles (85,000 kilometres) of road connecting the capital with the frontiers of the far-flung empire. Twenty-nine great military roads, the *viae militares*, radiated from Rome. The most famous of these was the Apian Way, started in 312 BC, following the Mediterranean coast south to Capua, then turning eastward to Beneventum, where it divided into two branches, both reaching Brundisium (Brindisi). From Brundisium the Apian Way traversed the Adriatic coast to Hydruntum, a total of 410 miles (660 kilometres) from Rome.

There are differences of opinion concerning the origin of the Roman road-building methods, but the consensus credits the Etruscans of northern Italy as Rome's principal teachers, though the Cretans, Carthaginians, Phoenicians, and Egyptians probably also contributed.

Roman
road-
building
practice

Roman roads were remarkable for preserving a straight line from point to point regardless of obstacles. They were carried over marshes, lakes, ravines and mountains, and by their bold conception, they have excited the admiration of modern engineers. In its highest stage of development the Appian Way was constructed by excavating parallel trenches about 40 feet (12 metres) apart to mark its exact location and to indicate the nature of the subsoil (Figure 1E). The foundation was then covered with a light bedding of sand or mortar on which four main courses were constructed; (1) a *statumen* layer of large flat stones 10 to 24 inches (250–600 millimetres) in thickness; (2) a *rudus* course of smaller stones mixed with lime about 9 inches (225 millimetres) thick; (3) the *nucleus* layer, about one foot (300 millimetres) thick, consisting of small gravel and coarse sand mixed with hot lime; and (4) on this fresh mortar a *summa crusta*, or wearing surface, of flint-like lava about six inches (150 millimetres) deep. The total thickness thus varied from 3 to 5 feet (0.9 to 1.5 metres). The width of the Appian Way in its ultimate development was 36 Roman feet (35 English feet or 10.5 metres). The two-way central lane, heavily crowned, was 15½ feet (4.7 metres) wide flanked by curbs 2 feet (0.6 metre) wide and 18 inches (0.45 metre) high on each side and paralleled by one-way side lanes 7¾ feet (2.3 metres) wide. This massive Roman road section adopted about 300 BC set the standard of practice for the next 2,000 years.

Classes of
Roman
roads

The public transport of the Roman Empire was divided into two classes: (1) *Cursus rapidi*, the express service and (2) *agnarie*, the freight service. In addition there was an enormous amount of travel by private individuals. The most widely used vehicles were the two-wheeled chariot drawn by two or four horses and its companion, the cart used in rural areas. A four-wheeled *raeda* in its passenger version corresponded to the stage coaches of a later period and in its cargo version to the freight wagons. Fast freight *raedae* were drawn by eight horses in summer and ten in winter and, by law, could not haul in excess of 1,000 Roman pounds or 330 kilograms. Speed of travel ranged from a low of about 15 miles (24 kilometres) per day for freight vehicles to 75 miles (120 kilometres) per day by speedy post drivers.

The Silk Road. The trade route from China to Asia Minor and India, known as the Silk Road, had been in existence for 1,400 years at the time of Marco Polo's travels (c. AD 1270–90), but during this entire period incessant warfare and raiding by the Mongols and other nomads had kept it closed to traffic for all but 400 years. At its zenith in AD 200 this road and its western connections over the Roman system constituted the longest road on earth. The extreme western terminal of the Silk Road was at Gades (modern Cadiz, Spain) on the Atlantic Ocean; thence it ran northeastward across the Pyrenees north of Tarraco (modern Tarrasa) and around the shore of the Mediterranean through Genoa to Rome; from Rome south the road followed the Appian Way to Brundisium, where merchants took ship across the Adriatic, picking up the road again to cross the Balkan Peninsula to Byzantium (Istanbul) and continue southeastward through Antioch to Rhagae (near modern Tehrān) thence westward through Meshed, Bokhara, and Samarkand to Ferghana (Ush, the stone tower). From Ferghana the road traversed the valley between the Tien Shan and Kunlun Mountains through Kashgar where it divided and skirted both sides of the Takla Makan Desert to join again at Ansi. The road then wound eastward to Chia-yü-kwan (Su-chou) where it passed through the westernmost (Jade Gate or Yumen) gateway of the Great Wall of China. It then went southwest on the Imperial Highway to Sian and eastward to Shanghai on the Pacific Ocean. The Silk Road and its western connections bounds a globular rectangle 20° of latitude in height and 128° of longitude in breadth, a travel distance of 8,000 miles (12,800 kilometres) from Cadiz to Shanghai, for more than 2,000 years the longest road on earth. From Ferghana trade routes to the South passed over the mountains to the great trading centre of Bactria and to northern Kashmir.

Decline of roads: AD 200–1800. At the zenith of the

Roman Empire overland trade joined the cultures of Europe, North Africa, Asia Minor, China, and India. But the system of road transport was dependent on the Roman, Chinese, and Mauryan empires, and as these great empires declined in the early Christian era the trade routes became routes of invasion. The road networks nearly everywhere fell into centuries of disrepair. Transport wagons gave way to pack trains, which could negotiate the badly maintained roads and sufficed to carry the reduced stream of commerce. Eventually a commercial revival set in; by the 12th century old cities were reviving and new ones were being built, especially in western Europe. Some of the larger towns paved their principal streets. There was an awakened interest in better overland travel, better protection of merchants and other travellers, and the improvement of roads. Public funds, chiefly derived from tolls, were committed to road upkeep. The *corvée*, or road-labor tax, made an even more substantial contribution. Long-distance overland commerce increased rapidly and included a restoration of the trade route between Europe and China through Central Asia that Marco Polo travelled in the late 13th century.

During the 14th century the Black Death and other disasters brought a slowdown. During the 15th and 16th centuries street paving became more popular and wheeled vehicles increased in number and quality.

Inca roads of South America. Across the Atlantic, the period witnessed the rise of another notable road-building empire, that of the Incas. The Inca road system, extending from Quito, Ecuador, to points south of Cuzco, Peru, consisted of two parallel roadways, one along the coast about 2,250 miles (3,600 kilometres) in length, the other following the Andes about 1,650 miles (2,640 kilometres) in length with a number of cross connections. At its zenith when the Spaniards arrived early in the 16th century, it served an area of about 750,000 square miles (1,940,000 square kilometres) in which lived nearly 10,000,000 people. Some of the original Inca system was still in use in the 1980s. The Andes route was remarkable. The roadway was 25 feet (7.5 metres) wide and traversed the loftiest ranges with cutbacks and easy gradients. It included galleries cut into solid rock and retaining walls built up for hundreds of feet to support the roadway. Ravines and chasms were filled with solid masonry and suspension bridges with wool or fibre cables crossed the wider mountain streams. The surface was of stone in most areas and asphaltic materials were used extensively. The steeper gradients were surmounted by steps cut in the rocks. Traffic consisted entirely of pack animals (llamas) and people on foot; the Incas lacked the wheel. Yet they operated a swift foot courier system and a visual signalling system along the roadway from watchtower to watchtower. Interestingly, Inca roads resemble those of ancient China, which, it has been suggested, may indicate a direct cultural influence.

route

THE BIRTH OF MODERN ROAD BUILDING

The 17th and 18th centuries saw crude carts and wagons operating over rough, unimproved roads give way to regularly scheduled common-carrier stagecoaches and freight wagons running on stone-surfaced toll roads. The first engineering school in Europe, *École des Ponts et Chaussées* (the School of Bridges and Highways), was founded in Paris in 1747. Late in the 18th century Adam Smith in discussing conditions in England wrote,

Good roads, canals, and navigable rivers, by diminishing the expense of carriage, put the remote parts of the country more nearly upon a level with those in the neighbourhood of a town. They are upon that account the greatest of all improvements.

In the last half of the 18th century the fathers of modern road building appeared in France and England.

Up to this time the roads built had utilized, with minor modifications, the very heavy Roman cross section. In France in 1764, Pierre-Marie-Jérôme Trésaguet, an engineer from an engineering family, became engineer of bridges and roads at Limoges and, in 1775, inspector general of roads and bridges for France. In that year he developed an entirely new type of relatively light road surface, based on the theory that the subsoil, rather than

the surface should support the load. His standard section, 10 inches (250 millimetres) thick, consisted of a course of uniform stones laid edgewise covered by a layer of walnut-sized broken stone. The roadway crown rose six inches (150 millimetres) in its 18-foot (5.4 metres) width and had a uniform cross section.

John Metcalf, the first of England's pioneer road builders, was a contemporary of Trésaguet. Born in 1717, he was blinded by smallpox at the age of six, but became an expert climber, horseman, and swimmer. About 1754 he launched a stagecoach route between Knaresborough and York and in 1765 built a portion of the turnpike authorized between Harrogate and Boroughbridge. Over the next 37 years he built more than 180 miles (290 kilometres) of English turnpike roads and bridges. In his road building he emphasized the use of ditches for adequate drainage and special precautions for distributing the load by using baled brush as a subbase in marshy areas.

Thomas Telford, born of poor parents in Dumfriesshire, Scotland, in 1757, was apprenticed to a stone mason; intelligent and ambitious, he progressed to designing bridges and building roads. His Carlisle-Glasgow road was considered the finest road ever built up to that time (1816). Telford placed great emphasis on two features: (1) maintaining a level roadway with a maximum gradient of 1 foot in 30 feet and (2) building a stone-surfaced roadway capable of carrying the heaviest anticipated loads. His roadways were 18 feet (5.4 metres) wide, crowned only four inches (100 millimetres) and built in two courses, a lower course of 7 inches (175 millimetres) consisting of good quality stone carefully placed by hand (Telford base) and a second layer consisting of 7 inches of broken hardstone of 2½ inch (62.5 millimetres) maximum size and a layer of gravel one inch (25 millimetres) thick.

The
work of
McAdam

John Loudon McAdam, born in 1756 at Ayr, Scotland, began his road-building career in Bristol, then the second city in England. The roads surrounding Bristol were in poor condition and in 1816 McAdam, chosen general surveyor of the Bristol municipality, had an opportunity to test his theory that road building could be reduced to a science based on fundamental principles. Like Trésaguet, he believed that a well-drained, compacted subgrade should support all the load while the stone surfacing should act only as a wearing surface and a roof to shed water. There is evidence that McAdam was indebted to others for many of his ideas. McAdam insisted on a roadway with adequate side ditches and a subgrade elevated above the surrounding ground surface and compacted with a crown of 3 inches (75 millimetres) in 18 feet (5.4 metres) to drain surface water rapidly. He believed that 10 inches (250 millimetres) of surfacing was adequate for any load of his time. His stone surfacing utilized two-inch (50-millimetre) maximum size stone laid in loose layers and compacted under traffic. Weak spots were detected and replaced before the next layer was placed. Compaction under the wheeled traffic of the early 1800s proved to be very effective. McAdam's remarkable success was, however, due in large measure to his efficient system of administration.

By 1820 Britain had 125,000 miles (200,000 kilometres) of road, of which 20,000 miles (32,000 kilometres) were turnpikes. By 1836, 3,000 coaches operated on these roads; the rapid development of the railroads, however, brought road building virtually to a halt. Roadway improvements for the next 60 years were essentially confined to city streets.

Continental Europe and the U.S. had road-building histories virtually identical to Britain's, with a period of rapid construction of the new lightweight Trésaguet-McAdam type of roads followed by a sudden halt as railroads intruded on the transportation scene. The first engineered and planned road built in the United States was a privately constructed toll turnpike from Philadelphia to Lancaster, Pennsylvania, built between 1793 and 1794 at a cost of \$465,000. Its 62-mile (100 kilometres) length with 9 tollgates was surfaced with broken stone and gravel with maximum grades of 7 percent. The Cumberland Road, also known as the National Pike, was an even more notable road-building feat. It opened for traffic between Cumberland and Wheeling, West Virginia, in 1818, and

to Springfield, Ohio, and part of the way to Vandalia, Illinois, in 1838; total cost was about \$6,825,000. The road was maintained by government appropriations and by tolls collected by the states. Specification requirements called for a 66-foot (20 metres) right-of-way completely cleared. The roadway was to be covered 20 feet (6 metres) in width with stone 18 inches (450 millimetres) deep at the centre and 12 inches (300 millimetres) deep at the edge, the upper 6 inches (150 millimetres) was to consist of broken stone of 3-inch maximum size and the lower stratum of stone of 7-inch maximum size.

During the period 1840 to 1910, the era of railroad building all over the world, country roads everywhere remained virtually impassable in wet weather. The initial stimulus for a renewal of road building came not from the automobile, whose impact was scarcely felt before 1900, but from the bicycle, for whose benefit road improvement began in many countries during the 1880s and 1890s. Though the requirements of the lightweight, low-speed bicycle were satisfied by the old "macadamized" surfaces as the world entered the 20th century, the horseless carriage rather quickly rendered this type of road obsolete.

The responsibility for financing and building roads and highways has been both a local and a national responsibility of the nations of the world during many centuries. It is notable that this responsibility has changed along with political attitudes toward road building. English road building, for example, for centuries remained entirely local despite clear evidence that local responsibility was not providing adequate roads. Local authorities and private turnpike trusts dominated both British road building and maintenance throughout the 19th century, though the national government edged into the picture through increasing grants of funds, climaxed by the establishment in 1909 of a national Road Board authorized to construct and maintain new roads and to make advances to highway authorities to build new or improve old roads.

Except for the National Pike, early highway building in the United States was also carried on by local government. Toll roads, variously surfaced, were constructed in the first half of the 19th century under charters granted by the states. The Congress made a number of land grants for the opening of wagon roads but exercised no control over the expenditure of funds and, as in Britain, little road building was accomplished. Road labour to satisfy taxes was both unpopular and unproductive.

Road
administra-
tion and
financing

The automobile road

BASIC PROBLEMS

The automobile, and a little later the heavy truck, introduced totally new requirements for road and highway construction. Vehicle speeds increased rapidly; roadway alignment suitable for horse and buggy travel was completely inadequate, as were road surfaces, whose stones were torn loose by the heavily loaded tires. The early trucks, built with solid rubber tires, carried gross loads of 12,000 to 14,000 pounds (5,400–6,300 kilograms), which by the close of World War I had risen to 28,000 pounds (12,600 kilograms). The development of the pneumatic tire substantially reduced the destructive effect of truck loading on thin pavements intended for horse and buggy, but it was obvious that much stronger surfacing was required. Loads continued to increase, to gross weights of 40,000 pounds (18,000 kilograms) on tandem axles.

In western Europe and the United States, the world's principal automobile-using areas, approximately half of the total vehicle mileage travelled was travelled in urban areas. There was substantial amount of long distance travel both for business and pleasure, and the tonnage of intercity freight carried by trucks was increasing steadily, bringing a powerful demand for direct, long-distance express routes, including suitable links and bypasses in the metropolitan areas. In the late 1960s and early '70s increasing attention was being turned to the problem of safety in design of highways and their auxiliary equipment.

Highway planners and designers have had to take into account the speed and operating characteristics of the motor vehicles, wheel or axle loads, and the density and

Classifica-
tion and
design
standards

composition of vehicles in the traffic stream, as well as the safety, comfort, and convenience of the travelling public.

Depending upon the volume of traffic, composition of traffic, and major purpose, roads and highways may be divided into four functional classifications: (1) local roads and city streets; (2) collector and feeder roads, and secondary rural highways; (3) primary highways that carry relatively high volumes of traffic between population centres; and (4) expressways that serve major traffic flows.

In order to have reasonable uniformity in a given jurisdiction, design standards are usually established for each functional classification, taking into account the type of terrain in which the road or highway will be built (or rebuilt) classified as flat, rolling, or mountainous. Design standards are usually established on the basis of average daily traffic volumes, and it is common practice to set both a minimum standard and a desirable standard (Figure 1F). Design standards commonly provide for a right of way width, the speeds for which the roadway is to be designed, maximum permissible sharpness of horizontal curves, maximum permissible vertical gradient in feet rise per 100 feet of horizontal distance, minimum width of roadway and surfacing (pavement), minimum nonpassing sight distance (the distance a driver a normal distance above the roadway can see an object six inches [150 millimetres] high on the roadway ahead), and the clearance and capacity of bridges. For the two higher functional classifications most nations have governmental or quasigovernmental agencies that establish design standards.

TYPES OF PAVEMENT

Pavements were first developed for use on city streets. The earliest city pavements were stone block, wood block, vitrified brick, and bitumen (*e.g.*, natural asphalt). The first bituminous pavement was laid in Paris in 1854 using a natural rock asphalt from Switzerland. The first portland cement concrete pavement was built in Inverness, Scotland, in 1865. At the beginning of the automobile era rural road surfacing, where it existed, consisted of broken stone or gravel. Such roads were too rough and dusty, and inadequate in strength for automobile traffic.

Highway pavement may be defined as the portion of the highway cross section above the natural earth or subgrade. Figure 1G illustrates a typical pavement cross section for a divided highway in a rural area and the elements (surfacing, base, and subbase) that make up the cross section. In some pavement sections not all of the three elements will need to be used and in others a given element may consist of several layers of differing materials.

Flexible pavement. Pavements are divided into two types: flexible and rigid. A flexible pavement consists of base and subbase layers of natural aggregate materials (sand and gravel), or crushed stone, and a surfacing of aggregates mixed with a bituminous material, commonly an asphalt extracted from petroleum or coal tar. In some areas of the world natural mixtures of asphalt and rock, called "rock asphalts," occur; these make excellent surfacing materials. Base and subbases for flexible pavements may also be made of "stabilized materials," in which natural soils or poor quality sand and gravel are mixed with such materials as lime, portland cement, chemicals, asphaltic oils, and coal tars in order to increase the strength of these materials and reduce their susceptibility to loss of strength with increasing moisture contents. The terms soil-lime or lime stabilization, soil-cement or cement stabilization, soil-asphalt or asphalt stabilization are used to refer to mixtures of this type. Beneficial effects can be obtained in many cases by mixing two soils, or a soil and an aggregate, together to instill the good qualities of both in the finished mixture.

The surfacing portion of a flexible pavement may be produced by a range of processes that yields surfaces of varying texture, thickness, strength, and quality. The major processes described below are the surface treatment, macadam, mixed-in-place, and plant-mix types. The latter three processes are used for both the base and surfacing portions of the pavement structure.

Surface treatment. In this installation the pavement is placed over a completed, compacted base course. The first

step is to cover the base course with a thin asphaltic oil or tar sprayed on in sufficient quantity to fill cracks and crevices in the base without leaving excess oil or tar on the surface. After this prime coat has penetrated, the area is sprayed with a harder asphaltic oil or tar and covered with a layer of uniform-size gravel or stone chips, which is rolled to seat it in the bituminous material. A second, third, and even fourth layer of oil and stone may be applied to increase the pavement thickness. Surfacing so constructed are called single, double, triple, and quadruple surface treatments. Such surfaces are adequate for low volumes of traffic particularly in relatively arid climates.

Macadam construction. In this type of construction the surfacing is constructed by placing a layer of uniform size crushed stone or gravel in the size range of one inch (25 millimetres) to three inches (75 millimetres) on the completed and compacted base course. The layer thickness is somewhat greater than the maximum-size aggregate used. The stone layer is thoroughly compacted and is then bound together by one of several processes. In water-bound macadam a layer of stone screenings is worked into the surface by rolling, after which the surface is sprinkled with water and rolling is continued; the stone dust-water mixture forms a natural cement to bind the stone together. Water-bound macadam will not stand the abrasive effects of modern traffic and is seldom used today except for base courses. In penetration macadam, also referred to as asphalt or tar macadam (tarmac), the stone is impregnated with a substantial quantity of semisolid asphalt cement or tar heated to fluid temperature and sprayed into the compacted stone. A layer of stone of such size as to fill the interstices in the first course is then rolled on. If the penetration macadam is the surfacing, it is completed with the application of a single surface treatment. In cement-bound macadam a cement-sand slurry is worked into the interstices of the compacted stone to provide the necessary cementing action.

Mixed-in-place surfacing. Mixed-in-place (road-mix) surfacing involves mixing aggregates in the roadway cross section with bituminous or other cementitious materials in order to obtain watertight and stronger surfaces. This kind of processing is used extensively for base courses and to a limited extent for subbase courses. In the 1920s and 1930s when many of the highways in western sections of the United States were surfaced in this manner, the natural gravel or stone surfaces were loosened and thoroughly mixed, after which asphaltic oils or liquid tars were added by spraying and worked into the loose aggregate with graders until uniformity was obtained. The resultant mixture was then compacted. Surfaces of this type last several years under light to moderate traffic and are easily repaired by loosening, adding material and recompacting.

Plant mix. Plant mix surfacings possess the necessary strength and waterproofing to carry the highest volumes of traffic and the heaviest wheel loads under severe climatic conditions. They also provide a high quality riding surface. The process involves the assembly of excellent aggregates in several sizes, from walnut size to dust, drying these aggregates, heating to temperatures of 300–400° F (150–200° C) and mixing, in a central plant, with the proper quantity of asphalt cement or semisolid tar also at elevated temperature. The resulting compound is hauled to the roadway where it is placed by a laying machine or paver and thoroughly rolled before the mixture cools. Such mixtures are placed in thicknesses varying from one to four inches (25–100 millimetres) and a given surfacing may consist of two or more layers. The resulting surface is smooth and if properly designed provides good frictional resistance for vehicles operating over it. Its repair is simple and the surface can be upgraded easily by adding another layer mixed and placed in the same manner.

Rigid pavement. Rigid pavement is portland cement concrete surfacing placed directly on the subgrade or on a subbase course or base course. The pavement thickness is in the range of 6 to 12 inches (150–300 millimetres) and is dependent on the volume and weight of truck traffic using the highway. This type of surfacing is produced by assembling graded aggregates and cement at a central location where they are carefully proportioned on a batch

Surface
preparation

Figure 2: Three stages of concrete paving.

basis and then mixed with water to form concrete that will harden and yield adequate strength.

As the concrete changes from a plastic mass at placement to a hardened surfacing it undergoes a decrease in volume referred to as shrinkage. This shrinkage is accompanied by a tendency for the concrete to be pulled across the underlying layer, thus developing tensile stresses. In a continuous concrete mass the tension so developed exceeds the strength of the concrete and cracking occurs. The hardened concrete is also subject to volume changes and warping due to daily and seasonal temperature and moisture variations. As the temperature rises (or moisture content increases) there is an expansion of the surfacing while lower temperatures (or a decrease in moisture) cause contraction. In order to control these volume changes and the consequent cracking of the portland cement concrete pavement, three types of planned joints may be introduced. Contraction joints, spaced at intervals across the roadway, consist of grooves that extend partway through the pavement to insure that, when the concrete contracts, cracking will occur at these locations. Expansion joints, also transversely laid, consist of narrow openings through the pavement to provide room for expansion of the concrete. Elaborate measures are taken to keep these expansion joints water tight, and steel-rod dowels are provided across the joint to transfer part of the wheel loads from one slab end to the other. The third joint type is a longitudinal-tied joint used at the edge of the lanes and made by parting the pavement, as for contraction joints, and inserting steel tie bars under the parting strip to prevent the joints from opening. Such joints relieve the stresses caused by warping of the pavement slab due to temperature and moisture variations between the top and bottom. In the morning of a summer day the top of an 8-inch (200-millimetre) concrete pavement may be 25° F (14° C) hotter than the bottom. The weakened planes for the contraction and warping joints of concrete pavements were originally formed by hand methods, using a metal or fibre strip in the fresh concrete to produce the cut. However in recent years these joints have been formed after the concrete hardens by cutting the concrete to the desired depth and width with an abrasive circular saw blade.

Many of the maintenance problems in portland cement concrete pavements are associated with the jointing sys-

tems. It is difficult to keep the joints adequately sealed against water, dirt, and dust, and it is difficult to place dowel bars so that they permit expansion joints to open and close readily. For these reasons the continuously reinforced concrete pavement that does not require a jointing system has become increasingly popular. In this pavement (Figure 2) a continuous layer of steel bars is placed longitudinally at mid-depth of the pavement slab. The bars provide a steel area of about 0.5 percent to 0.7 percent of the cross section of the pavement. Shrinkage and temperature and moisture volume changes cause the concrete slab to crack transversely at intervals of 3 to 10 feet (1 to 3 metres) but the longitudinal steel absorbs the tension in the concrete so that the cracks are held tightly closed and no surface water can pass through. A small amount of transverse steel is used to hold the longitudinal bars in place and control longitudinal cracks. This method of construction permits the use of continuous slabs, several miles or kilometres long, with no jointing. Expansion and contraction of several inches may occur at the terminal ends of the continuously reinforced pavement and must be provided for in the design.

In deciding whether to use flexible or rigid pavement, engineers must take into account initial cost, probable life, probability of traffic disruptions for maintenance, riding characteristics, ease of repair, climatic conditions with their probable effects, and service to the travelling public.

MACHINERY AND EQUIPMENT

Highway construction in the developed nations has benefited from rapid and spectacular developments in construction equipment technology. These developments have been marked by substantial increases in capacity per unit and decreases in manpower requirements through automation. In the underdeveloped countries where labour is less expensive and less skilled, sophisticated highway construction equipment is uneconomic and rarely used. Highway construction equipment can be divided into four major categories: (1) equipment for clearing, earthmoving, and building the subgrade; (2) equipment for producing and handling aggregates; (3) equipment for mixing and placing pavements; and (4) equipment for bridge construction.

Clearing and earth moving. The bulldozer is most commonly used for clearing vegetation and undesirable materials from the roadway. Earth moving is accom-

Maintenance problems of concrete pavements

Rigid pavement jointing

plished with bulldozers, hauling scrapers, and motor-graders. Compaction is accomplished with large tamping and pneumatic-tired rollers; sprinkling trucks are used to adjust the moisture content for compaction. Rock cuts and fills utilize the mobile wagon drill capable of drilling 200 feet (60 metres) for blasting, shovels, or draglines (very large excavating machines) for loading the excavated material, and very large dump trucks for hauling. Grid, steel-wheeled, and pneumatic rollers are used for rock compaction.

Aggregates. The production of aggregates utilizes the wagon drill, shovel, or drag line and large-capacity hauling trucks to carry materials to the rock crusher and screening plant where aggregates are produced to size and quality specifications. Draglines or endless belts help load the aggregates; large trucks haul them to the roadway, or paving plant. Natural sands and gravels are handled by draglines, washed if necessary, and screened to the desired size gradation. Compaction of base and subbase aggregates is accomplished by steel-wheeled rollers and pneumatic rollers.

Mixing pavements. Surface treatment and macadam pavements utilize a bituminous distributor that sprays the bituminous material, hot or cold, at the proper rate. Both steel-wheel and pneumatic-tire rollers are used for compaction. The roadway is swept clean by a rotary broom. Mixed-in-place pavements utilize truck-water distributors, bituminous distributors, blade graders, and special mixers. Alternately, road-mix machines excavate the roadway surface, apply the bituminous material or other liquid stabilizer, mix the materials, and return the mixture to the roadway. Special hauling units to transport and spread lime and cement are used in stabilization.

Bituminous paving operations involve equipment to assemble aggregates, storage tanks for asphalt and tar, cold bins for aggregate loaded by dragline or belt, a mechanical cold-materials feeder, a cylindrical drier to dry and heat the aggregates, hot bins to proportion the hot aggregates, an asphalt or tar metering system, and a mill to perform the mixing operation. Recent developments have eliminated hot bins in many plants. The mixed material is hauled to the roadway in dump trucks and placed in a paving machine that distributes it uniformly on the base course. Compaction is accomplished by steel-wheeled and pneumatic rollers.

In portland cement concrete-paving plants, aggregates are assembled, placed in bins by size, and proportioned by weighing; the cement is separately weighed and added to the batch after which the materials are loaded into a stationary or truck-hauled mixer where water is added and fresh concrete produced. If a central mixer is used the completed mixture is hauled to the roadway in agitator trucks or in ordinary trucks with a bathtub-type body. The concrete mixture is distributed on the compacted roadway and placed by a paver that forms and smooths the concrete. Steel side forms that were necessary a few years ago have been eliminated by the formless paver.

The steel in continuously reinforced pavements is made up in sections by tying the longitudinal bars to the transverse bars. It may be placed on the compacted roadway ahead of placement of concrete or continuously with the fresh concrete. Joints are cut with heavy duty circular saws. Dowel bars for contraction and expansion joints in plain concrete pavements are held in place by heavy metal supports.

Bridge construction. Bridge building or viaduct building is a highly specialized operation using pile drivers, cranes, forming for concrete, riveting and welding equipment for steel and many other specialized types of equipment (see below *Bridges*).

DESIGN AND CONSTRUCTION

Highway location and plans. The design of a given road or highway involves the consideration of many factors and numerous decisions with respect to the necessary criteria for design. The designer must first establish the traffic volume to be carried at the beginning and at the end of the roadway's probable life. The number and loaded weight of trucks using the highway during its life must be determined. A speed for which the highway is to be designed

must be established, and the maximum gradient decided. The volume and character of traffic determine the design elements of the highway cross section, that is, number of lanes, lane width, shoulder width and median width. Speed and gradient determine the vertical alignment, and speed the horizontal alignment, including radii of curves and degrees of superelevation on curves.

It is next necessary to match the highway to the terrain through which it must pass. The first step, thus, is the establishment of the general route. When this has been refined to a narrow corridor a map showing the ground features, both natural and man-made, and variations in ground contours must be prepared. The designer then lays out the exact horizontal alignment or route, with alternates, on the map, and by using the contours obtains a vertical profile on the centre line and transverse profiles at desired intervals. A grade line is then established and earthwork quantities determined by comparing the finished roadway cross section with the ground cross section. The grade line is adjusted to balance the earth to be excavated with the fills to be made, to provide for moving the least amount of earth, and to satisfy the requirements for maximum gradient and minimum sight distances for vehicle operations. In setting the horizontal and vertical alignment the designer attempts to make the highway flow with the terrain so as to minimize the sense of tension with the driving environment.

New equipment, including a stereoscopic plotter utilizing aerial photographs for plotting points on a map and the computer, has taken much of the drudgery out of the work of highway design by permitting the automatic plotting of highway cross sections and the automatic computation of earthwork volumes. When the exact horizontal and vertical alignment has been established for the route selected, a set of plans is prepared showing the alignment details and the elements to be constructed. The required right-of-way is then purchased using location maps supplemented by ground surveys to establish precise ownership boundaries.

Earthwork. In order to design the pavement it is next necessary to establish the characteristics of the subgrade soils over which the pavement is to be constructed. Certain soil features can be determined by expert study of the aerial photographs. Detailed soil information must, however, be determined on the ground and in the laboratory. Ground subsurface explorations are carried out by means of auger borings in which the soil strata are identified, classified, and samples obtained for laboratory analysis. The engineering properties of the soil encountered, including its strength, susceptibility of its strength to moisture increase, and amount of shrinkage and swell with moisture change are established. Soils completely unsuitable in the final roadway section are identified for removal; embankment and cut slopes are established, and the degree of compaction to be achieved in the field determined. The probable strength or capacity of the materials to resist the traffic loads is also determined.

After the construction contract has been let and surveys have established the exact location of the finished roadway in plan and elevation on the ground, with suitable line and elevation indicators, construction of the subgrade begins. The first step is to remove all vegetation from the roadway section, an operation in which the bulldozer plays a large part. Heavy earth-moving machinery then moves materials from cut sections into fill sections, where the material is placed in layers, brought to the proper moisture content, and compacted to the required density. In 1970, the unit cost of earthwork, including excavation, hauling, placement and compaction, was not substantially greater in Europe, the United States, and Japan than it had been a generation earlier, in spite of huge increases in other construction costs. Higher capacity equipment operating at greater speeds has prevented increases in costs per unit. It is generally considered desirable to perform the earthwork operations, including installation of the drainage pipes and culverts, as the first element of construction for most highways, followed next by the bridges, and finally the pavements. If it is possible to permit some traffic to operate over the completed earthwork, it is desirable to

Bituminous paving

Soil analyses

do so in order to detect weak spots in the grade prior to placing the finished pavement.

Drainage. Highway drainage includes those elements of the roadway that remove surface water (rain) from the roadway and carry flowing streams across the roadway as well as those used to control ground water. It has often been emphasized that adequate drainage is the most important element in road and highway construction; John McAdam was one of the first to grasp the fact. The major drainage is carried in the streams that continuously or intermittently cross the highway route. Surface water from the roadway, as well as from the surrounding lands, is carried in these streams.

“Design storm”

The highway designer must estimate the amount of water that will be carried in the stream at the highway location for the “design storm,” which is either the most severe flood expected in a hundred years for a major stream, or merely that expected once in five years for a minor drainage channel on a low traffic-volume route. The elevation of bridges and the size of other drainage structures are fixed to carry this design storm without flooding the roadway. Hydraulic considerations are taken into account in the design of bridges and culverts, and construction may include work to increase the carrying capacity of the stream channel adjacent to the highway through channel changes, bank lining, and similar methods. In areas where land use is changing rapidly, particularly from agricultural to residential or business, attention must be given to the fact that ground water runoff and stream flow will materially increase as the area is covered with houses, drives, streets, business buildings, and parking lots.

The drainage of the roadway itself is an important consideration. Surface water drainage is insured by the crown in the pavement and the slope of the shoulders. Modern designs provide for surfacing the shoulders so that a complete waterproof surface is provided. It is important that all elements of the cross section, subgrade, subbase and base, as well as the surface, be crowned so that surface water entering the pavement system can drain outward to the ditch. Flat side slopes in the ditch section have two advantages. First they provide a better opportunity for vehicles leaving the roadway to recover without a serious accident occurring, and second, the ditch is further removed from the roadway laterally so that there is less opportunity for water in the ditch to penetrate and soften the subgrade. Both rounded V-bottom and trapezoidal ditch sections are commonly used. They must be sized to carry the maximum quantities at water elevations well below the elevation of the roadway shoulder.

In urban areas and at necessary locations in rural highways, particularly at intersections, the drainage of the highway pavement is accomplished by carrying the water laterally to shallow gutters at the edge of the shoulder, then along the gutter to storm-sewer inlets at frequent intervals. The water passes through these inlets into a pipe drainage system that carries it to a natural water course for discharge. For multilane freeways in areas of high rainfall the storm-drain system required is extensive and represents a substantial portion of the project cost.

Capillary water held in the pavement by surface tension is not subject to drainage. Where such water rises into the pavement and comes into contact with an overlying impervious layer, condensation occurs and may produce moisture problems. The use of impervious surfacing layers of appreciable thickness and free draining base and subbase courses minimizes this. If the ground water table is quite high relative to the elevation of the top of the pavement, capillary water problems can be severe; it may be essential to lower the level of the water table under the highway cross section by placing perforated drainage pipes, surrounded by free draining filters of gravel and sand, well below the water table. Ground water flows into the pipes, thus lowering the ground water table and reducing capillary moisture at the pavement elevation. The same procedure can be used to intercept ground water flowing under the highway cross section in pervious strata.

Drainage problems also occur when ground water can drain down the back slopes of cut sections and the fill slopes of higher fills. If these slopes are steep, severe ero-

sion may occur. The usual solution is to flatten slopes so as to permit control through vegetative cover. When this type of control is not feasible, the surface water is collected in shallow ditches or gutters at the top of the slope and carried along the roadway to a point at which it may be discharged into the ditch system or, alternately, carried down the slope in pipe drains to a suitable discharge point.

Design and construction of pavement elements. In order to design the elements of the pavement cross section the strength of the subgrade material must be determined in its condition of lowest probable strength or highest probable saturation. Strength is determined either by estimates based on experience with similar materials using routinely determined soil characteristics as an aid to judgment, or by means of laboratory test measurements. Materials tested are normally permitted to absorb water by capillarity prior to testing.

Where construction is to be in stages, the pavement section may be designed for the traffic to be carried during the early years, at the end of which added pavement material will be provided to increase the strength to that required for the next design period. Materials used for subbase and base courses must normally be located near the construction site to avoid high hauling costs. In some cases it may be advantageous to improve the strength of local materials by stabilizing with lime, cement, or bituminous materials. The subbase may also be constructed by stabilizing the top 6 to 12 inches (15–30 centimetres) of the subgrade. Operations involved in constructing the subbase and base courses consist of locating the materials to be used, processing these materials at the pit or quarry as necessary, hauling to the roadway, depositing in the proper quantities, mixing to provide uniformity, grading to proper elevation, adding water where necessary and compacting to the proper density.

Though for many years concrete pavements were placed directly on the subgrade, it is now recognized that the destructive ejection of water through joints and cracks and along the pavement edge can be avoided by providing granular bases or subbases or by providing stabilized bases under these rigid pavements. Most portland cement concrete pavements are now constructed over base courses stabilized with cement or bituminous materials. The thickness of the concrete pavement is determined on the basis of the strength of the concrete and the stresses induced by the heavier loads expected to use the pavement.

NOTABLE ROAD BUILDING ACHIEVEMENTS 1920–45

The parkway concept, forerunner of modern high-volume, high-speed, limited-access highways, was proposed first by William Niles White of New York as a part of the Bronx River protection program of New York City and Westchester County. The 15-mile (24-kilometre), four-lane drive known as the Bronx River Parkway was completed in 1925. Protected on both sides by broad bands of park land that limited access, the highway was located and designed so as to cause minimum disturbance to the landscape, and its use was restricted to passenger cars. The success of the concept led to the creation of the Westchester County parkway system and the Long Island State Park Commission. More parkways and expressways were built in the New York area, including the Merritt Parkway (1934–40), which continued the Westchester Parkway System across Connecticut as a toll road providing divided roadways and limited access.

The Italian *autostrada* system was started under Mussolini in the 1920s, beginning with an expressway from Milan to Varese. A national road board (Azienda Autonoma Statale della Strada) was given responsibility for the construction, maintenance, and repair of the state roads with advisory supervision over provincial and local roads. This body was assigned the funds from motor-vehicle taxes, and an annual matching grant of approximately the same amount from general tax funds. Superhighways were built primarily as toll roads under government supervision. The first of the major *autostrada* crossed northern Italy from Venice to Turin. The *autostrada* were built generally as undivided three-lane roadways with shoulders. All highway and railway grades were separated, access was limited,

Designing roads for future needs

and there were restrictions on use of the highways by commercial vehicles.

The Inter-American (Pan American) Highway was conceived at the Fifth Conference of American States in 1923 and formalized by cooperative agreements among the nations involved in 1928. Its route joined the highway system of the United States at Laredo, Texas, and went due south to Mexico City; thence southeast to Guatemala City, San Salvador, Managua, San José, and Panama City, a distance of 3,356 miles (about 5,400 kilometres). The U.S. Congress appropriated \$1,000,000 for the highway in June, 1934, and construction began in 1935. Work on the highway in Mexico progressed rapidly but lagged on most of the remainder of the route until World War II, when a large U.S. appropriation permitted construction of a usable pioneer trail for the entire route.

The
autobahn

The first fully modern highway system was the German autobahn network consisting of dual roadways separated by a substantial median area and providing for limitation of access. The idea of the motorway (expressway) was first conceived in Germany in 1926 and incorporated in the Cologne-Bonn roadway started in 1929 and opened to traffic in 1932. When Hitler came to power he implemented a plan for the construction of about 7,000 kilometres (4,350 miles) of an integrated highway network known as the "Reich Motor Roads." Construction began in 1934 on the Frankfurt-Mannheim-Heidelberg Autobahn. The entire system included three north-south routes and three east-west routes. The highway provided separate dual-lane roadways with a median strip of five metres (16 feet), and one-metre (three-foot) shoulders. Clearly military in intent, the roads were designed for large traffic volumes and speeds in excess of 100 miles (165 kilometres) per hour, bypassing cities, and providing limited access. The whole system, of about 2,500 miles (4,000 kilometres), was rushed to completion in a few years.

The Pennsylvania Turnpike Commission, established in 1937 to raise funds and build a toll road across the Appalachian Mountains, found an unusually favourable situation in the form of an abandoned railroad right-of-way, with many tunnels and excellent grades over much of the route. The turnpike provided a divided dual-lane highway with no cross traffic at grade and with complete control of access and egress at 11 traffic interchanges. Its alignment and grades were designed for high volumes of high-speed traffic and its pavement to accommodate the heaviest trucks. The favourable public reaction to this new type of highway provided the impetus for the post-World War II toll road boom in the United States, advanced the start of a major interstate highway program, and influenced highway developments elsewhere. The Pennsylvania Turnpike, originally running from Harrisburg to Pittsburgh, was later extended 100 miles (160 kilometres) east to Philadelphia and 67 miles (107 kilometres) west to the Ohio border, making it 327 miles (523 kilometres) long. An original feature of the turnpike, later widely copied, was the provision of restaurant and fuelling facilities.

The Alaska Highway was formalized in 1930 by a joint agreement between Canada and the United States. No funds were appropriated until the beginning of World War II when Alaska became an area of primary strategic importance, and an all-weather road link was needed to Fairbanks. In 1942 a pioneer road was cut from the Dawson Creek railhead northwest of Edmonton, Alberta, to Fairbanks. When complete, the motor-vehicle road was 20 to 24 feet (six to 7.3 metres) wide and more than 1,500 miles (2,400 kilometres) long. The road has been improved and has remained in continuous use since its pioneer days.

National highway and expressway systems

HISTORY

The Romans realized that a coordinated system of roadways connecting the major areas of their empire would be of prime significance for both commercial and military purposes. In the modern era the nations of Europe first introduced the concept of highway systems. In France, the State Department of Road and Bridges was organized in

1716 and by the middle of the 18th century the country was covered by an extensive network of roads built and maintained primarily by the national government. In 1797 the road system was divided into three classes of descending importance: (1) roads leading from Paris to the frontiers; (2) roads leading from frontier to frontier but not passing through Paris; (3) roads connecting towns. In the early 1920s this general plan remained essentially the same except that a gradual change in class and responsibility had taken place. At that time the road system was divided into four classes: (1) National highways (*routes nationales*), improved and maintained by the national government; (2) regional highways (*routes départementales*), improved and maintained by the Department under a road service bureau appointed by the Department Commission; (3) main local roads (*chemins des grandes communications* and *chemins d'intérêt commun*) connecting smaller cities and villages, built and maintained from funds of the communes supplemented by grants from the Department; and (4) township roads (*chemins vicinaux ordinaires*), built and maintained by the communities alone.

While the British recognized the necessity for national support of highways and a national system as early as 1878, the Ministry of Transport Act of 1919 first classified the roadway system and provided for 23,230 miles (37,168 kilometres) of Class I roads and 14,737 miles (23,579 km) of Class II roads with 50 percent of the cost of Class I roads and 25 percent of Class II roads to be borne by the national government. The need for a national through-traffic system was recognized in the middle 1930s and the Trunk Roads Act of 1939 followed by the Trunk Roads Act of 1944 created a system of roadways for through traffic. The Special Roads Act of 1949 authorized existing or new roads to be classified as "motorways" that could be reserved for special classes of traffic. The Highways Act of 1959 swept away all previous highway legislation in England and Wales and replaced it with a comprehensive set of new laws.

In the United States, New Jersey in 1891 enacted a law providing for state aid to the counties and established procedures for raising money at township and county level for road building. In 1893 Massachusetts established a state highway commission. By 1913 most of the states had adopted similar legislation but there was little coordination among the states. The Federal Aid Road Act of 1916 established federal aid for highways as a national policy, implemented by an appropriation of \$5,000,000. The Bureau of Public Roads, established in the Department of Agriculture in 1893 to make "inquiries with regard to road management," was given responsibility for the program; and an apportionment formula based on area, population, and mileage of post roads in each state was adopted. Funds were allocated for construction costs up to \$10,000 per mile and the states were required to bear all maintenance costs. The location and character of roads to be improved was left to the states, an arrangement that had some shortcomings. A national Good Roads Movement that had developed in the later years of the 19th century had long lobbied for a system of national roads joining the major population centres. This point of view was recognized by the Federal Aid Highway Act of 1921, which required each state to designate a system of state highways not to exceed seven percent of the total highway mileage in each state, and federal-aid funding was limited to this federal-aid system. The system was divided into interstate roads, not to exceed 3/7 of the total mileage with the balance to be intercounty highway. Bureau of Public Roads approval of the system was required, and federal aid was limited to 50 percent of the estimated cost. The first map of the federal-aid system of 168,881 miles (270,210 kilometres) was published in 1923. The Federal Aid Highway Act and the Highway Revenue Act of 1956 provided funding for an accelerated program of construction on the Interstate System. A federal gasoline tax was established, the funds from which, with other highway-user payments, were placed in a Highway Trust Fund. The federal-state ratio for funding construction of the Interstate System was changed to 90 percent federal and ten percent state. It was expected that the system would be completed

The U.S.
road
system

no later than 1971, but cost increases extended this time. The system connects nearly all of the major cities in the United States and was expected to carry 20 percent of the nation's traffic on slightly more than one percent of the total road and street system.

An important element in the United States highway system, overlapping the Interstate network, is toll road mileage, most of which was built in the years immediately following World War II. A total of 3,500 miles (5,600 kilometres) of toll road has been constructed in the United States, most of it in the 1950s.

Canada and China are other nations that have formulated national highway policies. The Canadian Highway Act of 1919 provided for a system of 25,000 miles (40,000 kilometres) of highways and provided for a federal allotment for construction not to exceed 40 percent of the cost. The Trans-Canada Highway jointly financed by the federal government and the provinces has made good progress since World War II. China passed "The Regulation of Highway Improvement in China," establishing a National Highway Commission and a system of highways and village highways in 1920, but little has been done to implement the ambitious plan.

The Soviet
road
system

The Soviet Union has a 1,000,000-mile rural highway system that consists primarily of two-lane roadways. The cities have adequate street systems with very wide paved sections. Most highways radiate from the major cities and while some intercity routes are planned most are formed when two city systems intersect. In order to overcome this problem the Soviet Union is now planning and building several intercity highways, some four-lane divided and some with controlled accesses. It was estimated in 1970 that 30 percent of the rural highway system was paved. Funding is provided by an annual tax on cars and trucks, 2 percent of annual income from industrial plants and collective farms, and some state appropriations. In the future the profits from transportation enterprise are expected to provide much of the cost for new roads. The relatively small automobile population of the Soviet Union in proportion to its large land area generates little demand for highway improvements. As motor vehicle numbers increase strong pressures for more road building will undoubtedly develop.

Japan has a national expressway system of 2,480 miles (4,696 kilometres) most of which is on the island of Honshu. Three major toll roads, comprising about 400 miles (640 kilometres), are major links in the system. The typical toll road section consists of two or three lanes in each direction separated by a 15-foot (4.5-metre) median. Because of land shortage in Tokyo and other major cities, urban expressway facilities are frequently double decked over existing streets or over rivers. In 1965 about one-fifth of Japan's national system was paved but good progress has been made since that time. The 117-mile (190-kilometre) Meishin toll expressway, Kōbe to Nagoya, was opened in 1969. Typical of expressway construction in Japanese cities is the 933-million-dollar construction program for the city of Ōsaka planned and partially completed to support Expo 70. The Ōsaka system includes a 35-mile (56-kilometre) ring highway, costing 135 million dollars, with three lanes in each direction and a 105-foot (32-metre) median. Almost one-third of the Ōsaka system is over water.

ADMINISTRATION AND FINANCING

Early road building was administered and financed on a local basis. The advent of the automobile created the necessity for integrated highway systems. Local roads and local streets are still generally administered by cities, towns, ships, and counties or similar units of local government.

The major highway and expressway systems of a nation must, of necessity, have a national administrative base to guarantee continuity of routes and reasonable uniformity in design and construction. This responsibility may be shared with local units of government. In the United States current national highway policies are established by the Federal Highway Administration, an agency of the Department of Transportation. The local point of view is represented by advisory bodies of national policies

and practices, notably the American Association of State Highway Officials. In England and Wales the Ministry of Transport, a cabinet-level department of national government, has authority over the motorways, the highest classification of highways, and the truck roads, the next highest, although this latter authority is often delegated to county or municipal authorities. In Scotland the secretary of state is the principal highway authority.

The financing of national highway systems is a national obligation. Before the automobile age, funds for highway systems were raised by general taxation in the form of labour taxes, by the issuance of bonds guaranteed by general tax revenues and to a limited extent by tolls charged against the users of highways and bridges. Since about 1920 the financing of highways has been almost entirely transferred to the highway user. A broad variety of taxes is employed, with motor-fuel taxes providing the largest single source of revenue. Vehicle licensing is common and trucks are usually licensed on a weight basis. Taxes on tires, rubber used in tires, lubricating oil, and on other motor-vehicle equipment items are widely applied for highway purposes. Excise and sales taxes on new car purchases more commonly accrue to general tax revenues. In periods of urgent demand for highways, for example, after World War II, governments employ credit financing for highway improvements, but the bonds are generally financed by highway-user tax revenues so the real source of funds does not change. Toll roads also become popular in periods of high demand, particularly over heavily travelled routes. The toll system permits rapid construction of a segment of the highway system through bond financing supported by tolls charged to the highway user. The toll, then, is in reality a special highway-user tax that assigns the tax to the particular highway. The toll system has proved effective in funding high-volume elements of national expressway systems.

Financing
of national
roads

SYSTEM PLANNING

Overall system study and planning. The planning of national expressway systems is an orderly, continuous process of assessing highway needs, determining the scope and requirements for a system, evaluating the required financing, and finally dealing with the complex relationships that occur among the various governmental units concerned with the system. The plan must provide for future extensions of the system, maintenance, and necessary rebuilding. System planning today is influenced by two major factors: the popularity of the automobile, which has provided new levels of mobility for many of the world's people; and the mass movement of people from rural areas to cities and from central cities to suburbs in the past quarter century, which has put great strains on urban expressway systems.

The need for transportation of both people and goods is closely associated with the physical location of most of the people. Consequently the major rural routes are easy to establish since they must join the major centres of population. The volume of traffic carried over such intercity routes is generally a function of the sizes of the terminal cities and the distances between them. Traffic volumes on intercity routes are established on the basis of current volumes and projections based on increasing population and vehicle ownership. Such volumes are customarily expressed in terms of the average daily traffic. For design purposes it is also essential that the traffic be classified by type with the heavy vehicles assigned to weight classification groups.

In urban areas the determination of traffic volumes assignable to various elements of the expressway systems is much more difficult. The automobile travel of individuals in urban areas is quite complex. Surveys of the origin and destination of present traffic are used to determine and project travel demands. In this procedure the travel of a percentage of the urban households and businesses is carefully studied with regard to trips made and their points of origin and destination. Future traffic is estimated on the basis of added demands as the city grows and on increasing use of the automobile. The result is a picture of the major travel-desire lines in the urban area and an

Deter-
mination
of urban
traffic
volume

estimate of the average daily traffic on each. The system must be designed to accommodate this traffic. While traffic-study techniques are constantly being refined and improved, the experience of the past 20 years is that urban traffic demands are chronically underestimated. In urban areas consideration must also be given to the parking of automobiles at their destinations. This problem involves both the quantity of parking area required and the methods for accepting and discharging the vehicles.

Rural expressways, urban expressways, and motorways are the most modern and expensive elements in the highway system of a country. Consideration must be given to the effect of this system on the lesser street and highway systems. Traffic must move to and from the expressways and motorways on these lesser systems; thus the proper design and operation of the whole requires careful attention to the needs of each of the system elements and to the proper connections between these elements. When the design and construction of a highway system element is the responsibility of several governmental agencies it is difficult to obtain proper coordination and proper consideration of the entire problem of traffic movement on a system basis. Only by the most effective use of all levels of highway facilities can the motoring public be served well. The result of a systems study for a nation or an urban area should be a network of roadways of varying complexity and traffic-service capability that will adequately serve the needs of the country or the urban area. For example, the Ministry of Transport plan for Great Britain's principal national routes calls for 720 miles (1,159 kilometres) of motorway (expressway) and 1,500 miles (2,400 kilometres) of other national routes. In September, 1950, most of the European countries adopted a system of major highways, totalling about 26,000 miles (41,600 kilometres), to be improved and known as the "E" system. Completion of the system prior to the turn of the century is unlikely. Only Germany has completed a substantial portion of the routes to expressway standards. Many of the world's urban areas have comprehensive plans for highway development in the area. All of these plans must be continuously reviewed to accommodate changes in traffic needs.

Design engineering and testing. The highway designer starts with information on traffic volumes; types of traffic; vehicle, axle, and wheel loadings; and maximum speeds anticipated. His task is to design the highway cross section and to fix its alignment both horizontally and vertically. He has the further obligation of producing a design that can later be modified or expanded to meet increasing traffic demands. The design process is simplified and uniformity in the system is insured by the use of "standards" that are established for highways of various classifications. These standards are fixed by the highway building agencies. Most agencies with direct responsibility for the construction and maintenance of roads, streets, or highways also have standards for design, construction, and materials. Loadings to be used in the design of expressway systems are based primarily on actual loading measurements of vehicles using the facility. While vehicle weights and axle loads are usually prescribed by law, these legal weight limits are frequently exceeded, hence design loadings are based on actual wheel and axle load measurements and reasonable estimates of trends.

Because they carry large volumes of heavy traffic, expressways justify more sophisticated studies of the probable loading during the life of the pavement. Materials to be used in their construction, as well as for other highway systems, are specified and tested for conformity in accordance with standard specification requirements and test procedures. In addition, most major agencies constructing highways have special specifications and testing methods that apply to their special conditions. The multiplicity of specifications for materials used in highway construction causes problems for the materials-supplying industries and increases construction costs. A given aggregate supplier may furnish the national government, two states or provinces, and a number of local jurisdictions all having different gradation specifications for essentially similar materials. This condition forces the supplier to make and store several materials that have only insignificant differences in size.

Materials selection. A most important element in the design of the highway system is the selection of materials to be used in its various segments. Major factors considered in materials selection are the initial cost in place, estimated annual maintenance costs, service life, and suitability for the driving public. The latter factor is an important consideration for expressways, particularly in urban areas. The high volumes of traffic that use these expressways on a nearly continuous basis create difficulty in maintenance and renovation and for the drivers using the expressway during periods of repair or change. For this reason materials and methods of construction for expressways are selected to minimize maintenance and renovation; *i.e.*, the highest types of pavement produced with high quality materials.

Limited access and special requirements. A prominent feature of an expressway system is the basic premise that the expressway has the function of moving through traffic safely at reasonable speeds and with the maximum feasible limitation of points of access to and egress from the system. For expressways the land service function is relegated to a very minor role. All points at which traffic enters or leaves the traffic stream are points of traffic turbulence and particular attention must be given to designing these entrances and exits to facilitate traffic movement. Vehicles entering the expressway must increase speed to that of expressway traffic and enter a gap in the traffic stream; this is accomplished by added lanes, called acceleration lanes, at points of entry. Similarly, deceleration lanes are provided at exit points.

Where two major expressways intersect, traffic flow is maintained uninterrupted by grade separation of the through traffic and the provision of separate lanes for each of the traffic movements from one expressway to the other, of which there are eight in all. The resulting pattern is commonly called a cloverleaf. Intersections of this type in urban areas often involve very complex problems, because of the unavailability of land, requiring compact intersections, and the need to accommodate traffic movements between the expressway and the street system. In such cases it is usually necessary to provide grade separations for some of the turning movements; three or four level grade separations may be provided by elevated bridge structures.

Urban expressways are also faced with the problem of clear separation of expressway traffic from that of the street system. This is accomplished either by depressing the expressway below ground and carrying the streets across the expressway on bridge structures or by elevating the expressway above the street system. The depressed expressway is generally better from the point of view of appearance but poses difficulty in maintenance of the back slopes, handling of storm water drainage, and construction in areas of high water table. The elevated expressway is expensive and often considered aesthetically objectionable, but its maintenance cost is lower and in areas of high water table or where large numbers of heavily travelled streets must be crossed it offers the most feasible solution to the traffic-separation problem. Expressway exits and access points in urban areas present difficult design problems for both the depressed and elevated freeways but are generally somewhat more difficult for the elevated system.

Expressways in urban areas require extensive lighting because of the movement of large volumes of traffic during the hours of darkness and the necessity for illumination to provide proper vision for the entrance, exit, and route-change movements. In addition to continuous lighting of the through lanes, special lighting and sign lighting is provided to accommodate entering and departing vehicles.

IMPACT OF THE NEW EXPRESSWAYS

Benefits. The new expressways and motorways have been very popular with the travelling public. Carrying large volumes of traffic at high speeds, they have excellent safety records due to the directional separation of traffic, absence of intersections, minimum interference from entering and leaving vehicles, more uniform traffic speed, and excellent visibility. Full control of access, as compared to no control, other conditions being equal, is responsi-

The use
of grade
separation

The
European
"E" system

ble for an approximate 60 percent reduction in accident rates and 45 percent reduction in fatalities based on travel mileage. The greatest reduction occurs in suburban areas. Urban and rural expressways have only one-fifth the accident rate experienced on city streets and rural highways.

There is also a substantial saving in time and operating costs for all types of vehicles on the expressway in comparison to operating costs on normal rural highways or city streets. Studies made in Los Angeles in the early 1960s indicated operating and accident cost savings of 3¾ cents per mile for passenger cars, 10 cents per mile for trucks. Expressways, furthermore, provide much better driving conditions for the motoring public, so that trips are completed with less physical wear and tear. This has led to increased recreational and cultural travel.

Controversies and problems associated with expressways.

The expressway, because of its greater traffic capacity produces problems of air pollution, noise, and, in the eyes of some, visual pollution. Air pollution due to vehicle operation has become a substantial problem in the larger urban areas of the world, particularly those in which common atmospheric conditions prevent rapid dispersion of the pollutants. Though this is not alone an expressway problem, the heavy concentration of vehicles on expressways makes them a major source of pollutants. The answer to the problem presumably lies in new technical developments that either will drastically reduce the volume of pollutants emanating from the internal-combustion engine or will facilitate the substitution of alternate, nonpolluting power sources for automobiles. Another possibility, explored at various times in such cities as Rome and New York City, is the restriction of vehicle use in the central city.

Urban
express-
ways

The urban expressway and to a lesser extent the rural expressway are considered by many to be poor neighbours. A major intersection of urban expressways consumes tens of acres of land and the construction of thousands of linear feet of bridge structure. Such an intersection in a built-up area means a substantial disturbance of the neighborhood. The same is true to a lesser extent along the entire route in built-up areas. Strong objections are often raised to expressway locations in urban areas; public opposition has sometimes halted construction. Conservationists have objected to the location of expressways that utilize lands now in parks, golf courses, and other green areas, or which run adjacent to recreation areas such as beaches. The destruction of historic buildings and landmarks by expressway construction has drawn much criticism in Europe and the United States.

In rural areas the problems of expressway location are much less severe because of the availability of alternate locations and the smaller numbers of businesses and residences involved. Rural expressway intersections are generally designed to provide for turning movements at grade, thus eliminating the need for long bridge structures, although requiring large land areas. There have nevertheless been protests, not only from conservationists but from rural property owners whose lands and homes were affected. It has been alleged that highway designers give insufficient attention to aesthetics and create ugly scars on the landscape. In the United States the Highway Beautification Act of 1965 authorized the partial withholding of federal funds from states that do not take proper action to build and maintain aesthetically pleasing highways. Funds have been authorized for the control of billboards and junkyards adjacent to expressways. The appearance of expressways can be materially improved by good planning and design to fit the roadway to the terrain, the retention of native trees and shrubs and landscaping by judicious planting. Wide median areas of natural vegetation or landscaping are popular. The wider rights-of-way required are considered to be justified by the improvement in driving conditions as well as appearance.

Rivalry
among
highway
users

Another area of controversy, principally in the United States, is the rivalry that exists among different elements of the transportation industry, particularly between the trucking and railroad industries. Unquestionably the expressways, which permit truck operations at high speeds and with few stops, substantially reduce the cost of operating these vehicles. In addition the trucking industry has

argued for increases in allowable gross vehicle weights and dimensions, increases that are opposed by highway administrators and designers on the grounds that existing expressways are not designed to accommodate these heavier vehicles. Railroad interests and some highway administrators contend that the commercial trucks and buses do not pay their fair portion of the highway-user taxes and are, therefore, being subsidized by tax and highway-user funds from the general public. The question has never been settled, but it is generally conceded that higher taxes on commercial vehicles approximately cover the incremental costs involved in constructing the expressway. Highway cost allocation remains a thorny fiscal and philosophical problem that has occupied highway economists for many years; the approaches presented do not have the approval of all interests involved.

Operation and maintenance

The glamorous phase of highway engineering is that of system planning, design, and construction of new highway facilities. Service to the driving public, however, is very much dependent upon operation and maintenance activities. The life of a highway is a function of the quality of maintenance and minor renovation, and long life provides the most important single element in highway economics.

The operation of traffic on roads and highways is subject to four types of control: (1) legal control, or the laws setting forth the rules of the road; (2) roadway signs and markings that provide instructions and information; (3) traffic light signals; (4) police action. Expressways are specifically designed to avoid the necessity for traffic signals, except on access or exit lanes, and police traffic control except in the case of traffic congestion due to accidents.

Maintenance consists of activities concerned with the condition of the pavement and shoulders, including surface conditions, structural integrity and adequacy, and the condition of the right-of-way areas outside the travelled way. It is also concerned with snow removal, debris removal, and the installation and care of pavement markings, signs, and signals.

Markings, signs, and signals. The marking of roadway surfaces with painted lines or types of permanent markers is standard practice throughout the world. While there are some disadvantages of pavement surface marking, notably high maintenance costs and problems in night visibility, it is generally accepted that the advantages far exceed the disadvantages. Interior lane lines and centre lines are marked with broken lines, either yellow or white, and dangerous conditions such as restricted sight distance and pavement edges are indicated with solid lines.

Signs are used to advise the driver of special regulations that apply at specific times and places and to provide information with regard to routes, directions, destinations, hazards, and points of interest. Expressway sign planning is particularly important because the driver who makes a mistake and misses an entrance or exit cannot recover quickly because of the limited access characteristic, which means that the next entrance or exit may be miles away. Signs are classified as: (1) regulatory signs, which provide notice of traffic laws and regulations such as speed-limit, stop and yield signs, and signs regulating traffic movement; (2) warning signs, which call attention to conditions in or adjacent to the roadway representing a potential traffic hazard such as turns, steep grades, low vertical clearance, or slippery pavement surface; (3) guide signs, which show route designations, destinations, distances, points of interest, and other similar information. In most nations signs have standard shapes and colours, with one shape used for the stop sign, another for warning signs, etc. Expressway directional signs, commonly mounted over the roadway on a sign bridge, are large in size for easy reading at high speeds and often have white letters and symbols on a green background. Special shapes and colours are used for route markers. A United Nations commission studied highway signs in 1951 and made recommendations for standard sign procedures that have been adopted by many nations. The commission found that the use of symbols is preferable to words; the advantage of wordless signs in Europe,

Types of
signs

with its large international traffic, is evident. The commission also found that three-colour signs are quite visible. European danger signs traditionally were triangular, but the commission recommended adoptions of the American diamond shape on the basis of better legibility and comprehension. Conferences in Bangkok (1967), Montevideo (1967), and Vienna (1968) were devoted to adoption of a convention for road signs and signals acceptable to most nations of the world.

The traffic signal has its primary use in traffic control in city street systems, but it also has a place on rural highways. At highway grade intersections accommodating large volumes of traffic the traffic signal is used to allocate the right-of-way to the various traffic streams. Systems known as traffic-actuated signals automatically monitor the demand in the traffic streams and allocate the green time or right-of-way correspondingly. Preference can be given to particular traffic directions by such signals. A recent development in expressway operation is the traffic-signal system to meter traffic entering on access lanes. These signals provide a red indication to entering traffic until a gap sufficient for entry occurs in the exterior expressway lane at which time the signal gives a green indication and the entering vehicle moves into the traffic stream. Signals are also used on expressways to indicate lanes open and closed ahead of the driver.

Rules of the road and speed limits. Legal rules governing the movement of traffic are an essential part of orderly movement on the highway. Such regulations may be nationwide, state- or province-wide, or local. In general the rules for operation of vehicles on the highway may be divided into three main categories. First are the rules applying to the vehicle and the driver such as vehicle and driver registration, vehicle equipment, accident reporting, and financial liability. Second are the general rules for drivers and pedestrians such as speed limits, right-of-way, and turn requirements known as the rules of the road. Third are those regulations which apply to limited roadway sections such as speed zones, one-way operations, and turn controls.

The important rules of the road are reasonably uniform throughout the world, except in two important aspects. First, the right-of-way is allocated to vehicles on the right-hand side of the highway in most nations, but on the left-hand side in a few, notably the U.K. This influences vehicle design since it is important that the driver be on the side of the vehicle adjacent to opposing traffic; *i.e.*, on the left side of the vehicle for the right-hand rule. The second major variation is in the regulation of vehicle speed by the use of speed limits. Speed limits on open rural highways and motorways are not specified in many European countries. Police control judgments are made as to whether or not a driver's speed is compatible with driving conditions. In the United States and Canada speed limits are widely used. The limits in the United States vary from 30 miles (48 kilometres) per hour for local service highways in built-up areas to 55 miles (88 kilometres) per hour on rural highways and expressways. Higher speed limits of up to 80 miles (128 kilometres) per hour have been used in a few jurisdictions. An important aspect of the speed question is traffic speed differential, which should be minimal. There is much less interference in a nearly uniform traffic stream and consequently greater safety. For this reason minimum speed limits are established on many expressways, particularly in urban areas, with the lower limits set at 10 to 20 miles per hour below the upper limits.

Special regulations are important to the efficient movement of traffic in specific segments of the street and highway system. One-way street systems in congested urban areas provide safer driving conditions and increase the traffic-carrying capacity of the system. The prohibition of turns at intersections contributes to safety and reduces conflicts. Such regulations, however, may adversely affect some businesses. Speed zoning is used to establish localized speed limits in special zones. Reduced speed limits are commonly used on highways approaching built-up areas and on dangerous highway sections where lower speed limits are justified. Higher than normal speed limits may also be established on particularly safe sections of highway.

Highway policing. Highway patrols or highway police were inaugurated to help in solving the highway accident problem by enforcing driving regulations on the major highway systems. In urban areas traffic patrol and enforcement of traffic regulations is a responsibility of the police department. Most large cities have a traffic division in the police department. On heavily travelled expressways in rural areas adequate patrol requires one patrolman for each four to five miles (6.4 to eight kilometres). In addition to patrolling to insure compliance with speed and other regulations, the patrolmen also investigate accidents, render assistance to disabled vehicles, and attempt to apprehend criminals.

An important aspect of traffic regulations and accident prevention is the control of excessive speed. Speed is commonly measured by radar devices or by pacing with a patrol car. Speed traps that involve travel time measurements over a fixed distance are ordinarily not permitted. In accident investigation speed is determined by skid marks. Another important factor in highway accidents is the driver who is under the influence of alcohol or drugs. Tests for intoxication are now widely used. The determination of the alcohol content in the blood or other bodily fluids is probably the most conclusive indication of excessive use of alcohol, but such tests are not practical for police identification of excessive drinking. The most widely used test for police identification of the state of intoxication from alcohol is the breath test in which the driver blows up a balloon and his breath is run through a series of chemical contacts in an analyzer. The results indicate to the detaining officer whether or not the driver's condition is due to alcohol and the approximate blood alcohol content. The alcohol blood concentration that is presumptive of poor driving ability is not firmly established. Maximum levels of 0.15 percent have been widely used to prove alcoholic influence, but many authorities believe that a limit of 0.05 percent is more realistic and that 0.10 percent is the maximum reasonable upper limit.

In addition to the traffic control and policing function, highway patrols regulate traffic at the scene of accidents, provide information and are in this and other ways very helpful to the driving public. The primary work of various expressway emergency patrols is to assist in emergencies and to carry on activities to insure efficient movement of high volumes of traffic. New developments in recent years include the use of light airplanes and helicopters for patrol purposes. They are particularly effective in locating trouble spots causing traffic jams and relaying this information to patrol officers on the ground for corrective action.

Proper road conditions. The proper and adequate maintenance of the highway after construction is one of the most important elements for proper functioning of the roads and highway system. Proper maintenance keeps the roadway safe, provides good driving conditions, and prolongs the life of the pavement, thus protecting the highway investment. Maintenance operations are carried on in all governmental jurisdictions by crews of men organized, trained, and equipped to carry out the maintenance function. Maintenance activities can be grouped into three major areas: (1) maintenance of pavements and shoulders; (2) maintenance of ditches, slopes, right-of-way areas, and drainage structures; and (3) maintenance of signs and markings and operations aiding traffic movement.

Maintenance of pavements and shoulders involves operations of the same type and involves use of much of the same equipment as for new construction. Maintenance of the ditches, slopes and right-of-way areas involves mowing operations to control vegetation and work to control and eliminate soil erosion. A major maintenance expenditure is involved in picking up and removing trash thrown or dumped in the ditch and right-of-way areas by the travelling public. Roadside containers for such trash provide only a partial solution to the problem. In the more rigorous winter climates substantial maintenance expenditures are required to remove snow and ice from the pavement including snow plowing, the spreading of salt for snow and ice removal, and spreading sand to provide traction.

activities

Future highway trends

One of the major questions for the future concerns the desirability of continued construction of expressways in urban areas. In many high-population-density urban areas the transportation problem can probably be solved more economically and with lesser requirement for land by the use of mass transit, both bus and fixed rail. The operation of the Bay Area Rapid Transit System in the San Francisco Bay Area will provide an indication of the potential success of well-designed mass transit in attracting riders and reducing automobile traffic. At the same time it seems reasonable to predict that the automobile and truck will have a large place in the world's transportation for many years. In most parts of the world automobile use is steadily increasing. In urban areas continued development of more adequate expressway facilities in limited land area requires new approaches. One possibility is to take the expressway system underground in tunnels. The primary difficulties in this type of construction are the high cost of tunnelling and the ventilation problem. Another possibility is to move the expressway system to the second story level with direct access to buildings and parking garages at this level and the allocation of the street level to pedestrians and a few local service vehicles. If the automobile and bus are to continue to be the primary source of transportation of the people in urban areas, new approaches will be needed to integrate expressway systems into the total facilities of the central city.

Highway safety will continue to demand attention, much of which will be given to the design of roads and highways. More four-lane divided highways will be built to replace existing two- and three-lane roads. Recent developments of easy-breaking signs and light poles, along with impact attenuators to protect the vehicle that strikes rigid fixed objects such as piers and expressway gores, have reduced the severity of accidents involving vehicles striking fixed

objects. Better roadway surfacing, alignments, and signing and marking will improve driving conditions and make highways safer.

A major safety feature under consideration is the development of an electronic highway in which vehicles entering the highway will be locked into a guidance system that will control their speed and path of travel. To be acceptable such a system will have to be absolutely reliable and provide a quality of travel that will insure the driver's willingness to give up his individual driving freedom.

Another potential development is the truck highway. There have been many examples of roads and highways on which trucks were prohibited, in particular the parkways around New York. Increases in transportation of goods by truck in the developed countries have led to truck traffic congestion on many highways. In some areas serious consideration will probably be given to the planning and construction of highways to be limited to truck traffic. Such highways would be financed by the trucks using them, thus eliminating the criticism that commercial vehicles are subsidized by automobile user taxes on the public systems.

One of the major question marks in the highway-building future is the outlook for the internal-combustion engine. Widespread problems of air pollution in major urban areas have led to the suggestion that the engine be legally regulated out of use or that very rigid controls on emissions be established. If this trend continues and new types of engines or other devices to power the automobile and truck are adopted, the changes may require substantial changes in the design of highway systems. As an example major changes in acceleration rates would have a serious effect on the design of the highway system for passing and merging operations. Changes in other vehicle operating characteristics will have similar impact for other elements of the system. (F.J.B.)

highways

BRIDGES

A bridge is a structure surmounting an obstacle such as a river, declivity, road, or railway and used as a passageway for pedestrian, motor, or rail traffic. In this article, the development of bridge design and construction is dealt with chronologically from early times. Consideration is given to the wide variety of foundations required, the superstructures of all types of bridges (*i.e.*, girder, arch, suspension, and combinations thereof), the materials used in construction and their strength and properties, advances in theory and methods of calculation, and the evolution of erection techniques. Late developments and trends are discussed.

Early bridge building

The first bridges were natural, such as the huge, pointed arch of rock that spans the Ardèche River in Ardèche *département*, France, or the rock bridge near Lexington, Virginia. The first man-made bridges were flat stones or tree trunks, laid across a stream to make a girder bridge, and festoons of creepers hung in suspension.

Three types of bridge—beam or girder, arch, and suspension—have been known and built from the earliest times (see Figure 3). The essential difference among them is in the way they bear their own weight. The ends of beam or girder bridges simply rest on the ground, the weight thrusting straight down. Arch bridges thrust outward as well as down at the ends and are said to be in compression. The cables of suspension bridges pull inward against their anchorages and are said to be in tension. In their simplest forms, beam or girder bridges are known as simple spans; if two or more are joined together over piers, they become continuous. A more complex form, the cantilever, is based on the girder (see below). Later variations of the arch have taken the shape of the tied arch, in which a tension member is supplied, usually at deck level, to carry the horizontal component of the thrust, creating a form similar to that of a string bow. In an analogous variation

of the suspension bridge, a strut is provided in the deck, between the two anchorages, to relieve them of horizontal pull. Such a bridge is called self-anchored. The three types—girder, arch, and suspension—may also be combined in a variety of ways to form a composite structure. Through the ages, materials of construction have evolved from those ready to hand, such as timber and stone, to manufactured materials, such as brick, dimension stone, concrete, reinforced and precast concrete, iron, and steel.

The type of bridge to be preferred at any site depends on the nature of the ground, the length of the span required, the kind of traffic anticipated, and the materials of construction available. For some of the early bridges in Persia (now Iran), where the riverbed was stony and no timber was available, a site was selected where there were outcrops of rocks across the river on which to build the piers. The resulting structures, such as the bridge over the Kā-rūn River at Shūshtar, were not straight but wound across from outcrop to outcrop. Alternatively, mounds of stone could be built up on the riverbed, or, if the ground was not too hard, timber piles could be driven through the water to form trestles, as in Caesar's bridge over the Rhine (55 BC).

Accounts by Herodotus and others tell of a remarkable bridge built more than 4,000 years ago across the Eu-

phrates in the city of Babylon. It is said that the river, which is very shallow in the dry season, was diverted well above the city so that the stone bridge piers could be built in the dry riverbed. Part of the timber roadway was removable and was taken up each night as a security measure.

Another prehistoric practice is believed to have been that of human sacrifice in the foundations of bridges to appease the river gods. Surviving into Roman times, the practice helped give rise to the Faust legend and is responsible for the many Devil's bridges that are to be found.

PRIMITIVE BRIDGES

Some of the simplest uses of beams are in the "clapper" bridges of Dartmoor, Devon. The beams are actually huge, flat boulders that outcrop on the surface. In the Postbridge over the East Dart River, for example, the three 15-foot- (4.6-metre-) wide openings of this bridge are spanned by unchiselled slabs of granite, 6 feet (2 metres) wide, on piers of piled-up stone. Elsewhere, as in southeast Cornwall, where timber is more plentiful than stone, primitive crossings take the shape of "clam" bridges, built of tree trunks laid side by side. "Clam" and "clapper" are Anglo-Saxon words denoting, respectively, timber and stepping-stones. Clapper-type bridges are also found in Spain and were probably used in Egypt, Babylon, and China.

A special type of beam bridge is the pontoon. The earliest account of pontoon bridges of substantial size, again by Herodotus, describes a bridge of boats built by Xerxes, king of Persia, across the Hellespont at Abydos in 481 BC. No fewer than 674 vessels were used, tied together by ropes and securely anchored. Persian armies then crossed, for the invasion of Europe, on a roadway of earth and brushwood, supported by transverse tree trunks. Then, as in modern times, pontoon bridges probably had the same disadvantages: short life, costly maintenance, and, in most locations, obstruction to navigation.

Most primitive suspension bridges were supported by three cables, two on either side acting as handrails and a third, stouter one, on which the passenger walked. Twisted lianas, creepers, oxhide thongs, bamboo, cane, or similar materials made up the cables. In construction, they were towed across the river, hauled up, and tied high on tree trunks or posts driven in the ground, beyond which they were carried again and securely anchored. Such bridges are found in India, Africa, China, and South America. Built with spans of up to 500 feet (150 metres), they sway and sag in use in a manner to alarm timid passengers.

ROMAN BRIDGES

The Romans were among the greatest bridge builders of antiquity. Their three most important contributions to the art may have been the discovery of a natural cement; the development of the cofferdam, a temporary enclosure built in the stream, within which a concrete pier foundation could be built; and their exploitation of the circular masonry arch. The cement, known as pozzolana, was made by mixing finely ground tuff (a rock formed of compacted

volcanic fragments) found near the Italian town of Pozzuoli with lime, sand, and water. The Romans also made pozzolanic cement from powdered pottery fragments. The pozzolanic cements were for a long time the only cements known to resist exposure to water. Their cofferdams were made by driving timber piles to enclose the site of the pier and then pouring in concrete through the water. Alternatively, if the riverbed was very soft, they drove a double row of sheathing piles and filled in the space between with clay to make the cofferdam watertight. They could then empty the cofferdam with waterwheels, dig out the greater part of the soft ground inside it, and pour the concrete for the pier in the dry. The Sant'Angelo Bridge in Rome stands on cofferdam foundations built in the Tiber River more than 1,800 years ago. Nevertheless, the Roman underwater foundations were rarely built deep enough or given sufficient protection against scour to enable them to survive for long. Most of the Roman bridges that remain were built on solid rock.

The superstructures of many Roman bridges, such as Emperor Trajan's bridge built by Apollodorus of Damascus over the Danube in AD 104–105, was of timber on stone piers. None of the bridges of this type has survived. The fame of Roman bridge builders rests largely on their majestic masonry bridges, built on the grand scale, always with circular arches (see Figure 5), which perhaps reached

Figure 5: Roman circular arch as seen in the original Pons Fabricius, Rome, 62 BC.

the peak of achievement in a mighty bridge over the Tagus at Alcántara, Spain. Built by Gaius Julius Lacer for Trajan, the tall granite piers and 98-foot- (30-metre-) wide arches that carry the roadway 170 feet (52 metres) above the river have stood for nearly 2,000 years. The huge stones forming the arch (voussoirs) weigh up to eight tons each and were so accurately shaped that no mortar was needed in the joints. The arches must have been built on temporary timber structures (falsework). The heavy arch stones were no doubt lifted by a system of pulley blocks, operated by means of a winch, probably powered by a treadmill.

Tools used by the Roman masons included saws, chisels, bevels, wedges, and trowels; their instruments for horizontal and vertical alignment included plumb bobs and levels.

Roman bridges required for a military campaign, such as that over the Danube, were usually built by legionaries and financed by the treasury; nonmilitary bridges employed forced labour and generally relied for finance on contributions by townships. Engineers and skilled workmen formed into semimilitary guilds were dispatched throughout the empire to supervise the work. By this means, engineering knowledge was spread and interchanged, and a foundation for schools in which professional standards were formulated was set down. From these fragmentary beginnings evolved the laws of the art of building drawn up by the Roman engineering authority Vitruvius in the 1st century AD in his work *De architectura*.

Roman Alcántara bridge over the Tagus

BRIDGE DEVELOPMENTS IN ASIA

A refinement of the beam that enables it to be used for longer spans is known as a cantilever. Primitive cantilever bridges were made wholly of timber; there are picturesque examples over the River Jhelum at Srinagar, the capital of Kashmir. For the foundations of the river piers, piles were driven, and old boats filled with stones were sunk at the site, until a desired height above low-water level was reached. Then, on top of the piers, layers of rough-hewn logs were laid crisscross, in such a way that the logs on two adjacent piers jutted further toward each other as the

(Left) Sakamoto Photo Research Laboratory, (right) Alice Schalek—Black Star

height increased. The two ends of these projecting arms, or cantilevers, were then joined below roadway level by long tree trunks placed across the gap. The roadways on these bridges were usually lined with shops, and the skeleton piers were able to weather severe floods, because they offered less resistance to the flow of water than would a solid pier. Similar ancient bridges are to be found in Tibet and Scandinavia.

A stone cantilever bridge 1,100 feet (335 metres) long is said to have been built over the Dragon River in Poh Lam, Fukien Province, China. The spans, up to 70 feet (21 metres) in length, were composed of three huge stones, two of which rested on top of the pier at each end, while the third spanned the gap between them. How stones of such a size, weighing up to 200 tons, were quarried and transported in those times is not known.

In other parts of China, where bridges had to stand in the spongy, plastic silt of the river valleys, construction developed along very different lines. Here, masonry arch bridges were built of thin, curved slabs, jointed in such a way that they could yield to considerable deformation before failure. These bridges might be described as consisting of stone chains employed in compression. The arches were originally built in the Roman semicircular forms; the bridges were high and narrow, often covered, and with stone steps at the ends. Their amazing flexibility enabled them to adapt both to the rise and fall of the silt foundations and to the weight of the traffic.

Other fine medieval bridges were built in Persia, such as the Red Bridge, which consisted of four pointed arches, on the road from Tiflis (Tbilisi) to Tabriz. Even more distinctive were bridges such as the Allah Verdi Khan and the Pul Khajoo, which were designed as cool, shaded retreats, where the traveller could find rooms for rest and refreshment after crossing the hot desert sands. The two-storied Pul Khajoo at Isfahan (1642–67) is composed of 24 pointed arches that carry an 85-foot (26-metre)-wide roadway, with walled passageways above it, along the top of a pierced dam. Flanked by tall, hexagonal pavilions and watchtowers, the bridge constitutes a magnificent example of engineering and architectural harmony.

In Japan are to be found small, picturesque bridges of timber arches, such as the famous Kintai-kyō (Kintai Bridge) at Iwakuni, which for centuries had its five arches rebuilt in succession, one every five years, so that the whole bridge was renewed every 25 years. Completely rebuilt in 1953, it now carries an automobile roadway across the Nishikigawa (Nishiki River).

MEDIEVAL AND RENAISSANCE BRIDGES IN EUROPE

After the fall of the Roman Empire, bridge building in Europe languished for some eight centuries. Its revival was marked by the spread of the ogival, or pointed arch, westward across the continent from Egypt and the Middle East, where it originated. Medieval workmanship was at first not as good as that of the Romans, and the pointed

arch may have been preferred because it demanded less precision than the circular form. In the pointed arch, the tendency to sag at the crown is less dangerous, and there is less thrust on the abutments.

Medieval bridges had other functions besides carrying traffic. Chapels, shops, tollhouses, and customhouses were built on them, and they were used for fairs and tournaments. Fortified bridges, such as the Pont Valentré at Cahors, France, the bridge over the Gave de Pau at Orthez, France, or the bridge over the River Monnow at Monmouth, Monmouthshire, Wales, were defended by

Chinese
stone
arches

means of ramparts, towers with firing slits, and often a drawbridge, an original medieval invention. The upkeep of bridges was considered a pious work, for which money was obtained by alms, by endowment, or from tolls levied on both road and river traffic.

One of the most famous medieval bridges in Europe is the Pont d'Avignon over the Rhône at Avignon, France, which was begun under the direction of St. Bénézet in 1177 and completed ten years later. The bridge spanned the river by means of about 20 lofty, elliptical arches, each 100 feet (30 metres) wide. St. Bénézet, who believed that he had been divinely inspired to build the bridge, died before its completion and was buried in a chapel on one of the piers. Because of the ravages of war and damage from ice in the river, little more than the chapel at the Avignon end of the bridge, which has now become a place of pilgrimage, remains standing.

A year before the commencement of the Pont d'Avignon, Peter of Colechurch undertook a far more formidable task—the building of the Old London Bridge. This was the first stone bridge with masonry foundations to be built in a swiftly flowing river having a large tidal range. The bridge was to consist of 19 pointed arches, each with about a 24-foot (seven-metre) span, built on piers 20 feet (six metres) wide (see Figure 8). The 13th arch from the city was designed as a tollgate for merchant shipping with a military drawbridge. The foundations were built inside cofferdams made by driving timber sheathing piles, which held the pier stones in place. Obstructions encountered in pile driving resulted in variations in the span of the arches of from 15 to 34 feet (five to 10 metres). The width of the protective starlings (loose stone filling enclosed by piles at the base of each pier) was so great that the total waterway was reduced to a quarter of its original width, and the tide flowed under the narrow archways like a millrace. Despite its peculiarities of structure, however, the Old London Bridge was completed in 1209 and survived, together with its famous tunnellike street of shops and houses, for more than 600 years.

The confidence and the unbounded enterprise of the Renaissance is reflected in Leonardo da Vinci's offer in 1502 to build a masonry arch bridge with a clear span of 787 feet (240 metres), over the Golden Horn at Istanbul.

Figure 8: Pointed arches of Old London Bridge.

Leonardo's design appears to have been practical, except for the difficulty of supporting the falsework (centring), the temporary wooden supports on which the enormous arch would have been built. Less grandiose but more economically and technically feasible bridges were actually built; they included some of the most famous bridges in the world, such as the Pont Notre Dame and the Pont Neuf in Paris, the Rialto in Venice, Italy, and the Sta. Trinità in Florence, Italy. Though engineers had learned much about bridge foundations since Roman times, they were still rarely able to excavate deep enough—i.e., down to rock or really hard strata—but they had learned to spread the base of the pier over a wide area and to lay the foundation stones on a broad timber grillage, supported, if necessary, on piles. In the foundation of the Rialto Bridge, for example, Antonio da Ponte, the designer, had 6,000 timber piles driven under each of the two abutments and placed the masonry in such a way that the bed joints of the stones were perpendicular to the thrust of the arch. So well were these foundations built that, although they have to support in soft alluvial

soil a wide arch carrying a street of shops, they stand today.

In his beautiful Sta. Trinità Bridge in Florence, built 1567–69, Bartolomeo Ammanati, working on scientific principles, evolved a new type of arch. He adopted the ogival (pointed) shape, with the angle at the crown concealed and the curves of the arches starting vertically in their springings from the piers. This elliptical shape of arch, in which the rise-to-span ratio was as low as one to seven, became known as basket-handled and has been widely adopted since. Demolished by the retreating Germans in World War II, the Sta. Trinità Bridge was later rebuilt exactly as it stood and, so far as possible, with the original materials, recovered from the bed of the river. An even earlier bridge in Florence, and one that was spared in World War II, was the Ponte Vecchio, ascribed to Taddeo Gaddi in the 14th century. Its three well-balanced arches, supported on peaked piers, are elliptical in shape. The narrow, gently sloping roadway is lined on both sides with tiny shops.

By the middle of the 18th century, bridge building in masonry reached its zenith. Jean-Rodolphe Perronet (1708–94), builder of some of the finest bridges of his day, developed very flat arches supported on slender piers. He served as director of the first engineering school in the world, the famous École des Ponts et Chaussées (School of Bridges and Highways), founded in 1747, and his works included the Neuilly Bridge, over the Seine, the Pont Sainte-Maxence, over the Oise, and the beautiful Pont de la Concorde, over the Seine, in Paris. In Great Britain, William Edwards built what many people consider the most beautiful arch bridge in the British Isles—the Pontypridd Bridge, over the Taff in Wales, with a lofty span of 140 feet (43 metres). In London, the young Swiss engineer Charles Labelye, entrusted with the building of the first bridge at Westminster, evolved a novel and ingenious method of sinking the foundations, employing huge timber caissons (boxes) that were filled with masonry after they had been floated into position for each pier. The 12 semicircular arches of Portland stone, rising in a graceful camber over the river, set a high standard of engineering and architectural achievement for the next generation and stood for a hundred years.

Also in London, John Rennie, engaged by private enterprise in 1811, built the first Waterloo Bridge, whose level-topped masonry arches were described by Canova as “the noblest bridge in the world.” It was replaced by a modern bridge in 1937–45. Rennie subsequently designed and built old Southwark Bridge (1814–19), which consisted of three cast-iron arches with spans of up to 240 feet (73 metres), and the New London Bridge of multiple masonry arches, which was completed in 1831, after his death, and subsequently widened.

Waterloo
Bridge

Development of the modern bridge

In the 17th and 18th centuries, bridge building became a science. Early in this period, scientists, including Galileo, had investigated the theory of beams and framed structures, and before the end of the period bridge builders were required to work to detailed specifications.

THE COVERED (TIMBER-TRUSS) BRIDGE

The truss, a structural form based on the triangle, had long been used to support roofs when it was adapted to bridge design by the Italian Renaissance architect Andrea Palladio. In the 18th century, Swiss carpenters used it to build a covered timber bridge having spans of 193 feet (59 metres) and 171 feet (52 metres) over the Rhine at Schaffhausen, Switzerland. This feat was followed by a similar timber bridge with a 240-foot (73-metre) span at Reichenau, Switzerland. The barnlike covering of timber-truss bridges was necessary to protect the structural members against the weather. In North America, many outstanding timber-truss bridges were built, the first probably that over the Connecticut River at Bellows Falls, Vermont, in 1785. The so-called Colossus Bridge, with a 340-foot (104-metre) span over the Schuylkill River at Fairmount

Pont
d'Avignon

Leonardo's
design for
the Golden
Horn

Park, Philadelphia, was constructed in 1812. One of the best long-span truss designs was developed by Theodore Burr, of Torrington, Connecticut, and based on a drawing by Palladio: a truss strengthened by an arch, which set a new pattern for covered bridges in the United States. Burr's McCall's Ferry Bridge (1815; on the Susquehanna River, Lancaster, Pennsylvania) had a record-breaking span of 360 feet (110 metres), and hundreds of his bridges are still in use.

THE IRON BRIDGE

It was not until late in the 18th century that iron came to be generally employed in structures, freeing bridge builders from their exclusive dependence on timber, brick, and stone. The possibilities opened up by the new material were quickly exploited, and by 1860 numerous iron arches, suspension bridges, and girders had been built. This period also witnessed the first use of compressed air in the construction of bridge foundations below water. Iron chains had been used in suspension bridges for centuries, but the world's first all-iron bridge was a semicircular arch with a 100-foot (30-metre) span, built over the Severn at Coalbrookdale, Shropshire, in 1779. It carried roadway traffic for more than 170 years. This was followed by a number of cast-iron arches designed by the gifted, self-educated Scottish engineer and road builder Thomas Telford, of which the first was the Buildwas Bridge, Shropshire, with a 130-foot (40-metre) span, and the most ambitious was a design for a high-level, 600-foot (180-metre) span (which was never built) to replace Old London Bridge.

In 1840 American patents were granted for a timber truss, in which the verticals consisted of iron ties. This was followed by numerous other trusses. The first major iron-truss bridge, with pin connections, was built in the United States in 1851, and the earliest iron-cantilever girder, which consisted of alternate cantilever and continuous spans, was built over the Main River at Hassfurt, Germany, in 1867.

The Britannia railway bridge (1845–50) across the Menai Strait, north Wales, was designed by Robert Stephenson and William Fairbairn. Employing the prototype of the box, or plate, girder of the kind now used throughout the world, it was originally intended to be a stiffened suspension bridge. It has four spans, each consisting of two wrought-iron tubes side by side, through which the trains run; the two spans over the water are each 459 feet (140 metres) long, and the shore spans are 230 feet (70 metres). In spite of the fact that L.-M.-H. Navier's lectures on the theory of elasticity and structures had been published some years earlier, so little was known of structural-design theory that Stephenson had to proceed empirically by testing, modifying, and retesting a series of models. Workshops were built at the site to fabricate the wrought-iron plates and sections (of the kind that had recently been produced for shipbuilding), which were raised and moved by means of overhead gantries. Rivetting was done mostly by hand but in part by hydraulic machines designed by Fairbairn. During the erection of the bridge, it was found to be possible to dispense with the suspending chains altogether, and the tubes for the spans over the water, each weighing 1,285 tons, were floated out on pontoons and raised to their final level by means of huge hydraulic jacks located on the piers. Carrying locomotives 12 times heavier than those in use when it was designed, the Britannia Bridge survived until it was severely damaged by fire in May 1970. Comprehensive reconstruction was at once undertaken with the object of reopening the bridge with the addition of a three-lane roadway above the two railway tracks.

A major early iron-bridge disaster occurred in December 1879, when the 13 high spans of the new railway bridge over the Firth of Tay, Perth, were blown down in a great gale 18 months after completion. The Edinburgh mail train was crossing the bridge at the time, and it is estimated that 75 persons lost their lives. Consisting of wrought-iron trusses 245 feet (75 metres) long, the girders that fell stood on cast-iron columns rising from piers of brick and concrete. At the time, little if anything was known of the wind pressures that should be considered

in the design of bridges. There was no continuous, lateral wind bracing provided below the deck, and, in fact, the designer subsequently said that no special provision had been made for wind pressure.

The second half of the 19th century was outstanding for the advances made in the theory of design and knowledge of the strength of materials by scientists such as Karl Culmann of Germany, and James Clerk Maxwell and W.J.M. Rankine of Britain. As a result of work in basic science and mathematics, graphic methods of structural analysis were developed, and engineers were able to draw stress diagrams and influence lines; *i.e.*, curves showing, for one component part of a beam or truss, the resistance to various types of stress for all positions of a moving load.

THE MODERN SUSPENSION BRIDGE

In the design of the Menai suspension bridge (1819–26), a 580-foot (177-metre) span in north Wales, Telford used chains of wrought-iron links, all of which were tested and pinned together. The chains, laid out full length, were then towed across the waterway and hoisted into place; and the deck was suspended beneath them. The roadway was only 24 feet (7 metres) wide and, in the absence of any kind of stiffening girders or storm bracing, was highly vulnerable to damage by wind and had to be rebuilt at least twice before the whole of the bridge was reconstructed in 1940. In view of the fate of most of the early suspension bridges in both Europe and the United States, it is a credit to Telford that the Menai Bridge survived for 115 years. Another chain suspension bridge that had a long life was a span over the Danube at Budapest, Hungary. Completed in 1849, it survived for nearly 100 years, until it was destroyed in World War II. The Union Bridge over the Tweed near Berwick, Northumberland, opened in 1820, was still standing in the early 1980s.

The first engineer to employ wire cables instead of chains on suspension bridges was Joseph Chaley, a French engineer who not only built the bridges at Beaucaire, Chaisey, and other places in the south of France but was also responsible for the Fribourg Bridge (1830–34) in Switzerland, which had a span of 870 feet (265 metres), at that time the longest in the world. Each of the main cables, 1,280 feet (390 metres) long from anchorage to anchorage, was made up of 2,000 separate iron wires, which passed over the top of masonry towers, beyond which they were anchored in 58-foot (18-metre)-deep shafts. The bridge carried a roadway 16 feet (5 metres) wide, separated by oaken balustrades from footpaths three feet (1 metre) wide on either side, all at a height of 163 feet (50 metres) above the River Saône. Another early suspension bridge with ironwire cables was the Bry-sur-Marne Bridge, opened to traffic in 1831 and destroyed during the war of 1870.

The multiple-span suspension bridge (*i.e.*, a bridge made up of more than three successive suspension spans without any intermediate anchorage) appeared as early as 1839 in the Dordogne River Bridge, with five equal spans of 357 feet (109 metres) each, supported on wire cables, at Cubzag, France; another was the Dnepr River Bridge (1853) at Kiev, Russia, with two spans of 226 feet (69 metres) and four spans of 400 feet (134 metres), supported by wrought-iron chains.

The weaknesses of the early suspension bridges in storms or under repeated rhythmic loads were fatal for most of them. In 1831 the Broughton suspension bridge collapsed because of oscillations set up by a body of troops marching in step. Four other bridges in the U.S. and Britain were destroyed simply by the impact of flocks of sheep or droves of cattle. The Chain Pier Bridge at Brighton, Sussex, was blown down. The first railway suspension bridge, built in 1830 to carry the Stockton and Darlington Railway over the Tees, was hammered to destruction in a few years by the weight and impact of the trains. In the U.S., the Fairmount Bridge, supported by a number of small wire cables, over the Schuylkill River, was a success, but a 1,000-foot (300-metre) span over the Ohio River at Wheeling, West Virginia, survived only five years.

Credit for designing and building the first suspension bridge that was rigid enough to withstand not only wind action but also the impact of railway traffic belongs to

Early
suspension
failures

Robert
Stephenson's
Britannia
Bridge

John A. Roebling, an immigrant from Germany to the United States. In his Grand Trunk Bridge of 821-foot (250-metre) span below Niagara Falls, there were two decks, one above the other, for rail and road traffic, respectively, with a pair of stiffening trusses 18 feet (five metres) deep connecting them. In addition, the deck was braced by means of inclined wire stays overhead and others below, anchored to the sides of the gorge. For the four main cables, instead of the separate stranded or twisted ropes that had been used for cables in Europe, Roebling used parallel wrought-iron wires, spun in place, bunched together, and wrapped, a process he had patented in 1841; each cable was 10 inches (25 centimetres) overall in diameter. The bridge was completed in 1855 and survived for 42 years, although not without considerable repair work and reconstruction necessitated by the wear and tear of traffic.

Brooklyn
Bridge

The famous Brooklyn Bridge (1869–83), with a record-breaking span of 1,595 feet (486 metres), was designed by John Roebling and erected under the direction of his son, Washington. It has four cables with an overall diameter of 15.75 inches (40 centimetres), built up of parallel steel wires. The method of cable spinning devised by Roebling was so simple and effective that it has been used in principle, although now much elaborated, for all the large suspension bridges subsequently built in the United States (see Figure 9). The wire is delivered to the site in reels, from which loops are carried over the tops of the towers to the far anchorage, where each loop is pulled off the sheave and placed around a strand shoe, by which it is anchored.

By the time of the Brooklyn Bridge, the stiffening truss had been established as an indispensable part of the suspension-bridge deck. In the Point Bridge at Pittsburgh, Pennsylvania (1877), an attempt was made to stiffen the cables instead of the deck, but this proved less effective.

THE FOUNDATION PROBLEM: COMPRESSED AIR

Up to the middle of the 19th century, cofferdams were the only means by which bridge foundations could be properly constructed below water. But, because of the limited length of the sheet piling and the difficulties caused by obstructions or by very hard or soft ground, cylinders or wells were employed and sunk either by dredging or

Figure 9: Method of spinning parallel wire cable on a suspension bridge.

Use of
pneumatic
caissons

under compressed air. The first use of pneumatic caissons (Figure 10) for bridgework was on the foundations of a bridge over the Medway at Rochester, Kent, in 1851. Subsequently I.K. Brunel used this method for sinking the foundations of Chepstow Bridge, Monmouth, and, on a much greater scale, for the Royal Albert Bridge at Saltash, Cornwall (1855–59). In the latter, a wrought-iron cylinder 35 feet (11 metres) in diameter was designed for the central pier and sunk through 70 feet of water and 16 feet (5 metres) of mud to a rock bottom. Water was expelled by compressed air from the floorless working chamber at the bottom of the cylinder; workers entered the chamber

Figure 10: Pneumatic caisson.

through an air lock and excavated the mud and rock, causing the caisson slowly to sink until a hard stratum was reached. They then securely plugged the bottom of the foundation with concrete.

Many early tragedies in the use of compressed air were caused by men working excessively long shifts or coming out of the air lock and decompressing too quickly and being afflicted by caisson disease, or bends. With the limiting of the length of the working shift according to the air pressure and with slow decompression in the air lock, the incidence of caisson disease was reduced. Further investigations at the beginning of the 20th century robbed the disease of its worst terrors, except for the danger of bone necrosis, for which no cure has yet been found.

THE STEEL BRIDGE

The last 30 years of the 19th century saw the introduction of steel plates and rectangular, rolled-steel sections, which

Figure 11: Royal Albert Bridge over the Tamar at Saltash, Cornwall. The designer, Isambard Brunel, employed a wrought iron cylinder 35 feet in diameter for the central pier in this innovative design of 1855–59.

The Eads
Bridge

came to be mass-produced and fabricated in shops by standardized methods. This inevitably led to an enormous production of steel-truss and plate-girder bridges throughout the world and to spans of ever-increasing size. Arch and cantilever bridges were favoured for long spans in the railway era because they could withstand the impact of heavy railway traffic better than could suspension bridges.

The first big bridge to be built of steel was the Eads Bridge built over the Mississippi River (1867–74) at St. Louis, Missouri. It was designed with three steel arches with spans of 502, 520, and 502 feet (153, 158, and 153 metres), respectively. The spans were made double-decked to carry wagon and pedestrian traffic on the upper deck and two railway tracks below. To reach bedrock, the foundations had to be excavated more than 100 feet (30 metres) deep, although this necessitated working under compressed air at depths greater than men had ever worked before. So little was known of the precautions needed under these conditions that, of the 600 men employed in sinking, there were 119 serious cases of bends and 14 deaths.

An innovation on this bridge that has since been widely copied was the erection of the arches by cantilevering. Arch ribs were built out in either direction from the pier and held by cables extending from a temporary wooden tower atop the pier. Halfway to the next pier (or abutment), the half-arch met and joined a half-arch similarly cantilevered out to meet it.

In 1898 an arch bridge with a span of 840 feet (256 metres) was completed below Niagara Falls; it stood for 40 years, until the ends of the steel ribs were wrecked by a huge ice jam in the river. In the same year, the first major steel bridge in France was opened, the Viar Viaduct, which consisted of an arch 721 feet (220 metres) long, flanked by cantilever spans of 311 feet (95 metres). Seven years later the Victoria Falls Bridge, with a braced arch spanning 500 feet (152 metres), was built in Africa to carry the Cape-to-Cairo Railway, then projected by Cecil Rhodes, across the 400-foot- (122-metre-) deep gorge of the Zambezi River.

For the design of the Forth Railway Bridge between North and South Queensferry (1882–90), with two main spans of 1,710 feet (521 metres) each, in Scotland, the designer conducted an extensive series of wind-pressure tests, using gauges installed at the site, over a period of two years. As a result, he was satisfied that the pressure of 56 pounds per square foot (274 kilograms per square metre), specified for the design by the committee set up after the Tay Bridge disaster, was “considerably in excess of anything likely to be realised,” and so it proved.

Each of the two main spans of the bridge consists of two 680-foot (207-metre) cantilever arms, with a 350-foot (107-metre) suspended span between them. About 54,000 tons of Siemens-Martin open-hearth steel, which has a substantially higher ultimate strength than modern, commercial mild steel, was used. The biggest compression members were designed as tubular struts 12 feet (3.7 metres) in diameter, and all of the steelwork was fabricated in shops built for the purpose at South Queensferry. The spans were built out as balanced cantilevers from each main pier, the tubular members being erected plate by plate by means of two-ton hydraulic cranes.

The latter half of the 19th century witnessed the construction in India of a large number of multispan railway bridges more than 1,000 feet (300 metres) long. Their British builders learned how to utilize the simplest kind of equipment and unskilled labour; they had to study and develop the use of guide banks as a means of keeping the rivers under the bridges and preventing them from meandering; and, sinking brick wells by dredging in the sand, they built the deepest foundations ever constructed up to then, as a safeguard against undermining when the sand of the riverbeds was scoured away during the flood seasons.

In 1896 the first Vierendeel truss, in which the bracing consisted of a series of framed portals with rigid verticals and no diagonal members, was built for the Brussels Exhibition.

REINFORCED-CONCRETE BRIDGES

Engineers in the late 19th century first demonstrated the possibilities of reinforced concrete as a new structural ma-

terial. Visualizing the novel forms that could be molded, with concrete resisting the compression forces and steel bars taking the tension, they designed bridges in sweeping curves. The basic element in reinforced concrete was the slab, which replaced the beams, posts, and ties associated with steelwork design. From the start, Switzerland, France, and the Scandinavian countries took the lead, and the longest and most impressive reinforced spans were built in those nations.

The first notable reinforced-concrete arch, the Pont de Chatellerault (1898), was designed with a span of 172 feet (52 metres). Robert Maillart designed three-hinged arches, in which the deck and the arch rib were combined to produce closely integrated structures. The first of these was the Tavanasa Bridge, a span of 167 feet (51 metres) over the Vorderrhein, Switzerland, which was destroyed by a landslide in 1927. In these bridges, Maillart recaptured the beauty of the pointed arch of medieval times. He then developed arches of very thin reinforced-concrete slabs, typified by the Schwandbach Bridge (1924) near Schwarzenberg, Switzerland, which was curved in plan and carried a roadway across a deep ravine.

Figure 12: Salginatobel Bridge near Schiers, Switzerland, a reinforced-concrete bridge designed by Robert Maillart and built 1929–30.

One of the biggest reinforced-concrete bridges in the United States, the Tunkhannock Creek Viaduct, Pennsylvania, was completed in 1915. Its overall length of 2,375 feet (724 metres) comprises ten semicircular arches that carry a double-track railway at a height of 240 feet (73 metres). In Great Britain, the first major reinforced-concrete structure was the Royal Tweed Bridge at Berwick. Completed in 1928, it has four arch spans varying from 167 feet (51 metres) to 361 feet (110 metres). It was followed in 1935–42 by the new Waterloo Bridge in London. Because of its slender simplicity and absence of decoration, it is frequently held to be the finest bridge over the Thames.

In France, a then record span of 430 feet (131 metres) was built in 1923 over the Seine at Saint-Pierre du Vauvray. It was surpassed seven years later by the Albert-Loupe (or Plougastel) Bridge at Brest. The latter had three arch spans of 567 feet (173 metres). The centring (supporting falsework) consisted of a timber arch 500 feet (152 metres) long and 90 feet (27 metres) high, the ends of which were tied together by cables. It was built on shore, floated out on pontoons, and secured in place for pouring each arch rib in turn.

In Sweden, the Traneberg Bridge was built in 1934 in Stockholm. It has an arch 593 feet (181 metres) long. It was surpassed by the Esla Bridge in Spain, with a 631-foot (192-metre) span completed in 1942, but a year later Sweden regained the lead with an 866-foot (264-metre) span

of the Sandö Bridge, over the Angermanälven River. In 1939, during the pouring of the rib, the wooden arch that formed the centring collapsed. Its failure was ascribed to persistent damp weather and the long loading period. New centring for the bridge had to be built in the form of huge timber trestles supported on 13 groups of piles 130 feet long, and the bridge was successfully completed in 1943.

Precast-concrete girders are sometimes used for economy and speed of construction in multiple short-span bridges. A typical example is the San Mateo Bridge across San Francisco Bay, which has 1,054 precast spans of 30 feet (9.1 metres) and 116 spans of 35 feet (11 metres). One of the main advantages claimed for reinforced-concrete bridges is that, if they are well designed and the construction is thoroughly supervised, they should be maintenance-free and not require cleaning and painting every few years, as do steel bridges. To achieve this, the concrete must have a solid, weather-resisting surface, free from cracks and honeycombs, or, alternatively, must be stone faced. Facing is costly but is a guarantee against deterioration of appearance. A successful example is the Waterloo Bridge in London, which is faced with slabs of Portland stone.

Reinforced-concrete bridges in the U.S.S.R. include the Saratov Bridge (1965), with five continuous trusses of 544 feet (166 metres) over the Volga River, and the old Dnepr Bridge (1952) at Zaporozhye, Ukrainian S.S.R., with an arch of 748-foot (228-metre) span. Two fine examples in Portugal are the low, slender arch over the River Tua at Abreiro (1957), which has a rise-to-span ratio of one to ten, and the 885-foot (270-metre) fixed arch of the Arrábida Highway Bridge over the Douro River. This span was surpassed in 1963 by that of the Foz do Iguaçu Bridge over the Paraná River between Brazil and Paraguay and by the Gladesville Bridge in Sydney, New South Wales (1964), with its span of 1,000 feet (305 metres) over the Parramatta River.

MOVABLE AND PONTOON SPANS

The bascule (draw) bridge, lifted on a hinge with the aid of a counterweight, was developed in the Middle Ages. Old London Bridge had such a drawbridge. The first swing, or pivot, bridges appeared in London early in the 19th century. The heavy, powered bascule and the vertical-lift bridge were evolved in the latter half of the 19th century. The Tower Bridge in London (1886–94) is a double-leaf bascule that provides an opening 260 feet (76 metres) wide and is operated by hydraulic power derived from steam (see Figure 13). The Sault Sainte Marie Bridge (1941), in Michigan, is a bascule that has an opening span of 336 feet (102 metres). Another variety of bascule is the Scherzer, or rolling lift, bridge, in which the leaves roll back on tracks to open the bridge.

In vertical-lift bridges, the span remains horizontal and is lifted by means of counterweighted cables that pass over the end towers. The Arthur Kill Bridge is of this type. Built in 1959 to link Staten Island, New York City, with New Jersey, it has a lifting span of 558 feet (170 metres).

From O.E. Hovey, *Movable Bridges* (1927), John Wiley & Sons, Inc.

Figure 13: Sectional elevation of the bascule, Tower Bridge, London, 1886–94.

The al Firdan Bridge (1965) over the Suez Canal, Egypt, is a swing bridge composed of twin swing spans, pivoted on piers at either shore, 552 feet (165 metres) from turntable to turntable. Ordinary swing spans, pivoted on a central pier, cause more interference with river traffic than bascules and may obstruct valuable wharf space. Another advantage of bascules is that they can be partially opened to let small craft pass.

Some of the longest floating spans in the world are clustered around Seattle, Washington, including the second Lake Washington Bridge, which stretches a distance of 7,998 feet (2,438 metres). Other famous floating bridges, since replaced by high-level fixed bridges, include a 3,165-foot (965-metre) curved pontoon span at Hobart, Tasmania, a pontoon bridge at Calcutta (built in 1874), and a 1,500-foot (457-metre) bridge over the Golden Horn at Istanbul. All these bridges had movable spans that could be opened to permit shipping to pass.

20TH-CENTURY LONG-SPAN BRIDGES

Loadings and forces. The most important weights and forces to which a bridge is subject are its own weight; the weight of the traffic and its dynamic effects; natural forces set up by wind, changes in temperature, snow loads, earthquakes, etc.; and stresses arising temporarily during erection. Railway bridges must withstand not only the weight of the locomotives and rolling stock but also the impact and effects of lurching and lateral motion of the locomotive. On the highways of several countries, automotive vehicles weighing up to 200 tons are not uncommon, and new bridges must be designed to support them.

Considerable research has been carried out on wind forces, which can now be closely estimated, but wind-tunnel tests on a model are still usually carried out to assess the effects of wind forces on a long-span suspension bridge. Although no bridge could withstand an earthquake of catastrophic force, bridges in India and New Zealand are designed to resist a horizontal force equal to one-tenth and, in Japan, Italy, and the U.S.S.R., to one-fifth of the weight of the superstructure. The designs of the Golden Gate and San Francisco-Oakland Bay bridges in San Fran-

Wind-tunnel tests on models

Notable modern bascules

cisco, the Auckland Harbour Bridge in New Zealand, and the Howrah and Ganga bridges in India were all calculated to resist earthquake shocks, which in the past have damaged or destroyed many bridges.

It remains for the engineer to exercise his judgment in assessing future traffic developments and deciding what combinations of loading and forces should be adopted and the factor of safety applicable in each case. Factors of safety are now considered from the point of view of "limit states," which are states in which the structure in whole or in part threatens to cease to fulfill the function for which it was designed. The field is enormous, because the effect of numerous factors, such as loading, impact, fatigue, and corrosion, must be assessed for different types of structures and materials of construction and suitable margins of safety provided for various causes of failure, such as deformation, buckling, fatigue, brittle fracture, or collapse of some element. While conferring greater uniformity of strength throughout all parts of the structure, this change in philosophy may also permit valuable savings to be made.

For a given ratio of strength to weight of materials there is a maximum span for each type of bridge beyond which it would have an insufficient margin of strength to support the weight of traffic in addition to its own weight and other forces to which it might be subject. For cantilever bridges built with modern high-tensile steel, the maximum span would approach 2,500 feet (760 metres) and, for arch bridges, 3,000 feet (900 metres). On account of the much higher strength-to-weight ratio of steel-wire cables as compared with structural steel, suspension bridges can be built with much longer spans. In a period of 80 years, the maximum suspension span has increased from 1,500 to 4,260 feet (457 to 1,298 metres), bearing out predictions made by Roebling in 1855.

Cantilever bridges. In 1904 work began on the first Quebec Bridge, which was to carry two railway tracks on a cantilever span of 1,800 feet (549 metres). The two giant cantilevers were erected, and the relatively short suspended span between was being assembled from both sides. Suddenly the whole of the structure on the south side, some 20,000 tons of steel, collapsed, killing 75 workmen, the most costly bridge-construction disaster on record. Investigation revealed that the failure was caused by buckling of web plates in which the lacing was too weak and by certain unriveted connections. Other grave disclosures, however, were that the specifications were inadequate, the weight of the bridge was underestimated, and the working stresses were unwarrantably high.

For the new design, made after an exhaustive series of tests on structural members and rivetted joints, high-tensile nickel steel was used for the main trusses, and the width of the bridge was increased from 67 to 85 feet (20 to 26 metres), greatly increasing its strength. The suspended span, 640 feet (195 metres) long, was built, floated out, and attached to lifting links at the four corners of the cantilever arms. As it arose, suddenly, one of the castings at the end of a lifting link failed, and the span tilted, broke, and fell into the water, carrying 11 workmen with it. Within 12 months, a new span had been constructed and successfully lifted into place. The bridge was first opened to traffic in August 1918.

Another great cantilever is the Howrah Bridge (1936-43), over the Hooghly River at Calcutta, which has a span of 1,500 feet (457 metres). An interesting innovation on the Howrah Bridge was that the high-tensile steelwork was pre-stressed during erection; this measure obviated secondary bending stresses that would otherwise have occurred at the rivetted connections. The span of the Howrah Bridge has since been exceeded by the Greater New Orleans Bridge (1958), in Louisiana, which has a span of 1,575 feet (480 metres), and the Commodore John J. Barry Bridge (1974) over the Delaware River at Chester, Pennsylvania, which has a span of 1,644 feet (501 metres).

Arch bridges. The Sydney Harbour Bridge (1924-32), New South Wales, may be considered the world's greatest steel arch because of its immense carrying capacity and the difficulties overcome in erecting it across a deep harbour in which no temporary supports were practicable

Figure 15: Quebec Bridge across the St. Lawrence River. The steel cantilever railroad bridge, spanning 1,800 feet, was completed in 1918.

By courtesy of Canadian National Railways

(Figure 16). With a span of 1,650 feet (503 metres), it was built to carry four interurban rail or streetcar tracks, in addition to a roadway 57 feet (17 metres) wide and two pedestrian walkways.

The two-hinged arch, flanked by granite-faced pylons, has a deck suspended at a height of 172 feet (52 metres) over the water. Most of the 38,390-ton arch is of rivetted, high-tensile silicon steel made in Britain and fabricated in shops built for the purpose in Sydney. The 11-foot- (3.5-metre-) wide webbed chords (top and bottom members) of the arch are some of the heaviest steelwork of this kind ever constructed. The two halves of the arch were built out as cantilevers, temporarily held back by wire-rope anchorages until they met and were joined in the middle. All of the steelwork was assembled by two cranes that moved out along the upper chords of the arch until it was complete and then erected the hangers and the deck as they retreated.

Another large steel arch, the Bayonne Bridge, over the Kill van Kull between Staten Island and Bayonne, New Jersey, was begun after the commencement of Sydney Harbour Bridge and completed a few months before. It was built over a waterway shallow enough to permit erection of the arch on temporary trestles. Twenty-five inches

Bridge

(64 centimetres) longer than the bridge at Sydney, it carries automobile and truck traffic.

Suspension bridges. In the series of suspension bridges of ever-increasing span built in the United States between World Wars I and II, cables of parallel wires were invariably used. Although the ultimate strength of a given weight of wire increases as it is drawn thinner, it is found most economical to use wire of about 0.19-inch (5-millimetre) diameter, because the thicker the wire the less length there is to be spun to make up a cable of the necessary diameter.

In Canada, cables of stranded-wire ropes have been adopted, notably on the Island of Orleans Bridge at Quebec (1935) and the 1,550-foot- (472-metre-) span Lions Gate Bridge at Vancouver, British Columbia (1939). A third variant, known as "locked-coil" cables, in which the wires of each strand are specially shaped so as to form a smooth circumference, was used in the Cologne-Mulheim Bridge over the Rhine in West Germany.

In the 1,750-foot (533-metre) span of the Philadelphia-Camden Bridge (1926) on the Delaware River, cold-drawn parallel wire continued to be used in the cables, and cellular construction, in which towers were built up of a number of vertical cells, was adopted for the first time.

To increase the allowable stress in the cables, heat-treated wires were introduced in the bridge at Mount Hope, Rhode Island, and in the 1,850-foot- (564-metre-) span Ambassador Bridge over the Detroit River in Detroit, both completed in 1929. During erection of the cables, however, a number of broken wires were detected at the bends around the strand shoes at the anchorages. Investigation showed that the fine-grained, heat-treated wires could not withstand the alternating stresses to which suspension cables were subject; they had to be replaced by cold-drawn wire, which has a tough, fibrous structure and can resist such stresses.

The next advance was the George Washington Bridge (1927-31), over the Hudson River at New York City. Designed by Othmar H. Ammann, a Swiss-born U.S. engineer, it has a span of 3,500 feet (1,067 metres) and two roadways, one above the other. Four cables, 36 inches (91 centimetres) in diameter, each built up of 26,474 parallel galvanized wires with an ultimate strength of 98 tons per square inch, were used. Initially, there were no stiffening trusses; only the upper roadway was built. The construction of the lower deck and of stiffening trusses between the two decks was completed in 1962. The great mass of wire in the cables (a total of 105,000 miles [168,000 kilometres]) prompted a higher degree of mechanization in the cable erection than had ever been achieved before.

In 1933 work began in San Francisco on two major suspension bridges, the double-decked San Francisco-Oakland Bay Bridge, designed with an overall length of nearly 5.25 miles (8.45 kilometres), and the Golden Gate Bridge, with a span of 4,200 feet (1,280 metres), across the entrance to the harbour.

The Mackinac Bridge (1954-57), with a span of 3,800 feet (1,158 metres) across the Straits of Mackinac in Michigan, remains one of the longest suspension spans ever built. The piers were specially designed to withstand the effects of severe winter storms and ice floes common to the area.

The Forth Road Bridge (1958-64) and the Severn Bridge (1961-66) in Great Britain are the first major suspension bridges outside the United States to be built with parallel wire cables spun in place. Although both exceed 3,000 feet (900 metres) in span, they were lighter in weight, more slender, and more economical in cost than other suspension bridges of comparable size. Like the Mackinac Bridge, the Forth Road Bridge, in latitude 56° N, was built in an area notorious for its high winds and storms and presented extraordinary difficulties during erection.

The Verrazano-Narrows Bridge (1959-64), with a main span of 4,260 feet (1,298 metres), stands at the entrance to New York Harbor. A double-deck structure, it carries and was planned to take 12 lanes of roadway traffic. It has rivetted-steel towers 680 feet (207 metres) high, built up of square vertical cells. There are four main cables, each 36 inches (91 centimetres) in diameter and made up of a total of 142,500 miles (229,300 kilometres) of wire. On a span of this magnitude, the tops of the vertical towers are 1.6 inches (four centimetres) farther apart than the tower bases, owing to the curvature of the Earth's surface, and the length of cable wire would stretch more than halfway to the Moon. The total weight of steelwork in the bridge is 144,000 tons, a weight (and cost) many times greater than that of the contemporary Severn Bridge. The Humber Bridge (1973-81) over the estuary of the Humber River on the east coast of England has lines that are similar to those of the Severn, but with a main span of 4,626 feet (1,410 metres) and side spans of 1,739 feet (530 metres) and 919 feet (280 metres). Also similar in design to the Severn is the Bosphorus Bridge, with a main span of 3,524 feet (1,074 metres), opened in 1973 over the strait at Istanbul. In 1966 the Salazar (now 25th of April) Bridge was completed across the Tagus River at Lisbon, with a span of 3,323 feet (1,013 metres), the first major suspension bridge so designed that it could subsequently be double decked, if desired, to carry railway traffic.

Other suspension spans of between 2,000 and 3,000 feet are the Quebec Road Bridge, built alongside the existing railway crossing, and named at its opening in 1970 the Pierre Laporte Bridge; the second Delaware Memorial Bridge (1968), built alongside the first; the Angostura Bridge in Venezuela; and the Tacoma Narrows II Bridge at Puget Sound, Washington. The Little Belt Bridge (1970), in Denmark, has a span of 1,968 feet (600 metres) and was designed to carry a six-lane highway on a streamlined box deck. The towers are of reinforced concrete and the cables built up of strands of twisted wire.

Foundation techniques. For the main piers of the Howrah Bridge in Calcutta, huge monolith foundations measuring 180 by 81 feet (55 by 25 metres) were required. Each reinforced-concrete monolith was divided into 21 wells 20 feet (six metres) square and was sunk by open excavating. The monolith on the Calcutta side was set at a depth of 103 feet (31 metres) under compressed air. This technique was applied to each well in turn, after a temporary steel air deck was fitted near the bottom of the well to form the roof of a working chamber. This method was successfully used on a number of major bridges in India and Burma and also on the huge Lower Zambezi Bridge in Mozambique.

There is rarely much difficulty with the foundations for large arch bridges, because they are usually in rock and at no great depth. For the foundations of the Sydney Harbour Bridge, it was necessary only to excavate yellow sandstone rock some 30 to 40 feet (nine to 12 metres) beneath each bearing. On the Hell Gate Bridge (1917), over the East River in New York City, however, there was difficulty, because when rock was reached, at a depth of 70 feet (21 metres), it was found to contain a wide crevasse that had to be bridged with concrete, all of this work being carried out under compressed air.

Among suspension bridges, the foundation for the New Jersey Pier of the George Washington Bridge (1931) was

Verrazano-Narrows Bridge

Figure 17: Cable compactor working on the George Washington Bridge over the Hudson River, New York City, during its construction in 1930.

The San Francisco-Oakland Bay Bridge

built inside two steel-piled cofferdams that were bigger and deeper than any previously used on bridge construction (Figure 18). The foundations for the San Francisco-Oakland Bay Bridge, at San Francisco, presented extraordinary difficulties because caissons of unprecedented size had to be sunk through deep water and a current of 7.5 knots to a depth considerably deeper than men can work under compressed air. For the biggest caisson, at the central anchorage, connecting two suspension bridges, an entirely new technique was devised. The caisson was a honeycomb built up of 55 vertical steel cylinders, each sealed by means of a steel dome welded on top. Built on a slipway, it was launched, towed to the site, anchored, and sunk onto a sloping bottom more than 200 feet (60 metres) down, which had to be levelled so that the caisson could be founded on a horizontal plane. To provide buoyancy and control during the sinking, compressed air was used inside the cylinders in turn to enable muck to be grabbed out as sinking proceeded, and new steel lengths had to be welded on before the domes were replaced, as the depth increased. When rock was reached, it was broken up by dropping pointed, five-ton weights through the cylinder, after which the surface was cleaned up and levelled by divers. The middle 25 cylinders were then sealed by concrete deposited under water, followed by the sealing of the remaining 30.

Still different problems were presented by the foundation for the Golden Gate Bridge. For the south pier, located in deep water, virtually in the open sea and exposed to ocean swell, it was decided to build the foundations inside a huge elliptical cofferdam, founded on bedrock 100 feet (30 metres) below water level. The rock was first excavated some 15 feet (4.6 metres) deep all over the area; blasting was carried out by bombs of increasing size exploded in holes bored in the rock. After the cofferdam had been closed, its bottom was sealed by depositing a 65-foot (20-metre) depth of concrete below water. The water inside the cofferdam was then pumped out and the pier of the bridge built in the dry.

Figure 18: Cable anchorage of the George Washington Bridge, New York City.

On the Verrazano-Narrows Bridge in New York City, the foundations for the main piers were located in shallow water a few hundred feet off shore at the entrance to New York Harbor, where few difficulties were encountered. The site of each pier was enclosed by a rectangular cofferdam and the water inside pumped out. A reinforced-concrete monolith with a steel cutting edge, measuring 130 feet by 230 feet (40 × 70 metres) in plan and enclosing 66 circular wells 17 feet (5 metres) in diameter, was sunk by open dredging, the walls being built up to keep them above water level. The monolith on the Staten Island side was finally founded at a depth of 170 feet (52 metres).

Tacoma Narrows failure, 1940; impetus to aerodynamics. The collapse of the Tacoma Narrows Bridge, at Puget Sound, in 1940, only 4 months after its completion and

after more than 50 years of immunity from suspension-bridge failure of this kind, brought the study of aerodynamic stability sharply to the fore. This bridge was by far the most flexible among its contemporaries. It had a span of 2,800 feet (853 metres) with a width of only 39 feet (12 metres), and the deck was stiffened throughout its length not by the deep open trusses formerly used but by two plate girders only 8 feet (2.4 metres) deep. Under quite moderate winds, the deck not only swayed sideways but also was subject to severe torsional (twisting) vibrations, and ultimately, in a wind of only 42 miles (70 kilometres) per hour, the vibrations became so violent that the deck was torn away and crashed into the water. Other U.S. suspension bridges had also shown undesirable aerodynamic action, and further bracing or stiffening was quickly incorporated.

A committee appointed to investigate the Tacoma failure found that the oscillations caused by wind were due to (1) natural turbulence or gusts and (2) the eddies created by the solid cross section and shed from the bridge structure. A dangerous buildup of oscillations, possibly leading to collapse, might result if the frequency of the eddies coincided with any of the natural frequencies of oscillation of the bridge. Bridge designers thereafter reverted to the use of heavy, stiff deck structures to provide torsional rigidity and also left longitudinal openings or slots along the deck, between the dual roadways and the girders, similar to the antistall slots originally used in the wings of aircraft. All these modifications were adopted for the Tacoma Narrows II Bridge, completed in 1950, in which width and rigidity were considerably increased as compared with its predecessor, and also for the Mackinac Bridge, the Forth Road Bridge, and others.

Engineers completing the final design for the Severn Bridge, however, realized that serious eddy sheddings might well be avoided on bridge decks by adopting the principles that had been used for years to avoid it in aircraft structures. The deck of the bridge was designed as a box girder, shaped like an aerofoil, and enclosed by stiffened plates at the top and bottom and inclined plates at the sides, so as to make it in a large measure streamlined. The upper surface constitutes the deck, on which the roadway is constructed, projecting platforms being provided at the sides to carry cycle tracks and footways. Extending throughout the span, the deck is only 10 feet (3 metres) deep and is suspended from the cables by inclined hangers at 60-foot (18-metre) intervals. These triangulated hangers damp out the small degree of oscillation that might otherwise occur with winds blowing slightly upwards from the horizontal.

Considerable economy is achieved not only by the saving in weight in the deck itself but also by the fact that its shallow airfoil profile reduces the wind loads on the bridge and, thus, leads to further economies in the weight of cables and towers. Moreover, the tower legs are of single-box section, so that their weight is reduced to a minimum. These innovations have undoubtedly set high standards of economy and sophistication for the future of suspension-bridge design.

Aerodynamic action may also be a source of trouble during the erection of a suspension bridge. When the north tower of the Forth Road Bridge had reached a height of over 400 feet (122 metres), it began to sway alarmingly under quite light crosswinds of only 20–25 miles (32–40 kilometres) per hour, although in a heavy gale it moved only a few inches. The sway developed an amplitude of over 7 feet (2.1 metres) at the tower top, with a period of 4.5 seconds, and built up and died down every few minutes. This novel phenomenon was quickly checked by means of a damping device consisting of a 16-ton counterweight that was connected to the top of the tower by long steel cables and arranged so that it could slide up and down a ramp inclined at 45° to the horizontal. Any movement of the tower top of more than a few inches began to pull the counterweight up the ramp; this interrupted the rhythmic buildup of the oscillations and brought the top of the tower to rest. The steelwork of the suspended deck of this bridge was erected in two passes by four 15-ton derricks, working outward from each of the towers to the centre and then returning again. Wind-tunnel tests made on models of the

Sway and torsional vibrations

Damping oscillation in the Forth Road Bridge

deck during erection demonstrated that it was necessary to leave a longitudinal strip 20 feet (six metres) wide open along the centre line of the bridge, during the first pass of the derricks, in order to maintain the aerodynamic stability of the deck, until the first pass had been completed, connecting the stiffening trusses of the deck at midspan.

Contemporary developments in bridge engineering

The period since World War II has been the greatest bridge-building era in the history of the world. This is due partly to postwar reconstruction and urban development but even more to the unprecedented advance of motorways. In the U.S.S.R. the seven-year plan of the 1960s called for 650 large and 2,600 medium-sized bridges, four times as many as in the previous seven-year period. In China, too, there has been a great upsurge in the construction of roads and railways, all requiring their quota of bridges. This unprecedented activity has led not only to important improvements in materials available for bridge construction but also to novel types of foundations and superstructures and new techniques of calculation, fabrication, and erection.

IMPROVED MATERIALS

Steel. Research in steelwork has concentrated on the commercial production of structural steel of high-tensile quality that is also suitable for electric-arc welding and fabrication by flame cutting. Other important qualities sought include ductility and resistance to fatigue and corrosion. New forms of connection include welding, which reduces the weight of the structure, and the use of friction-grip bolts. Steel trusses may be built of all-welded, mild or high-tensile tubular members; hollow rectangular sections up to 13 inches (33 centimetres) square and one inch (2.5 centimetres) thick, which are seamless and rolled, can be obtained. Meehanite, a form of cast iron, is increasingly used for bearings of bridges, and expansion joints may be built up of layers of rubber bonded between steel plates.

For girder bridges of span greater than 300 feet (90 metres), steel is usually the most economical material to use; for arches, the economically critical span is longer. As the length increases, low-alloy or high-tensile steel is preferable. The saving in weight on long spans is suggested by the fact that, on the Sydney Harbour Bridge, every ton of steel in the arch required 0.7 tons to support it. The new, stronger, low-alloy steels can be used at substantially higher working stresses than mild steel. Low-alloy steels cost little more to produce than mild steel but are not usually as readily available. Other, even stronger special steels have been produced, but their cost is double that of mild steel. About 3,000 tons of such a steel were used in the second Carquinez Bridge (1958), near San Francisco.

Laminations in steel plates are more serious in welded than they are in rivetted work, and a system of ultrasonic tests has been evolved whereby laminations can be detected before fabrication. Light alloys such as aluminum may play a greater part in bridge building when their elasticity and cost can be reduced. They have been used to make light service spans used in the erection of bridges and also to reconstruct the decks of old bridges at reduced weight. It has not yet proved possible to produce stainless steel of structural quality, but high-tensile weathering steel is being increasingly used. When exposed to weather, this kind of steel forms a coat of oxide on the surface, which inhibits any further corrosion.

Prestressed concrete. The process of prestressing concrete, which consists of putting it into a state of compression by tensioning steel bars or wires that pass through it, was conceived at the beginning of the 20th century and came to be recognized as the most important advance to have taken place in bridge construction since reinforced concrete came into general use. The economies in material that prestressing rendered possible led to its rapid development in the period of shortages during and after World War II.

To obtain the full benefits of the process, concrete of high quality and strength is necessary. Rapid advances

in concrete technology have resulted in its strength being doubled and its surface greatly improved since World War II. The use of precast units, often of substantial size, supported on novel systems of cantilevered and suspended centring and thereafter prestressed, have led to a marked increase in the length of simple or continuous spans, which can now be built economically up to lengths of 400 feet or more.

Quality of concrete. Concrete can be made with an ultimate compression strength of 8,000 to 12,000 pounds per square inch (564–846 kilograms per square centimetre). This permits working stresses in the range of 2,000 to 3,000 pounds per square inch, but the upper limit must not be exceeded because, beyond it, the rate of creep (*i.e.*, nonelastic deformation resulting from stress) of the concrete increases too quickly. This improvement in quality was achieved by further refinements in the water-to-cement ratio, the grading of the aggregate (by improvements in vibrating), and by innovations such as steam curing. Because of the thinness of the wire used in prestressed work, it is essential that it should be completely protected against corrosion. The elimination of cracks in the concrete and the production of a dense, flawless surface therefore become of first importance. The compression induced in the concrete tends to eliminate cracks, and new materials for forms, such as hardboard, have enabled the surface of the concrete, whether flat or curved, to be of good texture, free from imperfections, easy to clean, and pleasing to the eye.

Systems of prestressing. During World War II, when shortages of timber for forms and steel for reinforcement precluded the use of conventional reinforced-concrete design, Eugène Freyssinet reconstructed bridges in Tunisia by designing them to be built of precast blocks subsequently assembled on site and joined together by prestressing done by threading steel wires and grouting them in. Various systems of prestressing have since been evolved, but the most usual procedures are those outlined below. For reinforcement, narrow, high-tensile-steel bars with an ultimate strength of 64 to 72 tons per square inch (one ton per square inch = about 141 kilograms per square centimetre) are used at a working stress of about 45 tons per square inch. Alternatively, cables made up of a number of parallel steel wires, with an ultimate strength of 90 to 110 tons per square inch (similar to those used in the parallel-wire cables of suspension bridges), may be used at a working stress of about 70 tons per square inch. Another development has been the use of stranded-wire ropes. There is always a loss of about 15 percent in the working stresses due to shrinkage and creep of the concrete and relaxation (reduction in stress intensity) of the steel.

Before the concrete is cast, thin-gauge, flexible sheathing is fixed permanently in position in the molds for the bars or wires to pass through. When the bars or wires have been placed in position, they are tensioned; in bars, the tension is held by screwing nuts on the ends of the bar against steel anchor plates; if wires are used, the tensioning is done by means of hydraulic jacks, after which the wires are held by wedges. Cement is then forced into the sheaths under pressure to grout in the wires or bars and prevent corrosion or slip.

The amount of prestress is usually greater than the tension stress that would otherwise be induced under full dead load and live load. The methods can be applied to concrete, whether it is poured at the site or precast. On account of the great saving in material, which amounts to at least one-third of the volume of concrete and three-quarters of the weight of reinforcement that would otherwise be used, prestressed-concrete bridges are striking in their slender proportions. They are also economical in cost, provided the necessary trained labour is available, and in favourable circumstances may be competitive with structural-steel designs for spans up to about 500 feet (152 metres). Because of the very high stresses employed, skilled supervision is, of course, essential throughout the work.

NEW DESIGNS

Battle decks and composite construction. Battle decks, first used in ships but adapted for bridges after World War

Use of
precast
concrete
units

Use of
low-alloy
steel

II, consist of decks made of flat steel plates welded together and stiffened by means of flats, angles, or some other section welded on the underside. Further economy can be achieved by making the deck act integrally with the main members of the bridge, in effect becoming the top flange of a box girder. Battle decks are economical on long spans, where their saving in weight is important. They require more maintenance than do reinforced-concrete slabs.

In composite construction, the concrete roadway slab is anchored to the steel girders and made to act in conjunction with them. This form of deck was used on an all-welded steel highway bridge with a span of 334 feet (102 metres) over the Moscow River in the U.S.S.R. (1956). In the 1,240-foot (378-metre) Cologne-Rodenkirchen Bridge over the Rhine (1954) in West Germany, the concrete deck was prestressed; it not only carries the traffic but also acts as part of the upper chord (horizontal member) of the stiffening trusses and provides lateral bracing.

On both steel and concrete decks, waterproofing and wearing surfaces have to be provided. The most satisfactory solution appears to be a coat of mastic asphalt, a mixture of asphalt with fine aggregate rolled in, which produces a dense, hard-wearing surface and gives waterproof protection for the steel beneath.

Steel-plate and box girders. The modern tendency in steel-bridge design, particularly in western Europe, is towards box girders, of rectangular or trapezoidal section, in preference to simple or continuous trusses. The destruction of nearly 5,000 bridges in West Germany in World War II gave an opportunity for the development of new designs and techniques, and the fact that steel was then in short supply stimulated the search for economy in weight. The Cologne-Deutz Bridge (1947-48), the first of the big postwar box-girder spans over the Rhine, showed the sort of major advances in appearance, span, and economy that could be made by taking full advantage of modern techniques. In the triple box girders of this bridge, web plates 25 feet (8 metres) deep over the piers and only about 0.5 inch (1.27 centimetres) thick were first employed, stiffened both horizontally and vertically. Much of the 5,760 tons of steelwork is high-tensile, and its weight is only 61 percent of the steelwork in the old bridge it replaces. Three years later, the Düsseldorf-Neuss Bridge, with its 675-foot (206-metre) span and steel battled deck, was completed. Both these bridges were erected in heavy sections of 200 to 300 tons assembled on the riverbank, floated out, and lifted by cranes that had been used to clear away the debris of the old bridges.

The plate-girder bridge across the Sava River at Belgrade, Yugoslavia, was completed in 1957, has a span of 856 feet (261 metres), and replaced the King Alexander suspension bridge. Designed in West Germany, it consists of an inverted-U-shaped girder of high-tensile steel. The autobahn bridge over the Wupper Valley (1959) in West Germany, with seven spans varying from 144 to 239 feet (44 to 73 metres), has a reinforced-concrete deck slab in composite construction with steel box girders of novel trapeze-shaped section and inclined webs. The basic similarity of these modern box girders to the Britannia tubular bridge first conceived more than a century before is notable. Apart from materials and details of construction, the most significant difference is that in the first the trains ran through the boxes, whereas in the modern bridges the roadway traffic flows on top.

In comparison with plated I-girders, rectangular box girders have the advantage of reducing the initial cost by providing stable compression flanges (horizontal surfaces) and torsional rigidity (resistance to twisting forces). They also conceal all the web and flange stiffeners and thus improve appearance and reduce maintenance charges. Trapezoidal sections, in which the outer web plates are inclined, may be used to limit the lower flange area to the desired amount while at the same time providing a wide flange plate for the deck, as in the 770-foot-(235-metre-) span Wye Bridge in England. While offering reduced wind resistance, these inclined webs tend to increase the cost of fabrication and erection, unless the bridges are erected in preassembled units or boxes. Preassembly has been generally adopted in the U.K., but on the Continent erection is usually done

on the site, plate by plate. Thus boxes with inclined webs have been favoured by British engineers (e.g., the Beachley, Severn, Erskine, and White Cart bridges) but rectangular box girders have been employed on the Continent (e.g., the Europa Bridge, the Fourth Danube Bridge in Vienna, Austria, the Zoo Bridge in Cologne, West Germany, and the Lehenner Bridge in Salzburg, Austria). The Rio-Niterói high-level box girder bridge (1971), with a continuous span of 984 feet (300 metres), stands over Guanabara Bay at Rio de Janeiro.

Steel cable-braced bridges. A further development, in which the girders are supported by groups of prestressed cables passing over the tops of towers on the main piers, was first introduced in the Strömsund Highway Bridge in Sweden (1956). This method was adopted in the Theodor Heuss Bridge (formerly the North Bridge; 1957) over the Rhine at Düsseldorf, West Germany, which has a main span of 853 feet (260 metres). The two box girders, of shop-welded low-alloy steel, are supported by three parallel tiers of cables that were prestressed during erection. In the Severin Bridge (1959) at Cologne, there is a cable-braced span of 991 feet (302 metres) supported by three sets of cables that pass over the top of an A-shaped tower built on a pier near the east bank. The first monocable bridge was built over the Elbe at Hamburg (1961). The 564-foot (172-metre) span was braced by cables only on the longitudinal centre line of the bridge. The towers over which they pass consist of single posts with roadways on either side. Since then, many cable-braced bridges have been built, mostly in western Europe, including the Duisburg-Neuenkamp Bridge, in West Germany, with a span of 1,148 feet (350 metres), completed in 1970. Monocables have only about 70 percent of the weight of dual cables, because they are less affected by asymmetric live load.

Steel truss bridges. In the United States and Japan, continuous trusses are favoured for spans in the 700- to 1,250-foot range (about 210 to 380 metres). The Astoria Bridge in Oregon, completed in 1966, has a span of 1,232 feet (376 metres) and the Tenmon Bridge (1966) at Kumamoto, Japan, has a span of 984 feet (300 metres). Two major bridges of this type in China are the huge double-deck rail and road bridges over the Yangtze River, the first completed in 1957 at Wu-han, Hupeh Province, and the second, replacing the train ferry and opening up a long-needed north-south route, at Nanking, Kiangsu Province, in 1968. Other great multispan include the

The monocable bridge at Hamburg

The Cologne-Deutz Bridge

Figure 19: Steel truss bridge over the Yangtze River at Nanking, China. Completed in 1968, it carries rail and highway traffic.

2.25-mile- (3.62-kilometre-) long Lower Zambezi railway bridge (1934) in Mozambique; the Ava Bridge, comprising nine spans of 350 feet (107 metres) carrying railway and road over the Irrawaddy River in Burma; the mile-long Ganga Bridge (1959) at Mokameh, India; and the Brahmaputra Bridge (1962) at Amingaon-Pandu in India, both of which carry road and rail traffic.

Prestressed-concrete bridges. A wide variety of designs, including simple or continuous beams, cantilevers, arches, and girders, can be made with prestressed concrete. For spans of up to 140 feet (43 metres), simply supported beams are generally the most economical. The Vauban

highway bridge (1956) in Strasbourg, France, has four simple spans of varying lengths, consisting of 8 beams of I-section, prestressed by 17 cables of 12 strands. As the span increases, continuous beams, as used in the Oléron Viaduct, France (1966), with 26 spans of 259 feet (79 metres), become economical. A bridge built over the Moscow River in 1957 has three continuous, prestressed-concrete spans, including a midspan of 485 feet (148 metres).

For still longer spans, cantilever bridges may be used. The 500-foot (152-metre) span of the Medway Bridge (1963) at Rochester was surpassed by the 682-foot (209-metre) span of the Bendorf Bridge, completed in 1964 in Koblenz, West Germany. It is notable that the Bendorf Bridge, together with two other major cantilever bridges, the Eastern Scheldt Bridge (1965) constructed in The Netherlands and the Öland Bridge (1972) built in Sweden, were designed as twin cantilevers with no suspended spans. Work on the destruction of John Rennie's London Bridge, dating from 1831, began in 1967, and the masonry facades of the old arches of the bridge were sold to a private developer and re-erected at Lake Havasu in Arizona. In 1972 London Bridge was replaced by a new prestressed-concrete structure.

Concrete arch bridges are rarely prestressed to any significant extent, because an arch is normally in compression. The Luzhniki Bridge (1959) in the U.S.S.R. is a prestressed-concrete tied arch, with spans of 147, 354, and 147 feet (45, 108, and 45 metres). Portal bridges and multiple portals simply represent an angular type of arch, so shaped that prestressing is helpful to keep the resultant thrust due to dead load and external loads within allowable limits. A fine multiple portal with sloping legs is the Saint-Michel Bridge (1957), at Toulouse, France, which has one span of 197 feet (60 metres) and five of 214 feet (65 metres) each.

Bridges of latticed construction are economical in material, but the unit costs are high; the saving in weight afforded with latticed construction, however, makes it possible to achieve longer spans. The first prestressed-concrete latticed girder constructed was the Mangfall Valley Bridge (1958-60), with three spans of 295, 354, and 295 feet (90, 108, and 90 metres) over the Munich-Salzburg highway in West Germany.

The first self-anchored suspension bridges with continuous stiffening trusses were built in Belgium. These are the Merelbeke and the Mariakerke bridges near Ghent, with main spans of 185 and 328 feet (56 and 100 metres), respectively. A novel method for prestressing the girders on the Merelbeke Bridge consisted in jacking up the towers, which were independent of the deck and stiffening girders. The jacks were afterwards replaced by permanent steel castings.

A novel form of construction was adopted for the five

775-foot (236-metre) navigation spans of the 5.5-mile (8.8-kilometre-) long multispan bridge over the Maracaibo Lagoon in Venezuela (1958-61). These are designed as six continuous beams in prestressed concrete, supported on double trestles below and by tension cables above. The cables pass over the top of A-shaped towers on the piers and are connected near the ends of each beam. Another bridge of this type, with a span of 983 feet (300 metres), was designed to cross over the Wadi Kuf Gorge in central Cyrenaica, Libya; construction was completed in 1971. Two notable new bridges in Mozambique are multispan suspension bridges of five spans each with inclined suspenders supporting prestressed-concrete decks. The first is 2,860 feet (872 metres) overall and was completed in 1970 over the Save River; the second, with an overall length of 2,360 feet (719 metres), was completed a year later at Tete over the Zambezi River.

IMPROVEMENTS IN TECHNIQUES

Shop fabrication. Shop fabrication now includes the use of techniques by which steel can be flame-cut and the edges bevelled for welding, if required; rotary jigs are used for the assembly of members, and automatic submerged-arc machines, which give complete penetration, are used for welding the seams of columns or girders. The quality of the welds can be determined by means of X- and gamma-ray photographs.

Methods of erection: steel bridges. For erection on the site, welding may be used for plate girders, but it is not usually suitable for trusses. Rivetting has been largely superseded by the use of friction-grip bolts which can be used in clearance holes and act as high-tension clamps. Pneumatic wrenches are used to tighten the bolts and calibrated torque wrenches to check their tension. The system is quicker, cleaner, more efficient, and more economical than rivetting. It was used in the erection of the Forth Road Bridge, the Mackinac and Carquinez bridges in the United States, and the Adomi Bridge (formerly Volta) in Ghana. The method employed in using these friction-grip bolts in the 805-foot (245-metre) steel arch of the Adomi Bridge represented a major advance in bridge-building technique. At the connections between the chord members in the bridge, four friction-grip bolts were used longitudinally as pretensioned ties, so arranged as to interconnect pairs of plates welded across the corners of the section. During erection of the two halves of the arch as cantilevers, therefore, the stability of the structure depended on these groups of bolts acting in tension in the connection of the upper chords.

On box girders, the tendency in the U.K. is to prefabricate the structure in large sections (*i.e.*, full-width steel boxes that may be 60 feet [18 metres] long and weigh up to 100 tons) before erecting them in position. This saves the cost of assembling many small sections in high

and exposed places under awkward weather conditions. Cantilever erection may be adopted, as on the Wye and Erskine bridges, where the boxes were rolled out along the top of the cantilever arm, lowered into position by two heavy launching arms, adjusted against the section last erected, and connected by butt welding or bolting. On the European continent, the system of "pushing out" large lengths of superstructure on rollers over the tops of the piers has been successfully used. Assembly is carried out in an erection bay located behind the abutment. This system was used in Switzerland in 1968 on the Veveyse Bridge, which consists of two box girders, built on a curve and supporting a composite slab deck. The box girders of the Lao Bridge in southern Italy are supported on some of the highest piers in the world. The three spans of the bridge, which also curves, were erected to carry the motorway over a deep ravine, the bottom of which is 800 feet (244 metres) below roadway level.

Cable-stayed bridges are usually erected as cantilevers, temporary supporting trestles being used where necessary. The cables are assembled on the towers and connected to the box girders and tensioned at the appropriate stages of erection.

Methods of erection: prestressed-concrete bridges. Prestressed-concrete bridges can be built by one of three techniques: (1) assembly of precast units at the site; (2) casting in place; or (3) a combination of precasting and casting in place.

The Narrows Bridge (1959) over the Swan River at Perth, Western Australia, which has five spans with an overall length of 1,100 feet (335 metres), is a good example of a bridge built up of precast units and subsequently prestressed after assembly at the site. The 24-mile (39-kilometre) long Pontchartrain Causeway (1956) in Louisiana, was surpassed by a slightly longer sister span in 1969. The first causeway consists of a series of spans 56 feet (17 metres) long and 28 feet (8.5 metres) wide, supported by beams resting on hollow prestressed-concrete piles. Each span, made up of seven beams and the roadway slab, was precast in one piece and erected by means of a floating crane. So well was the work organized for this construction that eight spans weighing 180 tons each and comprising 448 feet (137 metres) of bridge were placed each day.

Precasting has been widely adopted in the U.S.S.R., an outstanding example being the huge two-level bridge (1959) over the Moscow River at Luzhniki, Russian

S.F.S.R., which, with its approaches, measures 6,650 feet (2,027 metres) and carries a six-lane roadway on the upper deck and interurban railways below. The three spans, of 147, 354, and 147 feet (45, 109, and 45 metres), over the river were assembled in halves longitudinally on the shore from large, precast units, floated out on barges, and set on piers. In the U.S.S.R., standardization developed to such an extent that, by 1958, reinforced-concrete designs were automatically adopted for new railway bridges having spans of less than 50 feet (15 metres) and prestressed-concrete designs for bridges having spans of 50 to 90 feet (15 to 27 metres).

Casting in place is more likely to be economical when there is little, if any, repetitive work; this technique was adopted for the three arches of 499, 479, and 452 feet (152, 146, and 138 metres) designed in 1953 for the Caracas-La Guaira highway in Venezuela. In these bridges, the decks were prestressed both longitudinally and laterally, and prestressing cables were used temporarily to relieve the arch ribs during erection. Cantilevered centring was built out from each arch pier for a quarter of the span. For the middle, timber forms were built in the valley below and hoisted into place.

A combination of precast and in place construction may be economically used for continuous and cantilever bridges, the concrete ends of the span near the piers being poured in place and the central parts precast. In the 214-foot (65-metre) spans of the Casalmaggiore Bridge, over the Po in Italy, the lengths over the piers and the cantilever arms were poured in place, and the 118-foot (36-metre) suspended beams, each weighing 65 tons, were precast and erected by floating cranes. In the Mancunian Way, opened in Manchester, Lancashire, in 1967, although a high degree of standardization of precast units was achieved, it was found preferable to cast certain lengths of the overpass in place.

Pile-cylinder foundations. The most significant trend in foundation design is the tendency to support bridge piers on groups of large-diameter piles or thin-shelled cylinders, where possible, in preference to using pneumatic caissons. In the foundations of the Narrows Bridge in Perth, 180 long piles nearly three feet (one metre) in diameter were driven as hollow cylinders by means of a hammer running inside the pile and striking near its foot and were subsequently reinforced and filled with concrete. For the huge Wu-han double-deck rail and road bridge built in 1955-57 over the Yangtze River in China, a new system of colonnade foundations on large-diameter piles was designed by Soviet specialists. In the Tasman Bridge, Hobart (1965), the foundations were of boxed cylinder piles, some of which penetrated to a depth of 260 feet (79 metres). The three cylinder piles used per pier of the three-mile (4.8 kilometre)-long Eastern Scheldt Bridge (1965) in The Netherlands are of 14-foot (4.3-metre) diameter and up to 165 feet (50 metres) in length.

In the U.S.S.R., thin-shelled reinforced- or prestressed-concrete cylinders are sunk by electric-powered vibro pile drivers.

Use of computers. In the last decade, computers have been increasingly relied upon for making the necessary calculations involved in the design and erection of both steel and concrete bridges. Consequently the most laborious and detailed calculations can be made quickly and economically.

During the erection of the Forth Road Bridge and the Severn Bridge, computers were used to calculate the shapes that the suspension cables would assume under the changing pattern of applied loads as the deck panels were assembled. Computers can be used just as efficiently in reinforced- and prestressed-concrete work and provide a full set of calculations and detailed instructions, which entirely replace traditional drawings and details of reinforcement.

SAFETY PROBLEMS AND SOLUTIONS

During the last few years, much more attention has been paid to reducing accidents on bridges and, indeed, on all engineering structures. Most failures occur during erection, and safety can be considered under three heads: the safety

Casting in place

The world's longest precast structure

The three main safety factors

of the structure during erection or demolition, the safety of construction plant, and the safety of personnel. Statutory regulations, which are continually being widened, exist in all countries to ensure the safety of structures, plant, and personnel. But, in spite of these regulations, far too many accidents still occur.

The castastrophic failure of the all-welded Duplessis Bridge at Trois-Rivières, Quebec, at a temperature of -30°F (-34°C), in February 1951, followed by that of the Kings Bridge at Melbourne, Victoria, in July 1962, were ascribed to brittle fracture from the nature of the steel used and the low temperatures prevailing at the time. The failure of three Vierendeel truss bridges in Belgium in 1938-40 and 250 all-welded Liberty ships in 1942-52 had drawn attention to the liability of steel to brittle fracture. The flange plates of the 180-foot (55-metre) plate girders of the Duplessis Bridge that failed proved to be of poor-quality steel that was abnormally notch sensitive, even at ordinary temperatures. In June 1958, two spans of the six-highway Second Narrows Bridge in Vancouver collapsed, wrecking 2,500 tons of steel and killing 18 men, during the cantilevering of the 465-foot (142-metre) anchor arm. The cause was the failure of a steel grillage supporting one of the temporary trestles, on which the stiffeners had been omitted due to an error in calculations. During the erection of the Barton High Level Bridge, England, there were two accidents in February and December 1959, in which six men were killed. The first accident was due to the failure of two inadequately designed and braced temporary trestles, and the second was due to four steel girders standing side by side overturning because they were inadequately braced together.

A most unusual accident to a completed span was the 1967 collapse of the Silver Bridge over the Ohio River at Point Pleasant, West Virginia, with a loss of 46 lives. This was a chain-suspension bridge with a span of 698 feet (213 metres), built as recently as 1928, and its failure ruled out the building of any more bridges suspended in this way in the U.S. Another accident, but without any loss of life, occurred immediately after the closure of the Fourth Danube Bridge in Vienna in November 1969. This structure was a three-span motorway bridge built of twin box girders. A sudden fall of temperature at night resulted in failure at the closing joint; the bridge sagged three feet (one metre), and within ten seconds two more bucklings occurred several hundred feet away on either side of the first failure. In this case, the margin of safety was eroded by four different factors, one of which was the sudden temperature differential.

Two tragic collapses of sophisticated designs of trapezoidal-box-girder bridges, resulting in the death of 4 men and 35 men, respectively, occurred during erection in 1970. The first of these was the Milford Haven Bridge, Pembrokeshire, in which a 196-foot (60-metre) steel cantilever collapsed in June 1970, owing to the failure of the vertical steel diaphragm over the pier from which it was being cantilevered. The second was the collapse of a 367-foot (112-metre) steel span of the West Gate high level bridge over the Lower Yarra River in Melbourne, in October 1970. Failing at the middle, the span plunged to the water, bringing down the river pier in its collapse. Failures have also occurred on concrete bridges. In August 1967 two completed sections of the Calder Bridge, which was being built to carry the M.1. motorway over the River Calder near Wakefield, Yorkshire, collapsed. Here the collapse was caused by the failure of temporary supports due to mild-steel joists being used by mistake instead of joists of high-tensile steel.

In order to combat risk of brittle fracture, high-tensile steel has now been greatly improved in strength at low temperatures. Another most complex problem under research is that of metal fatigue, to which both steel and aluminum are prone, caused by undergoing continual variations of stress that reduce ultimate strength and cause cracks or failure. Susceptibility to fatigue is increased by welding; particularly, by welds across tension members; or by an abrupt change of shape or thickness. All possible data are being obtained as to the number and nature of the stress cycles to which bridges are subject and to the types of

construction and the quality of steel that can successfully withstand them.

Accidents caused by failure of plant are too varied to detail here. They can be largely avoided by ensuring that all plant and equipment is kept in good repair and used only within its capacity, with all moving parts adequately guarded and with fail-safe devices provided as necessary. The causes of accidents to personnel are also diverse. The first necessity is to provide safe means of access and safe place of work, by means of ladders, gangways, and working platforms with guardrails, toeboards, and cradles, as necessary. Accidents to men working aloft can be prevented by means of safety harness and safety nets; safety helmets should be worn by all men on site.

FUTURE TRENDS

Great suspension spans of the future include a crossing of the Strait of Messina between Sicily and the Calabria region of southern Italy, where the major difficulties are presented by the great depth of water (400 feet [122 metres]) and the fact that the site is in a recently active earthquake area. A favoured design includes an immense main span of about two miles (3,200 metres); this two-deck structure would require towers more than 1,000 feet (300 metres) high. Far more ambitious schemes have been suggested for crossings of the English Channel and the Strait of Gibraltar, but neither seems likely for many years to come.

In Japan, construction of bridges linking the islands of Honshu and Shikoku began in the mid-1970s. Included are a bridge over Naruto Strait, with a main span of about 2,900 feet (884 metres), and another suspension bridge over Akashi Strait, with a main span of more than 5,800 feet (1,768 metres). These structures were designed to withstand typhoons and seismic shocks. Another great span has been proposed for a bridge over Tokyo Bay. With materials of the weight and strength available today, engineers could theoretically build a suspension bridge to carry normal traffic, with a single span two miles long. But there would be many imponderable factors to consider in such a vast enterprise, which must be many years ahead. In the near future, it appears that the system of cable spinning may soon be simplified by pulling across strands each consisting of some hundreds of parallel wires and subsequently compacting them together, instead of simply carrying over a few loops of wire at a time by means of spinning wheels. A major economy would also be achieved in the weight and cost of the main cables if some means could be found by which to vary their cross-sectional area, so that it would conform throughout the length of the cable to the actual section required, which is much smaller at midspan. Improved methods of protection will, no doubt, also be found, as was attempted in the Newport Bridge, Rhode Island (1967), where the cables were protected by a layer of glass-reinforced resin.

In trying to foresee the materials of the future, it must be borne in mind that all normal structural materials, such as steel, aluminum, glass, and wood, have very similar elasticity-to-weight ratios. To make lighter, stiffer structures, new materials are needed, with high elasticity and low weight, such as carbon fibres and carbon-fibre plastics. Compared with a high-tensile aircraft steel, these carbon fibres have about a quarter of the weight and more than twice the tensile strength. They have been developed primarily for use in the aerospace field, in chemical plants where resistance to corrosion is important, and for bearing materials and marine purposes. But it would appear that the materials to be used in long-span bridges of the future will be evolved through development along the above lines. The essential reduction in cost of such new materials can be made only through large-scale production. But in the light of the immense diversity and the amazing advances in the production of plastics, which have led to their worldwide adoption in a very few years, for thousands of applications, there seems little doubt that the economic production of greatly improved bridge materials is only a question of time.

CANALS AND INLAND WATERWAYS

Despite modern technological advances in air and ground transportation, inland waterways continue to fill a vital role and, in many areas, to grow substantially. This article traces the history of canal building from the earliest times to the present day, describes both the constructional and operational engineering techniques used, and the major inland waterways and networks throughout the world.

Transport by inland waterways may be by navigable rivers or those made navigable by canalization (dredging and bank protection) or on artificial waterways called canals. Many inland waterways are multipurpose, providing drainage, irrigation, water supply, and generation of hydroelectric power as well as navigation. The lay of the land (topography) and particularly changes in water levels require that many rivers be regulated to make them fully navigable, thus enabling vessels to proceed from one water level to another. The chief regulating method is the lock, the development of which contributed significantly to the Industrial Revolution and the development of modern industrial society.

For many types of commodities, particularly such bulk commodities as grains, coal, and ore, inland-waterway transport is still more economical than any other kind of transport. Thus, it is hardly surprising that modernized inland waterways, using the latest navigational aids and traction methods and traversing the great land masses of North America, Europe, and Asia, play an increasingly important economic role.

History

ANCIENT WORKS

Most of the improvement of rivers and construction of artificial waterways in antiquity was for irrigation purposes. In the 7th century BC the Assyrian king Sennacherib built a 50-mile (80-kilometre) stone-lined canal 66 feet (20 metres) wide to bring fresh water from Babylon to Nineveh. The work, which included a stone aqueduct 300 yards (330 metres) long, was constructed in one year and three months, according to a plaque that survives on the site. Surprisingly advanced techniques were used, including a dam with sluice gates allowing regulation of the flow of the water stored. The Phoenicians, Assyrians, Sumerians, and Egyptians all constructed elaborate canal systems. The most spectacular canal of this period was probably Nahravān, 400 feet (120 metres) wide and 200 miles (335 kilometres) long, to provide a year-round navigation channel from near Samarra to al-kūt, using water provided by damming the unevenly flowing Tigris. Many elaborate canals are known to have been built in Babylonia. In Egypt, the Nile was dammed to control its flood waters, and an extensive system of basin irrigation was established. The Persian king Darius in the 5th century BC cut a canal from the Nile to the Red Sea. The Romans were responsible for very extensive systems of river regulation and canals in France, Italy, The Netherlands, and Great Britain for military transport. The legions in Gaul canalized one of the mouths of the Rhône to protect their overseas supply route. In the 1st century AD, the Roman consul Marcus Livius Drusus dug a canal between the Rhine and Yssel to relieve the Rhine of surplus water, and the Roman general Corbulo linked the Rhine and Meuse with a canal 23 miles (37 kilometres) long to avoid the stormy North Sea passage from Germany to the coast. Attempting to reclaim the Fens in England, the Romans connected the River Cam with the Ouse by an eight-mile (13-kilometre) canal, the Nene with the Witham by one 25 miles (40 kilometres) long, and the Witham with the Trent by the Fosse Dyke (ditch), still in use.

Outside Europe and the Middle East, between the 3rd century BC and the 1st century AD, the Chinese built impressive canals. Outstanding were the Ling Ch'ü in Kuangsi, 90 miles (144 kilometres) long from the Han capital; Ch'ang-an (Sian) to the Huang Ho (Yellow River); and the Pien Canal in Honan. Of later canals, the most

spectacular was the Grand Canal, the first 600-mile (960-kilometre) section of which was opened to navigation in 610. This waterway enabled grain to be transported from the lower Yangtze and the Huai to K'ai-feng and Lo-yang. These canals had easy gradients (changes in water levels); and at about three-mile intervals there were single gates of stone or timber abutments with vertical grooves up or down along which the log closure was manually hauled by ropes to hold or release the water, thus controlling the water level. A few more elaborate gates had to be raised by windlasses. Where water level changes were too great for such simple devices, double slipways were built and vessels were hauled up the inclines.

MEDIEVAL REVIVAL

In Europe, canal building, which appears to have lapsed after the fall of the Roman Empire, was revived by commercial expansion in the 12th century. River navigation was considerably improved and artificial waterways were developed with the construction of stanches, or flash locks, in the weirs (dams) of water mills and at intervals along the waterways. Such a lock could be opened suddenly, releasing a torrent that carried a vessel over a shallow place. The commercially advanced and level Low Countries developed a system of canals using the drainage of the marshland at the mouths of the Scheldt, Meuse, and Rhine; about 85 percent of medieval transport in the region went by inland waterway.

Because shipping was handicapped where barges had to be towed over the weirs with windlasses or manually, the lock and lock basin were evolved to raise boats from one level to another. Although a primitive form of lock had been in operation at Damme, on the canal from Bruges to the sea, as early as 1180, the first example of the modern pound lock, which impounded water, was probably that built at Vreeswijk, The Netherlands, in 1373, at the junction of the canal from Utrecht with the River Lek. Outer and inner gates contained a basin, the water level of which was controlled by alternatively winding up and lowering the gates. This system became widespread in the 14th century. In the 15th century, the lock-gate system was much improved with the addition of paddles to control the flow of water in and out of the lock chamber through sluices in the gates or sides of the lock.

Commercial needs soon encouraged canal construction in less ideal locations. The Stecknitz Canal, built in Germany (1391-98), ran 21 miles (34 kilometres) from Lake Möllner down to Lübeck, with a fall of 40 feet (13 metres) controlled with four stanches; the canal was later extended south to Lauenburg on the Elbe to establish a link between the Baltic and the North Sea. To deal with a fall from the summit to Lauenburg of 42 feet (13.5 metres) in 15 miles (25 kilometres), two large locks were built, each capable of holding ten small barges.

Italy, the other principal commercial region of medieval Europe, also made important contributions to waterway technology. The Naviglio Grande Canal was constructed (1179-1209) with an intake on the River Ticino, a fall of 110 feet (33 metres) in 31 miles (52 kilometres) to Abbiategrasso and Milan, the water level being controlled by sluices. To facilitate transport of marble from the quarries for the building of the Milan cathedral, the canal was linked with an old moat, and in Italy the first pound lock with mitre instead of the earlier portcullis gates was constructed to overcome difference in water level.

China may have been ahead of Europe in canal building. Between 1280 and 1293 the 700-mile (1,120-kilometre) northern branch of the Grand Canal was built from Huai-an to Peking. One section, crossing the Shantung foothills, was in effect the first summit-level canal, one that rises then falls, as opposed to a lateral canal, which has a continuous fall only. The Yellow River was linked with a group of lakes about 100 miles (160 kilometres) south, where the land rose 50 feet (15 metres) higher; and, to overcome water lost through operation of the lock gates,

Use of
sluice gates

Use of
stanches

two small rivers were partially diverted to flow into the summit level.

16TH TO 18TH CENTURIES

The mitre lock

The development of the mitre lock, a double-leaf gate the closure of which formed an angle pointing upstream, heralded a period of extensive canal construction during the 16th and 17th centuries. The canalized rivers and canals of that period foreshadowed the European network to be developed over many years.

France. In France, the Briare and Languedoc canals were built, the former linking the Loire and Seine and the latter, also known as the Canal du Midi, linking Toulouse with the Mediterranean. Both were remarkable feats of engineering. The Briare Canal (completed 1642) rose 128 feet (39 metres) to a plateau with a summit level 3.75 miles (6.2 kilometres) long and then dropped 266 feet (81 metres) to the Loing at Montargis. It included 40 locks, of which a unique feature was a staircase of six locks to cope with the fall of 65 feet (20 metres) on the descent from the Loing to Rogny. Construction of the 150-mile (241-kilometre) Canal du Midi joining the Bay of Biscay and the Mediterranean via the Garonne and the Aude ran through very rugged terrain. Begun in 1666 and finished in 1692, it rose 206 feet (61 metres) in 32 miles (51 kilometres) from the Garonne at Toulouse to the summit through 26 locks, and, after a three-mile (4.8-kilometre) stretch along the summit, then descended 620 feet (189 metres) through 74 locks for 115 miles (185 kilometres). Near Béziers a staircase of eight locks was built, and six miles (ten kilometres) further upstream a tunnel 180 yards (165 metres) long was constructed; three major aqueducts carried it over rivers, and numerous streams were diverted beneath it in culverts. The most notable technical achievement was a complex summit water supply that included unique diversion of flows and storage provision.

Flanders. The canal system in Flanders included one from Brussels to Willebroeck on the Rupel to shorten navigation by half, an 18½-mile (30-kilometre) canal with four locks; another of 44 miles (70 kilometres) was constructed from Bruges to Passchendaele, Nieuport, and Dunkerque and was later extended to Ostend, while Dunkerque was linked with the River Aa, at the mouth of which a large tide lock was constructed at Gravelines. The outstanding achievement in Flanders was a lock at Boesinghe on the canal from Ypres to Boesinghe beside the River Yser. The fall of 20 feet (six metres) on this four-mile (6.5-kilometre) stretch was contained by a single large lock. Side ponds with ground sluices were provided for the first time to reduce the loss of water during the lock's operation. The ponds took one-third of the water when the lock was emptied and returned it for the filling.

Germany. In Germany, the 15-mile (25-kilometre) Friedrich Wilhelm Summit Canal, completed in 1669, rose from Neuhaus on the Spree for ten feet (three metres) in two locks and from west of the summit fell 65 feet (20 metres) to Brieskow on the Oder. An extensive system of waterways in this part of Germany was finally established with the opening of the Plauer Canal in 1746, which ran from the Elbe to the Havel. The 25-mile (42-kilometre) Finow Canal along the Havel to the Liepe, a tributary of the Oder, had been built earlier but fell into decay because of flooding and neglect and was not rebuilt until 1751. In the late 17th and early 18th centuries, under the Great Elector of Brandenburg and Frederick I of Prussia, the three great rivers, the Elbe, Oder and Weser, were linked by canal for commercial and political reasons, including the bypassing of tolls charged by the numerous states and petty principalities of the Holy Roman Empire. In the Low Countries, wars, political considerations, and the rivalry between the Dutch and Belgian ports handicapped canal building. The Dutch, for example, strongly opposed a Rhine-Meuse-Scheldt canal, fearing diversion of trade to Antwerp.

England. The first lock was not built on an English canal until the 16th century, and the canal era proper dates from the construction of the Bridgewater Canal to carry coal from Worsley to Manchester in the 18th century by the engineer James Brindley. Opened for navigation in

1761, it was extended to the Mersey in 1776. Its success promoted a period of intense canal construction that established a network of inland waterways serving the Industrial Revolution and contributing to Britain's prosperity in the half-century preceding the railway era, which began in the mid-19th century. The Grand Trunk Canal established a cross-England route by linking the Mersey to the Trent, opened up the Midlands, and provided water transport for exports to European markets. There followed the link between the Thames and the Bristol Channel provided by the Severn Canal and the Gloucester and Berkeley Ship Canal from Sharpness on the Severn to Gloucester. Birmingham's growth and industrial prosperity were stimulated because the city became the centre of a canal system that connected London, the Bristol Channel, the Mersey, and the Humber. The Caledonian Ship Canal across Scotland, joining the chain of freshwater lakes along the line of the Great Glen, was built between 1803 and 1822.

One of the few canals to be built after the canal era was the 36-mile- (60-kilometre-) long Manchester Ship Canal, which was opened in 1894 to give oceangoing vessels access from the Mersey estuary to Manchester.

Technological development. This spate of canal construction was accompanied by technological development both in construction methods and operation. Locks, inclined planes, and lifts were developed to cope with changes in water level. At Bingley, for example, on the Leeds and Liverpool Canal, a lock staircase was built; and on the hilly areas at Ketley in Shropshire, inclined planes were constructed in 1788 to haul tugboats from one level to another. The longest plane, about 225 feet (67 metres), was on the Hobbacott Down plane of the Bude Canal in Cornwall. Vertical lifts counterweighted by water were also used; a set of seven was built on the Grand Western Canal; while at Anderton in Cheshire, a lift was later converted to electrical power and was still operating in the 20th century. The most spectacular inclined plane was built in the United States on the Morris Canal, which linked the Hudson and Delaware rivers. For a rise of 900 feet (265 metres) to the Alleghenies watershed, 22 locks were installed at the head of an inclined plane, and descending on a gradient of 1 in 10 to 1 in 12, ran down to the pound below. Barges 79 feet (22 metres) long with loads up to 30 tons were hauled up by trolleys running on rails, on which they settled as the lock emptied; the barges descended under gravity into the lower pound to float on an even keel when the water levelled off. In the reverse direction, they were hauled up by drum and cable mechanism.

19TH CENTURY

Europe. In Europe, where the canal era had also started toward the end of the 17th century and continued well into the 18th, France took the lead, integrating its national waterway system further by forging the missing links. In the north, the Saint-Quentin Canal, with a 3½-mile tunnel, opened in 1810, linked the North Sea and the Scheldt and Lys systems with the English Channel via the Somme, and with Paris and Le Havre via the Oise and Seine. In the interior, the Canal du Centre connected the Loire at Digoin with the Saône at Chalon and completed the first inland route from the English Channel to the Mediterranean; the Saône and Seine were linked further north to give a more direct route from Paris to Lyon; and the Rhine-Rhône Canal (Canal du Rhône au Rhin), opened in 1834, provided a direct north-to-south route; while the Canal de la Sambre à L'Oise linked the French canal system with the Belgian network via the Meuse. Toward the end of the 19th century, France embarked on the standardization of its canal system to facilitate through communication without trans-shipment. The ultimate result was a doubling of traffic between the opening of the century and World War II.

Industrial development in the early 19th century prompted Belgium to extend its inland waterways, especially to carry coal from Mons and Charleroi to Paris and northern France. Among the new canals and extensions built were the Mons-Condé and the Pommeroeut-Antoing canals, which connected the Haine and the Scheldt; the

Dutch
canals

Sambre was canalized; the Willebroek Canal was extended southward with the building of the Charleroi-Brussels Canal in 1827; and somewhat later the Campine routes were opened to serve Antwerp and connect the Meuse and Scheldt. When the growth of the textile trade in Ghent created a need for better water transport, the Gent Ship Canal, cut through to Terneuzen, was opened in 1827, giving a shorter route to the sea. The Dutch extended their canals to serve the continental European industrial north. The Maastricht-Liège Canal was opened in 1850, enabling raw materials and steel to be transported from the Meuse and Sambre industrial areas by waterway throughout The Netherlands. In 1824 a long ship canal was built to bypass silting that obstructed navigation on the IJsselmeer (Zuiderzee) and to enter the North Sea in the Texel Roads. Later, an even shorter ship canal was built to IJmuiden.

In Scandinavia, new canals were built to facilitate transport of timber and mineral products. In 1832 the new Göta Canal was opened, crossing the country from the Baltic to the Skagerrak and incorporating 63 locks. The political climate was less favourable for canal building in central Europe, but the Ludwig Canal, forming part of the Rhine-Main-Danube route, was opened in 1840. At the same time, steps were taken to improve river navigation generally, to provide speedier transport, and to enable a greater volume of freight to be carried. The Danube was regulated for 144 miles (230 kilometres) from Enns-mundung to Theuben, and the Franz Canal was dug in Hungary to join the Danube and Tisza. A nationwide Russian canal system connecting the Baltic and Caspian seas via the Neva and Volga rivers became navigable in 1718. A more direct route was established in 1804 with a canal between the Beresina and Dvina rivers. In the 19th century, Russia concentrated on making connections between the heads of navigation of its great rivers, the Volga, Dnepr, Don, Dvina, and Ob.

The
Corinth
ship canal

An outstanding engineering achievement in Greece was the cutting of a deep ship canal at sea level through the Isthmus of Corinth to connect the Aegean and Ionian seas. The Roman emperor Nero had first attempted this linking in the 1st century AD; the shafts sunk by him were reopened and sunk to their full depth. The canal, 4.8 miles (6.3 kilometres) long, 81 feet (25 metres) wide, and 27 feet (eight metres) deep in its centre section, running 280 feet (86 metres) below almost vertical rock cliffs, was opened in 1893.

United States. In the U.S., canal building began slowly; only 100 miles of canals had been built at the beginning of the 19th century; but before the end of the century over 4,000 miles were open to navigation. With wagon haulage difficult, slow, and costly for bulk commodities, water transport was the key to the opening up of the interior, but the way was barred by the Allegheny Mountains. To overcome this obstacle, it was necessary to go north by sea via the St. Lawrence River and the Great Lakes or south to the Gulf of Mexico and the Mississippi. A third possibility was the linking of the Great Lakes with the Hudson via the Mohawk Valley. The Erie Canal, 363 miles (580 kilometres) long with 82 locks from Albany on the Hudson to Buffalo on Lake Erie, was built by the state of New York from 1817 to 1825. Highly successful from the start, it opened up the Midwest prairies, the produce of which could flow eastward to New York, with manufactured goods making the return journey westward, giving New York predominance over other Atlantic seaboard ports. The Champlain Canal was opened in 1823; but not until 1843, with the completion of the Chamblly Canal, was access to the St. Lawrence made possible via the Richelieu River. Meanwhile, Canada had constructed the Welland Canal linking Lakes Ontario and Erie. Opened in 1829, it met the 326-foot (98-metre) rise of the Niagara River with 40 locks, making navigation possible to Lake Michigan and Chicago. Later, the St. Mary's Falls Canal connected Lake Huron and Lake Superior. To provide a southern route around the Allegheny Mountains, the Susquehanna and Ohio rivers were linked in 1834 by a 394-mile (630-kilometre) canal between Philadelphia and Pittsburgh. A unique feature of this route was the combination of water and rail transport with a 37-mile (59-kilometre) portage by

The
Susque-
hanna-
Ohio
Canal

rail by five inclined planes rising 1,399 feet (413 metres) to the summit station 2,334 feet (689 metres) above sea level and then falling 1,150 feet (340 metres) to Johnstown on the far side of the mountains, where a 105-mile (170-kilometre) canal with 68 locks ran to Pittsburgh. By 1856 a series of canals linked this canal system to the Erie Canal.

Meanwhile, the Louisiana Purchase of 1803 had given the United States control of the Mississippi River, and it became the main waterway route for the movement of Midwest produce via New Orleans and the Gulf of Mexico. Developments included the Illinois-Michigan Canal, connecting the two great water systems of the continent, the Great Lakes and the Mississippi. Entering Lake Michigan at Chicago, then a mere village, the canal triggered the city's explosive growth. Several canals were constructed subsequently to link up with the Erie and Welland canals and the St. Lawrence, and a comprehensive network of inland waterways was established.

Impact of the railways. With the development of rail transport in the 19th century, canals declined as the dominant carriers of freight, particularly in the U.S. and Britain. In continental Europe the impact was less marked because the great natural rivers already linked by artificial waterways constituted an international network providing transport economically without trans-shipment; the terrain was more favourable and the canals larger and less obstructed by locks. Elsewhere, canals could not compete with rail. They were limited both in the volume carried per unit and in speed; they were too small, too slow, and fragmented; and the railways, as they became integrated into national systems, provided a far more extensive service with greater flexibility. The canals were further handicapped because they were not, for the most part, common carriers themselves but were largely dependent on intermediate carrying companies. Although transport on the canals was for some time cheaper than rail, the railways gradually overcame this advantage. To modernize and extend the waterways to enable larger boats to ply them, to reduce the number of locks that slowed down movement, and to provide a more comprehensive service, all this required capital investment on a scale that made the return problematical. The railways exploited the difficulties of the canals by drastic rate cutting that forced many canal companies to sell out to them. In Britain, in the 1840s and 1850s a third of the canals had become railway owned and many were subsequently closed down. In the U.S., half the canals were abandoned. The railways thus succeeded in eliminating their competition and obtained a near-monopoly of transport that they held until the arrival of the motor age.

The Kiel Canal. The 19th century saw the construction of three of the world's most famous canals—the Kiel, Suez, and Panama canals. The Kiel Canal carries tonnage many times that of most other canals. Frequent attempts had been made to make a route from the Baltic to the North Sea and thus to bypass the Kattegat and the dangerous Skagerrak. The Vikings had portaged ships on rollers across the ten-mile Kiel watershed, but not until 1784 was the Eider Canal constructed between the Gulf of Kiel and the Eider Lakes. A little over 100 years later, to take the largest ships, including those of the new German navy, the Kiel Canal was widened, deepened, and straightened to cut the distance from the English Channel to the Baltic by several hundred miles. Running 59 miles (95 kilometres) from locks at Brunsbüttel on the North Sea to the Haltenau locks on the Gulf of Kiel, the canal crosses easy country but has one unique engineering feature. At Rendsburg, to give clearance to the largest ships, the railway was made to spiral over the city on an ascending viaduct that crosses over itself before running on to the main span above the water.

The Suez Canal. The Isthmus of Suez so obviously provided a short sea route from the Mediterranean to the Indian Ocean and beyond as against the sea voyage around Africa that a canal had been dug in antiquity, had fallen into disuse, had been frequently restored, and finally had been blocked about the 8th century. Later there were many projects and surveys, but nothing happened until 1854 when Ferdinand de Lesseps, who had served as

Takeovers
by railways

Improvements in the Suez Canal

a French diplomat in Egypt, persuaded Sa'îd Pasha, the viceroy of Egypt, to grant a preliminary concession for construction of a new canal across the isthmus. A later report recommended a sea-level lockless canal between Suez and the Gulf of Pelusium; and the original concession was superseded by one granted in 1856 to the Suez Canal Company, an international consortium. The concession was for 99 years from the canal's opening to navigation, after which it was to revert to the Egyptian government; the canal was to be an international waterway, open at all times to all ships without discrimination. In addition to the ship canal, the company undertook to excavate a freshwater canal from the Nile at Bûlâq to Ismailia, with a branch extending to the Suez, to be available for smaller ships. Work on the ship canal lasted ten years, during which political, financial, contractual, and physical difficulties were overcome, and the canal was opened on November 17, 1869. As ultimately constructed, it was a 105-mile (169-kilometre) lockless waterway connecting the Mediterranean and the Red Sea. From its northern terminal at Port Said, the canal passes through the salt marsh area of Lake Manzala, with the freshwater canal running parallel. About 30 miles (50 kilometres) from Port Said, a seven-mile (12-kilometre) bypass built between 1949 and 1951 enables convoys to pass. At about the halfway point the canal enters Lake Timsah and passes Ismailia. Thence the waterway proceeds through the Bitter Lakes and on to Port Tawfiq, the southern terminal on the Red Sea, a few miles from the town of Suez. Since its construction, the canal has been constantly improved: originally 200 feet (60 metres) wide with a maximum depth of 24 feet (7.5 metres), it was widened in 1954 to 500 feet (150 metres) at water level and 196 feet (58 metres) at a depth of 33 feet (ten metres) with the main channel 45 feet (13 metres) deep, enabling ships of a maximum draft of 37 feet (11.3 metres) to navigate the canal.

The canal remained open despite much political controversy. Nationalized by Egypt in 1956, it was blocked in 1967 after the Arab-Israeli War and remained so until 1975.

The Panama Canal. After his success with the Suez Canal, de Lesseps was attracted to the Isthmus of Panama, where many projects had been suggested for cutting a canal to join the Atlantic and Pacific oceans and thus make unnecessary the passage around South America. De Lesseps proposed a sea-level route via Lake Nicaragua, but construction difficulties forced him to abandon this project in favour of a high-level lock canal via Panama. Further problems, especially yellow fever among the work force, halted construction after about 78,000,000 cubic yards (60,000,000 cubic metres) of material had been excavated. Meanwhile, United States interest had been actively maintained, but the situation was complicated by political difficulties and questions of sovereignty. A treaty between Britain and the U.S. recognized the exclusive U.S. right to construct, regulate, and manage a canal across the isthmus; but Panama was Colombian territory, and the Colombia Senate refused ratification of a treaty with the U.S. After a revolt, a treaty was signed with independent Panama that granted the U.S. in perpetuity exclusive use, occupation, and control of the Canal Zone. (See below *Waterway systems: administration* for later history.)

Although preliminary work started in 1904, little real progress was made because of disputes over the type of canal that should be built; not until 1906 was the high-level lock plan finally adopted, as opposed to the previously favoured sea-level plan. Largely responsible for this decision was John F. Stevens, who became chief engineer and architect of the canal. Completed in 1914, the canal is 51.2 miles (85 kilometres) long. At its start from the large harbour area in Limon Bay on the Caribbean Sea, it rises over 80 feet (22 metres) above sea level to the Gatun Lake through the Gatun Locks and is retained at the north by these locks and dam and at the south by the Pedro Miguel Locks and Dam. The waterway then runs through the Gaillard Cut, which channels it through the Continental Divide, then between the Pedro Miguel Locks and the Miraflores Lake at an elevation of 54 feet (16 metres), ships to the Pacific Ocean being lowered by them to the

Balboa Harbor entrance. The Gatun Lake, with its area of 166 square miles (450 square kilometres), is an integral part of the waterway and the principal source of its water. The minimum channel depth throughout the length of the canal is 37 feet (11.3 metres) and its width 300 feet (91 metres). There are 23 angles or changes of direction between the entrances. Ships normally travel through the canal under their own power except in the locks, through which they are towed by electric locomotives.

(E.A.J.D.)

Modern waterway engineering

Waterways are subject to definite geographical and physical restrictions that influence the engineering problems of construction, maintenance, and operation.

The geographical restriction is that, unlike roads, railways, or pipelines, which are adaptable to irregular natural features, waterways are confined to moderate gradients; and where these change direction, the summit pounds (ponds) require an adequate supply of water, while valley pounds need facilities for disposal of surplus.

The primary physical restriction is that vessels cannot travel through water at speeds possible for road vehicles or railway wagons. Because transport economics are based on the Transport Unit (x tons moved y miles in 1 manhour), waterways must provide larger tonnage units than those possible on road or rail in order to be competitive.

Modern waterway engineering, therefore, is directed toward providing channels suitable for larger vessels to travel faster by reducing delays at locks or from darkness and other natural hazards. While such channels and associated works are designed to minimize annual maintenance costs, the costs of operating vessels, locks, wharves, and other waterway works can be minimized by increased mechanization.

The Transport Unit

CHARACTERISTICS OF BASIC TYPES

Fundamentally, waterways fall into three categories, each with its particular problems: natural rivers, canalized rivers, and artificial canals.

On natural rivers navigation is subjected to seasonal stoppages from frost, drought, or floods, all of which lead to channel movements and to the formation of shoals. While minimizing natural hazards, attention is primarily directed to retaining the channel in a predetermined course by stabilization of banks and bed, by elimination of side channels, and by easing major bends to obtain a channel of uniform cross section that follows the natural valley.

On canalized rivers navigation is facilitated by constructing locks that create a series of steps, the length of which depends on the natural gradient of the valley and on the rise at each lock. Associated with the locks for passing vessels, weirs and sluices are required for passing surplus water; and in modern canalizations, such as the Rhône and the Rhine, hydroelectric generation has introduced deep locks with longer artificial approach channels, which require bank protection against erosion and, in some strata, bed protection against seepage losses.

On artificial canals navigation can depart from natural river valleys and pass through hills and watersheds, crossing over valleys and streams along an artificial channel, the banks and sometimes the bed of which need protection against erosion and seepage. The route of an artificial canal can be selected to provide faster travel on long level pounds (stretches between locks), with necessary locks grouped either as a staircase with one chamber leading directly to another or as a flight with short intervening pounds. Where substantial differences of level arise or can be introduced, vertical lifts or inclined planes can be constructed. Storage reservoirs must be provided to feed the summit pound with enough water to meet lockage and evaporation losses; other reservoirs can be introduced at lower levels to meet heavier traffic movements entailing more frequent lockage operation. If supplies are insufficient to offset the losses, pumps may be needed to return water from lower to upper levels.

CHANNELS

Channel design. Natural rivers and canalized rivers away from artificial cuts need no protection against seepage and only light protection of banks against erosion. The widening or cutting off of major bends assists navigation, but wholesale straightening is undesirable because the natural sinuosity of the river, though modified, should be retained. Local widening is effected by dragline excavators cutting into the channel and dumping the material ashore either direct to form levees or to be removed elsewhere. Deepening or widening beyond the reach of shorebased excavators requires a floating plant that discharges to hopper barges for transport to a disposal point or to pipelines for pumping ashore.

Cross
section of
artificial
canals

Artificial canals should provide a waterway with a cross-sectional area at least five, and preferably seven, times the cross-sectional area of the loaded vessel. In rock cuttings, such as those of the Corinth Canal, the waterway cross section could be rectangular, but the normal cross section is trapezoidal, with bed width three to four times and surface width six to eight times the width of the vessel, while the depth must be enough to allow the water displaced by the moving vessel to flow back under the hull.

Channel construction. The physical construction of a canal has been facilitated by the development of very large mechanical excavators. Walking draglines with 20-ton buckets such as were used on the St. Lawrence Seaway are more suitable for quarry or opencut coal workings; for general channel construction the more versatile tracked machines are preferred. Scrapers and dumper trucks with oversize pneumatic tires for fast travel over rough ground readily dispose of excavated materials to form embankments or other fill.

Water losses by percolation through bed or banks must be prevented on embankments and wherever permeable strata are encountered. While the watertight skin was originally obtained by a layer of puddled clay with protective gravel covering, other materials later became available, such as fly ash from power stations, sometimes with a cement admixture; bentonite; bituminous materials; sheet polythene; or concrete.

Bridges, aqueducts, and tunnels for waterways. Canals must frequently cross over or under roads and railways, rivers, and other canals. These crossings are made by a variety of bridges, sometimes carrying the road or railroad, sometimes carrying the canal. Most are fixed, though movable bridges are also used. On the Weaver River in England, four movable bridges, carrying main roads across the waterway, swing on pontoons.

Canals originally crossed valleys on heavy masonry structures supporting the full formation, including puddled clay lining. Cast-iron flanged and bolted troughs later provided a lighter and watertight channel; current practice uses concrete with bituminous sealing.

Canals were originally carried through hills and watersheds in small bricked tunnels through which vessels were propelled by manual haulage, by poling, or by legging—that is, by crewmen lying on their backs on the cabin and pushing with their feet against the tunnel roof. Later, tunnels were provided with towpaths.

Bank protection. On natural or canalized rivers of relatively large cross section, bank erosion can be checked by rubble roughly tipped or by natural growth such as reeds or willows.

On artificial canals of smaller dimensions, where passing vessels create a serious wash, some revetment (bank protection) is essential. Sloping banks are readily protected by close laid stone pitching, by bundles formed of interwoven willow branches, or by bituminous carpet; more permanent protection is provided by steel or concrete piles, close driven, overlapping or interlocked, and protected against impact damage by horizontal fendering above the waterline and below the waterline by roughly tipped rubble. In cuttings, the slopes are stabilized by berms (level strips) six to ten feet (two to three metres) wide at intervals determined by the nature of the soil. On long embankments safety stop gates can minimize water losses in the event of a breach.

Towpaths. Originally provided for animal haulage, tow-

paths were adapted on many French canals for mechanical and electrical haulage until the general use of powered craft terminated this service in 1969. But the towpaths are still useful; in addition to providing ways for some local haulage by mechanical tractor, they provide valuable access to the canals for inspection and maintenance.

LOCKS

On canalized rivers and artificial canals, the waterway consists of a series of level steps formed by impounding barriers through which vessels pass by a navigation lock. Basically, this device consists of a rectangular chamber with fixed sides, movable ends, and facilities for filling and emptying: when a lock is filled to the level of the upper pound, the upstream gates are opened for vessels to pass; after closing the upstream gates, water is drawn out until the lock level is again even with the lower pound, and the downstream gates are opened. Filling or emptying of the chamber is effected by manually or mechanically operated sluices. In small canals these may be on the gates, but on larger canals they are on culverts incorporated in the lock structure, with openings into the chamber through the sidewalls or floor. While the sizes of the culverts and openings govern the speed of filling or emptying the chamber, the number and location of the openings determine the extent of the water disturbance in the chamber: the design must be directed toward obtaining a maximum speed of operation with minimum turbulence. The dimensions of the chamber are determined by the size of vessels using, or likely to use, the waterway. Where the traffic is dense, duplicate or multiple chambers may be required; in long chambers intermediate gates allow individual vessels to be passed.

Lock dimensions vary from the small narrow canal locks of England with chambers 72 feet (21 metres) long and seven feet (two metres) wide to the 1,500-ton capacity waterways of Europe with chambers 650 by 40 feet (190 by 12 metres). On the St. Lawrence Seaway the dimensions are approximately 800 by 80 feet (240 by 24 metres); on the Mississippi and Ohio rivers, where push-towing units are operating, the dimensions rise to 1,200 by 110 feet (360 by 33 metres).

Lock
dimensions

On canalized rivers the present trend is for locks to be deeper, particularly where they form an integral part of a hydroelectric dam. On the Rhône the lock at Donzère-Mondragon has a depth of 80 feet (24 metres); in Portugal, where the Douro was being developed in the early 1970s for power and navigation, the Carrapateiro Lock has a depth of 114 feet (35 metres).

On artificial canals, where conservation of water is essential, depths do not normally exceed 20 feet (six metres): water consumption can be reduced by the provision of side pounds either adjacent to the lock, as at Bamberg on the Rhine-Main-Danube waterway, or incorporated in the lock walls, as in the (1899) Henrichsburg Lock on the Dortmund-Ems Canal.

Locks are located to provide good approach channels free from restrictions on sight or movement. Where traffic is heavy or push tows operate, adequate approach walls are needed both to accommodate vessels awaiting entry and to provide shelter from river currents while vessels move slowly into or out of the lock.

Lock gates. Movable gates must be strong enough to withstand the water pressure arising from the level difference between adjacent pounds. The most generally used are mitre gates consisting of two leaves, the combined lengths of which exceed the lock width by about 10 percent. When opened, the leaves are housed in lock wall recesses; when closed, after turning through about 60°, they meet on the lock axis in a V-shape with its point upstream. Mitre gates can be operated only after water levels on each side have been equalized.

On small canals gates may be manually operated by a lever arm extending over the lock side; on large canals hydraulic, mechanical, or electrical power is used. On the Weaver Navigations Canal in England, the hydraulic power for operating the lock gates has for 100 years been derived from the 10-foot (three-metre) head difference between the pounds.

Vertical gates, counterweighted and lifted by winch or other gearing mounted on an overhead gantry, can operate against water pressure; as the gate leaves the sill, water enters the chamber, supplementing or replacing the culvert supply. The turbulence is more difficult to control and the overhead gantries impose restrictions on masts and other superstructure of a vessel.

The use of sector gates, which turn into recesses in the wall, depends on the physical characteristics of the site and on the traffic using the waterway; falling gates lower into recesses in the forebay; and rolling gates run on rails into deep recesses in the lock walls.

Lock equipment. Ladders recessed into the walls provide access between vessels and the lockside and are vital in case of accidents.

Bollards (mooring posts) on the lockside are used for holding vessels steady by ropes against the turbulence during lock operation; mooring hooks set in recesses in the walls provide an alternative anchorage against surging. Floating bollards are provided in deep locks; retained in wall recesses, they rise or fall with the vessel, obviating the need for continuous adjustment of the ropes. Signals, physical or visual, erected at each end of the lock indicate to approaching craft whether the lock is free for them to enter and, in the multiple-chamber locks, which chamber they should use. Control cabins, centrally situated, enable all operations of the lock gates, sluices, and signals to be carried out by one man from a pushbutton control panel. Telephone or radio communication between adjacent locks gives the operator advance information enabling him to have a lock prepared in anticipation of the vessel's arrival. Experiments in France in the early 1970s were directed toward the automatic passage of a vessel through a flight of locks, the various operations at each lock, once initiated, continuing automatically until the vessel left.

Lock bypasses. The passage of a small pleasure boat through a deep lock is an expensive operation if it is passed alone and can be hazardous if it is passed with large barges that might surge against it. Canoes are normally brought ashore and manually moved around a lock on a portable trolley; larger pleasure craft can be transported on a cradle mechanically towed on a lockside rail track.

Water chutes have been introduced in Germany for canoes and rowboats where there are rises of 30 to 80 feet (nine to 24 metres); although more costly to install than lockside rail track, they are more popular. The canoeist, entering the approach channel, pushes a button actuating the head gates, which rise to allow the water to carry the canoe into and down the chute, where it is kept in the centre of the chute by guide vanes. For upstream passage, canoes are kept afloat by descending water but require manual towage.

Boat lifts. Vessels can be transported floating in a steel tank or caisson between adjacent pounds by a vertical lift, replacing several locks. Vertical lifts can be operated by high-pressure hydraulic rams, by submersible floats, or by geared counterweights. Hydraulic lifts with twin caissons were constructed in 1875 at Anderton, England, with a 50-foot (15-metre) lift for 60-ton vessels; in 1888 lifts were constructed at Les Fontinettes, France, for 300-ton vessels and at La Louvière, Belgium, for 400-ton vessels; in 1905 similar lifts were constructed at Peterborough and Kirkfield in Canada. Float lifts were constructed in 1899 at Henrichenburg, Germany, with a 46-foot (14-metre) lift for 600-ton vessels; in 1938 at Magdeburg, Germany, with a 60-foot (18-metre) lift for 1,000-ton vessels; and in 1962 a new lift at Henrichenburg for 1,350-ton vessels.

Counterweighted lifts were introduced in 1908 when the Anderton lift was reconstructed. Each caisson was separately counterbalanced by a series of weights and ropes with electrically driven gearing. This method was used in 1932 at Niederfinow, Germany, with a 117-foot (35-metre) lift for 1,000-ton vessels.

Inclined planes. In the 18th century, inclined planes were constructed to transport small boats on trucks between adjacent pounds, using animal power and gravity and, later, steam. A series of planes was built in the U.S. on the canal between the Delaware and Hudson rivers to transport 80-ton vessels in caissons; a similar plane for

60-ton vessels was built at Foxton, England, to bypass ten locks.

Three planes have been constructed in Europe, at Ronquières, Belgium, for 1,350-ton vessels; at St. Louis Arzwiller, France, for 300-ton vessels; and at Krasnoyarsk, Russia, for 1,500-ton vessels. At Ronquières and Krasnoyarsk, vessels are carried longitudinally up relatively gentle inclines with gradients of 1 in 21 and 1 in 12, respectively, while at Arzwiller the site permitted only a steep gradient of 1 in 2½, necessitating vessels being moved transversely. At Ronquières the plane rises 220 feet (66 metres) and replaces 17 locks; at Arzwiller the rise is 150 feet (45 metres), and here, too, 17 locks have been replaced. At Krasnoyarsk the plane rises 330 feet (98 metres) from the downstream water level of the River Yenisei to surmount the hydroelectric dam; on top of the dam the caisson moves on to a turntable, where it is rotated through 38° before passing to a second plane running down to the water level impounded upstream of the dam.

INLAND WATERWAY CRAFT

While early navigation of natural rivers was dependent on the use of sail for upstream operation, towpaths and animal haulage were provided when rivers were canalized and artificial canals constructed. Later, mechanical haulage was developed and is still used for local movement of unpowered craft.

Steam, and later diesel, tugs improved speed of travel, particularly where lakes or estuarial lengths were encountered. Powered barges, towing one or more unpowered (dumb) barges, were introduced on rivers with adequate lock chambers; but on artificial canals double (or treble) lockage operations made this method uneconomical; and, except for local lighterage (loading, transporting, and unloading) or maintenance duties, dumb barges are little used on artificial canals.

To meet competition from road haulage, with its greater flexibility and higher speeds, water transport must find its solution in larger units, thus necessitating the enlargement of channels and locks. Consequently, the 300-ton barges operating economically early in this century have been replaced by craft as large as 1,350 tons and more.

In North America, transport operators grouped dumb barges into assemblies, lashing them on either side or ahead of a power unit with similar barges secured in rows ahead. These assemblies of unpowered and individually unmanned barges are known, somewhat illogically, as push tows and the power unit as a push tug. While these assemblies operate most advantageously on natural rivers, their development has justified heavy capital expenditure for enlarging lock chambers on some canalized rivers to avoid delays and increased operational costs arising from multiple lockage. In Europe, push tows normally operate with fewer than six barges, but on the Mississippi, with its deep channel and 700 miles (1,120 kilometres) without a lock, a push tow may aggregate 40,000 tons, an assembly of 40 barges being controlled by one 9,000-horsepower push tug, with cabins and facilities for 24-hour operation. On the Ohio River, the original 600-foot lock chambers are being lengthened to 1,200 feet (355 metres) to obviate double lockage.

Movement of push tows around bends, as on the Moselle River, is facilitated by portable power units attached to the bows and operated as required. Similar units can be attached to individual barges for transfer from push tow to wharf or vice versa; they can also be used for handling dumb barges in docks and for moving hopper barges short distances from dredger to disposal site.

WATERWAY MAINTENANCE

Inspection vessels, self-propelled and equipped with echosounding appliances, are necessary for regular survey of the waterway. On natural and canalized rivers, which are subject to droughts and floods, attention is particularly directed to the location of the navigable channel: transverse soundings reveal channel movements and enable marker buoys or perches to be relocated and shoals removed by dredging; longitudinal echo-sounding readings normally suffice to locate shallow lengths on artificial canals.

The dredging plant

The dredging plant is an expensive item of waterway maintenance. Bucket dredgers for major operations are supplemented by suction, or grab, dredgers for localized work; hopper barges are required for transporting dredged materials to disposal sites, which should be numerous enough to minimize the transporting period, so that the dredger remains fully operational with a minimum of hopper barges and towage units.

Bank revetment requires special vessels for carrying piling frames and light lifting tackle; other service craft are needed for concrete mixing and general duty.

Lock-gate renewal is normally planned to ensure that a predetermined number of gates are replaced annually; special vessels equipped with heavy lifting tackle are needed for transport and site handling.

Divers carry out underwater inspections and repairs; although skin diving has been developed for some operations, helmet diving is still needed for prolonged work. Both types of diving require special craft with specialized crew and equipment for servicing the divers. Salvage craft with pumps and heavy lifting tackle are used for removing obstructions from the channel or for raising sunken vessels. Tugs handle the service vessels because many are used only intermittently, and thus power units are not economical. Dry docks or slipways, workshops, fitting shops, welding bays, and other special facilities, usually grouped in the vicinity of the administration offices, are part of every modern canal-maintenance system. (C.M.)

Waterway systems

ADMINISTRATION

Modern inland waterway development has been largely carried out by governments, in contrast to early canal construction, which was mainly undertaken by private enterprise. Most of the older canals were subsequently acquired by the state and are administered by them or their agencies and are subject to comprehensive regulation, frequently by independent commissions. International commissions comprising the states concerned regulate navigation on the international waterways. In the United States, the waterways are basically a federal responsibility, with their development undertaken by the U.S. Army Corps of Engineers, but state governments and local authorities also participate in the administration of many local waterways. The Interstate Commerce Commission has responsibility for the regulation of the common carriers and requires them to publish their rates. For some major multipurpose projects, public corporations were established to undertake and administer them.

In Europe and the Soviet Union, the national networks, mainly based on navigable and canalized rivers linked by canal, were developed by the governments, who retain responsibility for finance and administration. In Britain, most canals were brought under government ownership beginning January 1, 1948, and are administered by the British Waterways Board.

European waterway regulation

Europe's main waterways have long been accepted as international waterways with navigation free to all vessels and equality of treatment of all flags guaranteed. The chief regulatory commissions are the Central Commission for the Navigation of the Rhine, the Danube Commission, and the commission for the canalized Moselle. There are also a number of bilateral agreements between states. Wars and political considerations following them have from time to time interrupted the freedom of navigation. A provisional Rhine Commission was operating in the early 1970s; a new Danube Commission was established in 1953 after the signing of the Austrian state treaty, when freedom of navigation throughout the river's length was fully restored. With the creation of a number of international organizations in Europe, a high degree of cooperation between states for the development of the inland waterways and the regulation of navigation was achieved, particularly through the United Nations Economic Commission for Europe, the European Economic Community, the Organization for Economic Cooperation and Development, and the Council of Europe.

In North America, a U.S.-Canadian International Joint

Commission has functioned since 1909 with general authority over the boundary waters. The St. Lawrence Seaway is a joint project, administered by the St. Lawrence Seaway Authority in Canada and the St. Lawrence Seaway Development Corporation in the United States.

The Panama Canal was originally administered under the Panama Canal Convention of 1903 by the United States, under the supervision of the army. Panama-U.S. relations were frequently strained, and in 1964, the United States agreed to negotiate new treaties concerning the existing canal and construction of a new canal at sea level. Later, both countries agreed to a new treaty recognizing Panama's sovereignty over the Canal Zone.

The international status of the Suez Canal, constructed and administered by the Suez Canal Company, has frequently been a matter for dispute, peaceful and otherwise. Only in 1904, under an Anglo-French agreement, was the Constantinople Convention of 1888, establishing the Suez Canal as an international waterway open to all in war and peace, finally implemented. In 1956 British presence in the area ended, and troops were withdrawn from the canal zone; the Egyptian government nationalized the assets of the canal company and the administration was assumed by Egypt, but the 1967 war closed the canal until 1975.

MAJOR INLAND WATERWAYS AND NETWORKS

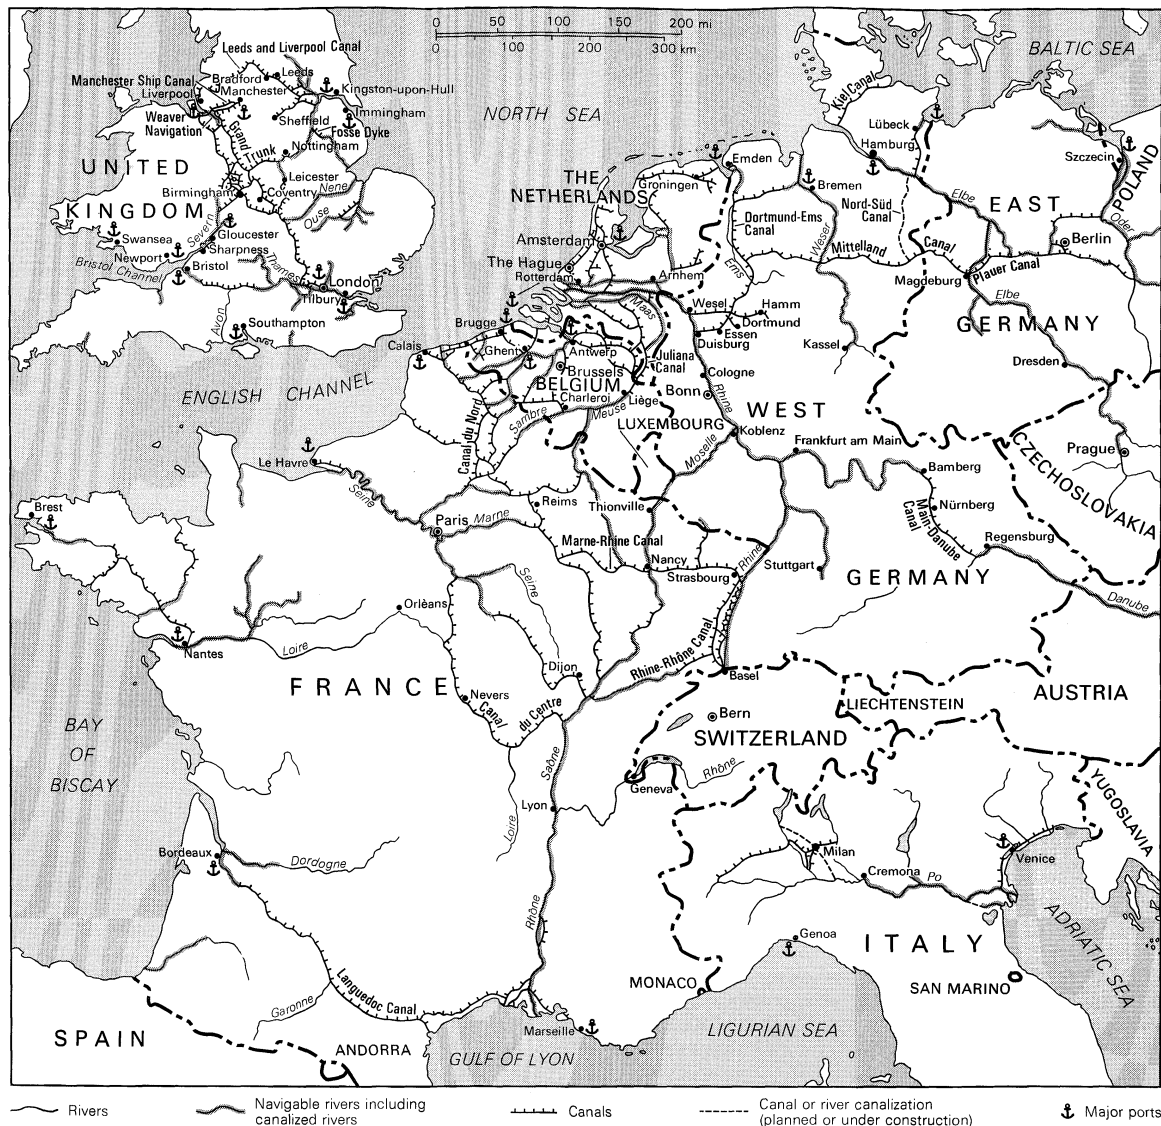

Europe. After the end of World War II, the growth of transport by inland waterway in Europe, coordinated by the various international authorities, resulted in an enlarged and integrated network brought up to a minimum common standard for craft of 1,350 tons. With the Rhine, Moselle, and their tributaries dominating the German system and providing outlets for the Dutch and Belgian systems and connecting with the French network, main improvements were concentrated on the international Main-Danube Canal and on improving the north-south route of the Nord-Sud Canal (or Elbe-Seitenkanal). The latter canal (completed in 1976) leaves the Elbe about 20 miles (32 kilometres) above Hamburg and, running south, joins the Mittelland Canal near Wolfsburg, Germany, reaching a total of 71½ miles (120 kilometres) and shortening the route between Hamburg and the Ruhr by 134 miles (220 kilometres).

The Main-Danube waterway connecting the Rhine with the Black Sea is planned to provide a route for traffic between east and west Europe through Germany by 1992, accommodating craft of 1,350 tons throughout its length. Following the River Main to Bamberg in Germany, the route proceeds by artificial waterway, including a section of the Regnitz Canal to Dietfurt, thence by the River Altmühl to below Kelheim, where it joins with the Danube, crossing the Austrian border at Jochenstein. The 44-mile (71-kilometre) Bamberg-to-Nürnberg canal section, completed in 1972, includes seven locks with a combined lift of 268 feet (80 metres). All locks are 623 feet (190 metres) long and able to accommodate vessels of 1,500 tons. Improvements of the channel of the German Danube, begun in 1965, include a pair of locks at Kachlet, just above Passau. In Austria, four pairs of locks to take 1,350-ton craft have been built and others are planned.

In 1970 the damming of the Danube at Djerdap, the Iron Gate rapids, on the border between Yugoslavia and Romania, was begun in conjunction with the improvement of navigation through these dangerous waters; it will incorporate vast hydroelectric power plants. Two locks, 1,017 feet (310 metres) long and 112 feet (34 metres) wide, with two chambers each, are being built to facilitate passage through the Iron Gates. Journey time for ships travelling from Black Sea ports upstream to Belgrade, Vienna, and central Europe will be reduced from around 100 to 15 hours by this project, and traffic is expected to rise from the present 12,000,000 tons annually to 50,000,000 tons.

France's waterway network of nearly 5,000 miles (8,000 kilometres) is based primarily on its rivers, but many of the low-capacity canals are being raised to the 1,350-ton standard. The major development under way in the 1970s, in cooperation with West Germany, was the construction to this standard of the North Sea-Mediterranean waterway via the canalized Rhône and Rhine rivers. With

The Main-Danube waterway

Inland waterway systems of western Europe.

four existing locks built for the Grand Canal d'Alsace, a projected lateral canal between Huningue and Strasbourg, the project was modified in 1956, and the four remaining dams were to be built on the Rhine itself and bypassed with short canals including four locks, three with two chambers each. Canalization of the Rhône started with the building of the Port of Edouard-Herriot downstream from Lyon, and work proceeded on 12 locks and dams. Two new ports, serving Valence and Montélimar, were being constructed. Improvements were also made on the Marne-Rhine waterway, which provides an important internal trade route connecting the Paris Basin with the industrial regions of Alsace-Lorraine. The improvements included major works on either side of the Vosges summit level, replacing 23 old locks. At Réchicourt a new lock with a lift of 32½ feet (ten metres) bypasses six locks and a winding section of the old canal; on the other side of the summit a new canal section bypasses 17 locks, which formerly required eight to 12 hours to navigate. On this section the inclined plane of Saint-Louis Arzwiller deals with a difference in level of 146 feet (44 metres) with a horizontal length of 422 feet (125 metres). Two tanks each carry a 350-ton barge. Their 32 wheels run on four rails, and two sets of 14 cables connect the tanks to the two concrete counterweights. Improvements have been made to routes connecting the Seine with the north and east. The Canal du Nord was completed in 1965, and a bottleneck was removed on the Oise Lateral Canal with the building of two locks to accommodate through convoys to Paris.

In The Netherlands, the extensive canal system based on large natural rivers and serving the ports of Rotterdam and Amsterdam has required comparatively little modernization; but to avoid the River Maas (Meuse), between Roermond and Maastricht, the Juliana Canal was built in 1935 and improved after World War II. The Twente Canal, opened in 1936, improved communication with the industrial east. Most important of the postwar projects was the building of the Amsterdam-Rhine Canal to enhance the capital's value as a trans-shipment port. The Noord-Hollandsch Canal from Amsterdam to Den Helder was constructed, and the IJsselmeer was linked with the Ems estuary across the north of Holland. To shorten the distance between Rotterdam and Antwerp by 25 miles (40 kilometres), the Schelde-Rhine Canal has been built.

Italy's waterway system, based on the Po Valley, is cut off from the European network by the Alps, but it is also being brought up to higher standards. In Scandinavia, there are two major commercial artificial waterways; the first, the Trollhätte Canal, connects the Götaälv (river) upward from Göteborg with Lake Vänern and with the Finnish lakes and connecting canals; the second, the Saimaa Canal, in southeast Finland, which carries the vast Saimaa Lake system to the sea, was being reconstructed at the time of World War II. After the Soviet-Finnish War, part was ceded to the Soviet Union; but in 1963 it was leased back to Finland, modernization continued, and the canal, with eight large locks replacing the previous 28, was reopened in 1968.

Principal
Soviet links

In the Soviet Union, water navigation plays a major role in the country's economy; and after World War I its great rivers—the Dnepr, Dvina, Don, Vistula, and Volga—were linked to form an extensive network, making through navigation possible from the Baltic to both the Black Sea and the Caspian. The Black Sea and the Baltic are connected by three different systems, of which the most important is the link between the Dnepr and the Bug, a tributary of the Vistula, by way of the Pripyat and Pina rivers, a 127-mile (203-kilometre) canal connecting with the River Mukhavets, a tributary of the western Bug. This system is the sole wholly inland waterway connection between western Europe and the Soviet systems, giving through access to the Caspian and Black seas. When the Rhine–Danube and Oder–Danube canals are completed, a second route will be provided, via the River Berezina, a tributary of the Dnepr, the Viliya, a tributary of the Niemen, and a 13-mile (21-kilometre) canal through Latvia to Riga. The last link reaches the Baltic through Lithuania and Poland from the Dnepr by way of the Szara, a tributary of the Niemen; the Jasiolda, a tributary of the Pripyat; and a 34-mile (54-kilometre) canal. Other important links are the Volga–Don Canal, 63 miles (101 kilometres) long and completed in 1952, and the Moscow–Volga Canal, built between 1932 and 1937, which flows 80 miles (128 kilometres) from the Volga to the Moskva River at Moscow. The White Sea–Baltic Canal, built in 1931–33, runs from Belomorsk on the White Sea through the canalized Vyg River across Lake Vyg and through a short canal to Pavenets at the northern end of Lake Onega, through which it passes to the canalized Svir River, Lake Ladoga, and the Neva River to the southern terminal at Leningrad. The total length of the system is 140 miles (225 kilometres), reducing sea passage between Leningrad and Archangel by 2,400 miles (4,000 kilometres); through its 19 locks it rises to 335 feet (100 metres) above sea level. Further developments in the Soviet Union are mainly in the distant Asian territories, where the Ob and Yenisey in Siberia are connected by canal, and the Karakumsky Kanal has been built from Kerki on the Amu Darya and is being continued westward to the Caspian.

North America. The United States and Canadian networks of inland waterways are based on the great navigable rivers of the continent linked by several major canals. Additionally, to reduce the hazards of navigating the Atlantic seaboard and to shorten distances, intracoastal waterways (protected routes paralleling the coast) have been developed. The total inland U.S. system, including protected coastal routes, approximates 25,000 miles (41,000 kilometres), of which well over half has a minimum depth of nine feet (three metres). The largest system is based on the Mississippi, which is navigable for about 1,800 miles (2,880 kilometres) from New Orleans to Minneapolis, and its vast system of tributaries. This system connects with the St. Lawrence Seaway via Lake Michigan, the Chicago Sanitary and Ship Canal, and the Illinois River and with the Atlantic coast via the New York State Barge Canal (Erie Canal) and the Hudson River. The two intracoastal waterways are the Atlantic and the Gulf, the former extending from Boston, Massachusetts, to Key West, Florida, with many sections in tidal water or in open sea. The Gulf Intracoastal Waterway comprises large sheltered channels running along the coast and intersected by many rivers giving access to ports a short distance inland. New Orleans is reached by the Tidewater Ship Canal, a more direct and safer waterway than the Mississippi Delta. The Pacific coast canals are not linked with the national network, but two major projects of importance are the Sacramento Deepwater Ship Canal and the Columbia River development, which will provide over 500 miles (800 kilometres) of navigable river from the Pacific to Lewiston, Idaho.

The opening of the St. Lawrence Seaway in 1959 saw the fulfillment of a project that had been envisaged from the times of the earliest settlements in Canada. A continuous, navigable, deep waterway from the Atlantic to the Great Lakes was the obvious route for opening up the interior of North America; but natural obstacles, such as the Lachine Rapids north of Montreal, had prevented its realization. The completion of such a waterway required agreement between the U.S. and Canada, which was difficult to achieve. In 1912 the Canadian government decided to improve the Welland Canal to provide a 27-foot (eight-

metre) depth with locks 800 feet (236 metres) long and 80 feet (24 metres) wide; but because of World War I, it was not completed until 1932. Although a joint project to include hydroelectric power development on the International Rapids section had been provisionally agreed upon, final agreement between Canada and the U.S. was not reached until the early 1950s. The Canadian government undertook to raise the standard of the waterway to a 27-foot navigation depth between Montreal and Lake Erie, and the U.S. agreed to carry out other works, including the bypassing by canal and locks of the Barnhart Island-Cornwall generating dam at the foot of the Long Sault Rapids. This agreement enabled work on the seaway to begin in 1954. The resultant deep waterway, navigable by oceangoing ships, extends about 2,300 miles (3,830 kilometres) from the Atlantic Ocean to the head of the Great Lakes in the heart of North America.

After Montreal Harbour the first lock is the St. Lambert, which rises 15 feet (4.5 metres) to the Laprairie Basin and proceeds 8.5 miles (14 kilometres) to the second Côte Ste. Catherine Lock, which rises 30 feet (nine metres) to Lake St. Louis and bypasses the Lachine Rapids. Thereafter, the channel runs to the lower Beauharnois Lock, which rises 41 feet (12 metres) to the level of Lake St. Francis via a 13-mile (21-kilometre) canal. Thirty miles (50 kilometres) farther, the seaway crosses the international boundary to the Bertrand H. Snell Lock, with its lift of 45 feet (14 metres) to the Wiley-Dondero Canal; it then lifts another 38 feet (12 metres) by the Dwight D. Eisenhower Lock into Lake St. Lawrence. Leaving the western end of the lake, the seaway bypasses the Iroquois Control Dam and proceeds through the Thousand Islands to Lake Ontario.

Eight locks raise the water 326 feet (98 metres) over 28 miles (45 kilometres) from Lake Ontario to Lake Erie. The St. Marys Falls Canal, with a lift of about 20 feet (six metres), carries the waterway to Lake Superior, where the seaway terminates.

Indian Subcontinent. In Asia, the full potential of the rivers for navigation had not been developed by the second half of the 20th century; though the rivers constitute one of the main means of transport, there are few navigable canals and no integrated system of inland waterways. The Indus River Basin was being developed in the 1970s, however, and there were plans for international cooperation in developing inland waterway transport on the Mekong and Ganges-Brahmaputra systems.

ECONOMIC SIGNIFICANCE

Despite the large capital investment required to modernize existing inland waterway systems and for new construction, water transport has demonstrated competitive strength as a carrier for commodities in the movement of which the time factor is not of prime importance, such as minerals, timber, and many agricultural products. In the same way as the canals of the 19th century contributed to the development of the Midwest in the United States, the St. Lawrence Seaway has led to an expansion of industrial activity on the regions bordering the Great Lakes. Economic expansion along North America's rivers has followed capital investment in improvement of navigation along them.

In the Soviet Union, similar development of vast areas, including the distant Asian territories, was made possible by linking the major rivers to provide through routes.

In continental Europe, the eight member countries of the Conference of European Ministers of Transport (ECMT) experienced a growth in total tons carried by inland waterways from 385,000,000 tons to 472,000,000 tons in the years 1964-68. Whereas in 1938 Germany carried 90,000,000 tons of freight on its inland waterways, by the end of the 1960s the Federal Republic of Germany alone was carrying over 230,000,000 tons a year; East Germany was carrying an additional 12,000,000 tons. Nor was this increase limited to the earlier years of the decade, as is shown by the volume of goods passing along the Rhine, which rose from 187,000,000 tons in 1963 to 265,000,000 tons in 1969. Most European countries had the same experience: the Soviet Union, which carried over its 145,000 kilometres of navigable waterways 239,500,000 tons in 1963, transported 322,700,000 tons in 1969.

It is difficult to judge the economics of water transport compared with other transport forms because of the different operating systems. On most international rivers, for example, there are no navigational charges; but on most national artificial waterways, tolls are charged. Costs of water transport are therefore mainly operating costs, which are considerably lower than the total costs of movement by other transport modes. This situation partly accounts for the fact that in the 1950s and 1960s in the U.S., costs per ton-mile stayed practically the same or fell slightly. Mergers of carrier companies and technological developments also contributed to price stability.

In West Germany it has been calculated that one horsepower could move by road 150 kilograms (330 pounds), by rail 500 kilograms (1,100 pounds), and by inland waterway 4,000 kilograms (8,800 pounds). The water-transport cost is said to be one-sixth the cost of transport by road and two-thirds the cost of transport by rail. Other transport carriers contend that such comparisons are not valid because public investment in permanent structures (*i.e.*, canals and locks) is not always taken into account, whereas for railways, private investment in right-of-way costs is reflected in carrying charges. Nor has the inland-waterway industry been without its difficulties. In Europe, for example, in the 1960s a surplus of carrying craft adversely affected the industry's profitability, but by the 1970s this problem had largely been overcome.

In summary, it may be said that the real advantages of water transport are being maintained or enhanced by modern techniques, especially by more powerful towboats capable of hauling up to 50 barges carrying 80,000 tons; around-the-clock operation is made possible with towboats refuelled in midstream and barges attached or detached while the tow proceeds along the river; at ports, automatic loaders cut turnaround time to a minimum. It remains to be seen whether the resurgence of water transport so evident through the 1960s and 1970s will be maintained. A major question mark is the barge-carrying ship, analogous to railway piggybacking of truckloads, which promises to provide through transport by barge from inland ports across oceans to foreign inland destinations. DAMS

A dam is a structure built across a stream, river, or estuary to retain water. Its purposes are to meet demands for water for human consumption, irrigation, or industry; to reduce peak discharge of floodwater; to increase available water stored for generating hydroelectric power; or to increase the depth of water in a river so as to improve navigation. An incidental purpose can be to provide a lake for recreation.

Auxiliary works at a dam may include spillways, gates, or valves to control the discharge of surplus water downstream from the dam; an intake structure conducting water to a power station or to canals, tunnels, or pipelines for more distant use; provision for evacuating silt carried into the reservoir; and means for permitting ships or fish to pass the dam. A dam therefore is the central structure in a multipurpose scheme aiming at the conservation of water resources. The multipurpose dam holds special importance in the underdeveloped countries, where a small nation may reap enormous benefits in agriculture and industry from a single dam.

Dams fall into several distinct classes, by profile and by building material. The decision as to which type of dam to build depends largely on the foundation conditions in the valley and the construction materials available. Broadly, the choice of materials now lies between concrete, soils, and rock fill. Though a number of dams were built in the past of jointed masonry, this practice is now largely obsolete. The monolithic form of concrete dams permits greater variations in profile, according to the extent water pressure is resisted by the deadweight of the structure, is transferred laterally to buttresses, or is carried by horizontal arching across the valley to abutments formed by the sides of the valley.

History

ANCIENT DAMS

The Near East. The earliest recorded dam is believed to have been on the Nile River at Kosheish where a 15-metre-high (49-foot) masonry structure was built about 2900 BC to supply water to King Menes' capital at Memphis. Evidence exists of a masonry-faced earth dam built about 2700 BC at Sadd-el-Kafara, about 19 miles (30 kilometres) south of Cairo; this dam failed shortly after completion when, in the absence of a spillway, it was overtopped by a flood. The oldest dam in use is a rock-fill structure about 20 feet (six metres) high on the Orontes in Syria, built about 1300 BC.

The Assyrians, Babylonians, and Persians built dams between 700 and 250 BC for water supply and irrigation. Contemporary with these was the earthen Ma'rib Dam in South Arabia, 50 feet (14 metres) high and nearly 1,970 feet (600 metres) long. Flanked by spillways, this dam delivered water to a system of irrigation canals for more than 1,000 years. Other dams were built in this period in Ceylon (modern Sri Lanka), India, and China.

The Romans. Despite their undoubted skill as civil engineers, especially in the field of water supply, the Romans' role in the evolution of dams is not remarkable for quantity or for advances in height. Their skill lay in the comprehensive collection and storage of water and in its transport and distribution by aqueducts. Remarkably, at least two Roman dams in southwestern Spain, Proserpina and Alcantarilla, are still in use, although a third, the Alcantarilla Dam, has overturned, and the reservoirs of some others have filled with silt. The Proserpina Dam, 40 feet (12 metres) high, has a masonry-faced core wall of concrete backed by earth; it may be regarded therefore as a forerunner of the modern earth dam. The Proserpina is strengthened on the upstream face by buttresses (Figure 25A). Of similar construction, 46 feet (14 metres) high and 1,804 feet (550 metres) in length, Alcantarilla Dam was supported by a great weight of earth, which eventually caused failure of the wall. Cornalbo represented a further advance in design; the masonry wall was constructed of

cells, which were filled with stones or clay, and faced with mortar. It differs from Proserpina and Alcantarilla in having a sloping upstream face and in being straight in plan. Proserpina and Alcantarilla were polygonal in plan. The merit of curving a dam upstream was not apparently fully appreciated by the Romans until such a curved structure, the forerunner of the modern "arch-gravity" dam, was built in AD 550 at Dâra on the present Turkish-Syrian border by Byzantine engineers.

Early dams in the Orient. Quite independently, dam construction evolved in the East. In 240 BC a stone crib was built across the Gukow River in China; this structure was 98 feet (30 metres) high and about 985 feet (300 metres) long. Many earth dams of moderate height (in some cases, of great length) were built by the Sinhalese in Ceylon after the 5th century BC to form reservoirs or tanks for extensive irrigation works. The Kalabalala Tank (formed by an earth dam 79 feet [24 metres] high and nearly 3.75 miles [six kilometres] in length) had a perimeter of 37 miles (60 kilometres) and helped store monsoon rainfall for irrigating the country around the ancient capital of Anuradhapura. Many of these tanks in Ceylon are still in use today.

In Japan the Diamonike Dam reached a height of 105 feet (32 metres) in AD 1128. Numerous dams were also constructed in India and Pakistan. In India a design employing hewn stone to face the steeply sloping sides of earth dams evolved, reaching a climax in the 10-mile (16-kilometre)-long Veeranam Dam, Tamil Nadu, built from AD 1011 to 1037.

In Iran the Kebar, a pioneer arch dam, was built early in the 14th century (Figure 25B). Spanning a narrow limestone gorge, it reached 26 metres (86 feet) high with a thickness of less than five metres (16 feet). The central curved portion, 38 metres (124.6 feet) in length and radius, was supported on two straight abutments.

FORERUNNERS OF THE MODERN DAM

15th to 18th century. In the 15th and 16th centuries dam construction resumed in Italy and, on a larger scale, in Spain, where Roman and Moorish influence was still felt. Of these dams, the Tibi (1579–89) was an arch-gravity structure 138 feet (42 metres) high; this height was not surpassed in western Europe until the building of the Gouffre d'Enfer Dam in France, almost three centuries later. Almanza Dam in Spain is illustrated in Figure 25C. An attempt to build a dam 170 feet (52 metres) high near Lorca, Spain, at the end of the 18th century failed disastrously in 1802, when earth and gravel below the piled structure washed out. In Europe, where rainfall is ample and well distributed throughout the year, dam construction before the Industrial Revolution was on only a modest scale and was restricted to forming water reservoirs for towns, driving water mills, and making up water losses in navigation canals. An exception was the 115-foot (36-metre)-high earth dam built in 1675 at St. Ferréol, near Toulouse, France, to supply the Canal du Midi; for more than 150 years it was the highest earth dam in existence.

19th century. Up to the middle of the 19th century, dam design was entirely empirical. Knowledge of the properties

Rankine's
contribu-
tions

of materials and structural theory had been accumulating for 250 years; Galileo, Newton, Leibniz, Hooke, Daniel, Bernoulli, Euler, de la Hire, and Coulomb had made outstanding contributions. In the 1850s W.J.M. Rankine, professor of civil engineering at Glasgow University, successfully demonstrated how applied science could help the practical engineer. Rankine's work on the stability of loose earth, for example, provided a better understanding of the principles of dam design and performance of structures. This led in turn to improved construction techniques and larger dams. Furthermore, in certain countries, Rankine's work encouraged acceptance of civil engineering as a subject for university study and added to the status of civil engineers. Much remained to be learned of soils and natural rocks in the 100 years after Rankine. Many scientists and engineers made, and continue to make, noteworthy contributions.

Development of modern structural theory. Concrete dam design is based on conventional structural theory. In this relationship two phases may be recognized. The first, extending from 1853 until about 1910 and represented by the contributions of a number of French and British engineers, was actively concerned with the precise profile of gravity dams in which the horizontal thrust of water in a reservoir was resisted by the weight of the dam itself and the inclined reaction of the dam's foundation. Starting about 1910, however, engineers began to recognize that concrete dams were monolithic three-dimensional structures in which the distribution of stress and the deflections of individual points depended on stresses and deflections of many other points in the structure. Movements at one point had to be compatible with movements at all others. Owing to the complexity of the stress pattern, model techniques were gradually employed. Models were built in plasticine, rubber, plaster, and finely graded concrete. In recent years the digital computer has facilitated use of the analytical method of finite elements, by which a monolithic structure is divided into an assembly of separate blocks. Study of both physical and digital models permits deflections of a dam's foundations and structure to be taken into account.

During the 100 years up to the end of World War II, experience in design and construction of dams advanced in many directions. In the first decade of this century many large dams were built in the U.S. and western Europe. In succeeding decades, particularly during the war years, many impressive structures were built in the U.S. by federal government agencies and private power companies. Hoover Dam, built in 1936, is an outstanding example of an arch-gravity dam built in a narrow gorge across a major river and employing advanced design principles. It has a height of 726 feet (221 metres) from its foundations, a crest length of 1,243 feet (379 metres), and reservoir capacity of 48×10^9 cubic yards (37×10^9 cubic metres).

Among earth dams, Fort Peck Dam, completed in 1940, contained the greatest volume of fill, 126,000,000 cubic yards (96,000,000 cubic metres). This volume was not exceeded until the completion in 1975 of Tarbela Dam in Pakistan (190,000,000 cubic yards or 145,000,000 cubic metres).

The modern dam

BASIC PROBLEMS IN DAM DESIGN

Most modern dams continue to be of two basic types: masonry (concrete) and embankment (earthfill). Masonry dams are typically used to block streams running through narrow gorges, as in mountainous terrain; though such dams may be very high, the total amount of material required is limited. Embankment dams are preferred to control broad streams, where only a very large barrier, requiring a great volume of material, will suffice. The choice of masonry or embankment and the precise design depend on the geology and configuration of the site, the functions of the dam, and cost factors.

Site investigation and testing. Investigation of a site for a dam includes sinking trial borings to determine the strata. The borings are supplemented by shafts and tunnels which, because of their cost, must be used as sparingly as

possible. In the shafts and tunnels, tests can be made to measure strength, elasticity, permeability, and prevailing stresses in strata, with particular attention given to the properties of thin partings, or walls, between the more massive beds. The presence in groundwater of chemical solutions harmful to the materials to be used in the construction of the dam must be assessed. Sources of construction materials need exploration. As dams continue to increase in height, the study of foundation conditions becomes increasingly critical.

Model tests play a major part in the structural, seismic, and hydraulic design of dams. Structural models are particularly useful in analysis of arch dams and in verifying analytical stress calculations. Various materials have been used for model tests; on some early tests for Hoover Dam, rubber was employed. The need for accurate reproduction of stress patterns in complex models is met by using material of low elasticity. In a sense, dams themselves are models for future design. The instruments built into them to record movements under load, strains within materials after construction, temperature and pressure changes, and other factors are installed primarily to study the performance of the structure and to warn of possible emergencies, but their value in confirming design assumptions is important.

The digital computer has permitted considerable advance in analytical methods of design. Its ability to handle a great volume of data and to solve large sets of simultaneous equations containing many variables has made practicable the method of Finite Element Analysis. In this method a complicated structure is divided into a number of separate equilibrium conditions, and strains are rendered compatible, thus leading to a complete analysis of stress and strain distribution throughout the structure.

Problems of materials. Each of the two basic dam materials, concrete and earth or rock fill, has a weakness that must be overcome by the proper design of the dam.

Weaknesses of concrete. Concrete is weak in tensile strength; that is, it can be pulled apart easily. Concrete dams must therefore be designed to place minimum tensile strain on the dam and to make use of concrete's great compressive strength, or ability to support vertical loads. The chief constituent of concrete, cement, shrinks as it sets and hardens, due to water absorption in the crystalline structure, to evaporation of water to the atmosphere, and to cooling from the higher temperatures reached when the chemical reactions in the cement are in progress during hydration. Because of the large volume of concrete in a dam, shrinkage presents a serious cracking hazard.

Various expedients are used to overcome the problem. Concrete is usually cast in separate blocks of limited height. Gaps may be left to permit heat losses and filled in later. Low-heat cements may be used; these are specially blended so that rates of heat evolution are retarded. Cement content can be safely reduced in the interior concrete in the dam, in which strength and resistance to climatic and chemical deterioration are less important. The cement content, and therefore the heat caused by hydrating, can also be reduced by using aggregate (the other major constituent of concrete) of larger stones. Another expedient is to use other fine-grained materials, such as fly ash (pulverized fuel), as filler, reducing the total cement volume in the concrete. Another is to use certain additives, surface-active agents, and air-entraining agents that permit using a lower water-to-cement ratio in mixing the concrete. Techniques used to speed the cooling process include replacing some of the water in the mix by ice, circulating water through pipes laid in the concrete, and extracting excess water from surfaces by vacuum.

Weaknesses of earth and rock fill. Soils and rock fragments lack the strength of concrete, are much more permeable, and possess less resistance to deterioration and disturbance by flowing water. These disadvantages are compensated for by a much lower cost and by the ability of earth fill to adapt to deformation caused by movements in the dam foundation. This assumes, of course, sufficient usable soil available close to the dam site. In bare mountain country it may be necessary to quarry rock and construct a rockfill rather than an earthfill dam. Earth fill

Finite
Element
Analysis

Seepage in
earth dams

is of course more economical, and often a suitable borrow area can be found close to the site.

Soil consists of solid particles with water and air in between. When the soil is compressed by loading, as occurs in dam construction, some drainage of air and water takes place, causing an increase in pressures between the solid particles. When there is a high rate of seepage, the soil tends to develop differential pressures and reach a condition called quick, in which it behaves as a fluid. Even if it does not reach this condition, there is often some weakening of its structure, and steps must be taken to counter this.

The earthquake problem. Many large dams have been built in the seismically active regions of the world, including Japan, the western United States, New Zealand, the Himalayas, and the Middle East. In 1968 the Tokachi earthquake damaged 93 dams in Honshu, the main Japanese island; all were embankment dams of relatively small height.

Despite a great deal of work on the distribution of seismic activity, the measurement of strong ground motions, and the response of dams to such motions, earthquake design of dams remains imprecise. The characteristics of strong ground motions at a given site cannot be predicted, and all types of dams possess some degree of freedom, imperfect elasticity, and imprecise damping. Nevertheless, the digital computer and model testing have given promise of considerable progress. It is now possible to calculate the response of a concrete dam to any specified ground motion; this has been done for the Tang-e Soleyman Dam in Iran and the Hendrik Verwoerd Dam in South Africa.

There has also been considerable advance in the theoretical estimation of the effects of ground motion on embankment dams.

TYPES OF DAMS

The modern concrete dam. *Concrete gravity dams.* Concrete gravity dams share certain features with all types of concrete dams. Running in virtually a straight line across a broad valley, they resist the horizontal thrust of the retained water entirely by their own weight; at each level in their height the water's thrust is deflected down toward the foundation by the weight of the concrete. In this action their purpose resembles that of the abutment of an arched bridge or the buttresses and pinnacles of a church. A gravity dam is a right-angled triangle; its hypotenuse forms the sloping downstream face. The base width is approximately three-quarters the height of the dam.

The three main forces acting on a gravity dam are the thrust of the water, the weight of the dam, and the pressure, or reaction exerted by the foundation, which is necessarily inclined in respect to the superstructure. It is also essential to consider the thrust exerted on the upstream face by silt deposited in the reservoir or by ice on the water surface, the inertia forces that can be caused by seismic action, and, in particular, the buoyant uplift force of water seeping under the dam or into the horizontal joints.

Uplift due to seepage has caused sustained discussion among engineers. It calls for the greatest of care in design and construction. Where a dam is founded on solid rock, a simple downward projection of concrete into the rock will generally suffice to cut off seepage and eliminate uplift pressures. Usually, however, the rock foundation is permeable, sometimes to considerable depths, so construction of an absolutely reliable cutoff is either difficult or impossible. Reliance must then be placed on an extensive system of grouting the fissured rock and on relieving uplift pressures by means of drainage. Many dams possess both cutoffs and underdrainage.

Post-tension
construction

A relatively new development in the construction of gravity dams is incorporation of post-tensioned steel into the structure. This helped reduce the cross section of Allt Na Lairige Dam in Scotland to only 60 percent of that of a conventional gravity dam of the same height. A series of vertical steel rods near the upstream water face, stressed by jacks and securely anchored into the rock foundation, resists the overturning tendency of this more slender section. This system has also been used to raise existing gravity dams to a higher crest level, economically increasing the storage capacity of a reservoir.

Of special interest are three concrete gravity dams all of which feature a straight sloping downstream face. Bratsk, built across the Angara River at Irkutsk, in the Russian S.F.S.R., and completed in 1964, stands 410 feet (125 metres) above foundation level and, excluding the earth side dams, is nearly 5,000 feet (1,525 metres) in length; it contains 5,900,000 cubic yards (4,500,000 cubic metres) of concrete. Grand Coulee Dam, completed in 1942, was built across the Columbia River, Washington; its main structure is 550 feet (168 metres) high, 4,198 feet (1,280 metres) in length, and contains 10,600,000 cubic yards (8,100,000 cubic metres) of concrete. Grande Dixence Dam in Switzerland, completed in 1962 across the narrower valley of the Dixence, has a crest length of 2,296 feet (700 metres) and contains approximately 7,790,000 cubic yards (5,957,000 cubic metres) of concrete; at 935 feet (285 metres) it was the highest dam in the world until the Nurek was completed. By comparison, the Pyramid of Khufu contains 3,400,000 cubic yards (2,600,000 cubic metres) of masonry.

Concrete buttress and multiple-arch dams. Unlike gravity dams, buttress dams do not rely entirely upon their own weight to resist the thrust of the water. Their upstream face, therefore, is not vertical but inclines about 25–45 degrees, so the thrust of the water on the upstream face inclines toward the foundation. Embryonic buttresses existed in some Roman dams built in Spain, among them the Proserpina. As technology advanced, dams with thin buttresses of reinforced concrete supporting inclined panels of similar construction were built. In today's buttress dams, less account is taken of effecting maximum economy in the use of concrete. The trend is to reduce the area of costly formwork necessary and to avoid use of steel reinforcement. With greater heights, modern buttress dams are inevitably less slender.

Several variations are possible in the design of the junction between the buttresses at the water face. Where no relative movement in the buttress foundations is anticipated, the design can link individual buttress heads rigidly, by means of arches, to form a multiple-arch dam. A recent Canadian example of this type is the 703-foot (214-metre)-high multiple-arch Daniel Johnson Dam on the Manicouagan River, Quebec. The dam has a total of 14 buttresses used in its crest length of 4,297 feet (1,310 metres); two very much larger buttresses support the structure over the original riverbed.

Design of
a multiple-
arch dam

Where buttress foundations might yield, the design must allow some freedom of movement between the heads of the buttresses. This is normally achieved by enlarging the heads until they are almost in contact, then joining them with flexible seals. Thus joined, they present a solid face to the water. Such a design was used in the construction in the Farahnaz Pahlavi Dam in Iran. Built for the Tehrān Regional Water Board, this dam has a maximum height of 351 feet (107 metres) and a crest length of nearly 1,181 feet (360 metres).

A comparison between the Daniel Johnson multiple-arch dam and the Farahnaz Pahlavi buttress dam shows that the buttresses have to be placed much closer together than is necessary with a multiple-arch dam. This allows each buttress to be more slender, however, and spreads the load more easily over the foundation. The detailed design at the bottom of the Farahnaz Pahlavi buttresses was necessitated by weak foundation conditions at the site and by the need to limit the length of each buttress to reduce its response to seismic action. By contrast, the Daniel Johnson buttresses could be founded individually, exploiting fully an important advantage of buttress dams over gravity dams, that of smaller uplift forces.

Arch dams. The advantages of building a dam curved in plan, utilizing the water pressure to keep the joints in the masonry closed, was appreciated as early as Roman times. An arch dam is a structure curving upstream, where the water thrust is transferred either directly to the valley sides or indirectly through concrete abutments. Theoretically, the ideal constant angle arch in a V-shaped valley has a central angle of 133 degrees of curvature. This leads to the development of the cupola (or variable radius) arch dam with the crest portion overhanging downstream (Figure

Figure 26: Plan view of an arch dam showing double curvature.

From W. Creager, J. Justin, and J. Hinds, *Engineering for Dams* (1945); John Wiley & Sons, Inc.

26). The constant radius arch dam generally has a vertical upstream face. There are many other factors, however, to take into account, including fixity at the abutments at the upper levels and the vertical cantilever effect of the arch at the riverbed level.

An arch dam is therefore a shell structure, admittedly sometimes of significant thickness, that owes its strength essentially to its curved profile but that is supported at the riverbed and up the valley sides by constraints that cause both flexure and shear on the membrane. Dependent for its strength upon effective support at its abutments, its very strength and rigidity make it sensitive to movements at the abutments. Only favourable sites providing sound rock are suitable for arch dams.

The great reserves of strength inherent in an arch dam were dramatically displayed in 1963 when the reservoir behind Vaiont Dam in Italy was virtually destroyed by a landslide. Vaiont, at that time the second highest dam in the world, was built across a narrow gorge on limestone foundations so that the crest 858 feet (262 metres) above the valley bottom was only 623 feet (190 metres) in length. Some large-scale instability in the mountainside above the reservoir had been observed earlier by the engineers during filling; they were allowed to proceed very slowly and three years later on October 9, 1963, with filling still incomplete, about 314,000,000 cubic yards (240,000,000 cubic metres) of soil and rock slid down into the reservoir, sending a tremendous volume of water to a height of 853 feet (260 metres) on the opposite side of the valley. The flood overtopped the dam to a depth of 328 feet (100 metres) and surged down the valley, causing a major tragedy, the destruction of several villages with a large loss of life. Yet only superficial damage was caused to the dam, which, at its crest, is about 11.2 feet (3.4 metres) thick.

Embankment dams *General characteristics.* Earlier embankments were undoubtedly built as simple homogeneous structures, with the same material used throughout. No effort was made at first to subdivide the dam into separate zones with the best suited material in each zone. The homogeneous dam nicely illustrates the general behaviour of an embankment dam and demonstrates the reasons for the rather baffling pattern of heterogeneous dam profiles employed.

Like a concrete gravity dam, the weight of an embankment dam deflects the horizontal thrust of the water pressure down to the foundation. The resultant pressures on the foundation must not cause excessive deformation or collapse.

Unlike concrete, embankment dam materials possess only limited resistance to water penetration. The rate of penetration depends on the pressures exerted by the water in the reservoir, the length of seepage paths through the dam, and the permeability of the material of construction. Soils and rock range from substantially impermeable clays, through silts and sands, to coarse-graded gravels and rock fragments that possess little resistance to the movement of water. The range is extremely wide; the seepage rate through clean gravel is 10,000 times that through sand, 10,000,000 times that through silt, and 100,000,000 times that through dense clay.

An embankment dam must be stable in itself. Its side

slopes must not slip or slide; liquefaction of the soils must not occur; erosion of the soils, as the result of water overtopping the crest, by wave action on the upstream face, or by seepage washing out the fine material through the coarser, must be avoided. As with a concrete dam, seepage of water from the reservoir through the foundation and under the actual embankment also must be controlled.

Potential weakness. There are three parts of a dam where weakening of the soil structure and liquefactions can occur. In Figure 27A the pattern of seepage through a

Figure 27: Paths of seepage through embankment dams.

(A) Homogeneous dam. (B) Dam with a drainage blanket.

homogeneously filled dam is shown. Near the downstream toe the gradient of the pore-water pressures is steep and constraints holding the soil structure together are low; this is one area of weakness in an embankment dam. One solution is to introduce drainage as indicated in Figure 27B where the area of steep seepage gradients has been moved to where the soil is constrained near the centre of the dam. Seepage gradients at the vulnerable downstream toe are eliminated.

A second area of potential weakness is the upstream face when the water in the reservoir is rapidly drawn down. If the pore-water pressures cannot adjust themselves fast enough to this change in the free-water surface in the reservoir, severe seepage gradients begin; these can cause failure. A zone of freely draining fill of coarser grading can be placed on the upstream face to counter this.

Water seepage from the reservoir through the foundations under the dam is another potential weakness. Owing to their great widths, embankment dams can be constructed on unfavourable sites, such as open-joined rock or weaker and possibly locally permeable clay. It is necessary, however, either to check or to drain away harmlessly the seepage water that would otherwise weaken the downstream parts of the dam, in extreme cases causing it to fail. Several countermeasures, possibly in combination, can be employed: the foundation can be grouted or a cut-off trench excavated and backfilled with an impermeable material; a drainage blanket can be constructed at the base of the downstream part of the dam, or individual drainage wells or galleries can be excavated; the length of the seepage paths under the dam can be extended by means of an impermeable blanket laid on the upstream side of the dam, or additional free-draining fill can be placed at the downstream toe of the dam.

Construction techniques. Today, all large embankment dams have a core of lower permeability built near their centre. Suitable materials, such as a plastic clay, are weaker than more permeable soil. The width of the core is restricted to that necessary to lower sufficiently the pore pressures in the downstream part of the dam. Though the top of the core must be at the crest of the dam, the core itself need not be vertical. On some rockfill dams the core can slope forward to an extreme position where it lies on the upstream face. Usually a sloping core occupies an intermediate position so it can be constructed on a sloping face of a partially built dam.

Where seepage is inevitable, the use of finely graded core material in proximity to coarser material is avoided. Bands of intermediately graded material must be inserted to prevent the finely graded material from leaching through the coarse zones. Filter zones are graded so each band is four to five times coarser than the preceding band.

Dam, an embankment 365 feet (111 metres) high, built of dune sand and rock fill on a very permeable foundation of deep alluvium. Here, the central clay core is vertical; this barrier to seepage is extended to the original riverbed as grouted sand and below the riverbed to a depth of 740 feet (225 metres) as a grout curtain. A corrugated blanket of clay extends upstream within the dam from the base of the core. Within the upstream and downstream cofferdams, partly of rock fill, much of the filling is of compacted sand. Filter layers separate the cofferdam filler from the outer layers of freely draining rock fill. Drainage wells will be observed below the downstream toe. The early stages of construction were carried out under deep water; hence the grouted coarse sand between the clay core and the grout curtain.

The rather simpler section of Oroville Dam, in California, is shown in Figure 28B. Until the 1,040-foot (317-metre)-high Nurek Dam in the Soviet Union was completed, Oroville (774 feet, or 236 metres) was the highest embankment dam in the world. Unlike the Aswān High Dam, Oroville was not built on deep permeable alluvium, nor was it necessary to place part of the fill under water. Unusual is the concrete block at the base of the sloping core designed to fill in the incised gorge of the Feather River Canyon. The grout curtain, compared with that of the Aswān High Dam, is of nominal depth. On each side of the sloping core, transition zones separate the core from the main mass of more pervious filling. The downstream transition zone is backed by a curtain drain of selected pervious material connected to a drainage blanket on the downstream side. The upstream face of the dam is protected against wave action by a one-metre layer of broken stone (riprap).

Efficient compacting of soils requires maximum density of dry particles consistent with an economic number of passes of the compacting plant. The process of compacting a soil by kneading it involves expelling as much of the air as practicable; water content is not normally much reduced. The optimum water content for maximum dry density—which results in maximum strength—can be achieved for a given amount of work done on the soil in compaction. In arid climates water must often be added to excavated soils. In temperate climates, however, water content is usually too high except in deeply excavated and well-drained soils.

Normally, soils are placed in embankment dams in thin layers individually compacted by rolling. Finer soils, such as those used in cores, may be harrowed before rolling. Coarser soils, including rock fragments, are compacted by

vibration and rolled. Coarse rock fragments (rock fill) are compacted to a limited extent by impact on being dumped from the construction plant; compaction of smaller fragments is assisted by sluicing with water.

In the process of hydraulic filling, sands are dredged from borrow pits, transported in water by pipelines to the filling area, and deposited there by draining off the surplus water. Hydraulic filling is widely practiced in maritime works, if sand is the only construction material available. It has also been used in the construction of embankment dams, although on some inland sites too much water would be required to transport the material. The practice has tended to fall out of favour for dams, but renewed interest in hydraulic filling has been taken in the Soviet Union.

Auxiliary structures. Spillways. Serious consequences follow if a dam is overtopped. Disaster is likely in the case of an embankment dam not designed to permit uncontrolled flow of water on its downstream slope. In March 1960 the partially completed embankment dam at Orós, Brazil, was accidentally overtopped during a period of unexpectedly heavy rainfall. Despite heroic efforts to avert disaster, the water level rose nearly one metre above crest level, eroded about half the fill in the dam, and cut a deep breach about 660 feet (200 metres) wide in the structure. Although there was time to evacuate 100,000 people living downstream, half were subsequently rendered homeless and about 50 perished. Spilling over a concrete gravity dam is also serious since the floodwater would erode the foundations at the downstream toe. Arch dams possess greater resistance to failure after overtopping.

Flood hydrology is a difficult subject. Much effort is being made to establish relationships between rainfall and river discharge, both in quantity and in time lag. Such statistical methods cannot estimate the maximum possible flood. At best they indicate only the probability of a specified flow being exceeded in a particular period. In constructing the Kariba Dam on the Zambezi, analyses of the available records of river discharge yielded the estimate that a flood of 9,950 cubic yards (7,600 cubic metres) per second should be expected once in four years. During the first year of construction on the riverbed a flood of 11,100 cubic yards (8,500 cubic metres) per second was experienced, and in the second year the Zambezi discharged 21,200 cubic yards (16,200 cubic metres) per second.

In these circumstances civil engineers attach much importance to the design of spillways on dams. Inadequate spillway capacity caused failure of many older earth dams built before modern flood data became available.

Four general aspects of spillways should be emphasized. First, the uncontrolled discharge of surplus water past the dam should be automatic and, like a safety valve on a steam boiler, not under human control. Second, the spillway intake should be wide enough so that the largest floods can pass without increasing the water level in the reservoir enough to cause a nuisance to riparian inhabitants and property upstream. Third, the rate of floodwater discharge should not increase much above that experienced before the construction of the dam. An increase creates a flood nuisance downstream. A dam usually reduces the peak discharge rate due to the lag effect caused by a flood passing through the reservoir. Fourth, floodwater discharged over the height of a dam can be destructive to the dam structure itself and to the riverbed unless its energy is controlled and dissipated in harmless turbulence.

With embankment dams, a separate spillway structure is normally constructed to one side of the dam itself. With concrete gravity dams the sloping downstream face of the structure serves as the spillway. The water travels at very high speeds (about 100 miles [160 kilometres] per hour in the case of a dam 330 feet [100 metres] high), forms a standing wave where it enters the riverbed and proceeds downstream at lower mean velocity, but in a highly turbulent state. Grand Coulee Dam utilizes a spillway of this type. An obstruction known as a kicker, placed at the toe of the dam to project the water slightly upward, can move further downstream the area in which erosion of the riverbed is most intense. With higher dams, it is possible to deflect the jet of spilling water from a level above the base of the dam; this is known as a ski-jump spillway.

Hydraulic filling

Ski-jump spillway

Spillways need not be open to the atmosphere. Shaft and tunnel spillways can destroy the energy of the water at a predetermined point downstream of the dam. At the upstream end, the intake can be self-priming siphons or bell-mouthed drop shafts; the latter are also known as morning-glory spillways.

With arch dams it is convenient to construct gated openings in the shell structure at some distance below the crest of the dam, ensuring that the discharging jets fall well clear downstream. A line of six such gates is used in the design of Kariba Dam.

Spillways constructed to one side of earth dams are featured in the design of Oroville Dam, California, and of Mangla in Pakistan. The spillway at Mangla discharges 36,600 cubic yards (28,000 cubic metres) of water per second; the upper stilling basin has the dimensions of an Olympic Games stadium with its grandstands.

Rock-fill dams, specially designed to be overtopped in times of flooding, are a new development. The first such permanent dams have been constructed in Australia. For temporary works the technique has been used on the Blue Nile.

Gates, sluices, and outlets. In addition to spillways, openings through dams are also required for drawing off water for irrigation and water supply, for ensuring a minimum flow in the river for riparian interests downstream, for generating power, and for evacuating water and silt from the reservoir. These gated openings normally are fitted with coarse screens at the upstream ends to prevent entry of floating and submerged debris. Provision for cleaning these screens is essential.

Several forms of gates have been developed. The simplest and oldest form is a vertical-lift gate that, sliding or rolling against guides, can be raised to allow water to flow underneath. Radial or tainter gates are similar in principle but are curved in vertical section better to resist water pressure. Tilting gates consist of flaps held by hinges along their lower edges that permit water to flow over the top when they are lowered.

Drum gates can control the reservoir level upstream to precise levels, automatically, and without assistance of mechanical power. One drum gate design consists of a shaped steel caisson held in position by hinges mounted on the crest of the dam and supported in a flotation chamber constructed immediately downstream of the crest. Water pressure in the reservoir and buoyancy of the caisson in the flotation chamber hold the caisson in rotational equilibrium. Raising or lowering the water level in the flotation chamber causes the caisson to rotate in the same direction, thus reducing or increasing flow from the reservoir over

the gate. This action can be linked to and operated automatically by a float control device in the reservoir. Two drum gates are installed at Pitlochry Dam in Scotland.

Reservoirs. Modern engineers have learned the value of giving attention early to potential problems in reservoir maintenance. Sediment in rivers seriously influences the effective life of a reservoir and therefore the financing of a dam. Some modern dams have been rendered useless for storing water because the reservoir has filled with silt. In many others effective storage capacity has been seriously reduced. At the Nile barrages, the heavy silt-laden floodwater is allowed to pass through the sluices and only the cleaner water at the end of the flood season is stored.

Fish passes. For many years hydroelectric dam design has taken into account the need to conserve certain species of migratory fish. Success has been achieved with salmon in Scotland and on certain rivers in the U.S. and Canada. Notable examples of conservation measures are to be found at Bonneville, Priest Rapids, and Wanapum dams and at many dams in Scotland.

Adult salmon striving to reach their spawning grounds upstream must be prevented by screens from entering the turbine tailraces at power stations, and induced instead to enter a fish pass that allows them to surmount the dam. Similarly, young salmon must be allowed to pass a dam safely on their journey downstream to feeding grounds in the ocean. Young salmon are remarkably insensitive to sudden changes of pressure and have been known to pass safely through turbines operating at heads of up to 160 feet (50 metres). Nevertheless, it is preferable to induce them to use the fish passes.

Fish passes usually take the form of fish ladders and fish locks. A fish ladder is utilized at Pitlochry Dam in Scotland; it consists of a series of stepped pools, through which water is continuously discharged during the migratory seasons. The individual pools may be separated by a series of low weirs or linked by short inclined underwater pipes to provide the necessary steps of one to two feet (0.3 to 0.6) metres in water levels. Sometimes both weirs and pipes are provided.

The Borland fish lock was developed in Scotland as an alternative to fish ladders. It operates on the same intermittent principle as a ship lock but is constructed as a closed conduit. Intermittent closure of the gates at the bottom causes the continuous flow through the lock to fill the conduit at intervals, and thus allows fish waiting in the bottom chamber to be raised through the height of the dam. The lock also serves at other seasons to flush young salmon down past the dam. (J.G.B.)

Fish ladder

HARBOURS AND SEA WORKS

The construction of harbours and sea works offers some of the most unusual problems and challenges in civil engineering. The continuous and immediate presence of the sea, nature's most restless, temperamental, and most powerful element, provides the engineer with an adversary certain to discover any weakness or fault in the structure built to resist it.

Principles of maritime engineering

Objectives. The principal objectives of such works fall broadly into two classifications: transportation, and reclamation and conservancy. Under the first fall works directed at providing facilities for the safe and economical transfer of cargo and passengers between land vehicles and ships; fishing ports for the landing and distribution of the harvest of the sea; harbours of refuge for ships and small craft; and marinas for the mooring or laying up of small private craft. Under the heading of reclamation and conservancy come works directed to the protection of the land area from encroachment by the sea, to the recovery and conversion to land use of areas occupied by the sea, and to the maintenance of river estuaries as efficient means for the discharge of inland runoff. In many places,

without continuous attention to such maintenance, the coincidence of high tides with heavy rainfall would lead to frequent disastrous flooding of inhabited areas.

The civil-engineering techniques used for either of these objectives are broadly similar, and indeed the realization of both objectives at the same time will frequently be a feature of the same project. An operation of maintaining a river estuary at a depth sufficient for navigation, for example, may at the same time greatly improve its capacity for the drainage of upland floodwaters.

Hydraulic models. The planning of maritime civil-engineering works, whether for transportation, reclamation, or conservancy, has been facilitated by the development of the technique of model studies. Once regarded as scientific toys, such studies are now considered an essential preliminary step to any large-scale redevelopment of a port or coastal area and are useful even for minor modifications or additions.

Scale models of the area, harbour, or estuary are made, so that water can be caused to flow in such a way as to reproduce the various tidal and other streams in the same direction and with equivalent velocities to those occurring on the site. A variety of devices, usually electronically controlled, has been developed to produce both wave and tidal effects.

Figure 29: Tidal model of the Humber estuary in England.

Predicting
long-range
tide effects

The value of these experiments derives from the reduction in the time scale, which has been found to correspond to the reduction in the dimensional scales of the model. Thus, the large model of the Clyde Estuary of Scotland works on a tidal cycle of about 14 minutes or about 50 times the actual frequency. The effect of three years of tides following any modification of the profile of the harbour can thus be studied on the model in a matter of three weeks, and any tendency to otherwise unanticipated scour (clearing by powerful current) or siltation can probably be detected. The relative values of alternative positions of breakwaters in affording shelter can be similarly studied, using the wave-generating devices available; and the development of secondary, or reflected, waves with undesirable disturbances within the sheltered area may be anticipated and, if possible, forestalled.

Natural and artificial harbours. In certain favoured points on the world's coastlines, nature has provided harbours waiting only to be used, such as New York Bay, which the explorer Giovanni da Verrazano described as "a very agreeable location" for sheltering a ship. Such inlets, bays, and estuaries may require improvement by dredging and of course must be supplied with port structures, but basically they remain as nature made them, and their existence accounts for many of the world's great cities. Because such natural harbours are not always at hand where port facilities are needed, engineers must create artificial harbours. The basic structure involved in the creation of an artificial harbour is a breakwater, sometimes called a jetty, or mole, the function of which is to provide calm water inshore. Locations for artificial harbours are of course chosen with an eye to the existing potential of the coast; an indentation, however slight, is favoured. Yet it has often been found justifiable on economic or strategic grounds to construct a complete harbour on a relatively unsheltered coastline by enclosing an area with breakwaters built from the shore, with openings of minimum width for entry and exit of ships.

Sea works for transportation

CLASSICAL HARBOUR WORKS

Improvements to natural harbours and construction of artificial harbours were undertaken in very ancient times. There is no conclusive evidence for the date or locality of the first artificial harbour construction, but it is known that the Phoenicians built harbours at Sidon and Tyre in the 13th century BC.

The engineers of those days either knew or thought little about conservancy even as applied to the ports they constructed. Evidence is to be seen in the once thriving ports around the shores of the Mediterranean that now are not merely silent ruins but seem so far from even

sight of the sea that it is difficult to imagine the presence of seagoing ships at the wharves, the alignment of which can occasionally be traced in the fertile alluvial land now occupying the site. Ephesus, Priene, and Miletus, on the Aegean shores of Asia Minor, are examples of this type of harbour disappearance, the destructive agent in each of these cases being the picturesque River Meander (now the Menderes), the efforts of which toward the creation of new land from the sea are readily perceivable from high ground adjacent to the river mouth. The formation of further bars can be seen to be preceding and, as there is, at the moment, no port in the vicinity whose livelihood can be threatened, it is interesting to speculate how far out to sea this process will ultimately continue in the course of the next millennium or so.

At Side, facing the island of Cyprus, the remains of an ancient breakwater, built to protect the anchorage, can still be seen, but the area enclosed between it and the advancing shoreline is now not a stone's throw wide. In this case, not only the river in the vicinity but littoral drift, a current that tends to parallel the coast, that produces and maintains extensive beaches to the east and the west, must be held partly responsible for the scale of siltation.

Of many of the ancient port structures no physical trace remains, but knowledge of the fact that they existed and even a measure of technical description has come down through the written word. With these descriptions and the monuments that still remain, some picture may be formed of the work undertaken by the maritime civil engineers of ancient times.

Given the frailty of the craft for which they were providing, shelter from the weather was the prime consideration; and much effort was devoted to the construction of breakwaters, moles, and similar enclosing structures. Cheap labour was abundant and the principal material used was natural stone. Surviving structures built in this way are likely to give an appearance of indestructibility, which occasionally attracts favourable comparison with the lighter, more rapidly depreciating modern structures. It is not, however, necessary to credit the engineers of antiquity with a conscious intention to build forever. Given the materials they had to use and the purposes they were implementing, they could do little else; moreover, because there was no rapid pace of advance in the development of ships or land transport, they were undisturbed by the shadow of obsolescence. In the 20th century, far from wanting to build forever, the port engineer has to be careful to avoid saddling posterity with structures that may long outlast their usefulness and turn into liabilities. The modern balance between excessive durability and dangerous frailty is one that the ancients never had to strike.

Aided by the characteristics of the material they employed, the ancients constructed maritime works on a scale that is certainly remarkable to this day, which they emphasized by the addition of embellishment, such as statues and triumphal arches.

Interesting technical practices included the use by the Romans of the semicircular arch in constructing moles or breakwaters, an arrangement that allowed a measure of ingress and egress by the sea to produce a beneficial scouring action in the harbour. The Romans underpinned their structures with timber piling and frequently resorted to the construction of cofferdams (watertight enclosures) that they could de-water by the employment of Archimedean screws and waterwheels. This practice enabled them to carry out much of their foundation work in the dry; and the use of their famous hydraulic cement, pozzolana, gave their structures a durability far exceeding that afforded by the lime cement available to their predecessors.

Among the more interesting harbours of the ancient world are Alexandria, which had on the island of Pharos the first lighthouse in the world; Piraeus, the port of Athens; Ostia, the port of Rome; Syracuse; Carthage, destroyed and rebuilt by the Romans; Rhodes; and Tyre and Sidon, ports of the earliest important navigators, the Phoenicians.

BREAKWATERS

Because the function of breakwaters is to absorb or throw back as completely as possible the energy content of

Disappearance of ancient harbours

The durability of ancient sea works

the maximum sea waves assailing the coast, they must be structures of considerable substance. The skill of the designer of a breakwater lies in achieving the minimum initial capital cost without incurring excessive future commitments for maintenance. Some degree of maintenance is of course unavoidable.

Breakwater design. A common breakwater design is based on an inner mound of small rocks or rubble, to provide the basic stability, with an outer covering of larger boulders, or armouring, to protect it from removal by the sea. The design of this outer armouring has fostered considerable ingenuity. The larger the blocks, the less likely they are to be disturbed, but the greater the cost of placing them in position and of restoring them after displacement by sea action. Probably the least satisfactory type of armour block, frequently used because of its relative ease of construction, is the simple concrete cubic, or rectangular, block. Even the densest concrete seldom weighs more than 60 percent of its weight in air when fully immersed in seawater; consequently, such blocks may have to be as much as 30 tons (27,000 kilograms) in weight to resist excessive movement.

Boulders of suitably dense natural rock are generally much more satisfactory and, in a project completed in the United Kingdom in the 1960s, it was found by experiment, and subsequently confirmed in experience, that armouring of this type could be composed of blocks of as little as six to eight tons (5,400 to 7,300 kilograms) to resist the action of waves up to 18 feet (five metres) in height. The same experiments showed that to afford the same protection in the same circumstances, concrete blocks of 22 tons (20,000 kilograms) would have been necessary.

In such cases, an intermediate layer of smaller blocks or boulders is inserted between the armouring and the inner core to prevent the finer material in the core from being dragged out by sea action between the interstices of the armour—a process that leads to ultimate settlement and possible breaching by overtopping of the breakwater.

The increasing cost and frequent unavailability within economic distance of suitable natural rock has provoked considerable thought to the design of concrete armour units that can, by reason of their shape, overcome the disadvantages of the simple cubic, or rectangular, block. One of the most successful has been the tetrapod, a four-legged design, each leg projecting from the centre at an angle of $109\frac{1}{2}^\circ$ from each of the other three. Legs are bulbous, or pear-shaped, with the slightly larger diameters at the outer end. These units have the property, when placed, of knitting into each other in such a way that the removal of a single unit without the displacement of several others is almost impossible, while the interstices between them act as an absorbent of wave energy. Weights substantially less than those needed for cubic blocks are adequate in the case of tetrapods in similar storm conditions. The tetrapods can be mass-produced adjacent to the site through the employment of re-usable steel forms.

It is usual to construct some form of roadway along the crest of a breakwater, even when this is not required for any other dockside purposes, to facilitate inspection and access for labour, materials, and equipment for damage repairs.

Solid breakwaters. In certain circumstances, particularly in parts of the world where clear water facilitates operations by divers, vertical breakwaters of solid concrete or masonry construction are sometimes employed. Some preparation of the seabed by the depositing and levelling of a rubble mound to receive the structure is necessary, but it is usual to keep the crest of such a mound sufficiently below the surface of the water to ensure its not becoming exposed to destructive action by breaking waves. Repulsion of the waves by vertical reflection rather than their absorption is the philosophy of protection in all such cases, but it is not possible to state categorically which arrangement produces the most economic structure.

This type of breakwater can be conveniently constructed through the use of prefabricated concrete caissons, built on shore and floated out, sunk into position on the prepared bed and filled either with concrete or, less frequently, simple rubble or rock filling. A historical example of this

arrangement was the Mulberry Harbour, built by the Allies and floated into position for the invasion of Normandy in 1944. No previous preparation of the seabed was possible, and only partial filling of the caissons had been carried out when the progress of the war rendered further operations unnecessary. Nevertheless, the fact that several of the caissons remained in position basically undamaged for nearly a decade after the invasion on this notoriously stormy coast demonstrated the possibilities of the method.

Floating breakwaters. Because of the large quantities of material required and the consequent high cost of breakwaters of normal construction, the possibility of floating breakwaters has received considerable study. The lee of calm water to be found behind a large ship at anchor in the open sea illustrates the principle. The difficulty is that to resist being torn away in extremes of weather, the moorings for a floating breakwater must be very massive. They are therefore difficult to install and subject to such constant chafing and movement as to require substantial maintenance. Another problem arises, especially in areas of large tidal range. The unavoidable, indeed, essential, slack in the moorings may allow the breakwater to ride large waves, so that they pass underneath it carrying a considerable proportion of their energy into the area to be sheltered.

One approach to the problem is based on the concept of causing the waves to expend their energy at the line of defense by breaking on a large, floating horizontal platform.

Pneumatic breakwaters. Finally, the pneumatic, or diffusion, breakwater has been widely discussed. Experiment and limited experience have shown that a curtain of air bubbles blown up from the seabed through a row of perforated nozzles acts as a barrier to the movement of waves over the surface. The mechanics of the arrangement appear to be that the rising bubbles generate streams flowing on the surface, outward in both directions, and the flow meeting the oncoming waves can be made sufficient to hold them up. There is reason to believe that jets of water would be almost as effective as air. Although the volume of air or water necessary completely to restrain the waves generated in severe weather over a wide front would require installation of a plant of uneconomical size, the device can be useful for the temporary protection of a short length of shore to allow the execution of specific works. The air or water pipes can be laid on the seabed at the perimeter of the area to be protected and fed from a mobile plant on shore, and the whole body of equipment can be removed after the operations have been completed.

DOCKS AND QUAYS

Because the principal operation to which harbour works are dedicated is transfer of goods from one transportation form to another (*e.g.*, from ships to trucks), it follows that docks, wharves, and quays are the most important assets of a port.

Ships must lie afloat, in complete shelter, within reach of mechanical devices for discharging their cargoes. Although in emergencies ships have been beached for unloading purposes, modern vessels, particularly the larger ones, can rarely afford contact with the seabed without risking serious structural strain. The implications of cargo handling, as far as civil-engineering works are concerned, do not differ much whether the loading and discharge are effected by shore-based cranes or by the ship's own equipment. In either case, large areas of firm, dry land immediately alongside the ship are required; the engineer must find a way to support this land, plus any superimposed loading it may be required to carry, immediately adjacent to water deep enough to float the largest ship.

The capital cost of such works probably increases roughly in proportion to the cube of the deepest draft of ship capable of being accommodated; thus the economic challenge posed by the increase in the size of modern ships is considerable. The advent of containerization—the packaging of small units of cargo into a single larger one—has not fundamentally altered this problem except perhaps in time to reduce the number of separate individual berths required and to increase greatly the area of land associated with each berth. A figure of 20 acres (eight hectares) per

Tetrapods

Facilities required in a dock

berth is freely mentioned as a reasonable requirement. The problem of land support at the waterline remains the same.

Gravity walls. The solution initially favoured, and, indeed, predominant for many years, was that of the simple gravity retaining wall, capable of holding land and water apart, so to speak, through a combination of its own mass with the passive resistance of the ground forming the seabed immediately in front of it. Both to ensure adequate support without detrimental settlement of the wall, to insure its lateral stability, and to prevent problems of scour, it is necessary to carry the foundations of the wall below the seabed level, in some cases a considerable distance below. In earlier constructions, the only guide to this depth, in the planning stage, was previous knowledge of the ground and the acumen of the engineer in recognizing the characteristics of the ground when he saw it. Many projects were carried out in open excavation, using temporary cofferdams to keep out the sea. In particularly unfavourable or unstable soils, accidents caused by collapse of the excavation were not unknown.

In modern practice, no such project is initiated without exhaustive exploration of the soil conditions by means of borings and laboratory tests on the samples. Continuous monitoring of the soil conditions during construction is also considered essential. Even so, accidents caused by soil instability still occasionally occur.

Materials
for gravity
walls

The material composing the walls is today almost universally concrete, plain or reinforced, according to the requirements of the design. This material has entirely superseded the heavy ashlar (natural rock) masonry at one time used for such construction, when the techniques for the large-scale production of concrete were not so well developed as they are today.

In some circumstances, particularly those in which the water is reasonably clear or the design and soil conditions do not require very deep excavation into the seabed, the construction of quay walls is adopted by means of large blocks, sometimes of stone but generally of concrete, placed underwater by divers. The economics of this method of construction are influenced by the high cost of skilled divers and by the cumbersome nature of diving equipment. The development of lightweight, self-contained equipment, which leaves the diver considerably more mobile, may relieve this problem.

Concrete monoliths. The risks and difficulties attendant on the construction of gravity walls have, in suitable conditions, been avoided through the use of concrete monoliths sunk to the required foundation depth, either from the existing ground surface or, where the natural surface slopes, from fill added and dredged from the front of the quay wall on completion. This technique amounts to the construction above the ground of quite large sections of the intended wall, usually about 50 feet (15 metres) square in plan, which are then caused to sink by the removal, through vertical shafts, of the underlying soil. Another lift of wall is then constructed on top of the section that has sunk, more soil is removed, and the process is repeated until the bottom has reached a foundation level appropriate to the required stability. Considerable skill is sometimes necessary in the sinking process to keep the monoliths (usually provided with a tapered-steel cutting edge to the lowest lift) sinking uniformly and not listing, an eventuality that can occur if any part of the periphery encounters material particularly difficult to penetrate. Differential loading of the high side and special measures to undercut the material composing the obstruction may be necessary.

The shafts through which the excavated material is removed are generally flooded throughout the operation simply from the intrusion of the groundwater; if necessary, this water can be expelled by the use of compressed air. The excavation of difficult material in detail and in the dry can then be undertaken. It is an operation of some delicacy because the flotation effect of the compressed air adds a further element of instability to the monolith, and a blow (sudden leakage of air) under the cutting edge may result in flooding of the working chamber. When the bottom edge of the monolith has reached the designed level,

the excavation shafts are sealed by concrete plugs. The shafts themselves can then be filled, either with concrete or with dry filling to give the final wall the required mass for stability.

Success in this form of construction cannot be guaranteed. In the case of the Western Docks at Southampton, Hampshire, constructed between World War I and World War II, it was found impossible except at inordinate cost to get the monoliths to sink through the opposing strata to the depth required for stability as a retaining wall. It was therefore necessary to reduce the thrust involved in this function by cutting the retained material back to a natural slope and spanning the gap between the back of the monoliths and the top of this slope by means of a reinforced concrete relieving platform, supported along its other edge on reinforced concrete piles. This arrangement has served well enough as far as the quay wall itself is concerned, but the maintenance of the natural slope, stone-pitched as a protection against erosion, has been a continuing liability. In addition, the presence behind the quay of the relieving platform constitutes a formidable obstacle to further construction work; e.g., warehouses or multistory transit sheds.

The
problem of
Southampton
quay

Concrete caisson walls. In situations in which the depth from ground level to the final dredged bottom is not excessive and the material available for retention as reclamation is of good self-supporting qualities, quay walls can be constructed of precast concrete caissons floated into position and sunk onto a prepared bed in the same manner as that described for breakwaters. Care is taken to design caissons able to withstand the thrust of the retained material, which is carefully selected for the areas immediately behind the quay wall. The conditions suitable for this form of construction are generally typical of the Mediterranean, where the slightness of the tidal variation keeps the depth required to a minimum. An outstanding example of this kind of construction is the extension to the area of the Principality of Monaco, which is being increased by as much as 22 percent by reclamation retained by this technique. Similarly constructed installations for transportation and ship-repair purposes exist elsewhere in the Mediterranean, in parts of which the earthquake factor is an additional influence on the retaining-wall design.

In all cases of dock-wall construction by concrete monolith or caisson, it is the basic structure of the wall that is provided by these means; the final superstructure, above highest tide level, will depend for its detail on the requirements for dockside services, crane tracks, and other elements.

The piled jetty. The high cost, difficulties, and possible dangers of providing dock and quay walls of the kind just described have always encouraged a search for alternative solutions that would eliminate the need for operations on or below the seabed. Of these, the earliest and most obvious is the piled jetty—its piles can be driven from floating craft and the deck and superstructure added thereto, working wholly above water. In regions in which there is a large tidal range, it may sometimes be both advantageous and necessary to take the opportunity of extremely low tides to make attachments to the piles for bracing and stiffening purposes. With a reasonable programming of the work, this operation can usually be done without particular difficulty, assuming that the seabed is of a composition reasonably amenable to penetration by piles to a sufficient depth to secure the lateral stability of the structure. A hard rock is not suitable, although some of the more friable rocks can be pierced by steel piles.

Piles may be of timber, reinforced concrete, or steel. Timber is a popular choice if there is a large natural supply. Lateral stiffness and stability can be achieved by using a sufficiently close spacing of the piles in both directions and adequate rigid bracing between the tops, timber being a material readily amenable to the workmanship required. Its chief drawback is lack of durability, particularly in the area between wind and water, although a timber jetty with reasonable maintenance can often outlast normal operational obsolescence. There are examples of construction in which the piles are connected together by casting around the heads a reinforced concrete slab, its soffit (underside)

Timber
piles

just below lowest water level. By this means, the timber is kept continually submerged, a condition under which its durability is prolonged. On the other hand, in tropical or semitropical waters or waters accidentally kept warm by industrial effluents, the use of timber may be inhibited by the presence of marine borers. Timber jetties have a considerable advantage in the comparative ease with which repairs to accident damage or deterioration can be effected.

Reinforced concrete piled piers and jetties, soundly constructed, exhibit great durability. Attachment to the piles for bracing and similar purposes tends, however, to be more complicated than in the case of timber. This is a disadvantage that applies also to subsequent maintenance and repairs.

Sheet-piled quay. An extension of the piled jetty concept is a quay design based on steel sheetpiling, the design becoming increasingly popular with improvements in the detail and manufacture of the material. Steel sheetpiling consists in essence of a series of rolled trough sections with interlocking grooves, or guides, known as clutches, along each edge of the section. Each pile is engaged, clutch to clutch, with a pile previously driven and then driven itself as nearly as possible to the same depth. In this way a continuous, impervious membrane is inserted into the ground. In most designs the convexity of the trough sections is arranged to face alternately to one side and the other of the line along which the membrane is driven, so that a structure of considerable lateral stiffness is built up. At the same time, a measure of flexibility in the clutches allows some angular deviation so that a membrane curved in overall plan is obtainable, a feature of considerable convenience in developing the layout of a series of wharves or quays.

The development of steel sheetpiling over the years has largely been characterized by the increasing weight and stiffness of the sections becoming available from the rolling mills. In one design, the clutch is a separate unit from the main structural element, generally of broad-flanged or universal beam section. In this case, the clutch unit appears in a profile of two grooves, or channels, back to back, each capable of embracing the flanges of adjacent beams, which are thus locked together in a continuous sheet, or membrane, of considerable strength. Each universal section is entered, when pitched for driving, into the clutch on the previously driven section and usually carries the clutch for the next section with it. In another design, made economically possible by the advances in the technique of automatic continuous welding, rolled universal beam sections are welded by one flange into the troughs, or pans, of conventional sheet piles, the composite construction producing a unit of unique strength and stiffness.

The development of steel sheetpiling has kept ahead of the development of hammers capable of driving it, probably because the stiffer the section is, the greater the length of pile that can be incorporated in a design. The combination of heavier section and greater length demands a greater proportion of the energy delivered by the hammer being unproductively absorbed in the temporary elastic compression of the pile, leaving less energy to drive the pile further into the ground. Simply increasing the amount of energy delivered, by using a heavier hammer or a higher drop, does not necessarily provide the solution; it may only result in damage to the head of the pile without achieving greater penetration. This difficulty has been in part overcome by the use of high-strength steel piles. Nevertheless, it is not unknown for a pile to appear to be going down with little or no head damage when it is, in fact, sustaining extensive damage below seabed level that gravely compromises its efficiency as a retaining quay wall. This situation, usually the buckling of a pile, can occur particularly where the material of the seabed contains boulders or similar obstacles to penetration.

The problem has obvious major implications for the construction of quay walls and has provoked much debate among engineers. The skill of the quay designer and the advice of the soil mechanics specialist both contribute to the satisfactory reconciliation of the various conflicting factors outlined in order to achieve the most effective and economical solution.

In the normal design of sheet-piled quay or wharf wall, the sheetpiling itself forms the quay face, although it is generally found advisable to protect the piles from the impact of ships berthing by timber fenders. Vertical timbers at intervals are generally used. Horizontal walings (wooden ridges) between these timbers can also be employed, but they have a disadvantage, particularly at small wharves and with ships having their own protective belting: on a rising tide the beltings become entangled with the walings, occasioning damage or even minor disaster.

The upper part of the sheetpiling, being laterally unsupported on the sea side, is generally anchored back to resist the thrust of the retained soil. This resistance is commonly effected by using tie rods secured to anchors buried in the retained soil itself to a depth that, for reasons of overall stability, is beyond the natural slope line of the soil. As often as not, these anchors are themselves composed of lengths of sheetpiling driven, if possible, below the retained soil into the strata beneath. The mild, or alloy, steel tie rods, coated and wrapped against corrosion, can be carried through the exposed sheetpiling of the quay wall with large retaining nuts on the outside or can be secured to welded attachments at the back of the piling. The latter practice is the more commonly favoured arrangement, largely on account of its more finished appearance. The sheet-piled quay just described is completed by casting a reinforced concrete cope beam to cover as well as contain the exposed heads of the sheetpiling.

The advantage of this type of quay wall is that the space behind the wall is not occupied, as in the case of the suspended-pile supported deck, by a monolithic, fully structural element, the arrangements of which can only be disturbed for subsequent modification of the services layout at some cost and usually by a potentially complicated design operation. As in the case of a gravity wall, the space can be filled with suitable material that can subsequently be treated, to all intents and purposes, as natural ground in which service ducts can be buried if required. This arrangement is often an advantage in the case of freshwater mains for fire fighting or watering ships because they can thus be protected from frost. Alternatively, it is possible to place concrete-lined service and cable trenches in this material, sometimes conveniently by the use of precast sections, because the ground loads imposed are seldom sufficient to give rise to serious settlement problems.

Structural reinforcement. Identifiable structural loading, arising, for example, from crane tracks, can be supported on reinforced concrete beams on piles driven through the filling to the strata beneath. Dockside railways, a decreasing requirement because of the transfer of much shore-to-ship delivery to road vehicles, need not necessarily have piled support because the loading from these can be spread to remain within the bearing capacity of the filling. Some settlement is bound to take place, and the need for compensating by packing up and rellevelling of the track has the incidental disadvantage of breaking up the surfacing of the quay, which is almost always provided to facilitate quayside access by road vehicles.

Sheet-pile quay walls are readily applicable to sites at which only relatively shallow or medium-depth water alongside is needed. As the required depth increases, a sheet-pile section of sufficient strength and stiffness to hold the retained material without further assistance becomes impractical from the point of view of handling and driving. A solution increasingly favoured is the so-called Dutch quay. In this design, after the line of sheetpiling, using one of the heavier and stiffer sections, has been driven, the ground behind is excavated for a distance back determined by the natural slope of the material to be used as filling and taken down as far as possible to lowest water level. At this level, a reinforced concrete relieving platform is constructed up against the sheetpiling but with independent vertical support from bearing piles driven through the bottom of the excavation to an appropriate depth. Piles for crane tracks are driven at the same time as these; that is, before the construction of the relieving platform.

Filling material is returned above the relieving platform, and although the latter now prevents further pile driving in the area, the probability of this being required is remote,

Protecting
the quay

The Dutch
quay

whereas the retained load against the sheetpiling is much reduced. The advantages of having filled material behind the sheetpiling for installing services remain. In addition, the relieving platform affords the sheetpiling considerable help in resisting horizontal blows from the impact of berthing ships, and to increase this resistance, some of the piles supporting the platform are often driven toward the quay face. Reinforced concrete counterforts between the platform and the sheeting can be an additional help.

Durability. A question mark that hung over the use of steel sheetpiling in salt water in its early years concerned its durability in potentially hostile conditions. Experience of the rate of corrosion, particularly at the waterline or within the tidal range, varied from one locality to another according to the state of the water and the effect of such factors as the degree of salinity and the presence of industrial effluents. Precoating of the pile with a protective film such as tar or a bituminous paint is only of transient value, requiring regular renewal, and is effective only down to lowest water level.

The inclusion in the composition of the sheet-pile steel of a very small percentage of copper was tried as a means of increasing its durability, but the effectiveness is doubtful.

Cathodic
protection

The confirmation of the electrochemical basis of much of the corrosion affecting steel sheetpiling led to the development of cathodic protection, a process that has wide application in many other fields, especially shipbuilding. Electrolytic corrosion arises from the passage through the piling of electric currents, causing the pile, or part of it, to become the anode, or positive pole, in what amounts to a galvanic cell, or battery. In such a cell, metal is normally removed from the anode and may reappear on the cathode, or negative pole, which remains unaffected. These currents in sheetpiling may arise from stray leakages from adjacent electrical installations or be generated within the pile itself by differences in the electrolytic conditions at differing levels on the pile.

Cathodic protection is a means whereby cathodic polarity is imposed upon the whole pile, and its operation as an anode (with consequent deterioration) is prevented. This can be done either by the supply from a suitable source—e.g., a battery—of an electric current that will overcome and reverse the direction of that naturally generated or by connecting the piling at intervals to sacrificial anodes of an element—generally aluminum or magnesium—the atomic relationship of which to the steel in the piling is such as to generate such a current without external assistance. These anodes are buried in the surrounding ground and care must be taken to ensure full electrolytic continuity between them and the piling to complete the circuit. It is sometimes necessary, in order to ensure electrical continuity in the piling itself between the anode connections, to weld adjacent piles together after driving.

By whatever means cathodic protection is applied, a small liability for operational maintenance arises, either for the continuous supply of the imposed current or the periodic renewal of the sacrificial anodes. The considerably increased durability of the structure usually justifies this.

Enclosed docks. Whenever possible, commercial quays are built open to the tide range to provide maximum freedom for shipping. There are, however, some parts of the world in which the range between low water and high water is so great that the resulting variations in the level of the ship's decks and hatches impose unacceptable disabilities on the handling of cargo. In such circumstances the quay walls, the net clear height of which, disregarding depth of foundations, must span the distance from the lowest seabed level acceptable for navigation at low tide to an adequate freeboard for the coping of the quay wall above the level of the highest high tide, may become of such dimensions as to be uneconomic. This condition is equally applicable in cases in which only the berths themselves are made to be usable no matter what the stage of the tide.

Locks

The problem can be met by constructing the quays as enclosed docks in which the water level is kept constant and access to the tidal areas is by means of a lock or locks. An obvious condition for the success of such an arrangement is that the strata of the bed under the enclosed dock area

be sufficiently impervious to preclude any significant loss of water through the bottom during low-tide conditions. In this way the tidal range, as a limit on the height of the quay walls, can be eliminated.

Apart from the fact that they have gates at each end, the structure of maritime navigation locks and the problems involved in their design are very similar to those of dry docks. Although, in normal usage, a lock is never completely dry, it is essential that it should be designed to be capable of withstanding the stresses imposed by this condition, so that it may be possible to de-water the lock completely for inspection and maintenance.

It is common practice to design enclosed docks so that the normal water level maintained is not below the highest likely high tide because the invasion of an enclosed dock by a high tide significantly above the normal water level can be disastrous.

Although enclosed docks are frequently of such an area that they can supply the lockage water lost when a ship passes through the lock without any drop in level that cannot be made up on the next high tide, it is normal to provide a measure of impounding capacity in the form of pumps for lifting additional water from outside into the dock. Such a provision is essential for situations in which it is required to keep the enclosed dock water level above the highest tide.

It has sometimes been possible to accommodate ships of larger draft than originally planned for in large, but relatively old, enclosed docks. This is done by installing impounding pumps for topping up the water level to give an increased depth.

Enclosed docks generally suffer the operational disadvantage of restricted times of entry and exit because they are subject to a fairly rigid tidal schedule. First of all, the lower the tide level outside, the greater the amount of water lost in the locking operation; and, second, it is seldom economically feasible to maintain full navigation depths at all states of the tide in the approach channel to the lock entrance. This situation is particularly the case in which enclosed docks are sited adjacent to and operating from a tidal river estuary. The tidal lock at Dunkirk, France, opening to allow the passage of the night channel ferry, which runs on a timetable, is an example of a tidal lock operated whatever the state of the tide.

If possible, the access locks are usually duplicated, lest an accident involving the gates or the structure of the lock put the whole dock area out of action. Stability calculations of the quay walls within an enclosed dock are important; in older installations such calculations may have been based on the continuing presence of water at the designed normal level, and in the event of a serious failure at the lock—resulting in a considerable drop in the water level—the stability of the quay walls could come into question.

ROLL-ON, ROLL-OFF FACILITIES

An enormous increase in the use of the roll-on, roll-off technique of loading and unloading developed in the late 1960s. The principle of embarking whole vehicles under their own power was not new. The report of Hannibal ferrying his elephants over the Rhône in the 3rd century BC might be regarded as the earliest example from which the vast amphibious operations of the invasion of Normandy in 1944 were descended. Since the 1960s, however, the spectacular increase in the use of road transport for heavy freight and the increase in handling charges at ports for the loading and discharge of cargo by conventional means have combined to provide the impetus for the rapid commercial development of the roll-on, roll-off technique. In addition, the tendency to assemble machinery at its place of manufacture in larger and larger units has encouraged the development of special transport vehicles, and the economies of moving load and vehicle together from origin to destination are valuable.

The principal problem for the port engineer is the provision of the special berthing for the ferry vessels and the means of access for the vehicles from the shore to the ship's decks. Rail-car ferries, involving somewhat similar problems, have been known for some time, but because of the severer limits on gradients for such vehicles there has

Berthing
and access
problems

been a tendency to limit the operation of these services to terminals at places where the tidal range is inconsiderable. For the Dover-Dunkirk ferry, opened shortly before World War II, a special enclosed dock was constructed at Dover in which the water level could be kept constant for loading and unloading, while at Dunkirk the entire dock system is totally enclosed, accessible through sea locks.

Many of the new roll-on, roll-off terminals for road services are, by contrast, in tidal water; and where the tide range is of considerable extent, access bridges of considerable length are often needed to keep the change of gradient between low and high tide within acceptable limits. The change in the ship's trim between conditions of light loading and full loading creates yet another problem.

At first sight, the solution might appear to be to support the outer end of the link span on a float, or pontoon, so that it would automatically follow the rise and fall of the tide. Several disadvantages of structural detail arise, however, and the system is vulnerable to damage caused by the movement of the pontoon under adverse weather conditions. A means of adjustment in the height between the span and the supporting pontoon to accommodate changes in ship's trim is still required; and, therefore, the overall economies of a pontoon are less than might at first be imagined.

It is, thus, almost universal practice to support the outer end of the link span from an overhead structure, either through conventional wire-rope hoisting gear or by means of hydraulic rams. The level of the end of the span can thus be continually adjusted, either automatically or by manual control, to match changes in the level of the ship's deck, whether caused by the tide, by the trim of the ship, or by differences in deck levels between one ship and another. Maximum flexibility of access has become increasingly important with the appearance, on some services, of ships with two independent car decks, both of which must be equally accessible to the link span. This situation has sometimes been achieved by the use of two-decker link spans, which has the effect of keeping the length and, unless the span is intended to carry loads on both decks simultaneously, the weight of the span to a minimum.

The sudden proliferation of roll-on, roll-off services simultaneously has led to the rather unfortunate development: a number of the terminals have tended to be tailor-made to suit particular ships and to be unable to accept different ships without, in some cases, quite major structural alteration. This feature clearly reduces the otherwise great flexibility of this technique, and an International Commission to examine the question was appointed in 1970 by the Permanent International Association of Navigation Congresses.

Maximum advantage of roll-on, roll-off is gained in relatively short sea passages. On longer voyages, the idle road vehicles make the economies questionable. This problem can be overcome to some extent by embarking only semi-trailers and leaving the tractive units ashore; the practice has no effect on the terminal details.

BULK TERMINALS

The enormous increase in the marine transit of materials in bulk, with petroleum leading the way, has given rise to the development of special terminals for the loading and discharge of such materials. The principal factor influencing the design of these installations is the still-increasing size of the ships. A single example of the effect of this change on design limits will be sufficient. The "Queen" liners, long the world's largest ships, in conditions of maximum load never drew more than 42 feet (13 metres) of water. Supertankers, on the other hand, when fully loaded, draw up to 72 feet (22 metres). If these ships required berthing structures of the type provided for conventional cargo and passenger liners and if the formula relating the capital costs of such structures to the deepest draft were applied, the cost of building an appropriate berth for such a tanker would reach a figure over six times that of the "Queen Mary's" old berth. Fortunately, the high mobility of the cargo renders such drastic and expensive measures unnecessary. Heavy capacity access for individual shore-based vehicles to carry away the cargo is not required,

nor does the provision of services for the relatively small crews who man these great ships present any problem. The berthing positions can therefore be sited well out from the shore in deep water, and the structure itself can be limited to that required to provide a small island with mooring devices.

In the case of oil terminals, the link to shore can be a relatively light pier or jetty structure carrying the pipelines through which the cargo is pumped ashore, with a roadway for access by no more than average-sized road vehicles, which will probably be in small numbers or even only one at a time (see Figure 30). As the ship herself carries the pumping machinery for delivering the cargo ashore, heavy mechanical gear for cargo handling is not required.

By courtesy of the British Petroleum Co.

Figure 30: The oil jetty at Rotterdam, The Netherlands.

Unloading
oil from
tankers

In the case of bulk carriers bringing more solid commodities, such as iron ore, the problem is more complicated. Hoisting grabs for lifting the ore out of the holds are necessary, even though transit between ship and shore can still be effected by continuous conveyors, corresponding to pipelines. Heavier foundation work is probably necessary at the berthing point to carry this machinery, and, for this reason, ore terminals have not, up to now, sought sites as far out in deep water as the oil terminals. It seems unlikely that the size of ore carriers will reach anything like the dimensions already attained by supertankers.

The employment of piled structures to meet these requirements is almost universal, and a variety of techniques has been evolved for handling and sinking into the seabed the long heavy piles required. At the sites likely to be chosen, penetration by piles may not be easy, particularly in places where most of the reasonably accessible deepwater sites tend to be located on the rockier shores.

One problem that arises is that of shelter in adverse weather conditions. While the ships themselves are reasonably robust, the relatively fragile berthing structures might break up, setting the ship loose, possibly without power immediately available, threatening disaster. As the cost of building breakwaters to protect sites in the depth of water required is likely to be prohibitive, the search has been for natural shelter. In the British Isles, the sheltered creeks of the western shores, such as Milford Haven, Pembrokeshire, have become valuable. Milford Haven had known little shipping other than fishing fleets since the early 19th century, but in the early 1970s boasted four bulk oil terminals. Two supply refineries were built on the spot; the third pumps to a refinery 60 miles (100 kilometres) away.

Another aspect of the terminals is the need for protection against the effects of unavoidable collision impacts. A slight impact from a vessel of these dimensions, by reason of the large kinetic energy of such a mass, can cause considerable damage to the light berthing structure. Much ingenuity

Disadvan-
tages of
pontoons

and theoretical analysis have gone into devising fendering systems that will absorb this energy. Some use the displacement against gravity of large masses of material disposed pendulumwise in the berthing structure as the energy absorber; others use the distortion by direct compression, shear, or torsion of heavy rubber shapes or sections; still others rely on the displacement of metal pistons against hydraulic or pneumatic pressure. The common feature of all the devices is that at least part of the energy absorbed is not dissipated but is used immediately to return the ship to its correct berthing position. This feature is not exhibited by the older forms of fenders, which relied on the compression and, in extreme cases, on the ultimate destruction of coiled rope or timber to absorb the impact. A major question still is the exact ship velocity to be allowed for, the determination of which is primarily an exercise in probability, balancing the economics of designing to a specified velocity against the cost of repairs after impacts at greater velocities. The key factor is the frequency of such impacts, which can only be determined by experience.

DRY DOCKS

The largest single-purpose structure to be built by the maritime civil engineer is not directly connected with loading, unloading, or berthing but is indispensable to prolonging the life of ships. This is the dry dock, which permits giving necessary maintenance to the underwater parts of ships. The problem of dry-docking is aggravated by the tendency of ships to grow in size by increases in beam (width) and draft (depth below waterline) rather than in length, a process that rapidly renders many of the world's largest dry docks useless for servicing an increasing proportion of the traffic.

A classic example is the King George V Drydock at Southampton. Opened in 1933, it was 1,200 feet (370 metres) long and 135 feet (41 metres) wide and was capable of accommodating the largest vessels afloat, namely, the two Cunard liners "Queen Mary" and "Queen Elizabeth," each over 80,000 tons (73,000,000 kilograms) deadweight. The later supertankers have deadweight tonnages of 135,000 tons (122,000,000 kilograms) and more, within a length of about 1,150 feet (350 metres) but with a beam of about 175 feet (50 metres), which precludes them from entering the King George V dock. The lengthening of a dry dock would be a comparatively simple and economical operation; widening, on the other hand, involves at least the complete demolition of one sidewall and its rebuilding to give the increased clear width to the other wall, assuming space can be made available. Increasing the depth would mean a new dock altogether, but because tankers generally dry-dock in the unloaded condition in which their draft can be considerably less than that of a conventional ship, this problem has not so far been a practical one.

Structural requirements. Moreover, in a great many cases, the maximum state of stress in a dry dock occurs not when it is carrying the weight of the ship (always considerably less than the weight of the water occupying the dock when flooded) but when it is completely empty and subject to the pressures generated by water in the surrounding ground, particularly under the floor, the support of which may lie at a considerable depth below the level of the adjacent water table. To ensure against any tendency to lift under this pressure, the floor must either have sufficient weight in itself (one foot, or 300 millimetres, depth of concrete will resist a little less than 2½ feet, or 750 millimetres, head [depth] of water) or be designed as a structural element capable of transmitting this pressure laterally to the walls of the dry dock, which can then be designed to contribute the additional extra weight required. Obviously an operation involving both the complete rebuilding of one wall of a dry dock and the strengthening of the floor to cover an increase in its span as an inverted arch or beam is almost tantamount to the construction of a complete new dock.

This problem received somewhat tardy recognition, so that although several large new dry docks were built around the world in the 1960s, only a minority were capable of allowing the entry of tankers of more than 200,000 tons.

Design. The design of a dry dock probably depends more on the ground conditions than any other engineering structure, with the possible exception of large dams. Mention has been made of the need in many cases to resist upward pressures under the floor. Apart from the simple solution of using the weight of the dock structure itself for this purpose, which is not economical, such devices have been tried as "pegging" the floor to the underlying strata by means of piles or pre-stressed anchors, or extending the floor slab itself beyond the sidewalls and so gaining assistance from the weight of the material filling behind the walls, which are designed to act as retaining walls to this filling. Venting of the floor to relieve water pressure can sometimes be of help provided the volume of water so released is not excessive. If it is, continuous pumping to keep the dock dry will be necessary. On sites in which water pressures do not have to be resisted, the design is generally simpler, and sufficient strength and stiffness to spread the loads from the ships' keels over the underlying ground so as not to exceed the bearing resistance of the latter is the controlling floor-design factor.

The use of dry docks for the building rather than the maintenance of ships is a practice that has been increasingly adopted. Both the building and the launching of a ship in these circumstances can be considerably simplified. The designs of such dry docks are no different from those hitherto described; what is possibly the largest dry dock in the world was completed in Belfast, Northern Ireland, in 1970. This dock, built along the site of a former channel between two open basins, is capable of accommodating the three Cunard liners "Queen Mary," "Queen Elizabeth," and "Queen Elizabeth 2" simultaneously and is to be used for the building of large tankers. It is spanned by a crane of 400 tons (360,000 kilograms) lifting capacity to handle large prefabricated ship sections.

Entrances. Dry dock entrances are closed by gates of different designs, of which the sliding caisson and the flap gate, or box gate, are perhaps the most popular. The sliding caisson is usually housed in a recess, or camber, at the side of the entrance and can be drawn aside or hauled across with winch and wire rope gear to open and close the entrance. The flap gate is hinged horizontally across the entrance and lies on the bottom, when in the open position, to be hauled up into the vertical position to close the dock—a process occasionally facilitated by rendering the gate semibuoyant through the use of compressed air.

The ship type of caisson gate, a quite separate vessel, floated and sunk into its final position across the entrance, is largely out of favour. Although it was comparatively easy to remove for maintenance and had the further advantage that a spare caisson could be kept in reserve in case of damage, the tie-up of capital is usually found unnecessarily expensive merely as an insurance premium.

The maximum degree of watertightness obtainable between the gate and its seating is essential if continuing and expensive operational commitments for pumping out leakage water are to be avoided. The pressure of the water outside the gate is available to provide a powerful sealing force, but special treatment of the actual contact faces is necessary to make this force fully effective. For a long time it has been held that the only satisfactory arrangement was by the use of a timber lining (generally greenheart) around the contact face on the gate, bearing against stops in the dock structure composed of granite dressed and polished to a high degree of accuracy. The increased expense of such methods and the diminishing supply of skilled labour capable of dressing the granite have led to a search for alternatives. These include such devices as the use of stainless facing bars set in concrete, in place of the dressed granite, and rubber linings on the gates themselves. While these have generally proved effective when first installed, more experience is needed to determine their durability as compared with older methods.

Keel and bilge blocks. Keel and bilge blocks, on which the ship actually rests when dry-docked, are of a sufficient height above the floor of the dock to give reasonable access to the bottom plates. Such blocks are generally made of cast steel with renewable timber caps at the contact surfaces. Individual blocks can generally be dismantled

Dry docks
in ship-
building

Danger of
obsoles-
cence

under the ship to allow access to that part of the plates, if required, and can be reassembled to take their appropriate share of the weight after the operation required has been completed. Most modern ships, particularly tankers, are of nearly square section over a large part of their middle length and can be kept upright in dry dock by the support of the bilge blocks under their bilge keels. In the most up-to-date dry docks, the bilge blocks are provided with mechanical means for traversing them across the dock and altering their height by remote control while the dock is still flooded. This arrangement permits them to be adjusted in their correct position according to the shape of the ship while the latter is still just afloat but in contact with the centre-line keel blocks. The economic advantage of this arrangement is considerable because it allows one ship to be removed and another put into the dry dock on the same opening of the gate, whereas under previous practice it would have been necessary to close the dock and pump it out to reset the bilge blocks to the known profile of the next ship. Apart from the time needed, the power consumed in pumping out a large dry dock is a considerable factor.

As a consequence of the increasing number of ships suitable for bilge docking, the use of side shores to keep hulls upright in dry dock is a rapidly dying process, and indeed the altars provided for this purpose in dry docks of more old-fashioned design are often an embarrassment to the accommodation of a modern square-sectioned ship. Frequently this situation is remedied by cutting away some altars, an operation that must be conducted with discrimination because the removal of any quantity of material from the sidewalls may have a damaging effect on their stability.

Construction. Basic technique. Dry docks are usually constructed in open excavation in the dry, shutting out the sea by means of a cofferdam. Sometimes it is found convenient to construct the sidewalls first, in trench, and next to remove the loose material between them, then to lay the floor in stages so as not to endanger the stability of the walls before the floor is in position to give them toe support. Extensive pumping, to keep the excavations from filling with water during construction, is generally necessary.

In one rather unusual case, a dry dock for 240,000-ton tankers was constructed almost wholly under water because large fissures in the rock running through to the sea flooded the site beyond the capacity of any reasonable assembly of pumping equipment. The entire space required for the structure was therefore excavated to formation level by dredging, and the sidewalls were constructed first, using prefabricated concrete caissons, sunk into place and filled with concrete. The spaces between adjacent caissons were sealed by filling with concrete in the same way. Stone aggregate, to a depth of 23 feet (seven metres), was then deposited between these walls and consolidated into a concrete floor by a process of grouting in which colloidal cement grout was forced under pressure between the interstices of the aggregate, subsequently setting to form the whole into concrete. A similar process across the floor at the entrance incorporated a cofferdam of interlocking steel sheetpiling, which allowed the sill and gate hinge to be constructed in the dry. The gate, of the flap variety already mentioned, was floated and stepped into place by divers after the removal of the cofferdam. Only then was it possible to pump out the main body of the dock, which was completed by laying a reinforced concrete topping over the floor in order to provide a satisfactory working surface.

Floating dry docks. Floating dry docks have the initial advantage that they can be built and fully equipped in shipyard and factory conditions, in which their construction is not subject to unforeseen hazards arising from weather and variations in the ground conditions from those anticipated during design. The floating dock can be towed to the site, moored, and made ready for operation in a comparatively short time. Expenditure on temporary works, often a large fraction of the cost of a fixed dry dock, is also avoided.

Floating dry docks are usually fully self-contained (Figure

Figure 31: Operation of a floating dry dock.

(A) Dock afloat in its light-draft condition, with little or no water in its ballast tanks. (B) Dock submerged to its maximum draft by filling the ballast chambers; a vessel floats freely in the flooded channel. (C) Dock floor emerges from the water, and the vessel comes to rest on the support blocking. (D) All ballast is pumped out, raising the dock floor completely out of the water and providing a dry working area.

From A. Amirikian in "Transactions of the Society of Naval Architects and Marine Engineers," 1957

31). The sidewalls provide much of the residual buoyancy and stability required to keep the dock afloat when it has been so far submerged to allow the entry of a ship into the docking space over the main deck. Most of the machine tools and workshop equipment required for all the normal operations of ship repair and maintenance are also housed in the walls as well as the generating plant (usually diesel driven) to supply power for the operation of the dock and its equipment. Travelling cranes, for handling material off and onto the ship, run on the tops of the sidewalls.

A floating dry dock can be moved at relatively short notice to another site, should a long-term change in shipping-traffic patterns dictate a change. This advantage may be more apparent than real because the large work force required to man it may not be so readily transferable.

Moreover, floating dry docks tend to have large maintenance costs because the steel structure, being continually afloat, requires regular chipping and painting, as the hull of a ship does. The above-water structure presents no particular problem and can generally be given maintenance care without putting the dock out of use. The most vulnerable areas, those immediately adjacent to the waterline, can be reached by careening, a process that involves filling the water ballast tanks along one side to induce a list that lifts those on the other side part of the way out of the water. On completion, the process can be reversed for the other side.

Maintenance. Methods of underwater scaling and painting, or the use of limpet dams with which small areas can be covered with watertight enclosures inside of which men can work under compressed air, allow a limited measure of attention to be given to the bottom plating outside. Occasionally it is necessary to detach one of the sections of the dock, which is usually constructed in separate sections for this reason, and dry-docking it in the remainder, repeating the process until the whole dock has been renovated. This costly and tedious process is only resorted to for compelling reasons.

To give a floating dock sufficient depth of water for submerging the docking blocks below the keel of the ship to be docked, it may be necessary to dredge a berth for it. In areas subject to heavy siltation, this dredged area will

Keeping
out the sea

Underwa-
ter scaling
and plating

almost certainly act as a silt trap. Periodic removal of the dock from the berth to allow the latter to be redredged is an additional source of expenditure in such cases. Finally, in places where the tide range is of consequence, special mooring arrangements are necessary to restrain excessive lateral drift of the dock as the mooring chains become slack on low water.

The arrangement of keel and bilge blocks is generally similar to those described for fixed dry docks.

Sea works for reclamation and conservancy

An indispensable item of equipment over a wide range of the maritime civil engineer's activities is the dredge with its ancillary units, such as hopper barges, tugs, reclamation units, and servicing craft. There are few navigable harbours or harbour approaches that do not require, at varying intervals of time, removal of deposits of unwanted material, the continuing accumulation of which can ultimately obstruct navigation. With the current trend toward larger ships, dredging is especially important.

Extensive research has been devoted to the development of dredging equipment. Through more sophisticated techniques, including, in some cases, permanent profile modification of the harbours and waterways, efforts are made to keep the need for dredging to a minimum. Model studies, mentioned earlier, can be of the greatest assistance.

DREDGING

Estuarial
silt

The material to be removed by dredging operations is usually derived from one of two sources or from a combination of both. In harbours at the mouths of rivers, quantities of silt are carried down in suspension and tend, partly because of the deceleration of the flow in the increased waterway available and partly because of the effects of increasing salinity, to be deposited at the mouth, usually the site of harbour works.

This process has produced areas of marked agricultural fertility, such as the Nile Delta in Egypt. While over a large time span the action is one of great benefit, in the short term it is generally a considerable inconvenience. The skillful employment of modern dredging equipment, however, has indicated possibilities of getting the best of both worlds. The other source of deposited material likely to obstruct navigation is littoral (coastal) drift, especially in areas where there is a sizable tidal range. The incoming tide frequently brings suspended material some proportion of which settles to the bottom around the turn of the tide when the movement of water is at a minimum. In the absence of any countervailing tendency, an accumulation takes place, which again requires dredging.

For many years the workhorse of many of the world's dredging fleets has been the bucket-ladder dredge, operating a continually moving chain of open-ended shovels or scoops. At the bottom of the ladder the scoops are pushed into the face of the material, and empty themselves as they turn over at the top, the material falling into chutes that divert it into hopper barges for removal. A four-point mooring system enables the craft, and with it the bucket ladder, to be held up to the working face and, at the same time, swung sideways across it in either direction. By this means, an often remarkably level bed to the sea bottom can be closely controlled by adjusting the position of the ladder under the dredge's bottom. The positive action in filling the buckets enables such a dredge to tackle material of considerable stiffness, thereby extending its use to works of dredging and harbour development in which soils other than recently deposited silt or sand have to be excavated. Even some of the softer rocks can be removed in this way if the buckets are provided with hardened and stiffened edges and ripping teeth.

The principal disadvantage of the bucket-ladder dredge is the need for an elaborate system of fixed moorings. The area that can be covered by one placing of the moorings is limited. Continuous lifting and replacing of the moorings are not only time-consuming, but must be carried out in such a way as to offer minimum obstruction to navigation, a requirement that sometimes involves a great number of interruptions in dredging operations.

In areas in which the deposit silt is highly mobile and accumulates in considerable quantities, it can be economically removed by a suction dredge, which pumps water mixed with silt into open hoppers. By adjustment of the capacity of the hopper to the rate of flow from the pump, the water can be made to remain in the hopper long enough to deposit most of the silt. Careful design of the pumping machinery is required to assume a continuous mixture of maximum silt with minimum water.

The suc-
tion dredge

The first suction dredges generally operated from moored positions in the same way as bucket-ladder dredges, but a less elaborate system of moorings generally sufficed because the levelling of the seabed could be left to occur naturally through the mobility of the material. A marked advance was achieved by the elimination of much of the lifting and laying of moorings through the development of the trailer suction dredge. This craft has the capacity to dredge while on the move and cruises up and down the waterway or other area, sucking up silt as it goes. This operation does not eliminate all interference to navigation because a working trailer suction dredge moves more slowly than a ship under normal steerage way, but the obstruction is markedly less. The dredge's turn at the end of each sweep is usually facilitated by the incorporation of a bow side thrust propeller.

The growing tendency to use dredged material for reclamation purposes and the suitable condition for such purposes of the spoil as delivered by a suction dredge has encouraged its development. The seabeds and river bottoms in their natural state are often largely composed of relatively soft material and can be deepened by the use of suction dredges operating normally. Where rock or other hard material must be handled, conditions are favourable to the use of the suction-cutter dredge, which incorporates at the suction head a powerful rotating screw cutter that fragments the hard material. The increased dredging stresses arising from the use of a cutter require that a craft so equipped should be operated as a stationary dredge with moorings. Because such operations seldom take place in areas already under use by traffic, the obstruction problem is not often critical. Additionally, in modern equipment, the incorporation of heavy spud legs in the craft to anchor in the seabed reduces the number of separately laid moorings required.

A useful ancillary piece of equipment to all the above is the grab dredge, either self-propelled or towed to the site. Grab dredges are especially suitable for dredging close up to existing quay walls or other structures with minimum risk of damage, and the grab equipment is often capable of lifting individual boulders. Not infrequently grab dredges have value for maintenance dredging, particularly in restricted areas and with silt of sufficient mobility to level out the individual holes almost inevitably left. Although the return fall of the grab takes place with the bucket empty and is, to that extent, nonproductive, with skillful operators this element can be reduced to a minimum and, with some large craft operating four grabs simultaneously, considerable outputs can be achieved.

Dredges are characteristically designed to deliver their output either overside into attendant hopper barges or, in the case of self-propelled dredges, into hopper compartments incorporated in their own structure. These compartments are essential in the case of trailing suction dredges, but their value in other cases depends on the circumstances and the method of disposal of the spoil. When a long journey to the depositing area is involved, it is obviously more economical to leave the dredge continuously at work and remove the spoil in separate barges.

When the journey is short and the spoil is to be simply dumped, for which purpose the hoppers are provided with bottoms that fall open, then an economical work cycle between dredging area and spoiling ground, using one craft only, can frequently be established.

A special case is the side-boom dredge, which discharges straight back overside; by making the work coincide with an appropriate state of the tidal current, this arrangement secures the removal of the dredged silt by the tide's operation.

The side-
boom
dredge

Dredged spoil is less and less often disposed of by dump-

Figure 32: The giant sluices across the Haringvliet, part of the Dutch Delta Plan.

ing out at sea, a practice once almost universal; instead it is used for the reclamation of land from the sea and foreshore. This process has been stimulated by the rise in the value of the land so created and by the discovery that, in many instances, spoil taken out to sea frequently returns. This phenomenon has been investigated, both on hydraulic models and by mixing radioactive tracers with the dumped spoil in small quantities, permitting its subsequent movements to be followed with Geiger counters.

A variety of procedures have been developed for the combined operation of dredging and reclamation. Where the area to be dredged and the area to be reclaimed are in close proximity, as sometimes happens, the whole operation can be carried out by a single suction dredge pumping ashore through a floating pipeline. When, as is more often the case, there is a considerable distance between the two sites, transport in hopper barges is more economical. At the reclamation site, the barges can either be pumped out by a suction reclamation unit, or occasionally can dump their loads on the bottom; from there the material can be pumped ashore by the unit acting as a stationary suction dredge.

The layout of reclamation areas is a matter to which adequate scientific investigation should be devoted, covering such aspects as the adequacy and subsequent maintenance of any navigable waterways it is intended to provide through them, the design of the banks required to contain the pump spoil while the solids settle, and the relative positions of delivery and runoff points to obtain the maximum recovery of solid matter. Such schemes for reclamation, carried out in this way, can simultaneously ensure more valuable new land and improve navigation facilities.

THE DELTA PLAN

It was noted at the beginning of this article that maritime engineering has two large objectives: improvement of transportation and reclamation and conservancy of land. Outstanding among examples of human ingenuity in the second category has been the long effort of the people of The Netherlands to keep their country, large areas of which are below sea level, habitable and productive.

The purpose of these efforts has generally been twofold, first to recover, reclaim, and retain more land for occupation; and second, to prevent the percolation of seawater into the water table of both the recovered and the original ground, which, if not prevented, would seriously reduce or even altogether destroy the value of the land for agricultural purposes. This second purpose has sometimes been described as "pushing back the salt line."

A prime example of the first purpose was the enclosure, by means of a dike some 17 miles (28 kilometres) in length, in 1926–32, of the large inlet formerly known as the Zuiderzee and, after its enclosure, renamed the IJsselmeer. Considerable areas of this body of water have since been reclaimed by the pumping ashore of dredged sand, and the reclamation of further areas is either in hand or planned for the future. A large proportion of the area will, nevertheless, be maintained as a freshwater lake by the flow of the river IJssel, which takes off from one of the outfalls of the Rhine, known as the Lek, or Neder Rhine, just south of Arnhem. In the 1960s it was found necessary to place a dam across the Lek just below the takeoff of the IJssel, to divert an increased quantity of Rhine water down the IJssel to the IJsselmeer. The growth of shipping traffic on the canal, which connects Amsterdam with the

Enclosure
of the
Zuiderzee

North Sea, the locking operations of which necessarily discharge quantities of salt water into the IJsselmeer, would otherwise tend to nullify the effects of the freshwater flow of the IJssel.

To maintain navigation in the Lek, in spite of the reduction in water flow, two further dams are provided downstream toward Rotterdam, and all three dams are capable of being opened, in the event of excessive flood-water coming down the Rhine.

DESALINIZATION

The second purpose, that of desalinization or "pushing back the salt line," has been at the heart of the Delta Plan, one of the most imaginative civil-engineering projects ever undertaken. The incident that triggered the Delta Plan was the disastrous flooding of February 1, 1953, when the notorious North Sea surge brought tide levels higher than ever previously recorded, overtopping many of the existing dikes and causing untold damage and salt contamination of vast areas of agricultural land. The surge also caused considerable flooding and damage on the other side of the English Channel, along the east and southeast coasts of England. Statistical research suggests that tides of this level are to be expected at a frequency of at least once in 300 years.

The weak point in The Netherlands' defenses against flooding from the sea is the several deep inlets formed at the mouths of the Rhine and Maas rivers, through which the greater part of the water coming down these rivers discharges into the North Sea. Around the shores of these inlets run many miles of dikes, the maintenance of which is a constant burden and the strengthening and heightening of which to prevent a repetition of the disastrous 1953 floods represented a project of considerable magnitude.

It was considered that the most economical result would be obtained by a major operation of shutting out the sea, more or less at the main coastline, by a series of dams across the mouths of the inlets. By this means some 435 miles (700 kilometres) of dikes would be cut off from direct sea attack and reduced to a secondary function, whereas the total of the new dams that might still require a measure of maintenance is only 19 miles (30 kilometres). By conserving and controlling the vital flows from the Rhine and the Maas, the inlets themselves would be gradually transformed into freshwater lakes, thus greatly contributing to "pushing back the salt line."

A secondary effect in this direction will be an increase

in the flow of freshwater toward Rotterdam, as a result of the raising of the levels in the estuarial inlets, particularly in the most northerly, the Haringvliet. This result should greatly assist desalinization in the Rotterdam area, where the penetration inland of the salt line had reached alarming proportions, as a result of the improvement in the navigational approaches to the port, effected by the construction of the channel known as the New Waterway from the Hook of Holland.

A further benefit to be gained is the great improvement in communications between the mainland and the hitherto somewhat isolated communities on the islands lying between the inlets; the new dams across the inlets will provide foundations for motor roads.

The Delta Plan construction was scheduled to take nearly a quarter of a century and the total cost represents a significant percentage of The Netherlands' national budget.

Although the authors of the plan stress that it is not properly a land-reclamation scheme (little or no extra land will be created by it), there is no doubt that many of the techniques developed for reclamation work are of the utmost value in carrying out the work, and, conversely, lessons learned in the course of the project will no doubt find useful application in future reclamation work the world over.

Thus, for the construction of the sluices through the dam across the Haringvliet, necessary to provide for escape of river water in times of flood, a working island was created in what was almost open sea, by the continuous depositing of sand on the seabed until the level rose above that of the water. Procedures for the rapid waterproofing of the banks so created have been brought to a high pitch of efficiency. This has been accomplished through the use of nylon carpets or asphaltting by special high-speed placing machines. The former take the place of the previously well-tried practice of using fascine mattresses weighted down with stones for which labour on the scale required to cover large areas with sufficient speed is no longer available.

The closure of the final gaps in the dams, a hazardous operation because of the large volume of water rushing through the narrow remaining gap at this stage, is effected at the Delta by the use of concrete caissons floated into the gap and scuttled in position. The technique has progressed there from the use of solid-walled caissons that had the disadvantage of closing the gap suddenly, with consequent hazard, to caissons incorporating their own sluices, thus allowing the flow of water to continue until all were in place and the sluices could be safely closed. LIGHTHOUSES

Lighthouses, the centuries-old function of which is to provide the mariner with an identifiable seamark by day and by night, giving him positional information and warning him of a hazard, have been influenced by the continuing advance of technology. More advanced and sophisticated aids, such as radio navigation systems, may be considered part of the subject treated in this section.

A history of structures

LIGHTHOUSES OF ANTIQUITY

The forerunners of lighthouses proper were beacon fires, kindled on hilltops, the earliest references to which are contained in the *Iliad* and the *Odyssey*. The first authenticated man-made lighthouse was the renowned Pharos of Alexandria, which stood some 350 feet high. The Romans erected many lighthouse towers in the course of expanding their empire, and by AD 400 there were some 30 in service from the Black Sea to the Atlantic. These included a famous lighthouse at Ostia, the port of Rome, completed in AD 50, and lighthouses at Boulogne and Dover. A fragment of the original Roman lighthouse at Dover survived in the 1980s.

The Phoenicians, trading from the Mediterranean to Great Britain, marked their route with lighthouses, the present structure at La Coruña, Spain, being close to the site of an ancient Phoenician lighthouse (see Figure 33,

right). These early lighthouses had wood fires or torches burning in the open, sometimes protected by a roof. After the 1st century AD, candles or oil lamps were used in lanterns with panes of glass or horn.

MEDIEVAL LIGHTHOUSES

The decline of commerce in the Dark Ages halted lighthouse construction until the revival of trade in Europe about AD 1100. The lead in establishing new lighthouses was taken by Italy and France. By 1500, references to lighthouses became a regular feature of books of travel and charts. By 1600, at least 30 major beacons were established.

These early lights were similar to those of antiquity, burning mainly wood, coal, or torches in the open, although oil lamps and candles were also used. A famous lighthouse of this period was the Lanterna of Genoa, probably established about 1139. It was rebuilt completely in 1544 as the impressive tower that remains a conspicuous seamark today. The keeper of the light in 1449 was Antonio Columbo, uncle of the Columbus who crossed the Atlantic. Another early lighthouse was built at Meloria, Italy, in 1157, which was replaced in 1304 by a lighthouse on an isolated rock at Leghorn. In France the Roman tower at Boulogne was repaired by the Emperor Charlemagne in AD 800. It lasted until 1644, when it collapsed due to undermining of the cliff. The most famous French lighthouse of this period

was one on the small island of Cordouan in the estuary of the river Gironde, near Bordeaux. The original was built by Edward, the Black Prince, in the 14th century. In 1584 Louis de Foix, an engineer-architect, undertook the construction of a new light, which was one of the most ambitious and magnificent achievements of its day. It was 135 feet (41 metres) in diameter at the base and 100 feet (30 metres) high, with an elaborate interior of vaulted rooms, richly decorated throughout with a profusion of gilt, carved statuary, and arched doorways. It took 27 years to build, due to subsidence of the apparently substantial island. By the time the tower was completed in 1611, the island was completely submerged at high water. Cordouan thus became the first lighthouse to be built in the open sea, and the true forerunner of such rock structures as the Eddystone Lighthouse.

The influence of the Hanseatic League helped increase the number of lighthouses along the Scandinavian and German coasts. At least 15 lights were established by 1600, making it one of the best lighted areas of that time.

During this period, lights exhibited from chapels and churches on the coast frequently substituted for lighthouses proper, particularly in Great Britain.

THE BEGINNING OF THE MODERN ERA

The development of modern lighthouses can be said to have started from about 1700, when improvements in structures and lighting equipment began to come more rapidly. In particular, that century saw the first construction of towers fully exposed to the open sea. The first of these was Henry Winstanley's 120-foot (36.6 metre)-high wooden tower on the notorious Eddystone Reef, off Plymouth. Although anchored by 12 iron stanchions laboriously grouted into exceptionally hard red rock, it lasted only from 1699 to 1703, when it was swept away without a trace in a storm of exceptional severity; its designer and builder, on the lighthouse at the time, perished with it. It was followed in 1708 by a second wooden tower, constructed by John Rudyerd, which was destroyed by fire in 1755. Rudyerd's lighthouse was followed by J. Smeaton's famous masonry tower in 1759. Smeaton, a professional engineer, embodied an important new principle in its construction whereby masonry blocks were dovetailed together in an interlocking pattern. He also devised the curved hyperbolic profile, which became the classic design for the world's lighthouse builders. It was later modified to include a solid cylindrical base to break the main force

of the sea and reduce the tendency of waves to sweep up the sides.

Due to the undermining of the foundation rock, Smeaton's tower had to be replaced in 1882 by the present lighthouse, constructed on an adjacent part of the reef by Sir James Douglass, engineer in chief of Trinity House. The upper portion of Smeaton's lighthouse was dismantled and rebuilt on Plymouth Hoe, where it still stands as a monument; the lower portion or "stump" can still be seen on the Eddystone Reef. Following the Eddystone, masonry towers were erected in similar open sea sites, which include the Smalls, off the Welsh coast; Bell Rock in Scotland; South Rock in Ireland; and Minots Ledge off Boston, Massachusetts. The first lighthouse of the American continent, built in 1716, was on the island of Little Brewster, also off Boston. After about 1775, lighthouse construction spread rapidly. By 1820 there were an estimated 250 major lighthouses in the world.

While masonry and brick continue to be used, particularly for shore lighthouses, concrete and steel are the most favoured forms of construction, particularly offshore.

Structurally well-suited and reasonably cheap, concrete lends itself to aesthetically pleasing designs for shore-based lighthouses. The new lighthouse erected at Dunge Ness, England, in 1961 is a notable example of how concrete can provide strength without great mass. The slender 135-foot (41-metre) tower, rising from a spiral base, is admirably proportioned architecturally (see Figure 33, left).

Modern construction methods have considerably facilitated the building of lighthouses in the open sea. On soft ground, the submerged caisson method is used, a system first applied in 1885 to the building of the Roter Sand Lighthouse in the estuary of the Weser River in Germany, and then to the Fourteen Foot Bank light in the Delaware Bay, Delaware. With this method, a steel caisson or open-ended cylinder, perhaps 40 feet (12 metres) in diameter, is positioned on the seabed. By excavation of sand, it is sunk into the seabed to a depth of possibly 50 feet (15 metres). At the same time, extra sections are added to the top as necessary so that it remains above high water level. The caisson is finally pumped dry and filled with concrete to form a solid base on which the lighthouse proper is built.

Two other main types of construction are used for offshore lighthouses where the seabed is reasonably firm and level. The first utilizes concrete to build a "float out" lighthouse: a cylindrical tower on a large hollow concrete base, which can be 50 feet in diameter. The tower is constructed in a shore berth, towed out to position, and then sunk to the seabed where the base is finally filled with sand. Weighing 5,000 tons (4,500,000 kilograms) or more, these towers rely on their weight for stability and require a levelled, prepared seabed. For greater stability during towing, the cylindrical tower itself often consists of two or more telescopic sections, raised to full height by hydraulic jacks after being founded on the seabed. This design has been pioneered largely in Sweden, where at least eight have been constructed.

The other form of construction, using open steelwork, is largely based on the design of offshore oil and gas wells, including the so-called Texas Towers. A typical lighthouse of this type has an upper deck containing the plant, the equipment, and personnel accommodation. It is usually about 60 feet (18 metres) square, with a short tower on one corner to support the light. The deck also can provide a helicopter landing platform. The accommodation deck is supported on four to eight tubular steel piles, about two feet in diameter, driven into the seabed to a penetration of 150 feet (46 metres) or more. Before the piles are driven, a tubular steel braced framework, known as a "jacket" or "template," is placed in position on the seabed. The piles are driven down through the vertical tubular members of the jacket, which act as guides. Concrete grout is then forced into the annular space between pile and jacket tube. The deck is usually fabricated on shore, taken out on a barge, lifted into position on the substructure by floating crane, and welded on. The U.S. has built about 15 light towers of this type to replace lightships. The most recent is Ambrose Light off New York.

The development of modern lighthouse technology

ILLUMINANTS

Wood fires were not discontinued until 1800, though after c. 1550 coal, a more compact and longer burning fuel, was increasingly favoured, particularly in northwestern Europe. A lighthouse in those days could consume 300 tons (273,000 kilograms) or more of coal a year. In full blaze, the coal fire was far superior to other forms of lighting, preferred by mariners to oil or candles. The disadvantage of both coal fires and early oil lamps and candles was the prodigious amount of smoke produced, which resulted in rapid blackening of the lantern panes, obscuring the light.

In 1782 a Swiss scientist, Aimé Argand, invented an oil lamp whose steady smokeless flame revolutionized lighthouse illumination. The basis of his invention was a circular wick, with a glass chimney that ensured an adequate current of air up the centre and the outside of the wick for even and proper combustion of the oil. Eventually, Argand lamps with as many as ten concentric wicks were designed. These lamps originally burnt fish oil, later vegetable oil, and by 1860 mineral oil was in general use. The Argand lamp became the principal lighthouse illuminant for over 100 years. A few are still in use.

In 1901, Arthur Kitson invented the vaporized oil burner, which was subsequently improved by David Hood and others. This burner utilized kerosene vaporized under pressure, mixed with air, and burnt to heat an incandescent mantle. The effect of the vaporized oil burner was to increase six times the power of former oil wick lights. The principle is widely used for cooking stoves, pressure lamps, etc.

Early proposals to use coal gas at lighthouses did not meet with great success. A gas-making plant at the site was usually impracticable and most of the lights were too remote for a piped supply. The use of acetylene gas, generated in situ from calcium carbide and water, increased following the discovery of the dissolved acetylene process, which by dissolving the acetylene in acetone made it safe to compress for storage.

Acetylene gas as a lighthouse illuminant had a profound influence on the advancement of lighthouse technology, mainly through the work of Gustaf Dalén of Sweden, who pioneered its application between 1900 and 1910. Acetylene produced a light equal to that of oil, burnt either as an open flame or mixed with air in an incandescent mantle. Its great advantage was that it could be readily controlled; thus for the first time automatic unattended lights were possible. Dalén devised many ingenious mechanisms and burners, operating from the pressure of the gas itself, to exploit the use of acetylene. Most of the equipment he designed is still in general use today. One device is an automatic mantle exchanger that brings a fresh mantle into use when the previous one burns out. Another, economizing on gas, was the "sun valve," an automatic day-night switch capable of extinguishing the light during the day. The switch utilized the difference in heat-absorbing properties between a dull black surface and a highly polished one, producing a differential expansion arranged by suitable mechanical linkage to control the main gas valve.

The acetylene system facilitated the establishment of many automatic unattended lighthouses in remote and inaccessible situations, normally only requiring an annual visit to replenish the storage cylinders and overhaul the mechanism. Acetylene equipment is still widely used today because of its simplicity, robustness, and ease of maintenance. Liquefied petroleum gas, such as propane, is also used.

Electric illumination in the form of carbon arc lamps was first employed at lighthouses at an early date, even while oil lamps were still in vogue. The first of these was at Dunge Ness, England, in 1862, followed by a number of others. The majority of these, however, were eventually converted to oil, since the early arc lamps were difficult to control and costly to operate. In 1913, the Helgoland Lighthouse was equipped with arc lamps and searchlight mirrors to give a light of 38,000,000 candlepower, the most powerful lighthouse in the world at that time.

The electric-filament lamp, which came into general use in the 1920s, is the standard electric illuminant for lighthouses today. The light output is some ten times that of the vaporized oil burner. Electric lamps in common use range from a maximum of about three kilowatts down to as little as six watts or so for small buoy and beacon lights. When a specially powerful light is required, modern arc lamp equipment is employed. This is usually the compact type, with the arc enclosed in a glass bulb to make the lamp replaceable. While mercury arc lamps are used, they have a distinct bluish colour. The xenon arc lamp, originally developed for colour film work, is preferred for the intense white light it produces. The most powerful lighthouse in the world today, at Creach, Ile D'Ouessant, France, is a carbon arc installation. An augmented light, giving a beam of 500,000,000 candlepower, is brought into service only during fog or misty weather.

Various lighthouse authorities are currently experimenting with the electronic xenon flash tube, a novel type of lamp used in photography. This lamp produces a very short flash of a few millionths of a second duration of extremely high intensity, imparting a distinctive character to the light and making it particularly conspicuous against other background lights.

OPTICAL EQUIPMENT

With the advent of the Argand lamp, a reliable and steady illuminant, it became possible to develop effective optical apparatus for increasing the intensity of the light. In the first equipment of this type, known as the catoptric system, paraboloidal reflectors concentrated the light into a beam. William Hutchinson of Liverpool in 1777 produced the first practical mirrors for lighthouses, consisting of a large number of small facets of silvered glass, set in a plaster cast molded to a parabolic form. More generally, shaped metal reflectors were used, silvered or highly polished. These were prone, however, to rapid deterioration from heat and corrosion; the glass facet reflector, although not as efficient, lasted longer. The best metallic reflectors available in 1820 were constructed of heavily silvered copper in the proportion of six ounces of silver to one pound of copper (compare one-half ounce of silver to one pound of copper commonly used for plated tableware of the period). The cleaning cloths were kept for subsequent recovery of the silver. These mirrors could increase the intensity of an Argand lamp, nominally about five candlepower, almost 400 times.

Although the mirror could effectively concentrate the light into an intense beam, it was necessary to rotate it to make it visible from any direction. This produced the now-familiar revolving lighthouse beam, with the light appearing as a series of flashes.

Mariners were not favourably disposed to these early flashing lights, contending that a fixed steady light was essential for a satisfactory bearing. However, the greatly increased intensity and the advantage of using the pattern of flashes to identify the light gradually overcame their objections. The first revolving beam lighthouse was at Carlsten, near Marstrand, Sweden, in 1781.

In 1828 Augustin Fresnel of France produced the first apparatus using the refracting properties of glass, now known as the dioptric system. On a lens panel he surrounded a central bull's-eye lens with a series of concentric glass prismatic rings. The panel collected light emitted by the lamp over a wide horizontal angle and also the light that would otherwise escape to the sky or to the sea, concentrating it into a narrow, horizontal pencil beam. With a number of lens panels rotating around the lamp, he was then able to produce several revolving beams from a single light source, an improvement over the mirror that produces only a single beam. To collect more of the light wasted vertically, he added triangular prism sections above and below the main lens, which both refracted and reflected the light. By doing this he considerably steepened the angle of incidence at which rays shining up and down could be collected and made to emerge horizontally. Thus emerged the full Fresnel catadioptric system, the basis of all lighthouse lens systems today. To meet the requirement for a fixed all-round light, Fresnel modified his principle

Electric-filament lamps

The catoptric system

The Fresnel dioptric system

The Argand lamp

Use of acetylene gas

by producing a cylindrical drum lens, which concentrated the light into an all-round fan beam. Although not as efficient as the rectangular panel, it provides a steady, all-round light. Small drum lenses, robust and compact, are widely used today for buoy and beacon work, eliminating the complication of a rotating mechanism.

Prior to Fresnel's invention the best mirror systems could produce a light of about 20,000 candles, using an Argand lamp. The Fresnel lens system increased this to 80,000 candles, roughly equivalent to a modern automobile head lamp; with the pressure oil burner, intensities of up to 1,000,000 candlepower could be achieved.

For a light of this order the burner mantle will measure four inches in diameter. The rotating lens system would have four large Fresnel glass lens panels, 12 feet (3.7 metres) high, mounted about four feet from the burner on a revolving lens carriage. The lens carriage would probably weigh five tons, about half of it being the weight of glass alone. The rotating turntable floats in a circular cast iron trough containing mercury. With this virtually frictionless support bearing, the entire assembly can be smoothly rotated by weight-driven clockwork. If the illuminant is acetylene gas, the lens rotation can be driven by gas pressure. Installations of this type are still in common use, although many have been converted to use an electric lamp with an electric-motor drive. Modern lens equipment of the same type is much smaller, perhaps 30 inches (76 centimetres) high, mounted on ball bearings and electric-motor driven. With a 250-watt lamp, illumination of several hundred thousand candlepower can be readily obtained. Lens panels are now moulded in transparent plastic (Perspex), which is lighter and cheaper. Drum lenses are also moulded in plastic. In addition, with modern techniques high-quality mirrors can be produced easily and cheaply.

INTENSITY, VISIBILITY, AND CHARACTER OF LIGHTS

The candlepower of illumination is expressed in terms of the international unit, the candle (also called candela). Intensities of lighthouse beams vary from thousands to millions of candles. The range at which a light can be seen depends upon atmospheric conditions and elevation. Since the geographical horizon is limited by the curvature of the earth, it can be readily calculated for any elevation by standard geometrical methods. In lighthouse work the observer is always assumed to be at a height of 15 feet (4.6 metres), although on large ships he may be 40 feet (12.2 metres) above the sea. Assuming a light at a height of 100 feet (30 metres), the range to an observer at 15 feet above the horizon will be about 18 miles (29 kilometres). This is known as the geographical range of the light. In clear weather a light of 10,000 candles will be visible at 18 miles.

Known as the luminous range of the light, this distance is the limiting range at which the light is visible, in the prevailing atmospheric condition, disregarding limitations due to its height and the earth's curvature. A very powerful light, low in position, could thus have a clear-weather luminous range greater than that when first seen by the mariner on the horizon. Powerful lights can usually be seen over the horizon because the light is scattered upward by particles of water vapour in the atmosphere; the phenomenon is known as the loom of the light.

Atmospheric conditions have a marked effect on the luminous range of lights and are defined in terms of a transmission factor expressed as a fraction or a percentage up to a maximum of unity or 100 percent, assuming a perfectly clear atmosphere, never attained in practice. Clear weather in the British Isles corresponds to about 80 percent transmission, but in tropical regions it can rise to 90 percent, increasing the luminous range of a 10,000-candle light from 18 to 28 miles (29–45 kilometres). Conversely, in mist or haze at about 60 percent transmission, a light of 1,000,000 candles would be necessary to maintain a luminous range of 18 miles. In dense fog, with the visibility down to 100 yards (91 metres), a light of 10,000,000,000 candles could scarcely be seen at one-half mile. Because average clear weather conditions vary considerably from one region of the world to another, luminous ranges of

all lighthouses by international agreement are quoted in an arbitrary standard clear-weather condition corresponding to a daytime meteorological visibility of 10 miles (16 kilometres), or 74 percent transmission. This is known as the nominal range of a light. Mariners use nautical conversion tables to determine the actual luminous range in the prevailing visibility.

Fixed lights are still used in port, harbour, and estuarial areas where they give the mariner directional information by showing red or green over sharply defined sectors. Known as range or sector lights, they are often shown as fixed lights subsidiary to the main flashing light of the lighthouse. Another range system, sometimes called leading lights, consists of two lights at different elevations, about a half-mile (0.8 kilometre) apart. The mariner steers to keep the two lights in line one above the other.

Most lighthouses rhythmically flash or eclipse their lights to provide an identification signal. The particular pattern of flashes or eclipses is known as the character of the light, and the interval at which it repeats itself is called the period. International agreement restricts the number of different characters that can be used, through the International Association of Lighthouse Authorities in Paris, to which the majority of maritime nations belong. The regulations are too lengthy to quote in full, but essentially a lighthouse may display a single flash, regularly repeated at perhaps 5-, 10-, or 15-second intervals. This is known as a flashing light. Alternatively, it may exhibit groups of two, three, or four flashes, with a short eclipse between individual flashes and a long eclipse of several seconds between successive groups. The whole pattern is repeated at regular intervals of 10 or 20 seconds. These are known as group flashing lights. In another category, "occulting" lights are normally on and momentarily extinguished, with short eclipses interrupting longer periods of light. Analogous to the flashing mode are occulting and group-occulting characters. A special class of light is the isophase, which alternates eclipses and flashes of exactly equal duration.

The daymark requirement of a lighthouse is also important; lighthouse structures are painted to stand out against the prevailing background. Shore lighthouses are usually painted white for this purpose, but in the open sea or against a light background conspicuous bands of contrasting colours, usually red or black, are utilized.

SOUND SIGNALS

Periods of bad visibility led fairly early to the idea of a supplementary audible warning. At first, sound signals were explosive, created by a cannon, or bells. Both were being used in the 1970s.

The explosive can be heard up to four miles (6.4 kilometres). Charges are attached to a jib arm above the lighthouse lantern and detonated electrically at regular intervals of from two to five minutes. Sometimes the charges incorporate magnesium to give a bright flare. Often bells up to one ton (910 kilograms) in weight are arranged to sound at predetermined intervals. At times this action is automatic, with the use of a piston-operated striker powered by a compressed gas cylinder.

Fog signals that depend upon compressed air for their operation and emit a continuous note are most effective. The Reed operates like a reed musical wind instrument. It emits a rather high-pitched note at about 500 hertz. Although efficient, it is limited in power and not much used. The Siren has a slotted revolving rotor and fixed slotted stator at the throat of a suitable horn. The rotor is driven by an electric motor, or by the compressed-air supply, which is chopped by the rotating member. The Diaphone works on the same principle but uses a reciprocating slotted piston in a cylinder with matching ports. The Tyfon has a vibrating metal diaphragm operated by a system of valves and differential air pressure. Sirens, Diaphones, and Tyfons produce a low note of about 150 hertz.

The larger sizes of Diaphones are the most powerful fog signals in existence, with ranges up to eight miles. They consume as much as 40 cubic feet (1.1 cubic metres) of air a second during blast, however, and require a large and powerful compressing plant of 50 horsepower or more.

Sector
lights

Fog signals

The Tyfon is an efficient, compact unit with low air consumption. It is common practice to mount a number of emitters in a vertical column, which concentrates the propagation of the sound in a horizontal direction and minimizes wasteful dispersion of sound vertically. Such an array can have an audible range of four to five miles (6.4 to eight kilometres).

With fog signals capable of emitting a continuous note, the station is distinctly identified, as with lights, by a pre-determined number of short blasts regularly repeated. The Diaphone is much favoured by mariners because it has a distinctive sound, with a short, low-pitched characteristic grunt at the end of each blast. A compressed-air fog signal installation at a lighthouse can involve a formidable amount of machinery such as air compressors and storage reservoirs for the air, valves, piping, etc. Operating air pressures range from 30 to 60 pounds per square inch (2.1–4.2 kilograms per square centimetre).

Electric fog signals, sometimes called Nautophones, are of the vibrating diaphragm type. A metal plate between the pole pieces of a magnet vibrates because alternating current passes through windings around the magnet. Nautophones usually produce a note of about 300 hertz. The most powerful emitters can handle one kilowatt of power, supplied from special alternators or solid-state, electronic-drive units. It is common practice to arrange these emitters in vertical columns, as for the Tyfon. Typical installations have a total power of four to six kilowatts and a range of three to four miles (4.8–6.4 kilometres).

The propagation of sound in the open air is somewhat haphazard due to the vagaries of atmospheric conditions, which greatly affect its acoustic properties. Humidity, turbidity, and temperature all have an effect, and layers of air of different temperature can deflect the sound up or down. Ranges of fog signals therefore can vary greatly from day to day and quoted figures must be treated with caution, as it is impossible to guarantee performance.

A useful system around 1930 relied on the transmission of sound waves through the water, giving greater range and consistency. Underwater fog signals of this type were virtually abandoned but they were again being seriously reconsidered in the light of the modern technology of sonar.

RADIO AIDS

Sophisticated and complex radio-navigation systems such as Decca and Loran are not properly within the field of lighthouses, though in some countries they are operated as part of the lighthouse administration (see NAVIGATION).

Two aids that are strictly complementary to a lighthouse are the radio and radar beacons. Many lighthouses are fitted with medium-frequency radio-beacon equipment operating around 300 kilohertz. These transmit a characteristic signal lasting one or two minutes, with the station identification repeated continuously in Morse Code. A long dash of 20–25 seconds during the transmission enables a ship to take a bearing with its radio direction finder. Depending on the sector of the world, transmissions vary from five minutes every hour to continuously in busy waters. In Europe where there are a large number of radio-beacons, they are arranged in groups of three on one frequency to avoid interference. Each station in a group transmits for one minute of every three. This enables the ship to take three bearings in quick succession and to obtain a fix by triangulation.

Radar beacons are known as racons. Their purpose is to increase the strength of the reflected radar pulse from a seamark such as a lighthouse, lightship, or buoy and to enhance its presentation on the ship's radar screen. They also identify it positively from other echoes on the radar picture. In the passive method, polyhedral clusters of metal sheets are arranged to reflect as much as possible of the radar pulse emitted by the ship's radar. The racon is an active device, consisting of a small microwave transmitter-receiver. The radar pulse is picked up by the receiver and retransmitted in an amplified form. It is also processed so that it appears in an unambiguous form on the radar screen, usually as a short bright line immediately behind the target that can be broken up into an arrangement of dots and dashes to provide better identification.

AUTOMATIC LIGHTHOUSES

A fair degree of automation was first achieved with the acetylene-gas system. Today, with the increasing use of electrical equipment, modern industrial automation techniques are being applied. In the automatic lampchanger, from two to six electric lamps are carried on a rotating carriage. The lamps are arranged to bring a fresh replacement into position and focus when the filament of the lamp in use burns out. Lighthouses are costly to operate and maintain. If light keepers can be eliminated and maintenance visits reduced, considerable money can be saved.

Much effort has been devoted to the development of fog-detecting systems, capable of automatically starting the fog signal when the visibility falls. A number of satisfactory instruments are in use.

Lighthouses, lightships, and buoys are by their very nature located in remote or inaccessible situations where it may be difficult to provide electric power from a public supply. For lighthouses and lightships, power is often generated in situ from diesel generators. For buoys and minor lights replaceable electric batteries are used. Alternative power supplies are being developed to provide long periods of unattended service. Wind generators have been successfully used. Fuel cells and radioisotope generators, the latter offering 10 years' operation without refuelling, are also being investigated. Solar cells have been successfully used in a number of cases for small lights in extremely inaccessible positions. Electric generators that utilize the energy of the oscillating motion of the buoy in the sea have been tried with some success.

Other seamarks

Lightships. Lightships originated in the early 17th century, arising from the need to establish seamarks in positions where lighthouses were at that time impracticable. The first lightship, established in 1732 at Nore Sand in the Thames Estuary, was rapidly followed by others. These early vessels were small converted merchant or fishing vessels showing lanterns suspended from crossarms at the mast head. Not until 1820 were vessels built specifically as lightships.

A modern lightship is constructed of steel, measures about 120 feet (37 metres) in length, and has a 25-foot (7.6-metre) beam (see Figure 34, left). A crew of seven is usual. The lightship carries a full range of lighthouse aids, including a powerful light, a compressed air or electric fog signal, radio beacon, and racon. The light is usually revolving-mirror equipment to save weight, and intensities up to 500,000 candles are common. Since a lightship rolls and pitches in the sea, lighting equipment is gimbal-mounted on a pendulum-stabilized platform to keep the light beams horizontal. Light vessels do not usually carry any means of propulsion; they are moored by a single chain and anchor from the bow. There have been a number of unmanned lightships, usually in the form of a boat-shaped float fitted with automatic acetylene light and gas-operated bell that are adequate in sheltered waters and where high-powered illumination is not required. A recent development is a large 40-foot (12-metre) diameter unmanned buoy, originally developed for oceanographic purposes, that can survive the worst open-sea conditions (see Figure 34, right). It carries an automatic diesel-engine power plant for its powerful light and fog signal.

Buoys. Buoys delineate channels in estuaries; approaches to ports and harbours; and mark isolated dangers, wrecks, and local areas of special significance. Constructed usually of 1/2-inch (1.27-centimetre) steel plate, they vary in size from five to ten feet (1.5 to three metres) in diameter and from one to nine tons (910–8,200 kilograms) in weight. Buoys are moored to a two- or three-ton concrete or cast-iron sinker by a single length of chain, which is ordinarily about three times as long as the depth of water at the mooring location. Smaller sized buoys recently have been manufactured in glass-reinforced plastic (glass fibre). Buoys are inspected at regular intervals and removed periodically for cleaning, painting, renewal of moorings, etc.

Cardinal and Lateral systems

information to the mariner. Buoys must conform to one of two internationally agreed systems of buoyage, drawn up by the League of Nations in 1936. Known as the Cardinal and Lateral systems, they designate specific shapes and colours for the various buoy positions. With the Cardinal system the form of the buoy indicates the bearing of the significant feature it marks; with the Lateral system buoys are laid along routes or channels to indicate on which side of the buoy the ship should pass.

In the more widely used Lateral system there are three main daymark shapes: conical, cylindrical or can, and spherical, and two main colours, black or red, alternated with white or plain. Lights are white, green, or red, showing specified characters. For additional differentiation, topmarks in the form of can, cone, sphere, diamond, tee, or cross can be mounted above the buoy. With unlighted buoys the body profile incorporates the daymark shape. The top mark, if any, is carried on a staff fixed to the top of the buoy. Lighted buoys have a cylindrical body with the daymark shape carried on a superstructure. The light and sometimes a radar reflector are mounted above the superstructure. The buoy measures about 14 feet (4.3 metres) from keel to top of superstructure, carrying the light about nine feet above the sea. In high focal plane buoys an extra high superstructure increases the range of the light. A long, cylindrical tail tube attached to the bottom of the hull promotes stability and makes the buoy about 36 feet (11 metres) from top to bottom.

Lights can be acetylene, propane, or electric. A small drum lens six to eight inches (15–20 centimetres) in diameter provides a light of 100 to 200 candles with a clear-weather range of five to six miles (eight to 10 kilometres). With electric lights a 12-volt, 6- or 12-watt lamp is typical.

Gas-storage cylinders or electrical batteries, enclosed within the cylindrical hull, power the buoy lights for up to two years without attention. The light can be extinguished during the day by a photoelectric day-night switch or a "sunvalve," in the case of acetylene equipment. Buoys are sometimes fitted with small electric fog signals with a range of about a half-mile (0.8 kilometre). Bells can be actuated in a random fashion by the motion of the buoy or regularly by a striker operated from compressed carbon dioxide. Buoys also can be fitted with whistles, actuated by the motion of the sea, which draws air into a central tube and expels it.

National lighthouse systems

Lists of lights. All lighthouse administrations publish Lists of Lights that are comprehensive catalogues of all lighthouses, lightships, buoys, and beacons under their control. These lists give the mariner the needed information regarding location and characteristics of the various lights. The major maritime countries publish light lists in several volumes, covering all the lights in the world. In the U.S. this is undertaken by the United States Coast Guard, and in Great Britain by the Admiralty Hydrographic Department. These bodies also publish charts on a worldwide basis with similar information. Light lists and charts are kept up-to-date with information supplied by the lighthouse authority concerned. The latter publicize changes to lighthouses, lightships, and buoys by issuing Notices to Mariners, available to all ships' masters. Where a change occurs at short notice, for instance in the case of an emergency or breakdown, radio broadcasts notify mariners of the change.

Lighthouse administration. In most countries lighthouse administration comes under the appropriate department of the central government, financed as part of the government budget from taxation revenue. In many countries a number of lights, buoys, etc., are operated and maintained by dock and harbour authorities, often financed from harbour dues.

In the U.S., lighthouses and other aids are administered by the Aids to Navigation Division of the United States Coast Guard under the Federal Department of Transportation. Altogether the Coast Guard operates and maintains 500 lighthouses and nearly 40,000 other aids to navigation.

In Great Britain lighthouses in England and Wales are administered by the Corporation of Trinity House, a public corporation independent of the central government. The system is almost unique in that the service is financed by "light dues" levied on all shipping at every port in the United Kingdom based on the registered tonnage of the vessel. It evolved from the early medieval practice where lighthouses were operated by private individuals as a business enterprise under a dispensation purchased from the Crown, the granting of patents to erect and operate a lighthouse being vested in the Monarch of the day. Trinity House evolved from an early guild or fraternity of Pilots. In addition to its lighthouse activities it is also the United Kingdom Pilotage Authority.

Trinity
House

The arrangement in its present form originated with the Merchant Shipping Act of Parliament in 1894, which abolished all privately owned lighthouses. It converted Trinity House into a public corporation with responsibility for all seamarks. Annual revenue from light dues is about £6,000,000; the Corporation maintains about 90 lighthouses, 34 lightships, and 600 buoys. Lighthouses in Scotland and Ireland are separately administered by the Northern Lighthouse Board and the Commissioners of Irish Lights. These are semi-autonomous bodies, financed from the same fund of light dues as Trinity House, which remains the ultimate approving authority for all United Kingdom sea marks. In nearly all other countries the

lighthouse administration is either a government body in its own right or operates as part of or in association with a main department or ministry, as follows: West Germany—Ministry of Marine; France—Lighthouse Service in association with the Ministry of Public Buildings and Works; Sweden—National Administration of Shipping and Navigation; Norway—Directorate of Lighthouse Services; Canada—Aids of Navigation Division, Department of Transport; Japan—Navigational Aids Department, Maritime Safety Agency; and Italy—Inspectorate of Lights in conjunction with the Public Works Department and Ministry for the Mercantile Marine and General Navigation. (I.C.C./Ed.)

WATER-SUPPLY SYSTEMS

Water-supply systems in their most comprehensive sense include all of the world's water resources, all of its water requirements, and the complex interrelationships among resources and requirements. As growing population and economic development increase demands for water, it has become imperative to plan optimum resource development in large areas. It is now common to consider the total of resources and requirements of entire river basins and of the lands adjoining river basins in planning.

This article deals principally with the history of water-transport technology and with modern city water-supply systems, which typically include works for the collection, transmission, purification, storage, and distribution of water for homes, commercial establishments, industry, and irrigation; and for public needs such as fire fighting, street flushing, and other municipal activities.

History

EARLY CIVILIZATIONS

Abundant archaeological evidence indicates the preoccupation of the ancients with water supply. The earliest civilizations arose along some of the world's great rivers: the Tigris and Euphrates, the Nile, and the Indus. The earliest innovation in man's development of water supplies beyond their natural state was doubtless the digging of shallow wells. Archaeological excavations have shown that the ancients had highly developed well-construction skills. As requirements for water increased and tools were developed, the wells were made deeper. The Chinese are credited with sinking wells more than 1,500 feet (457 metres) deep. The ancients also built water collection, conveyance, and storage works. These included surface storage reservoirs at water sources; canals and aqueducts (from the Latin *aqua*, "water," and *ductus*, "to lead") to convey water to points of use; surface and underground storage reservoirs near points of use (see above *Canals and inland waterways*); surface and underground storage reservoirs near points of use; and water-distribution systems. The ancients also had some understanding of water quality and of rudimentary water treatment, such as improving water quality by storage and by boiling and filtering.

Highly advanced water systems were built as early as 2500 BC by the Harappāns at Mohenjo-daro and other city dwellers in the Indus River Basin. These works included well-built brick-lined wells for many of the city habitation blocks and excellent sanitary-drainage systems made of burned brick. (O.K.)

The *qanāt*

From time immemorial *qanāts*, or tunnels, driven horizontally into hillsides, transported water by gravity to irrigate the plains of Persia. This construction was particularly important in areas where small amounts of water were transported great distances and evaporation was a serious problem. Before 500 BC the *qanāt* was known in India, Armenia, Egypt, and many Near Eastern countries. In Mesopotamia, clay tablets dating possibly to the 25th century BC make frequent reference to canals or reservoirs supplying cities between the Tigris and Euphrates rivers. Letters of Hammurabi (c. 1760 BC) refer to cleaning of canals. The Minoans, who flourished on Crete (c. 2000–1400 BC), had highly developed sanitary facili-

ties, flushed with water, presumably tied to an aqueduct system.

One of the best known early tunnel aqueducts was built about 700 BC under King Hezekiah to supply Jerusalem with water. Cut through solid rock, the conduit (1,750 feet, or 530 metres, in length and six feet, or two metres, in height) brought water from the spring of Gihon to the reservoir or pool called Siloam. Built about the same time (691 BC) under Sennacherib was the great Assyrian aqueduct of Jerwan, which joined earlier systems to bring water from a tributary of the Greater Zab to Nineveh, some 50 miles (80 kilometres) away. One of the most striking features of this system was a limestone bridge more than 900 feet (275 metres) long that carried the waters over a stream and valley. Standing 30 feet (nine metres) high in some places, this portion of the aqueduct had five corbelled arches in the centre and carried a channel exceeding 50 feet (15 metres) in width. It is estimated that over 2,000,000 blocks of heavy limestone were used in its construction. Employed for both irrigation and domestic purposes, this appears to be the earliest of significant public water supplies extant.

Another notable aqueduct, named by Herodotus as one of the three greatest of Greek engineering works, was that on Samos, probably dating from the 6th century BC. Built under the direction of Eupalinus of Megara, the first hydraulic engineer whose name has been preserved, the aqueduct consisted of a tunnel and a pipeline supported on stone pillars. This tunnel, some 3,300 feet (1,000 metres) in length and nearly six feet (two metres) square, was bored from both ends (the headings missed connections, resulting in a jog in the middle) through a mountain of limestone rock nearly 1,000 feet (300 metres) high. The water was carried through clay pipes laid in a sloped recess in the bottom of the tunnel.

Most ancient aqueducts simply conducted the water by gravity, free of pressure, in pipes, channels, or tunnels along the hydraulic gradient, gradually descending from a higher to a lower elevation. Thus, water channels were normally carried across valleys on piles of stones or arches. Introduced by the Greeks in Asia Minor and elsewhere, the siphon (a pressure pipeline or tunnel) was a new hydraulic device that could be used as a shortcut to cross steep valleys. Since it usually followed the contour of the ground down one side of the valley and up the other, it was, of course, subjected to greater pressures in its lower portions. The scarcity of good materials for piping and jointing obviously limited its use. One example of a sizable Greek siphon was that built at Pergamon c. 180 BC. The water was carried by gravity some 35 miles (55 kilometres) from mountain springs to two settling tanks at Aýios Yeóryios two miles (three kilometres) east of and about 130 feet (40 metres) above the city. From this point the water passed through pressure pipes that crossed two valleys—one of which was more than 600 feet (180 metres) below the reservoir—and an intervening ridge, ending at the citadel. Still standing are stone collars about four feet (1.2 metres) apart with holes approximately 12 inches (300 millimetres) in diameter that indicate the course of the line. The nature of the pipe material is unknown, but the fact that pressures up to 300 pounds per square inch (21 kilograms

Introduc-
tion of the
siphon

per square centimetre) had to be accommodated in the lower section seems to rule out clay or lead pipe. Speculation indicates bronze or possibly reinforced wooden pipes. In Roman times the siphon was replaced by an elevated system, less subject to leakage and more reliable.

IN ROME

Writing in AD 97, Sextus Julius Frontinus, water commissioner of Rome, exclaimed, "With such an array of indispensable structures carrying so many waters compare, if you will, the idle pyramids or the useless, though famous, works of the Greeks!" Today, nearly 2,000 years later, Roman aqueducts are still impressive largely because of their magnificent arches, which stand in many parts of Greece, Italy, France, Spain, North Africa, and Asia Minor. Not widely known is the fact that the course of these aqueducts was mainly underground. For instance, in the time of Frontinus the combined length of all aqueducts entering Rome added up to about 260 miles (416 kilometres), of which only 30 miles, or about one-ninth, were on arches.

The Roman water system. In general, Rome's water system, originating in the hills several miles from the city, was gravity fed, low pressure, and designed primarily to serve urban needs rather than those of the farm. The water was lowered gradually some 800 feet (244 metres) in elevation through a series of free-flowing conduits, in large part underground, to elevated distribution tanks in the city. These tanks (247 in 1st century AD) had no great storage capacity, for the system worked on the principle of constant takeoff. Overflow was regularly used for sewer flushing. At the tanks the system was converted from one of gravitational flow in conduits to that of a low-pressure supply in pipes. In building the conduits, trenching was employed where possible, but tunnels, the more expensive channels on arches, and even siphons on rare occasions were used. Tunnels, which might be 50 feet (15 metres) or more underground, had shafts at intervals of 240 feet (73 metres) or less, to prevent air locks and to permit inspection and cleaning. The conduits and pipes, depending on time and place of construction, were made of a variety of materials. There is evidence of stone-built ducts, open ducts of masonry, fittings of bronze, and pipes of stone, terra-cotta, wood, leather, and lead. In the older aqueducts, such as Appia, the channel was lined with cut stone walls made of a friable gray tufa called *capellaccio*. Tufa is porous rock formed as a deposit from springs or streams. A harder reddish brown tufa, cut stone, and varieties of local limestone appeared later. Still later, in place of expensive cut stone, a rough concrete was introduced, and various combinations of block and brick, mixed rubble, and reticulate (diamond-shaped stones) came into being for both channels and arches.

The channels varied in width from about a foot and a half to five feet (0.5–1.5 metres) and in height from three to ten feet (one to three metres). On the average, they measured three and one-half by six feet (1.1 by two metres) and were generally lined with two or three layers of fine cement. To keep out rain and debris and to hold down evaporation they were covered over with flat, vaulted, or gabled roofs. Very often the floors and the roofs of the channels were made of the more highly prized peperino or travertine stones.

Since the system operated by gravity, determination of the gradient was highly important. The Roman surveyors relied principally on a number of simple instruments: a plumb-bob level; the *groma*, which traced right angles; the *dioptra*, which measured horizontal angles and sighted on a levelling staff; the *chorobates*, a water level some 20 feet (six metres) long; and the *libra*, a simple water level. Their surveying competence is indicated by the gradients they achieved; for example, the duct of La Brevenne in France had a minimum slope of 1 to 1,400. Despite this capability and the 1 to 200 minimum recommended by Vitruvius, there seems to be no continuity or consistency in the fall from one section to another in the aqueducts entering Rome. Aqua Marcia, for instance, had grades varying from over 1 to 1 to those of 1 to 300.

The major aqueducts of Rome. During a span of over 500 years, from 312 BC to AD 226, 11 major aqueducts

were built across the plains of the Campagna around Rome to supply the city with water. In order of construction they were: Appia (312 BC), Anio Vetus (272 BC), Marcia (144 BC), Tepula (127 BC), Julia (33 BC), Virgo (19 BC), Alsietina (2 BC), Claudia (AD 52), Anio Novus (AD 52), Trajana (AD 109), and Alexandrina (c. AD 226). Here are brief notes on the 11:

Aqua Appia. Built under the direction of the censor Appius Claudius Caecus, this aqueduct in the time of Frontinus measured 11,190 Roman paces (52,320 feet, or 15,947 metres) from its spring source on the Lucullan estates to its distribution point in the city. Over 99½ percent of the line ran underground.

Aqua Anio Vetus. Financed by booty from the war with Pyrrhus, this was the first aqueduct to draw water from the upper valley of the Anio some 43 miles (69 kilometres) away. The contract for the work was let in 272 BC by the censor Manius Curius Dentatus and completed three years later. Its turbid and unwholesome waters, which flowed almost entirely underground, were directed to gardens and meaner uses.

Aqua Marcia. Marcus Rex, the Praetor, was commissioned by the Senate in 144 BC to restore the old aqueduct and to investigate new water sources. Four years later he completed Marcia, the longest and the first high-level aqueduct in Rome. Its waters were the best, deriving from three spring sources in the region of the upper Anio, about 57 miles (91 kilometres) distant. Though much of the channel was underground, cut through virgin rock, nearly 7,463 Roman paces (about seven miles, or 11 kilometres) were above ground. This work is considered among Rome's first notable experiments in arch construction.

Aqua Tepula. Named for the tepid character of its waters, which originated a few miles from the city at the foot of the Alban Hills, this aqueduct was brought in by the censors Gnaeus Servilius Caepio and Lucius Cassius Longinus. No remains of the original channel have been identified, but a new structure built by Agrippa in 33 BC continued to draw from the original springs but brought their water into the city on the arches of Marcia.

Aqua Julia. Built by the eminent engineer, Marcus Vipsanius Agrippa, this aqueduct tapped a group of rich springs some two miles above the headwaters of Tepula. It may have been built as early as 40 BC or as late as 33 BC, the year Agrippa extensively repaired and restored all preceding aqueducts. Julia also came into the city on the arches of Marcia.

Aqua Virgo. Largely to supply the new great public baths in the Campus Martius, Agrippa brought in this supply from springs on the Lucullan estates a little over eight miles from the city. The circuitous route, however, extended the length of the aqueduct to nearly 14 miles (22 kilometres). Frontinus claims this aqueduct was named in honour of a young girl who showed the springs to soldiers who were looking for a water source. Still in operation today, Aqua Virgo feeds the famed 18th-century fountain, the Fontana di Trevi, whose sculpture bears a representation of the legendary maiden.

Aqua Alsietina. In 2 BC Augustus built a huge basin across the Tiber measuring 1,200 by 1,800 feet (366 by 549 metres). Named the Naumachia, it was designed to stage mock sea battles. To supply this basin, Augustus tapped the Alsietinian Lake and channelled the unwholesome water over 20 miles (32 kilometres), almost entirely below ground.

Aqua Claudia. Caligula razed part of Aqua Virgo to make a site available for an amphitheatre. To compensate for this loss he directed the start of two new aqueducts in AD 38. Both were completed 14 years later, during the reign of Claudius. The first, Claudia, tapped a source close to Marcia but, with a length slightly over 40 miles (64 kilometres), was considerably shorter than Marcia. Improved engineering practices involving long tunnels and high bridges accounted for this advance. In the Claudian period the aqueducts reached their full development in height and magnificence. One of Claudia's bridges in the hills reached a height of 130 feet (40 metres). Originally more than 1,000 stately arches—some rising to a height of 90 feet (27 metres)—crossed the Campagna, and even to-

The
Naumachia

day some 350 of these *opus arcuatum* are still in evidence. *Aqua Anio Novus*. The companion to Claudia, this aqueduct originally drew its waters from the Anio River and the Rivus Herculaneus. Initially the quality of its water was poor, but after having its intakes shifted during the time of Trajan, it ranked just after Marcia in quality and quantity. Its original length is unknown, but during the time of Trajan it extended 54 miles (86 kilometres). In general it was the highest of the aqueducts, achieving a maximum height above the ground of 110 feet (33.5 metres).

Aqua Trajana. To serve the industrial quarter Trajan had this aqueduct built on the right bank of the Tiber, following nearly the same route as Alsietina. Five springs near the lake of Bracciano supplied this aqueduct, which ran no less than 35 miles (56 kilometres), mostly below the surface, though in some places its height above ground exceeded 108 feet (33 metres).

Aqua Alexandrina. This aqueduct was built to supply the luxurious bath in the Campus Martius built by the emperor Severus Alexander. Its water came from springs on the eastern edge of the Patano some 14 miles (22 kilometres) from Rome. Much of the channel was carried on arches that reached a maximum height of 68 feet (21 metres).

Seven of these aqueducts took their waters from springs, two from lakes, and two from rivers. They entered the city at various heights from about 238 feet (73 metres) above sea level down to 55 feet (17 metres) in descending order: Trajana, Anio Novus, Claudia, Julia, Tepula, Marcia, Anio Vetus, Alexandrina, Virgo, Appia, and Alsietina. Their lengths and quantities of water delivered varied, of course, with their state of repair and restoration, but the usual statistics given on them date to the end of the 1st century AD (Trajana and Alexandrina excluded).

Augmenting substantial archaeological evidence, much of the information comes from the treatise *The Two Books on the Water Supply of the City of Rome* by Sextus Frontinus (c. AD 35–104). After serving in many important posts, (including governor of Britain) he was appointed curator aquarum, water commissioner, by Emperor Nerva in AD 97. His treatise was a brief history of public water supplies in Rome, a detailed account of the system then in existence (nine aqueducts) and a commentary on his stewardship. It was begun shortly after he took office and was completed under Nerva's successor, Trajan. According to Frontinus, slightly less than one-third of all water delivered by the nine aqueducts was distributed outside the city, about 58 percent for private parties, and 42 percent for the emperor's disposal. Within the city the distribution approximated 44 percent to public uses (75 public buildings, 39 ornamental fountains, 591 water basins, and the legions' barracks), 37 percent to private parties, and 17 percent to the emperor. To measure water flow, Frontinus used the *quinaria*, whose introduction he attributed to either Agrippa (63–12 BC), the first permanent water commissioner of Rome, or to Vitruvius (1st century BC), engineer and author of the classic *De architectura*. *Quinaria* was the name given to a standard pipe, five quarter digits in diameter (0.728 inch, or 18.5 millimetres). It was also the term for a volume of water flowing through this standard orifice under "normal velocity." Since the velocity obviously varies, there is no way to determine how much water flowed, despite the large number of statistics generated by Frontinus. His American translator, hydraulic engineer Clemens Herschel, calculates that with all aqueducts running a daily total of 84,000,000 gallons (318,000,000 litres) was carried but that with diversions, leakages, outages, and theft perhaps only 38,000,000 gallons reached the inhabitants in the city. Based on an estimated population of 1,000,000, this indicates that the Roman engineers supplied 38 gallons (144 litres) per capita per day, a figure not uncommon in European cities of the 20th century.

Elements in the construction of the Roman system. Selecting a good source of water was, of course, of prime importance. Vitruvius observed that water was probably good if (1) the general health of the people living near the source was good; (2) the water could be sprinkled into a Corinthian vase or other good bronze without leaving a

spot; (3) the water could be boiled and then poured off without leaving sand or mud; (4) green vegetables could cook in it quickly; (5) the water was clear and moss and reeds were absent when it was flowing. He did not favour lead pipe because of the dangers of lead poisoning. Waters flowing into Rome were kept separated when there was a great difference in purity, so that Marcia was used primarily for drinking water, while Anio Vetus was used for such purposes as washing clothes.

There is little evidence that Rome's water was treated, though settling tanks were usually placed near the middle and at the ends of aqueducts, and *piscina* performed a kind of filtering operation by catching pebbles to keep them from clogging the pipes. Private treatment was no doubt used on occasion, for Pliny wrote that, "It was the Emperor Nero's invention to boil water and then enclose it in glass vessels and cool it in snow. . . . Indeed, it is generally admitted that all water is more wholesome when it has been boiled."

In the time of Frontinus five of the aqueducts had sufficient head to supply any part of the city, but illegal tapping sometimes disrupted the system. In the words of the water commissioner himself, "The cause of this is the fraud of the water men, whom we have detected diverting water from the public conduits for private use; but a large number of proprietors of land also, whose fields border on the aqueducts, tap the conduits; whence it comes that the public water courses are actually brought to a standstill by private citizens, yea for the watering of their gardens."

Frontinus indicates that the organization for maintaining the aqueducts shifted at the time of Agrippa. In the Republican period, censors and aediles were in general charge. They let the maintenance work out to contractors and then inspected the work. As the first water commissioner, Agrippa employed his own workmen—about 240 slaves. Later, when the Emperor Claudius brought his aqueduct into the city, he employed a gang of 460. Both gangs had foremen, masons, linewalkers, reservoir keepers, and other classes of workers.

Repairs, said Frontinus, were necessitated by age, weather, lawlessness of the owners of property through which the aqueducts passed, and poor workmanship in original construction—particularly in the later aqueducts. Tree roots were also a source of trouble, bursting top coverings and sides. Of particular concern were the arches, the hillside sectors, and the concrete linings of the channels, for injury to the latter resulted in leaks that damaged the sidewalls of the channel and the substructure.

Throughout the Roman period the aqueducts tended to be under almost continual repair or restoration. There are records of restorations taking place under Diocletian and Constantine early in the 4th century and under Honorius and Arcadius very late in the same century. Much of the system was destroyed when the Goths besieged Rome in AD 537, but Belisarius, Justinian's general who reconquered much of Italy, effected extensive repairs shortly thereafter. Two centuries later Pope Adrian I and after him successive popes into the 9th century and possibly beyond attempted partial restoration, but the whole system continued to decay and fell into disuse during the Middle Ages, when Rome declined to a fraction of its ancient population. In 1870 an English company tapped the sources of the Marcian aqueduct above Tivoli and brought in a supply in modern pipe. Three others of the old aqueducts have been restored for modern use: Acqua Vergine (Virgo), restored in 1570; Acqua Felice (part of Alexandrina), restored by Sixtus V in 1585, and Acqua Paola (Trajana), restored by Paul V in 1611.

Aqueducts elsewhere in the empire. Throughout what was once the Roman Empire there remain evidences of the same engineering genius that created the magnificent water supply for the mother city. It is likely that the remains of more than 200 of these old Roman aqueducts—many with arches more striking than those around Rome—are extant. Prime among them is Agrippa's Pont du Gard (c. 19 BC) near Remoulins, France, which was damaged by the barbarians in the 5th century AD but repaired in 1743. The structure itself, which rises to 160 feet (49 metres) above the valley floor, is only a small

Sources of information about Roman aqueducts

Selecting water sources

Figure 35: Roman aqueduct at Segovia, Spain, probably built under Trajan (c. AD 100–110). Still in use, the 2,700-foot structure carries water from the Río Frio to the city of Segovia.

Archivo Mas, Barcelona

section of 25½ miles (41 kilometres) of conduit, mostly underground, which was used to supply the city Nîmes from the Eure and Airon Rivers. Three tiers of arches support the water channel. Another spectacular example is the section of the Spanish aqueduct at Segovia (see Figure 35), built c. 100–110 during the reign of Trajan. Standing on slender piers of cut stone without lime or cement, the 2,700-foot (823-metre) structure dominates the city, rising some 119 feet (36 metres) above the streets on two tiers of arches. Near Carthage the aqueduct of Zaghuan, erected in Hadrian's time, has had a long and exciting existence, being wrecked by the Vandals, restored by the Byzantines, demolished by the Spaniards, and used in part again by the Bey of Algiers in the 19th century. Significant use of lead-pipe siphons is evident in Lyons, another site of some first-class aqueducts. These include Agrippa's Mont d' Or; the Craonne, probably built about the same time; the Brevenne, 1st century AD in the time of Claudius; and the Gier, later in the 1st century under Hadrian. Examples seem endless. Suffice it to say that long after the Roman Empire had died, its aqueducts remained to be used and admired and to serve as an inspiration for builders of subsequent ages. For the most part, the engineering works of the Romans were not surpassed until the 19th century.

IN THE MEDIEVAL WORLD

As the Roman Empire gradually fell apart, the strong central authority it represented, with its taxing and public works funding capacity, came to a halt. There were exceptions in a number of areas, of course. In 6th-century Byzantium, the surviving eastern portion of the Roman Empire, Justinian is credited with restoring and improving upon the water system built under Constantine. Outstanding features included an imposing arched conduit and two great underground reservoirs. One of them, the Cistern of a Thousand and One Columns (Binbirdirek; AD 528), was two stories high and measured 60 by 70 yards (55 by 64 metres). The other, which still holds the city's water supply, has 365 marble columns in 28 rows, each column over 40 feet (12 metres) high.

In the Arab world there are a number of substantial examples, among them the 9th-century, arched conduit built by Ibn Kātib al-Faighanī to bring water from the southern desert to the new city of Cairo.

Though remnants of Roman works remained in some of the larger urban centres in western Europe to be patched and used for centuries, most people were forced to return to wells and other local sources.

Clerics took the lead in matters material as well as spiritual. The earliest plans for a monastery water supply extant are those of the Benedictine Priory of Christ

Church, Canterbury, carried out by Prior Wibert about 1153. Wells already existing in the cloister infirmary and outer cemetery were used for reserve, and the main supply was brought from springs three-quarters of a mile (1.2 kilometres) from the monastery, to a circular conduit house, thence through a perforated plate that trapped large impurities, and by lead pipe through five settling tanks. It then crossed a moat on a bridge, penetrated the city wall, and entered the monastery, where it was conducted underground to various points such as lavatory basins. This type of work by the churchmen was widespread. Cistercian abbies had aqueducts in England, France, Germany, and Italy. Black Friars, Carmelites, Carthusians, Dominicans, Knights of St. John, and many other orders all developed respectable water systems.

Throughout medieval Europe, water supplies developed by the churchmen for their religious communities were expanded to serve the townspeople and ultimately passed to the control of the municipal authorities. One such example was that at Southampton, where in 1290 the Franciscan friars received a license to enclose the fountain of Colwell. Twenty years later they gave the use of their surplus waters to the town. By the 15th century the pipes were in disrepair, but the friars were too poor to maintain them, so the town took over the system. The dissolution of the monasteries in England in the 16th century and the decline of their influence elsewhere accelerated the transition to lay control, but the burgeoning of trade and the expansion of towns stimulated secular systems even before that time. Dublin had a water supply brought in at the expense of the town in the middle of the 13th century; in this case the town gave water to the monastery. Bruges in the 14th century was a flourishing city of some 40,000, served by a complete system of underground conduits to public cisterns and fountains. Built in the latter part of the preceding century, the system originated with a collecting reservoir near St. Bavon. From there the water was conveyed to the Bruges *waterhuis* where it was raised by an ancient pumping device, a man or horse-driven wheel with buckets on a chain, and distributed by gravity. Bruges was a wonder in its day, but its water system could hardly be compared to that of ancient Rome. Despite the proliferation and growth of towns throughout Europe, the art of supplying water made no significant advance until the forcer pump was introduced in the late 15th and early 16th centuries.

Originating in southern Germany and installed all over Europe by travelling specialists, this pump apparently was first developed to remove water from mines. Driven by river currents, large waterwheels—installed under bridge arches—were connected to wood forcers, covered with leather, which worked in barrels of wood or bronze. Before the 16th century, wheels over 20 feet (six metres) in diameter were in operation. The resulting system was usually not very reliable, for it provided an intermittent supply with varying heads, but it marked great progress in municipal engineering. Heretofore, main systems originated in an area elevated above the city, relying on gravity for their flow. Pumping devices such as the Archimedean screw and variations of the waterwheel were known in Greek and Roman times, but they were used only to lift water to cisterns to supply individual dwellings. Now, pumping machinery became a significant adjunct to municipal water systems. The shift from the gravity-flow to pressure systems was under way.

Development of modern systems

ACHIEVEMENTS IN LONDON

In London, the first forcer pump appeared in 1582 when Peter Morice, a Dutchman, installed an undershot waterwheel under one of the arches of London Bridge. He amazed the population by pumping Thames water over the steeple of St. Magnus the Martyr. He installed a second wheel under another arch, and soon five arches were being used to give London its first pumped supply. Lifted to a high square tower at the bridgehead, the water was distributed by gravity through lead pipes to the eastern end of the city. Morice's franchise, drawn up to last 500 years,

Dublin's
water
supply

Arab
aqueducts

River
Company

remained in his family until 1701. The works existed until finally demolished along with the old bridge itself in 1822.

Piecemeal attempts to supplement Morice's system were made as London, toward the close of Elizabeth's reign, neared a population of 150,000. The first large, successful, communal effort was made by Sir Hugh Myddelton, citizen and goldsmith of London, who formed the New River Company early in the 17th century. Completed in 1613 after a construction period of five years, the New River was an open ditch that drew its waters principally from the Chadwell near the town of Ware and flowed some 38¾ miles (62 kilometres) to a reservoir in London. Yet it was more than a long ditch. With over 40 sluices, crossed by more than 200 small bridges, the stream traversed several roads by elevated timber troughs lined with lead. One such, near Edmonton, was an overhead aqueduct 660 feet (201 metres) long and five feet (1.5 metres) deep. Another, near Islington, known as Myddelton's Boarded River, was 460 feet (140 metres) long and 17 feet (5.2 metres) high. These timber structures were replaced with clay embankments toward the end of the 18th century. At Islington the water is reported to have been raised by a "great engine," powered originally by sails and then by horses. Thirteen wells along the way augmented the supply which originally totalled 13,000,000 gallons (50,000,000 litres) per day and was subsequently doubled. In the city the company's distribution system ultimately included more than 400 miles (640 kilometres) of wooden pipe. The New River Company remained in existence until 1902 when the Metropolitan Water Board took over, ending the era of the great private companies.

Following the lead of the New River Company, more private water companies came into existence in London, mainly in the 18th and 19th centuries. In the early 18th century a private supply to middle-class houses was common, and some tenements were also served. By the middle of the 19th century practically every house had a cistern filled at stated times; but a constant 24-hour supply was not introduced until 1873, and 35 percent of the total supply was on an intermittent basis as late as 1891. In 1867 nine companies, drawing their water from wells in the Chalk, Hertfordshire, the Lea, and the Thames, supplied London with 108,000,000 gallons (409,000,000 litres) daily.

ACHIEVEMENTS IN PARIS

The first significant step toward a Paris municipal water supply came sometime before 1200 when the monks of St. Laurent and Saint-Martin-des-Champs built aqueducts to carry water in conduits of lead and terra-cotta to the populace and the monasteries. These sufficed as the city's water source, along with private wells and the river, until the 17th century. Henry IV engaged Jean Lintlaer, a Flemish engineer, to install at Pont Neuf a pumping system similar to that at London Bridge. Lintlaer's machine, which continued in operation for two centuries, included a large waterwheel and four pumps capable of delivering 120 gallons (454 litres) per minute, most of which was used to supply the gardens of the Louvre and Tuileries. About 1670 a similar machine with three pumps was erected at the Pont Notre-Dame. Largely to serve his gardens at Versailles, Louis XIV began two water-supply projects near Paris, which were of great moment in their day. The first, a pumping plant at Marly, raised water over a ridge and into the aqueduct 525 feet (160 metres) above the Seine, with an ingenious combination of 14 undershot waterwheels, a series of reservoirs, and 253 pumps arranged in three lifts. The second, a gravity-fed aqueduct to carry water from the River Eure, was started with great ceremony but never finished. In the 19th century, however, long aqueducts were built to bring distant waters to Paris. Particularly outstanding were the Dhuys Aqueduct, transporting spring waters 81½ miles (130 kilometres), and M. Belgrand's Vanne Aqueduct, carrying spring water from Villeneuve l'Archevêque, 106 miles (170 kilometres) southeast of Paris.

Projects of
Louis XIV

OTHER NOTABLE SYSTEMS

Many examples of Roman influence persist, particularly in southern Europe. At Coutances, France, ruins of a

Gothic aqueduct built c. 1277 may still be seen; at Limoges, France, a subterranean aqueduct dates from an earlier time. On Malta, the Order of St. John had a long Roman-arched aqueduct built from Notabile to Valletta in the period 1610–15. Lisbon is served by an aqueduct carried on pointed arches with a Roman design.

The Hispano-Roman influence spread to the New World in such structures as the Mexican aqueduct of Zempoala (1553–70), built under the direction of a Franciscan monk, and the arched structure at Rio de Janeiro (1750), later converted to carry streetcars.

In North America early waterworks developed similarly at about the same time as in Europe. The first public supply in Boston in 1652 consisted of spring-fed water conveyed by gravity through wooden pipes to a reservoir. In 1796 the Aqueduct Corporation brought water into the city from Jamaica Pond in Roxbury 4½ miles (7.2 kilometres) away, and in 1848 a supply of water was brought by gravity through an oval brick conduit 18 miles (29 kilometres) from Lake Cochituate, developed by J.B. Jervis and E.S. Chesbrough, to a reservoir in Brookline, Massachusetts.

Montreal pioneered waterworks in Canada. In 1800 a private company furnished spring water through wooden pipes from Mount Royal, and by 1815 water was pumped from the St. Lawrence to elevated reservoirs. Water from outside the city limits was finally brought in with the construction of the five-mile Canal Aqueduct in 1853–56. Built under the direction of Thomas C. Keefer, this aqueduct carried water from the river above the Lachine Rapids. This reaching out from the city limits to greater and greater distances became particularly pronounced in the 19th century when new materials and technical advances made such extensions feasible and economical. The main progress came in pumping systems capable of generating greater pressures, in the development of materials for handling higher heads, and in construction techniques, particularly tunnelling.

Aqueduct
in
Montreal

THE INTRODUCTION OF PUMPS

When the York Buildings Waterworks of London was established in 1691, a horse-driven wheel was employed to pump water from the Thames. Waterwheels, however, continued to provide the power for most of the large waterworks up to, and in some cases well into, the 19th century. From the 16th to the 18th century, small pumps were often made of lead with handles of iron; brass or wooden pumps were also seen. Practically all the larger pumps were wooden; a transition to iron in all sizes came about gradually during the 18th century. This was reflected in the first U.S. attempt to pump a public supply. In 1754 at Bethlehem, Pennsylvania, a Danish millwright, Hans C. Christiansen, forced spring water through log pipes to a wooden reservoir 400 feet away.

The use of steam followed closely behind the development of the cast-iron pump. Early workers were more concerned with removing water from mines than with pumping a public supply. Though intermittent attempts were made to apply the steam engine to water supply in the 18th century, no substantial results were achieved until early in the 19th century. At the York Buildings Waterworks the horse wheel was replaced by a Savery engine that, in turn, gave way about 1720 to a Newcomen engine, which was improved by John Smeaton. In 1787 an early Boulton and Watt engine was installed; such progressive London waterworks installations as Hull (1795), Marly (1803), and Chelsea (1810) followed.

From England steam pumping operations spread rapidly to other countries. In the U.S., the practice was introduced by Benjamin H. Latrobe, who installed pumps built by Nicholas J. Roose (1800) to raise the waters of the Schuylkill at Philadelphia. Thus in the 19th century the steam engine and cast-iron pipe ushered in the era of modern waterworks.

USE OF THE PIPE AND OTHER CONDUIT MATERIALS

Nearly all ancient aqueducts were free-flowing channels; modern engineering has supplemented these with large-diameter pressure conduits, in which the water flow is

completely enclosed and entirely fills the conduit or tunnel. Thus, conduits eliminate much of the large-scale construction the Romans needed to carry their aqueducts across valleys and depressions. Instead, the water flows under pressure (either by siphon or pumping) and follows the depressions, elevations and other topographic features of the aqueduct route. Because water in such an enclosed conduit exerts pressure in all directions, much of the history of the modern aqueduct concerns the search for suitable materials.

Wood. Though wooden water mains were used occasionally by the Romans, their main period of development came in the 17th and 18th centuries. Typical were the mains of London's New River Company that, for the most part, were bored elm logs with the bark left on, varying in bore diameter from two to 10 inches (five to 25 centimetres), in outer diameter from six to 13 inches (15–33 centimetres), and in length from 10 to 22 feet (three to 6.7 metres). The joints were of spigot-and-socket type, the smaller tapered end being coated with white lead and driven into the larger end that was reinforced by an iron band.

In 1855 A. Wyckoff of Elmira, New York, patented a wooden pipe banded with iron, steel, or bronze spiralled around the pipe. The outside was protected by an asphalt coating; the pipe could withstand pressures up to 172 pounds per square inch (12 kilograms per square centimetre). At about the same time, continuous wood stave pipes appeared. By 1851 B.H. Hall made pipes in 12-foot (3.7 metre) lengths of pine planks. A fine 20th-century example was the mile-long, 13.5-foot (1.6 kilometre-long, 4.1-metre) diameter continuous pipe built in 1913 by the Pacific Coast Pipe Company for the N.W. Electric Company of Portland, Oregon. Diameters up to 17 feet (5.2 metres) have been installed.

Cast iron. In the 16th century cast-iron cannons up to three tons were made; it is possible some water pipe of the same material was cast at about the same time. There are no records of its extensive use, however, until the next century, when more than 15 miles (25 kilometres) of mains were laid to supply Versailles. In 1901 some of these pipes were taken up and found to be of good grey iron, clean on the inside, and only slightly rusted on the outside. All about three feet (one metre) long, they were joined by bolted flanges.

Despite its early use by the French, cast-iron water pipe remained largely in the experimental stage throughout the 18th century. In 1745 the London Bridge Waterworks Company had more than 54,000 yards (49,400 metres) of wooden pipe, 3,860 yards (3,530 metres) of lead, and only 1,800 yards (1,646 metres) of cast iron. In the following year the Chelsea Water Company of London laid a cast-iron flanged pipe but was forced to re-lay it in 1791 because of defective joints. Joining trouble prompted Thomas Simpson of the company to design the first ball-and-spigot and lead joints in 1785. The ball-and-socket flexible joint was devised some years later (1810) by James Watt, while he was laying a main on the bed of the Clyde for the Glasgow Water Company. During the second half of the 18th century other sporadic attempts were made to change over to cast iron, such as that in Edinburgh where a lead line was replaced with a cast-iron main in 1755. In Dublin iron pipes were contracted for in 1797, more wooden pipes were laid in 1806, and, finally, a complete changeover to cast iron was started in 1809. Thomas Telford used cast iron in his aqueduct, which carried the Ellesmere Canal over the Dee at Pontcysyllte, some 20 miles (32 kilometres) from Chester, England. One thousand feet long, Telford's structure was a cast-iron trough 20 feet (six metres) wide and six feet (two metres) deep on 20 spans resting on tall masonry pipes.

During the early 19th century the changeover to cast iron was particularly rapid in England and in France. The practice spread to the United States when, in 1817, the Watering Committee of Philadelphia imported from England some cast-iron pipes to replace the old bored logs. The first waterworks in Cincinnati, established in 1820, utilized the new material but hung on to the old as well. A force pump, operated by a horse or ox treadmill,

pumped water through wooden pipes to a reservoir of oak timber, 160 feet (49 metres) above the river. From here the water was distributed in cast-iron mains, wood branches, and lead services. Nine years later Lynchburg, Virginia, installed cast-iron pipes in what was claimed to be the first modern high-pressure main. The use of cast iron was further extended in 1848 when Dr. Robert Angus Smith, an Englishman, patented a cheap, effective exterior coating for protection against corrosion. His mixture of gas tar, pitch, linseed oil, and resin is basically unchanged. The coating with a hydraulic cement mortar, both inside and out, on sheet-iron water pipes was invented about the same time by Jonathan Ball and was used for domestic supplies in 1845 at Saratoga, New York. Cast iron continues in favour today, though a number of other materials are proving competitive as technology advances.

Wrought iron and steel. Most development of wrought-iron and steel pipes for water carrying has been American. The first large-scale use made of wrought-iron pipes was in 1856 in certain hydraulic mining operations in California. Between 1862 and 1892 some 72 miles (115 kilometres) of wrought-iron pipe were laid as part of the San Francisco waterworks. In addition, a wrought-iron submarine pipe 13,800 feet (4,206 metres) in length was laid across San Francisco Bay. About 1890 soft steel began to supersede wrought iron in aqueduct conduits, particularly inverted siphons, a notable example being New York's Catskill Aqueduct, constructed early in the 20th century, which included 14 siphons totalling six miles (9.6 kilometres). These were rivetted steel pipes, encased in concrete and lined with portland cement mortar, up to 11 feet 3 inches (3.4 metres) in internal diameter. Larger steel pipes have since become commonplace, notably the 30-foot (nine-metre)-diameter pressure pipes at Hoover Dam. Continued advancement in welding techniques has contributed to the replacement of rivetted by welded pipe and, in general, has greatly expanded the use of steel pipe. Among steel's advantages are its larger size limits than cast iron, its resistance to rupture, its lack of joints (which increases watertightness), its lightness and ease of handling. It is particularly adapted to long-span, self-supporting structures.

Stone and concrete. Though terra-cotta and stone pipes were used in ancient waterworks, their inability to withstand high pressure has made them impractical for modern use. While steam pumping was still in its infancy, the Weymouth Water Company of Weymouth, England, experimented with stone pipes in 1797. The West Middlesex Water Company of London also tried them early in the 19th century, but results were unsatisfactory. A coarse glass, covered on the outside, was tried briefly in France, but was unsuccessful.

Reinforced-concrete construction came into favour for large inverted siphons early in the 20th century, notably two siphons in the province of Huesca, Spain, the Sosa Siphon and the Albelda Siphon (1909). The latter, larger one, built to accommodate a head of 97 feet (30 metres), measured 13.12 feet (four metres) in diameter, 2,363 feet (720 metres) in length, and 7.87 inches (20 centimetres) in thickness. A part of the Los Angeles Aqueduct (1913), 10 feet (three metres) in internal diameter, was constructed for heads from 40–75 feet (12–23 metres), and on the Catskill Aqueduct (1915) heads less than 50 feet (15 metres) were provided with reinforced concrete siphons, 7³/₄–17 feet (2.4–5.2 metres) in diameter.

Other materials. About 1915 cement-asbestos pipe began to appear commercially. Ease of handling, strength in tension and compression, and chemical inertness made it popular in water-supply systems. Other pipe materials in use, less important in the large pipe field, include lead, copper, fibrous compounds, and plastics.

These materials have been largely associated with pressure piping; many have also been used in varying degrees in nonpressure sections of aqueducts—covered or open conduits, tunnels, and canals. In long unlined canals loss by seepage can run as high as 30 to 40 percent. The search for more effective canal linings has involved use of masonry, hand-placed concrete, machine-placed concrete, mortar and plaster, asphaltic concrete, membranes, rubber and plastic sheets, compacted soils, and soil and chemical

Wyckoff's

Canal

The search
for canal
linings

sealants. Portland cement concrete is favoured for canal linings, but its relatively high cost encourages the search for effective substitutes.

TUNNELLING TECHNIQUES

The long modern aqueduct has been made possible not only through the improvement in materials and pumping operations but also through new techniques in tunnelling. The first significant progress in rock tunnelling was the introduction of black powder on the Canal du Midi, in France, in the 17th century. Dynamite replaced black powder and mechanical drills replaced hand drills in the latter half of the 19th century, while early in the 20th century hammer drills and mechanical loaders appeared, followed by detachable and tungsten-carbide bits. Later, full-face boring machines proved increasingly successful, even in hard rock. Where the estimated rate of linear advance in tunnelling through rock (diameters 15–30 feet, or 4.6 to nine metres) in the 17th century was only two feet per week, it increased to 100 feet (30 metres) by the end of the 19th century, and up to 800 feet (244 metres) after the advent of full-face boring.

Where tunnels are low pressure and run in hard, sound, unfissured rock, they are often left unlined, but a smooth lining of concrete in conjunction with the supporting of unstable ground and sealing of fissured places by injection of cement grout is generally necessary. A notable pressure tunnel is the Eucumbene-Tumut Tunnel of Australia, part of the Snowy Mountains irrigation-water-hydroelectric project; 14 miles (22 kilometres) long, with a 21-foot (6.4-metre) finished inside diameter, the tunnel has a concrete lining 18 inches (46 centimetres) thick reinforced and supplemented, as ground conditions require, by heavy reinforcing steel rods, steel support beams and roof support anchor bolts, the surrounding rock being pressure grouted with cement.

Hydraulically, the most efficient cross-sectional shape is the semicircle running full. In a closed conduit, the most efficient shape is the circle running full, but it is less efficient than any reasonably shaped open channel. Most pipes are circular, but canals—due to construction restrictions—are generally trapezoidal. Concrete-lined tunnels are generally circular or horseshoe-shaped to permit equipment access. In modern work the rectangular shape, favoured by the Romans, appears rarely under specialized conditions. (See below *Tunnelling and underground excavation*.) (C.J.M.)

Principles of modern water-supply technology

WATER REQUIREMENTS

In addition to domestic needs, urban water-supply systems must meet public requirements for fire protection, irrigation of parks, and waste removal and industrial requirements, chiefly for cooling. In the United States water requirements average about 100 gallons (380 litres) per capita per day in residential communities and about 150 gallons (570 litres) per capita per day in industrial communities. The 150-gallon rate consists of: domestic use, 50 gallons; industrial use, 65 gallons; public use, 10 gallons; waste, 25 gallons. These rates are averages, subject to wide variation in different localities; extreme rates may range from 35 to 500 gallons (130–1,890 litres) per capita per day. Water requirements in England and Europe are substantially below those in the United States and in less developed countries may be as low as five gallons per capita per day.

These rates reflect withdrawals by the water-supply system. Seventy percent or more of the water withdrawn by an urban water-supply system returns as streamflow or to groundwater drainage. The water that does not return in this manner is said to have been used consumptively, largely through evaporation and transpiration.

Demand for public water supplies fluctuates seasonally, daily, and hourly. High water demands occur in the summer, for example, when water is used for irrigating lawns and for air conditioning and refrigeration. Household and industrial activities vary widely during different days of the week, and these variations are reflected in varia-

tions in water demand. Hourly fluctuations in household and industrial uses commonly produce peak requirements during the day. The approximate magnitude of these fluctuations must be estimated in order properly to design a water-supply and distribution system. In addition, allowance must be made for sudden heavy demands for water required for fire protection. The volume of water used for fire fighting is relatively small, but the rates at which water has to be supplied for this purpose are high. In small- and middle-sized North American communities, the requirement for fire protection frequently determines the capacity of the distribution system.

The monthly, daily, and hourly variations in demand are relatively greater in small water-supply systems than in large systems. They may also vary widely among cities because of differences in climate and industrial requirements.

WATER SOURCES

The total amount of water on the earth is fixed and has a volume of some 326,000,000 cubic miles or 1,100,000,000,000,000 acre-feet (one acre-foot = 1,234 cubic metres). Of this, it is estimated that 97.2 percent occurs in oceans and inland seas, 2.2 percent in ice caps and glaciers, and 0.6 percent is liquid fresh water. Most of the liquid fresh water occurs as groundwater, as shown in Table 1.

Table 1: Distribution of Liquid Fresh Water

location	cubic miles	million acre-feet	percent
Groundwater	2,000,000	6,760,000	97.74
Lake water	30,000	101,500	1.47
Surface soil water	16,000	54,000	0.78
River and stream water	300	1,000	0.01
Total	2,046,300	6,916,500	100.00

Terrestrial water is in continuous circulation. Great quantities evaporate from the ocean and land surfaces each year. The water vapour is held temporarily in the earth's atmosphere until it returns to the earth as precipitation. Much of it falls directly back into the oceans, but about 80,000,000,000 acre-feet of water annually falls back onto the continental land masses in the form of rain or snow. Most of the precipitation goes into groundwater storage or re-evaporates from the land surface; about 16,000,000,000 acre-feet enter the world's river systems each year. This represents 4.6 acre-feet of water per year for each of the slightly more than 3,500,000,000 people on earth or 4,000 gallons (15,000 litres) per day, an amount far in excess of present per capita requirements.

Overall average water-supply figures can be misleading because of the great regional imbalance of water supplies and wide variation in streamflow and precipitation. Despite the known abundance of water on the earth, man is almost continually faced with shortages because the water is not available at the times and places where it is needed. Many of the world's rivers discharge a large part of their runoff as flood flows that cannot be used economically or conserved. Populations have grown and regions have been developed where readily usable water supplies were inadequate. On the other hand, the Amazon River discharges one-sixth of the world's river flow to the oceans from a very thinly populated watershed. Much of the world's groundwater occurs either at great depths or in sparsely populated areas, both conditions that preclude economic development.

Water sources may be classified as either surface water or groundwater. Surface water includes rainwater collected from structures or prepared catchments and water from rivers, natural lakes, storage reservoirs, and oceans. Groundwater sources include natural springs, shallow wells, deep and artesian wells, and horizontal galleries and wells. Of these sources, rainwater, water from oceans, and water from groundwater sources are least used as major water sources for large modern cities. The desalting of seawater and other highly mineralized water, however, is being increasingly developed, as is the reuse of waste waters.

Both surface-water and groundwater sources are used for community water supplies. There is a strong tendency

Surface and groundwater

Demand fluctuation

for large municipalities to seek surface-water sources, but groundwater lends itself more readily to smaller community water-supply development.

WATER QUALITY

The quality of water from different sources varies widely. Precipitation absorbs gases from the atmosphere and removes particles from the air. As precipitation strikes the ground it becomes surface-water runoff or enters the ground. The surface water flows into larger and larger channels, ponds, lakes, and rivers until some of it reaches the sea. In its course, surface water picks up organic material, including bacteria, as well as minerals, salts, and other soluble substances. Water in lakes and swamps may acquire odours, tastes, and colours from decaying vegetation, algae, and other organic matter.

Water that enters the ground passes through earth containing organic and mineral matter, and it may absorb minerals and exchange gases. Oxygen usually is lost and carbon dioxide acquired. Hydrogen sulfide and methane may be absorbed. Carbonates, sulfates, and chlorides, iron, manganese, and fluorides may be acquired.

Pathogenic bacteria and viruses must be eliminated in any water-supply system. The source of pathogenic bacteria and viruses is the human body and the bodies of certain other warm-blooded animals. The disease organisms are most commonly transmitted to water supplies by fecal contamination. The most common waterborne diseases are typhoid fever, bacillary dysentery, and cholera. Water also is known to carry other specific diseases and is suspected of carrying some of the less well understood viral diseases.

Toxic chemicals that must be eliminated from water include lead, arsenic, selenium, chromium, cyanide, cadmium, and barium. Nitrates may be dangerous to infants. Fluorides in low concentrations benefit human health by reducing dental caries but in high concentrations may endanger health.

Pollution of water supplies by radioactive materials has recently become an increasing cause of concern. Some radioactivity is present naturally, but the industrial use of radioactive materials has increased the probability that these substances will be put into water supplies in increasing amounts. Radioactive substances emit alpha, beta, and gamma radiation, all of which can be injurious. Strontium-90 and radium-226 are particularly harmful to human health, and their concentrations must be kept very low.

Other constituents and characteristics that can make water unacceptable include total-solids content, colour, turbidity, off taste or odour, iron, manganese, copper, zinc, calcium, magnesium, sulfates of magnesium and sodium, chloride- and hydrogen-ion concentration, phenolic substances, carbon chloroform extract, and ethyl benzyl sulfonates, and other wastes not readily degradable. Products such as detergents, artificial fertilizers, and insecticides become pollutants when they get into water-supply systems. Efforts are being made to eliminate these pollutants, either by higher level plant-waste treatment of the products or by development of alternate products, such as biologically degradable detergents, which are quickly reduced to harmless forms by natural processes.

COLLECTION, TREATMENT, AND DISTRIBUTION

The planning, designing, financing, building, and operating of modern community water-supply systems are becoming more complex as new materials and techniques are developed and as competition for water sources becomes more intense. In addition to the extensive engineering problems, legal, political, social, and industrial matters have become increasingly involved. Where an adequate source of good water is readily available, community collection and purification works can be simple. If water can be withdrawn from natural lakes, ponds, or large rivers with dependably adequate flows, direct intakes may be used. Offshore intakes are usually used in lakes to obtain a better quality of water and to minimize freezing problems in cold climates. Such intakes are connected to the shore by tunnels or pipelines. On many rivers it is necessary to build diversion dams to insure that sufficient water will be available during all seasons of the year. Under unfavourable conditions,

elaborate collection and purification systems are required, usually including extensive water-storage facilities, long aqueducts, and complex water-purification works.

Water-collection works must draw from sources with sufficient volume to meet both the existing requirements and those reasonably expected to arise in the near future. Should a community seek an additional supply, its requirements and those of all other water users who will draw water from the same source must be considered. The consideration of uses and projected uses is particularly important in any area where withdrawal is approaching the limits of dependable supply. In the development of surface-water supplies, it may be necessary to provide storage capacity near the point of collection so that seasonal, often annual, water surpluses can be stored for release during low-flow periods. Groundwater sources cannot be developed in excess of their natural recharge rates without progressively lowering groundwater levels, unless the recharge rate is increased artificially.

Dams. Storage reservoirs or dams are usually constructed at or near points of water collection to ensure a dependable supply. Many reservoirs are intended for multiple use, including public water supply, irrigation, navigation, hydroelectric power, flood control, and recreation. Dams may include holdover storage capacity to provide sufficient water supplies during long periods of drought when stream flow may be grossly deficient.

Water-supply dams usually are of either the embankment or the masonry type. Embankment dams are constructed of earth, rock, or a combination of the two; they are well adapted to sites where the foundation may not be suitable for a masonry dam. Earth-embankment dams usually are built as compacted fills, and rockfill dams largely as dumped fills. Compacted fills consist of successive layers of earth materials that have been consolidated mechanically. The hydraulic-fill method of building earth dams largely has been superseded by mechanical placement methods. Rockfill dams consist of a relatively narrow-compacted central core covered by loose rockfill on both sides. Large masonry dams commonly are concrete and are either gravity, arch, or buttress types. Concrete dams are preferred where the site is relatively narrow and deep, is located on competent rock, and where there is a nearby source of suitable concrete aggregates. Sites suited to the construction of concrete dams are found less frequently than are sites for embankment dams. (See above *Dam*.)

Aqueducts and conduits. Water diverted by collection structures must then be carried by conveyance works to the site where it is to be used. Conveyance works may consist of either open or closed conduits or combinations of the two. Canals and flumes are open conduits that follow the hydraulic grade line, winding through irregular landscape much like railroads and highways. Closed conduits, such as aqueducts (see above), pipelines, and tunnels, may also follow the hydraulic grade line, in which case they are called grade structures, or they may operate under pressure. Grade tunnels are used to shorten otherwise excessively circuitous grade aqueducts. Pipelines are usually operated under pressure and closely follow the ground's surface. Aqueducts and tunnels may also operate under pressure. Pressure aqueducts commonly are used to cross rivers and valleys; pressure tunnels are used to shorten routes. Conduits may consist entirely of tunnels where the route would otherwise have to traverse rugged terrain. Pressure tunnels frequently are used for intakes from large lakes and reservoirs.

Tunnels may be unlined, if they are in exceptionally good rock, or lined with concrete. Grade aqueducts and tunnels usually are built to a horseshoe-shaped cross section to facilitate construction. Pressure aqueducts, pipelines, and tunnels are of circular section for structural reasons. Pipelines are made of cast iron, steel, cement, asbestos, or precast, reinforced pipe units. Wood also is used, although its use is diminishing; plastic materials have been introduced in small-diameter lines. Cast-iron and steel pipelines are protected against corrosion by coatings of bitumen or cement, or they may be protected against corrosion by cathodic protection. The protection of metallic lines by use of some of the new plastics is increasing.

Planning of water-supply systems

Construction and materials of conveyances

Potential contaminants

Treatment plants. Water that has been collected and conveyed to its point of use is treated to make it hygienically safe, attractive, and palatable, and economically suited for its intended uses before it is distributed. The term treatment may refer to a variety of processes, including long-period storage, aeration, coagulation, sedimentation, softening, filtration, disinfection, and other physical and chemical processes. Water-treatment works include different processes in varying combinations, depending primarily on the characteristics of the water source but also on intended use.

Long-period storage of water, which generally means storage in excess of one month, usually takes place in reservoirs or settling basins through which the water passes before it enters the treatment plant proper. Storage reduces suspended sediment and bacteria.

Storage
and
aeration

Aeration, the process of mixing air with water, is accomplished by contact bed or spray, cascade, multiple-tray, or air-injection aerators. Spray aerators force water through nozzles into the air. Cascade aerators consist of a series of steps over which the water falls. In multiple-tray aeration, water falls through nozzles in a series of vertically stacked trays. Contact beds are similar to multiple-tray aerators except that the vertically stacked trays are filled with gravel or some other contact media over which the falling water flows. Air-injection units consist of equipment to force small air bubbles through the water. Aeration is used primarily to reduce odours and tastes, to reduce hardness and corrosiveness by removal of carbon dioxide, and to eliminate iron and manganese.

Alum, sodium aluminate, ferrous sulfate with lime, chlorinated copperas, ferric chloride, ferric sulfate, and often other substances are added to the water, to aid coagulation. The addition of coagulants causes the colloidal, colour, and mineral particles to agglomerate into a settleable floc. Coagulation is usually accomplished in two stages: rapid mixing of the coagulant with the water and extended slow mixing during which the settleable floc is formed. The floc is then settled out by gravity in settling basins. Coagulation and sedimentation reduce the bacteria content of the water and are particularly effective in reducing colour and turbidity, while indirectly reducing odours and tastes. Some coagulants, however, may increase the hardness and corrosiveness of the water.

Softening is the process of removing calcium and magnesium from the water either by chemical precipitation or by ion exchange. The most widely used process is lime-soda softening, in which lime and soda ash are added to the water to cause calcium carbonate and magnesium hydroxide precipitation. Sedimentation follows the addition of chemicals to permit the precipitates to settle. After the addition of lime or lime and soda ash, the softened waters are unstable and require stabilization by recarbonation or other means.

In the ion-exchange process, water is passed through beds of ion-exchange resins or carbonaceous ion-exchange materials. Cation exchangers, which exchange their sodium ions for calcium or magnesium ions in waters, commonly are used. The action is reversible, and the cation exchangers are regenerated periodically with a salt solution. Both water-softening methods are effective, and the lime-soda

process also reduces bacteria, turbidity, odours and tastes, and iron and manganese.

Water filtration includes slow-sand filtration, rapid-sand filtration, and microstraining. In slow-sand filtration, low turbidity raw water or settled water is passed directly into beds of fine sand underlain by gravel and an underdrainage system. The sand beds remove suspended matter from the water. Rapid-sand filters allow the water to flow through larger grain sand at much faster rates but are otherwise similar to slow-sand filters. For rapid filters to be effective, prior treatment of the water by coagulation and sedimentation usually is necessary. Rapid-filter beds may be made of silicas and crushed quartz, or crushed anthracite coal. Both slow and rapid filtration reduce colour and remove iron and manganese, bacteria, and turbidity. Odour and taste are reduced as an indirect result of rapid-sand filtration. Modern water-treatment plant designs favour rapid-sand filters over slow-sand filters. Both types of filters require periodic cleaning.

Filtration
and
straining

Microstraining removes algae and other microparticles from water, usually prior to rapid-sand filtration. Microstraining can greatly increase the length of the rapid-sand filter runs. The microstrainer is a rotating-filter drum covered with a fine stainless-steel mesh having apertures of less than one micron in size. Water passes from the inner section of the unit outward, and the screen is continuously cleaned by a water spray at the top.

Chlorine is most commonly used for the disinfection of water, but ozone and ultraviolet radiation treatment are also used. Chlorine is applied both before filtration, the prechlorination, and as the final water treatment before distribution, the postchlorination. Most large treatment plants use liquid chlorine; usually it is added to the water in amounts that will ensure a small free chlorine residual throughout the water-distribution system. Chlorination is effective in destroying bacteria and inactivating viruses as well as in reducing faint odours and tastes in water; but chlorine causes problems by combining chemically with organic compounds. In the presence of intense odours and tastes, chlorination cannot always be employed because it may produce unpleasant-tasting by-products.

Chlorina-
tion

There are a number of special water-treatment processes in use. Copper sulfate is used for algae control. Activated carbon removes many organic chemicals and odours. Ammonia with chlorine is used for chloramine disinfection and odour control.

Efficiency and dependability are increased in modern water-treatment plants by automation and centralized control. A typical municipal water-treatment plant is shown diagrammatically in Figure 36.

Certain industries cannot use the water supplied by a community system directly but must provide additional specialized water treatment needed. An example of such treatment is the softening and other treating of water to prevent the formation of scale in boilers.

Desalting. As the competition for water resources becomes more intense, increasing attention is being given to waters that are widely available but unusable because of their salt content. In addition to ocean waters, these include brackish waters in inland seas, waste waters, and highly mineralized groundwaters. Desalting is presently

Figure 36: Stages in the purification of water in a modern treatment plant.

accomplished mainly by distillation processes, membrane processes, or crystallization processes but may also be accomplished by ion-exchange or solvent-demineralization methods.

Commercial desalting is most commonly based on evaporation and subsequent condensation of water. Large distillation plants are in regular operation in areas where freshwater sources are not economically available. Distillation processes currently in use include multistage-flash evaporation (multiple-effect distillation), vertical-tube evaporation, vapour compression, and solar distillation. The largest desalting plants in commercial operation use the multistage-flash evaporation process or vertical-tube evaporation. Vapour compression is used primarily in small portable plants; solar distillation is used only in relatively small plants in remote locations.

Membrane
processes
for
desalting

The membrane processes for desalting include electrodialysis and reverse osmosis. In electrodialysis an electric current is used to drive the positive and negative ions in mineralized water through semipermeable cationic and anionic membranes that retain the water, thereby decreasing the salt content of the water between the membranes. Semipermeable membranes are also used in the reverse osmosis process. Here, the natural process of osmosis is reversed by applying pressure to mineralized water that is in contact with an osmotic membrane. The membrane permits water to pass through but impedes the passage of ions, thereby desalting the water. The pressure applied in this process must be higher than osmotic pressure. Improved membranes are being developed for both the electrodialysis and reverse osmosis processes, and pilot plants using both processes are in operation.

The crystallization processes are freeze separation and hydration. The freeze-separation process takes advantage of the fact that under proper conditions salt water can be frozen to produce salt-free ice, which then can be separated from the salt water and melted to obtain desalted water. The hydration-separation process is similar, but it uses hydrate-forming materials that can be crystallized to include water and exclude salt. When the hydrated crystals have formed they can be separated from the concentrated salt water, and the fresh water can be recovered from the crystals. The hydrate-forming material can then be reused. Pilot plants using both of these processes are in operation.

Salt can be removed from water by passing it over materials that will selectively absorb salt. Granular exchange materials will absorb salt in a process similar to that for water softening and thereby produce desalted water. The process has been used in small specialized installations, but not in large-scale operations because of the high cost of regenerating the available materials. Certain liquids or solvents will selectively absorb water and exclude salts. After the solvent has absorbed water, it is separated from the remaining salt water and the desalted water extracted. The solvent can be reused. Pilot plants using this process are in operation.

Cost con-
siderations
in desalting

The first large land-based seawater-desalting plant was built in Kuwait in 1949, with a capacity of 1,200,000 gallons (4,500,000 litres) a day; this was increased to 5,000,000 gallons daily in 1958. Since then, the cost of desalting has been substantially lowered as a result of larger plant construction and use of improved materials and processes developed from operating experience and research. Costs also have been reduced where desalting plants could be combined with electric-power generating plants, thereby achieving better overall fuel utilization. Combining desalting plants with nuclear generating plants is particularly advantageous, an advantage that will increase when commercial nuclear breeder reactors become available. Combining different methods of desalting into a single installation also has been found worthwhile, and such combined process plants may be expected to increase. Of the new processes under development, electrodialysis, reverse osmosis, and freeze separation appear promising. Further decline in desalting costs will result from refinements in plant design, development of more economical materials, increased plant size, and more dual-purpose desalting and electric generating plants. New processes under development are not expected—in the foreseeable fu-

ture—to replace the distillation processes in large seawater-desalting plants.

Distribution. Water-treatment plants usually have pumps to transmit treated water directly to the distribution system under pressure or to lift the water to main distribution reservoirs. A distribution system includes pipes, valves, hydrants, and their appurtenances for conveying water; storage, equalizing, and distribution reservoirs; service pipes to consumers; and meters.

The fundamental purpose of a distribution system is to supply uncontaminated water to all parts of the system with adequate pressure under all operating conditions. Pressures must be sufficient at all times to meet the requirements of the consumers and to meet sudden increases in demands for uses such as fire fighting. Unduly high pressures, however, lead to excessive losses from the system and require unnecessary expenditures for equipment and operation. Since more than half of the cost of community water supplies is invested in distribution systems, they must be designed carefully. By including reservoirs in the distribution system for storage of water, pressure equalization, or to equalize rates of flow, the cost of pumping equipment and pipelines can be reduced.

Pressures between 30 and 100 pounds per square inch (two to seven kilograms per square centimetre) are usually provided in water-distribution systems. Forty to 50 pounds per square inch (2.8–3.5 kg/cm²) will satisfactorily supply water to the upper stories of four-story buildings. For fire fighting recommended water pressures range from 75 pounds per square inch (5.3 kg/cm²) in heavily built-up areas where fire-pumping engines are not used to a minimum of 10 pounds per square inch where pumping engines are used.

The majority of water-distribution systems are laid out in gridiron or loop patterns to obtain the most economical installation, but these cannot always be maintained as systems are extended. Distribution pipes usually are made of cast iron, ductile iron, steel, concrete, or asbestos cement. Small service pipes may be made of copper. Plastic pipe is being used increasingly in the smaller sizes. Cast-iron pipe is used for most water-distribution systems, and it has an excellent record of service over extended periods. Bell and spigot joints filled with lead are used for underground pipes, and elsewhere flanged, bolted joints are used. The use of lead-filled joints is decreasing as other materials and joint types become available. To prevent pollution of the treated water in a distribution system, positive pressure must be maintained at all times so that any leakage will be outward from the system and not into it.

TYPICAL WATER-SUPPLY SYSTEMS

Modern cities with growing populations and increasing water requirements often face difficult water-supply problems. Works must be planned, financed, designed, and constructed in time to meet rising water demands. The problems are particularly acute in areas of low precipitation and high water use. Typical of such cities is Denver, Colorado, located in a semi-arid part of the western United States. The total water requirements in the Denver area for municipal, industrial, and agricultural water supply greatly exceed the water supplies that are locally available. Long ago, Denver, as well as other cities in the area, fully developed the local surface waters by providing extensive reservoir storage capacity. Groundwater sources in the area are not adequate for large-scale development. Without sufficient water, the area faced economic stagnation; so, after the local supplies had been exploited, Denver began to reach out for water from distant sources.

Denver is located east of the Rocky Mountains, which divide the continental United States into two watersheds. All precipitation falling on the eastern slope of the Rocky Mountains flows eastward toward the Gulf of Mexico, and all precipitation falling on the western slope flows westward toward the Gulf of California or the Pacific Ocean. Precipitation on the higher elevation watersheds of the western slope is many times greater than on the eastern slope, and excess water is available there. Denver first constructed works to effect the transbasin diversion of water from western-slope sources in 1936. These diversions

The water-
supply
program
of Denver,
Colorado

and other works have since been expanded. In the present system, water is collected at high elevations from several river basins on the western slope of the Rocky Mountains and is conveyed by gravity through canals and tunnels across the Continental Divide to the eastern slope. Two major tunnels carry water eastward under the Continental Divide: the longer is 23.3 miles (37.3 kilometres).

Two major reservoirs were constructed in the western-slope watersheds to store excess streamflow, both for diversion in quantity and to provide water for western-slope uses in exchange for the water diverted. At one of the reservoirs a hydroelectric power plant was constructed to replace the power that was lost at other western-slope hydroelectric plants as a result of the diversion.

Water diverted from the western-slope watersheds is released into stream channels on the eastern slope, through storage reservoirs, diversion works, and conduits, and into the Denver water-treatment plants and distribution system. Six reservoirs have been built on the eastern slope for the long-term storage of water, in addition to four operating reservoirs. The total system reservoir capacity exceeds 600,000 acre-feet. Three treatment plants filter and sterilize the water. The distribution system comprises a number of pumping stations, nearly 1,500 miles (2,500 kilometres) of transmission and distribution mains, and distributing reservoirs. The resources required to develop the Denver water-supply system, with its extensive transbasin water collection and conveyance system, can be seen by comparing the \$14,000,000 value of the system in 1918 with its present \$225,000,000 value. The system served a population of more than 700,000 in the late 1960s.

In contrast with the frequently complex water systems of large cities, rural water-supply systems can be very simple. Rural water-supply systems usually serve small populations. Groundwater sources are widely available and frequently utilized. A typical small rural water-supply system using a groundwater source is shown diagrammatically in Figure 37.

Figure 37: Small community water-supply system.

COSTS

Water has been popularly viewed as a nearly free commodity, which it is not; but it is a cheap commodity, considering the extensive conveyances and complex processing involved in delivering the product to the consumers. In the United States, the average cost of water is seven cents per ton (910 kilograms) out of the tap, or 29 cents per thousand gallons (3,785 litres). The cost of the water-supply systems varies with the distance from, and the characteristics of, the water source, construction conditions, the size of the works, and the characteristics of the community to be served.

In many parts of the world, and particularly in rural areas, nearby sources of suitable water can be developed to meet local requirements at low cost. Where a single well supplies an entire village, for example, the cost of development may be only a few dollars per capita. In more highly developed areas the cost is usually higher because water-quality standards are usually more exacting, treatment and distribution facilities are more complex, and less suitable sources must be utilized. As more distant sources are developed, large expenditures are required for

the construction of storage and conveyance works. The cost of large modern water-supply systems averages about \$350 per capita and can be much higher. The total cost of a water-supply system is made up of approximately 25 percent for the collection works, 10 percent for treatment facilities, and 65 percent for the distribution system.

The overall cost of water, including the cost of the works, depreciation, and operation and maintenance, may vary from a few dollars per 1,000,000 gallons (3,785,000 litres) in simple systems up to \$500 per 1,000,000 gallons in complex systems. This is equivalent to a cost range of less than one cent up to 12 cents per ton of water delivered to the point of use, making water the cheapest commodity that is regularly supplied for human consumption.

Possibly because of the comparatively low cost of water, charges are not always proportional to consumption. In many cities of the world water is charged for at a flat rate based on the number of taps in a house, the size of the property frontage, or the value of the property. In such cases charges do not increase with excessive use, and waste is thereby encouraged. To minimize waste, and to rationalize charges, water meters are being increasingly installed in individual service lines so that water can be charged for in proportion to the volume delivered.

The cost of water can be expected to rise in the future. In most of the inhabited areas of the world the most economical sources have been utilized, and less attractive sources will have to be developed to meet future demands. The cost of construction also increases with time as labour, equipment, and material costs rise. Nevertheless, the value of a commodity as indispensable as water will always be equivalent to its cost of development and when the demand reaches the limit of the supply that can be developed using conventional works, new methods will be developed to conserve and to utilize available supplies more efficiently. Examples are the use of artificial turf for landscaping and the processing and recycling of waste water. Ultimately, self-contained recycling systems, founded on technology developed for spaceflights, may replace conventional water systems in areas where water is scarce.

FUTURE DEVELOPMENT

A steadily increasing demand for water will result from growing world population and economic progress. In the developing countries a large number of inadequate water-supply systems must be expanded and modernized. In the more advanced countries, where the readily available water has already been utilized, additional sources will have to be developed. These will include more distant sources, some involving extensive transbasin-diversion works, and poorer-quality sources. More water will be made available by technological advances in desalting, control of evaporation from reservoirs, increased artificial recharge of groundwater reservoirs, water-saving from improved industrial processes, increased use of lower-quality waters for noncritical applications such as cooling, and improved treatment of waste water to permit more extensive reuse.

Technological improvements also can be expected in water-treatment plant processes, particularly in controlling pollutants and ensuring the hygienic purity of water supplies. Further research will be done on the toxicology of many new contaminants.

Frequent water shortages are a historical fact, but, broadly, there is sufficient water available on the earth for several times the world's present population if it is properly developed and managed. (O.K.)

Notable modern aqueduct systems

Swelling populations, exhaustion of local supplies, improvements in materials and machines, and advances in construction techniques all caused municipalities in the 19th and 20th centuries to reach out for water with longer and longer aqueducts. Glasgow became the first city in Britain to bring water from a distant upland source. Built during the period 1855 to 1860, the aqueduct extended a distance of 25¼ miles (41 kilometres) from Loch Katrine to the reservoir at Mugdock, eight miles (13 kilometres) from Glasgow. Tunnels accounted for 13 miles (21 kilo-

Water: the
cheapest
commodity

Water for
Australia's
gold fields

metres), cut and cover for nine miles (14 kilometres), and iron pipes across valleys for $3\frac{3}{4}$ miles (six kilometres). In 1881 Liverpool began work on a 68-mile (109-kilometre) line from the Vyrnwy Valley; shortly thereafter Manchester developed an even greater system by going to Lake Thirlmere $95\frac{7}{8}$ miles (153 kilometres) away. A significant early 20th-century work was Vienna's Second Emperor Franz Joseph High Springs Aqueduct, planned by Francis Berger. Of its $113\frac{1}{3}$ miles (181 kilometres) almost 44 miles (70 kilometres) were made by tunnelling. Even larger was the 30-inch (76-centimetre) Coolgardie pipeline (1903) that stretched 350 miles (560 kilometres) across Western Australia to supply the gold fields. Also notable is the Apulian Aqueduct in Italy, designed to bring 110,000,000 gallons (416,000,000 litres) of water a day from the Caposele Springs through a ridge in the Apennines by means of a $9\frac{1}{2}$ -mile (15-kilometre) tunnel, thence west and south to Taranto 152 miles (243 kilometres) away. Numerous gigantic projects have appeared in the Western United States. Outside of California one of the most significant is the Colorado-Big Thompson Project (1938 to 1959), which includes 13 reservoirs and regulating basins, 27 earth and rockfill dams and dikes, six power plants, three major pumping plants, 20 tunnels (including the 13.1-mile (21-kilometre) Alva B. Adams Tunnel through the continental divide), 14 canals, 16 major siphons, and eight penstocks—traversing terrain that ranged from less than one mile to over 2.7 miles (4.3 kilometres) above sea level.

IN NEW YORK CITY

New York City draws nearly all of its water from three main systems, the Croton, the Catskill, and the Delaware. Its first successful municipal supply dates back to the Manhattan Company formed in 1799. By 1836 the company had 25 miles (40 kilometres) of mains and supplied 2,000 houses; it was replaced about 1842 by the Croton system.

The Old Croton Aqueduct, ultimately extending $45\frac{1}{2}$ miles (73 kilometres) from the dam to the Murray Hill Reservoir, was begun in 1837, began delivering water in 1842, and was completed in 1848 under the direction of J.B. Jervis. A distinctive feature was its 1,450-foot (440-metre) Roman-type masonry bridge that carried the water across in three cast-iron pipes. Additional water requirements were met by the New Croton Aqueduct (1885–93). Nearly the entire line of 31 miles (50 kilometres) was tunnelled. In combination with other city water supplies, Croton's safe yield is about 325,000,000 gallons (1,230,000,000 litres) per day.

Construction on the first phase of the Catskill watershed project by Jonas Waldo Smith was carried out from 1907 to 1917; the first water was delivered in 1915. The aqueduct extended 92 miles (147 kilometres) from the Ashokan Reservoir to the city, including 55 miles of cut and cover, 14 miles of concrete grade tunnels (24), 17 miles of pressure tunnels (seven), six miles of steel pipe siphons (14), and nearly two miles of flexible cast-iron pipe across the Narrows of New York Harbor. To keep the tunnel in solid rock, some remarkable depths were achieved, such as the rock tunnel siphon 14 feet in diameter, 1,114 feet below sea level, crossing under the Hudson near West Point. Under Manhattan itself City Tunnel No. 1 runs for 18 miles (29 kilometres) at depths from 200 to 752 feet (61–230 metres) below ground. The system was extended to about 120 miles (192 kilometres) from the city with the completion of the Gilboa Dam and the placing in service of the Schoharie Reservoir in 1924. Its safe yield is considered to be 555,000,000 gallons (2,100,000,000 litres) per day.

In common with the Catskill system, which draws its waters from the Schoharie and Esopus creeks, the Delaware system also draws from Catskill mountain streams—from Rondout Creek, the Neversink River, and the East Branch of the Delaware River. Both systems start at an elevation so high that they feed by gravity to the Kensico Reservoir at 355 feet (108 metres) above sea level, thence without pumping to the city where they arrive at a head some 160 feet (49 metres) above that of the Croton supply. Construction on the Delaware System began in 1937, was suspended during World War II (although placed in

limited use in 1944), and resumed shortly thereafter. The first stage, the Delaware Aqueduct, is a circular pressure tunnel running deep in bedrock for its entire length of 85 miles (136 kilometres) from the Rondout Reservoir to the Hill View Reservoir. With its extension in City Tunnel No. 2 its total length is 105 miles (169 kilometres). In some places it runs to a depth of about 2,500 feet (760 metres) below the surface and reaches a maximum diameter of 19 feet six inches (six metres) in its last 13.6 miles (22 kilometres). Subsequent extensions included the six-mile (9.6-kilometre) Neversink Tunnel in 1953, the 25-mile (40-kilometre) East Delaware Tunnel in 1955, and the 44-mile (70-kilometre) West Delaware Tunnel from the Cannonsville Reservoir to the Rondout Reservoir in 1965. With this addition the city could count on a total water supply from all sources amounting to 1,810,000,000 gallons (6,850,000,000 litres) per day.

IN CALIFORNIA

Of all political areas in the world the state of California must rank as a leader in the conveyance of water. Fundamentally, its need to move water stems from 70 percent of its surface supply originating in the northern third of the state, and 77 percent of its demand lying in the southern two-thirds. Agriculture uses between 80 and 90 percent of the state's imported and controlled water; approximately 95 percent of the crops harvested received some water supplemental to rainfall.

The first project of significance in the state was the Los Angeles Aqueduct (1908–13), which brought waters from the Owens River Valley in the Sierras some 250 miles (400 kilometres) away. Designed to deliver more than 280,000,000 gallons (1,060,000,000 litres) per day, the aqueduct proper consisted of a series of storage reservoirs and 23.7 miles (38 kilometres) of unlined canals, 37 miles (59 kilometres) of lined canals, 97.6 miles (156 kilometres) of covered conduit, 42.9 miles (69 kilometres) of tunnels (plus 8.8 miles [14 kilometres] of power tunnels), 12 miles (19 kilometres) of siphons, and two miles (three kilometres) of penstocks. In the recent past it has averaged 330,000 acre-feet annually (one acre-foot = 1,234 cubic metres). Following closely was San Francisco's aqueduct, which originates in the Hetch Hetchy Valley in Yosemite Park some 160 miles (256 kilometres) distant. The system was designed to carry 400,000,000 gallons (1,514,000,000 litres) per day. Of particular interest are two welded-steel, inverted siphons across the San Joaquin Valley, $47\frac{1}{2}$ miles (76 kilometres) long, ranging to 66 inches (168 centimetres) in diameter and operating under maximum heads of 500 feet (152 metres).

To the south, Los Angeles, in company with other municipalities, formed the Metropolitan Water District of Southern California in 1928 to build the Colorado River Aqueduct. Construction was begun in 1932. Statistics released by the district in 1963 gave the total length of the aqueduct system as 672 miles (1,081 kilometres), including 242 miles (387 kilometres) of main aqueduct, with a capacity of 1,212,000 acre-feet annually, or 1,000,000,000 gallons (3,785,000,000 litres) of water per day. The aqueduct system includes: five pumping stations which lift the water 1,617 feet (493 metres) over mountain barriers; 92 miles (147 kilometres) of tunnels; 63 miles (101 kilometres) of concrete-lined canals; 55 miles (88 kilometres) of concrete conduits; 29 miles (46 kilometres) of inverted siphons, totalling 144 in number; three miles (4.8 kilometres) taken up by reservoirs and pump delivery lines; 430 miles (688 kilometres) of distribution lines to service areas in the district, including 395 miles (632 kilometres) of large-diameter pipelines, 15 miles (25 kilometres) of concrete-lined canals, and 20 miles (32 kilometres) of tunnels; nine reservoirs; 321 miles (514 kilometres) of high-voltage power lines from Hoover Dam to aqueduct pump lifts; softening and filtration plant.

In 1947 the state legislature authorized an \$8,000,000 water resources study which took 10 years to complete. The final phase of the investigation, published in 1957, was a comprehensive master plan for the control, conservation, distribution, and protection of water in the state entitled *The California Water Plan*. This plan addressed

The
Delaware
system

*The
California
Water Plan*

itself to two categories of development: local works in various parts of the state, and long-distance system to transport waters via an aqueduct of record length from the north coastal region and Sacramento River basin to areas of deficiency—largely in the south.

Implementation of the second portion of the plan got under way in 1960. The program (California State Water Project), scheduled to take 25 to 30 years to complete, is designed to yield 4,230,000 acre-feet of water annually. Its cost was estimated at \$2,800,000,000. It extends some 600 miles (960 kilometres) from the Oroville Dam on the Feather River in the northern part of the state to Perris Dam south of San Bernardino. Interconnections at Perris with the Metropolitan Water District of Southern California make possible the transfer of northern waters all the way to the Mexican border. The major physical works of the project include: 20 dams, seven power plants, 21 pumping plants, 483 miles (773 kilometres) of lined canal, 166 miles (266 kilometres) of pipelines, 21 miles (34 kilometres) of conveyance tunnels, and 28 miles (45 kilometres) of unlined channels and reservoirs.

Among the outstanding facilities that form part of the project is the Oroville Dam (1962–67), at 770 feet (235 me-

tres) the highest in the United States. Another is the A.D. Edmonston Pumping Plant, the largest plant of its kind in the United States. Located northeast of Ventura on the California Aqueduct, it raises the waters to a point where they can cross the Tehachapi Mountain Range and flow into southern California. It is designed to raise the water in a single lift operation, 1,926 feet (587 metres) from the pump outlet to the penstock. The principal conveyance structure of the whole system, the California Aqueduct, runs from the delta east of San Francisco, south through the San Joaquin Valley, and over the summit of the Tehachapi Mountains, a distance of 293 miles (469 kilometres). At this point it divides into an East and West Branch, the former terminating some 444 miles (710 kilometres) from the delta. Sizes of channels vary along the aqueduct—a typical section being that of the initial reach, the North San Joaquin Division. This is a concrete-lined canal, 40 feet (12 metres) wide at the base, with sides sloping outward. The average depth of the flow is 30 feet (nine metres).

In summation, a description of the aqueduct empire of California is one of superlatives. Never in the history of the world has man moved such volumes of water such distances, and the end is not in sight. (C.J.M.)

WASTE TREATMENT AND DISPOSAL SYSTEMS

Sewage systems

Sewage systems are physical systems for the collection of waste water and its treatment before discharge back into the environment. Domestic waste water includes the used water of businesses and office buildings as well as dwellings; industrial waste water is that discharged during industrial operations. In addition to waste water, sewage systems also handle the flow of storm water, either separately or, more commonly, as part of a single system.

The volume of waste water discharged by a community is closely related to the volume of water supply required by it, and keeping the two separate has been one of the most critical problems of modern city engineers.

Because of the time required to plan, finance and build sewage disposal facilities, the engineer who designs such facilities is obliged to make an estimate of future population and industrial growth. The type of industry present or foreseen is important owing to the wide range of water-volume use by various industries—up to 50,000 gallons (189,000 litres) of water may be used to produce a ton of steel, and up to 100,000 to produce a ton of paper.

The complex and still evolving modern metropolitan sewage system has grown out of a long past, including many disastrous experiences with water-borne diseases and, more recently, other environmental problems such as ecological damage.

HISTORY

Ancient systems. Drainage systems may be traced to the early Christian Era and earlier; surviving examples include the city of Pompeii (1st century AD) and the even earlier Minoan sites on the island of Crete. Such ancient communities provided for conveying away roof water and rainwater from the pavements. Clay pipes for drain lines were the counterpart of lead pipe conveying water to certain buildings, though these refinements were chiefly limited to the official or wealthy class. In Rome drain water was conveyed to the Tiber principally by surface drains, but as early as the 6th century BC part of the cloaca maxima, the main sewer, was vaulted; in the 3rd century AD the entire sewer was vaulted. In addition to carrying storm runoff, the Roman system served a major source of waste water, the public baths.

Roman engineers introduced their techniques throughout their vast empire; even today, at such ancient bathhouses as that at Bath, England, may be seen the lead pipes bringing water in and the drains for discharge of used water.

The Middle Ages. The early Middle Ages witnessed few developments in the field of drainage; in the rude garrison towns and frontier outposts of northwest Europe the

disposal of human waste was largely in keeping with the injunction contained in the 23rd chapter of Deuteronomy that prescribed withdrawal outside the camp. But in the rapidly growing cities of the high Middle Ages, the first attempts at organized waste removal were made. Privy vaults, usually built to serve several families, were periodically cleaned. The system was none too satisfactory; wealthy families preferred to live adjacent to or over a watercourse, with the “garderobe” (privy) corbelled out over the water; London Bridge was a favourite residence because of its convenience in this respect. A more significant advance introduced in some places was the cesspool. But throughout the Renaissance wastes were universally dumped in city gutters to be flushed through the drains by floods.

Public health aspects. Not surprisingly, the crude sanitary arrangements of Europe contributed to the spread of epidemics. John Snow, a 19th-century English physician, compiled a list of outbreaks of cholera that he believed had moved westward from India over a period of centuries, reaching London and Paris in 1849. Snow traced a London recurrence of 1854 to a public well, known as the Broad Street Pump, in Golden Square, which he determined was being contaminated by nearby privy vaults. This was a noteworthy epidemiological achievement, especially since it predated by several years the discovery of the role of bacteria in disease transmission.

When the public health dangers became apparent, Londoners first, and soon after other European city dwellers, were ordered to discharge wastes into the drainage system originally provided to carry storm-water runoff only. It might be said that here stream pollution had its birth, as the concentration of such an organic load on a river like the Thames at London was more than the stream could assimilate without nuisance. The resulting stench was such that burlap saturated in chloride of lime was hung in the windows of Parliament House in an attempt to kill the odours. That experience developed into pressure for the treatment of sanitary wastes. Similar treatment demands arose in the large cities of Germany, which had also experienced major waterborne epidemics. Such catastrophes have today been virtually eliminated by vastly improved sanitation of water and modern water-pollution control. In the infectious hepatitis epidemic of 1955–56 in Delhi, India, a laxity in water-treatment techniques was shown to be the cause of the outbreak.

A major contributor to water pollution problems as they reached major intensity first in England during the early 19th century and in the United States and western Europe a little later was the Industrial Revolution, with its combination of concentration of population and industry.

Industry
and water
pollution

Roman
practice

Few major industrial users of water, in their early years of development, paid serious attention to waste products that left the plant. Even today, approximately 50 percent of the total wood used in a modern paper mill goes into the industrial waste-water stream and must be removed by treatment of the waste water. Textile mills discharge some waste fibres and also frequently discharge multicoloured dyes.

DEVELOPMENT OF TREATMENT METHODS

Early treatment techniques simulated natural methods of purification. It was observed that moderate amounts of organic wastes discharged into a watercourse eventually went through a natural purification process. In time the receiving water, as well as the waste water itself, regained a status of natural purity. If too much organic matter was imposed upon a watercourse, however, the water was badly degraded and would become a nuisance to sight and smell as well as become uninhabitable for fish and other aquatic life. Because of the absorptive capacity of the soil and the value of organic material as fertilizer, an early attempt at disposal was that of sewage farming, the spreading of raw sewage on the land. This met with particular favour in the large cities of Europe and was employed in Berlin and Paris until relatively recent years. This practice was followed in the early years of experimentation in Britain, but soon gave way to methods of treatment in which the final solids removed from the waste water could be used for organic fertilizers or soil conditioners. Such methods included plain sedimentation and, later, chemical precipitation or sedimentation aided by flocculation chemicals.

Development of the trickling filter. Even these methods were insufficient in many cases and further treatment of the waste water was necessary. Again, observing nature, workers sought to expose the waste-water flow to oxygen from the air by various means. An early attempt consisted of filling a large tank with stones from three to eight inches in average diameter and flooding the interstices with the settled waste water. After contact of several hours, the tank was drained and much organic matter remained on the surface of the stones enmeshed in the zoogeal (massive bacterial) growths that occurred there. Such a treatment scheme required several such tanks so they could be rotated on a fill-and-draw basis. Because of the labour involved with this manipulation and a desire for something better, the next big step was toward a so-called trickling or sprinkling filter. This was not a filter in the usual sense, but a large shallow concrete tank filled with medium-size stones, over whose surface the settled waste water was allowed to trickle, draining from the bottom of the unit. Such filters were operated intermittently so that air had free access to the zoogeal growths that formed on the filter stones and accomplished the oxidization of material from the waste-water flow.

Activated-sludge process. During the years 1912-15, the British developed another process that proved to be still more effective in the removal of organic material from the waste water. Recognizing the trickling filter as merely a means of bringing together the organic matter in the waste water and air as a source of oxygen, British engineers reasoned that by releasing compressed air in a tank of waste water they could achieve a greater measure of control, and hence degree of treatment. They also observed that the circulation of some of the sludge gave a vast area for the same biological action that was going on in the trickling filter, by combining the organisms carried by the sludge, oxygen supplied by the incoming air, and new food supplied by the settled waste water entering the aeration tanks. By varying the amount of air and the amount of sludge returned to the process, higher levels of treatment could be obtained. Because the sludge was teeming with bacterial and associated biological life, the sludge was called "activated" and the process called the "activated-sludge process." It proved highly efficient and was rapidly adopted by cities around the world with severe treatment problems.

MODERN TRENDS

A water-pollution control plant has been described as "a river wound up at one point," because a treatment

plant accomplishes, within a few hours, what a river requires days or even weeks to do. In the 1970s nearly all communities needed increasing waste-water treatment; in addition to the greater load from growing populations and industrial activity, there has been a significant increase in most parts of the world in both the stringency and level of enforcement of water-pollution control laws. One result of this pressure has been a search for methods to increase the levels of treatment or, specifically, the removal of organic material from the waste water. Practices of the past have employed biological and physical processes because of their economy.

Chemical treatment. With the increased demands for treatment effectiveness, serious consideration is now being given to the return to chemical precipitation methods. These methods were tried briefly in the 19th century; they were given up, however, because of high costs. The increased value placed by the 20th century on stream cleanliness tends to justify such higher costs, and the treatment plant of the immediate future will probably include chemical precipitation in addition to physical and biological processes.

Separate storm and waste-water sewers. Although most sewer systems still combine storm water and domestic waste water, it is generally recognized that separate systems are highly desirable. Where a combined system is used, heavy rainfall overloads treatment plants, with the result that untreated overflow becomes a source of pollution. Furthermore, where the two streams are kept separate, it is possible to handle each in accordance with the level of treatment required. One proposed method of handling storm runoff is that it be piped to holding reservoirs underground and gradually run through treatment plants.

Recycling. Even further, because of the exhaustion or near exhaustion of water supplies in some areas, there has been a major trend, particularly in the arid parts of the world, to treat waste waters to a level that will allow reuse of the water for various purposes. For many years such treated waters have been used for irrigation, industrial cooling, and certain other industrial processes. Studies are proceeding to reclaim water for many other purposes, with a growing likelihood of eventual reclamation and treatment to the level of drinking water. In the United States, the city of Dallas, Texas, studied the possibilities of reuse because the city has developed virtually all of the fresh-water sources within its reach. Many cities with similar problems, in the U.S. and elsewhere, will soon be studying reuse. The United States government has been carrying on an intensive research program in this area for several years. It is clear that the relation between water supply and water-pollution control is growing steadily closer.

A TYPICAL CITY SEWER SYSTEM: WASHINGTON, D.C.

Modern urban sewage treatments can best be described by reference to a specific city. The Washington, D.C., system has many aspects typical of any large modern city, though its early history is not representative of many others. The town's first bathtubs were installed in the White House and the Capitol, for the members of Congress in the 1840s; in 1850 the U.S. Congress authorized the Corps of Engineers of the U.S. Army to develop a city-wide water supply from the Potomac River. At this point Washington caught up with New York, London, and Paris, which were also encountering the problem of disposing of used water along with wastes. Washington's solution was the same as that of other cities; the existing system of culverts and drains, built for street drainage only, was extended and developed into a sewer system for the disposal of domestic waste water from residences, government offices, and businesses. The system followed the drainage pattern of the city street network and in general made a system of pipes with a sewer available to each private property. At the same time, again in common with other cities, street drains were built to empty into the nearest surface watercourse without any thought of degradation of the water quality. This was in spite of the fact that an engineering study and report (1890) recommended that all extensions of the sewer system separate storm runoff from domestic waste water.

Better law
enforce-
ment

Initial
develop-
ment

With continued growth of the city, the District of Columbia constructed in the first decade of the 20th century a series of intercepting sewers and a pumping station to lift the domestic waste water into an outfall line for discharge into the Potomac River south of the city. At the same time, pumping facilities were installed for the lifting of storm water drainage directly into the nearby Anacostia River. It was impossible to keep domestic and storm flow completely separate, but practical separation was attempted.

With the accelerated growth of the 1920s, concern over pollution of the Potomac increased. The Potomac estuary had a remarkable ability to assimilate pollution because of the large "flats" on both sides of the river that were kept in a state of constant circulation by tidal variations, but a study made by the Public Health Service in 1932 revealed that the river was in such a condition that low flow would bring about serious pollution effects. As a result, Congress decided to proceed with the construction of facilities for the treatment of waste water. This again was in line with decisions being made in many U.S. and European cities at the same period.

Treatment plant at Blue Plains. During 1934–38 a plant was constructed on the left bank of the Potomac in the part of the city known as Blue Plains to accommodate a flow of 130,000,000 gallons per day and serve a population of 650,000. Initially, with the help of the Federal Emergency Administration of Public Works, money was allowed for construction of a plant that would remove 90 percent of the organic matter from the waste-water flow. That level of treatment was in accordance with the Public Health Service recommendation contained in the 1932 report. Instead of constructing the plant in accordance with that recommendation, the District of Columbia decided to eliminate the second step in the treatment and construct a sedimentation plant, generally known as primary treatment. The plant was able to remove about 36 percent of the organic matter when it went into operation in August 1938, but, as the population load increased, accelerated by World War II, the plant was unable to maintain this level, and year by year efficiency dropped until it was regularly under 30 percent.

During World War II, initial plans were made for the relief of the treatment burden, and by 1950 the District of Columbia had begun major construction to increase the capacity of the plant and make further plans for inclusion of secondary treatment.

Activated-sludge plant. The activated-sludge process pioneered in Britain had by now been widely tested. Washington constructed a high-rate activated-sludge treatment plant in anticipation of 70 percent removal of organic matter. While the new plant brought a major improvement in the river, there was no real possibility of keeping up with the pollution burden, even though the plant grew to a capacity of 290,000,000 gallons daily. In the early 1970s the District began planning to extend treatment to a much higher level—once more, a decision that was forced on many cities of the United States, Europe, and Asia.

Coordination with surrounding areas. One of the awkward problems confronting city engineers of the 20th century in nearly all countries has been the impossibility of isolating a metropolitan area from neighbouring regions. Rivers carry pollution from city to city, even country to country. In Washington the problem was encountered in a relatively mild form; much of the Maryland suburban area drains into Rock Creek and the Anacostia River, which flow through the District of Columbia; to try to keep the two streams as clean as possible the District of Columbia and the Washington Suburban Sanitary Commission (of Maryland) entered into an agreement to handle each other's flow at a reasonable cost. All the domestic waste water of the suburban areas is now connected into District sewers, with payments made to handle the waste waters. As part of the agreement, the Maryland Commission helps to finance both the construction and the operation of the District of Columbia Water Pollution Control Plant.

Other developments. With continued growth and rising pollution control standards of the 1960s and 1970s, Washington like most other major cities has been turning to-

ward additional treatment, including chemical treatment. One proposal calls for achieving so high a level of treatment that the Potomac estuary into which the effluent flows could be used as an emergency water source.

Another direction in which Washington had headed in company with many other modern cities is toward separation of systems. This is a tedious and expensive process, requiring piping changes on private property. Its longrange wisdom, however, is irrefutable. The redevelopment of certain major areas, such as southwest Washington, has given favourable opportunities for large-scale separation.

An important advance in financing improvements has been adopted by Washington: the sewer-service charge on all those served by the drainage system. This system has been followed more and more by drainage systems serving both municipalities and industry.

Since about 1959 the D.C. sewer system has been interconnected with the areas in Maryland that naturally drain through the District via the Potomac River and major areas in Virginia related to the intercepting sewer serving Dulles International Airport near Herndon, Virginia. As a result of this connection, the area served increased by 436 square miles (1,129 square kilometres) in Maryland and 228 square miles (590 square kilometres) in Virginia. The Metropolitan area in Arlington County and much of the Virginia suburban area adjacent to Arlington County are served by other treatment plants.

Present treatment facilities. At the District of Columbia Water Pollution Control Plant (see Figure 38) the raw waste water enters the plant pumping station and is treated in the following successive steps: grit removal, preliminary sedimentation, aeration, and final sedimentation. In addition, chlorine treatment may be given the flow prior to preliminary sedimentation or it may be given to the final effluent. With the first application, the effect of chlorine is to minimize odours from the sedimentation tanks. When fed to the final effluent, chlorine has a disinfectant effect.

Figure 38: Basic steps in the sewage disposal process of the District of Columbia Water Pollution Control Plant.

Gas
production

The purpose of the sedimentation tanks, both preliminary and final, is to separate solids from the waste-water flow; the solids removed must be given further treatment. At the D.C. plant these solids are exposed to anaerobic digestion and dewatering on vacuum filters. The final product is a moist cake with approximately 70 percent water, suitable for land application as a soil conditioner. During the digestion of sludge, a gas consisting of approximately two-thirds methane is produced that is burned for heat for the plant buildings and to provide some power generation. The sludge gas has a heat value of about 600 BTU (British thermal units) per cubic foot and the quantity produced is about one cubic foot per person, per day. A sludge gas engine of 1,200 horsepower drives an 800-kilowatt generator for production of electric power. Initially, the power produced supplied about 95 percent of the needs of the plant, but with the growth of the plant, power requirements have increased rapidly and now the gas engine supplies only a minor proportion of the electric power. It supplies, however, through its jacket water-cooling system, a large amount of the heat necessary to maintain active biological digestion in the sludge digestion tanks.

The total cost of the plant exceeds \$25,000,000 and the annual operating costs in the late 1960s approximated \$2,500,000. More than 250 persons are employed in operation and maintenance.

The full extent of the undertaking may be appreciated when the vast waste-water collection system serving property throughout the area is visualized. In the District of Columbia alone, more than 1,700 miles (2,720 kilometres) of sewers serve this purpose, while 2,700 miles (4,320 kilometres) in the Maryland area give similar service to the properties of that jurisdiction. The maintenance of the system is a major activity, as 200 men are engaged in regular maintenance and minor construction related to the sewer system in the District of Columbia alone. Proper maintenance involves regular inspection of the lines and periodic cleaning to avoid difficulties that could cause great inconvenience and possibly property damage to those served by the drainage system.

WORLDWIDE SEWAGE DISPOSAL PROBLEM

Sewage disposal in non-Western areas is progressing at a rapid pace. The growth of cities and industries has made it necessary for such areas to have public water supplies. The full advantages of a public water supply cannot be realized without a proper drainage system that will remove promptly the used waste water along with the wastes contributed by its use. The advanced state of public health protection from persons living in an environment served by proper water and sewer service is properly credited to the advantage of these services.

Since World War II Japan has been converting from its outdated agricultural utilization of raw sewage to the modern water-carried drainage system. To build such a system in a metropolis like Tokyo, with its population exceeding 11,000,000, is truly a herculean task. The traditional communal bathhouses of Tokyo neighbourhoods eventually will be replaced by household plumbing systems. Thailand, India, Pakistan, and many countries on the African continent are following this pattern. Eastern as well as western Europe has its pollution problems; such densely populated countries as Romania, Czechoslovakia, Hungary, and Poland have intensive programs of water-pollution control under way. In areas where water is extremely short, such as Israel and South Africa, reclamation after full waste-water treatment is practiced. In Windhoek, South West Africa, approximately one-third of the waste water is circulated back to the domestic water supply; plans are being made to increase the return to 50 percent. This is accomplished by following the conventional methods of waste-water treatment with more refined techniques to restore the water to a completely satisfactory public-health quality. At the same time, the chemical characteristics of the water are improved, and hardness is reduced. The city of Bangkok, Thailand, is pursuing a gigantic program involving complete reconstruction of its water system and its sewer system along the most modern lines, including a high degree of recycling.

Recirculation

Future problems in the field include proper means of financing the construction and operation of sewer systems, including such appurtenances as pumping stations and plants for the control of water pollution, but most significantly higher and higher degrees of waste-water treatment. Research in progress in many countries of the world promises to achieve a high degree of reclamation, and even recycling at reasonable cost.

The control of water pollution is not dependent wholly on the civil and environmental engineers who customarily design the facilities for the collection and treatment of waste waters. For the intelligent operation of such structures, the cooperation of chemists, biologists, bacteriologists, and limnologists (freshwater scientists) has been considered essential for many years. Now, with the added emphasis on ecology and environment, the application of the principles of these broad fields of biology must also be included to meet the problems of the growing world population and its demands for a greatly improved environment. (R.E.F.)

Refuse disposal systems

The term refuse refers to solid wastes, and the two are used more or less synonymously to describe those discards of society that are not liquid or gaseous in nature. Solid-waste management is the development and operation of refuse disposal systems designed to handle community refuse in a healthful, economic, and conserving manner. The amount of solid wastes produced can be correlated to the output of goods and services; in the early 1970s the United States, which consumed nearly half of the world's annual production of industrial raw materials, produced about 300,000,000 tons (one ton = 0.91 metric ton) of solid wastes each year (see Table 2). This excludes wastes from agriculture, mining, and fossil fuels.

Table 2: Solid Wastes in the United States (1977)

waste source	amount (lb/capita/year)*
Municipal	
Residential, commercial, and institutional	1,340
Sewage sludge	46
Automobiles and construction demolition	410
Industrial	3,330-3,680
Radioactive	0.4
Mining and milling	21,210
Agricultural	23,030-30,640
Utility (electrical)	710
Total	50,076-58,036
*1 pound = 0.45 kilogram Source: U.S. Environmental Protection Agency, <i>Solid Waste Data</i> , 1981.	

A comparison of the average output of refuse per family (3-4) per week in eight countries is shown in Table 3. These figures indicate the effect of degree of industrialization on family refuse, entirely apart from the waste contributed by industry itself.

The character of refuse varies considerably. The ash content of refuse in the U.K. is 30-40 percent, whereas in the U.S. it rarely reaches 10 percent. Paper and paper products constitute by weight about 40-50 percent of the

Table 3: Generation of Household Refuse per Family per Week

U.S. and Canadian household refuse but in Europe rarely exceed 25 percent. Thus, American refuse is much lighter per unit volume.

There are three environmental depositories for society's discards—the air, the water, and the land. Air and water pollution control historically has been based on control or treatment of effluents discharged to the air or water. There has been little effort in the past to control the production of solid waste. Rather, control programs have centred on methods to salvage that part economically feasible and to reduce the remainder by burning or compaction to minimize transport costs and the environmental space required to harbour it.

Problems
of solid-
waste
manage-
ment

Community refuse collection and disposal is nearly everywhere regarded as a responsibility of local government and as a major public health and welfare service. Improperly handled refuse serves as a breeding ground and food supply for flies and rats. The formerly widespread practice of feeding raw garbage to swine has been demonstrated to be an important link in the transmission of trichinosis to man. Outbreaks of the virus disease of swine, vesicular exanthema, similar to foot-and-mouth disease, have resulted in requiring the heat treatment of garbage fed to swine and the virtual discontinuance in industrial countries of the ancient practice of raising hogs on garbage dumps. Heat treatment of garbage has been required in the U.K. since the early 1900s.

Many communities in Europe and the U.S. no longer permit burning of leaves. Smoke and odours from open burning dumps and particulate matter from the stacks of improperly designed or operated incinerators are sources of pollution in many urban areas. Furthermore, rubbish has been found to be a significant factor in causing fires in buildings.

Improper disposal of refuse has resulted in pollution of surface water and ground water. Indiscriminate dumping in pits or on the banks of rivers is not uncommon. A problem particularly acute in the U.S. is the littering of highways and roadside areas. Materials jettisoned in the U.S. in one year have been estimated at a bulk of 20,000,000 cubic yards (one cubic yard = 0.76 cubic metre).

Besides population growth, a number of other factors have contributed to the world's increased solid-waste problem: design of products leading to accelerated obsolescence; higher real income resulting in the increased manufacture and sale of consumer items; packaging to improve sales appeal, prolong shelf life, and reduce marketing cost per unit.

The refuse collection and disposal function is ordinarily grouped with other municipal sanitation functions in a major department of local government. Traditionally, collection and disposal service has been oriented to a single city institutional arrangement. In most metropolitan areas political fragmentation is a serious problem. Regional groupings have been suggested as an avenue of improvement, particularly for the disposal function.

MODERN COLLECTION AND DISPOSAL METHODS

Most cities require that household garbage be well wrapped and stored in durable, easily cleaned containers with tight-fitting covers. Ashes are stored in metal containers. Plastic or paper bags as container liners have come increasingly into use, particularly in commercial food-preparation areas and institutions. Many new multiple dwelling units are equipped with refuse compaction systems. A pneumatic pipeline refuse transport system, installed in a high-rise apartment development in Stockholm in the late 1960s, promised to be another valuable innovation.

Collection and disposal in urban areas. In some urban commercial areas bulk containers are mechanically lifted into large compactor-equipped trucks for transport to the disposal site. In Europe, because of the continuing, though decreasing, ash content of household refuse, service provided by some municipal authorities features dustless systems wherein heavy metal containers are mechanically dumped into the collection vehicle through a tight-fitting portal designed to accommodate standard bins of 2½ to 3½ cubic feet (0.07–0.1 cubic metres).

Household refuse collection in both the U.K. and the

Dustless
systems

U.S. is characterized most often as a combined collection of household food wastes and rubbish from containers placed at the house line, alley, or curb. Presently, loading is done by hand, but research is under way to reduce labour requirements through increased mechanization. Household refuse collection vehicle design incorporates a rear-, front-, or side-loading closed metal body equipped with a mechanically or hydraulically operated compaction plate to increase the load capability. This has become more important as travel distances to disposal sites have increased, and in many large cities transfer of refuse from neighbourhood collection vehicles to long-haul vehicles (which can carry 60 or more cubic yards of compacted refuse to disposal facilities) is not uncommon. In most of the world, household refuse-collection systems are operated by local government authorities. By contrast, in the U.S. private contractors and private systems provide almost half of the household and the bulk of the industrial service. Frequency of collection varies from daily to less than once per week. Reported collection costs vary widely, depending on such factors as haul distance, type of service, climate, and wage levels.

Incineration. Combustible wastes may be reduced to inert residue by high-temperature burning. An incinerator is composed of a furnace into which the refuse is charged and ignited, a secondary combustion chamber in which burning at a high temperature is continued to complete the combustion process, and flues wherein the gases of combustion are cleansed as they are conveyed to a chimney and thence to the atmosphere. Incinerator plants also include facilities for unloading and storing the refuse for short periods to permit uniform charging of the furnaces and a building to house the incinerator appurtenances.

The growth of large cities was primarily responsible for the development of refuse incinerators since it was not practical from nuisance, public health, and aesthetic viewpoints to permit refuse dumps in their midst. The burning of refuse provided an efficient means of inoffensively reducing the bulk of the refuse (about 90 percent by volume) to a readily transportable and often usable ash. Municipal refuse contains a great variety of combustible items; some require special treatment before processing through a conventional incinerator, and air pollution agencies in many places now regulate the use of such incinerators. Bulky refuse may be preprocessed by size reduction through such equipment as shredders, hammermills, and impact mills. Many special incinerators have been designed for bulky refuse. Hazardous and obnoxious wastes, such as highly volatile dusts and flammable liquids, are also usually disposed of in specially designed plants.

On-site incineration of combustible refuse is an economical method for many industries, multiple apartment dwellings, and large commercial establishments, as well as in certain instances for householders. The basic furnace design for such units is similar to that required for their larger municipal counterparts.

Apartment-house incinerators, which are often flue fed with a chute directly to the furnace, have been found to be a significant source of air pollution; increased attention has been given to regulation of their design and operation.

Heat from incinerator furnaces may be used to generate steam for use in industrial processes, for space heating, power generation, or in sewage disposal plants and other public facilities. The economics of the use of waste heat for steam generation are resolved primarily on the need for steam by users within a reasonable distance of the plant and the market rates. Such European cities as Paris, Munich, and Frankfurt operate steam-generation plants in conjunction with municipally operated power plants. Montreal, Canada, has a steam-generating plant which began operations in 1970. In such arrangements the price of coal is a crucial factor.

Disposal into sewerage system. Garbage ground into minute particles can be discharged into the community sewerage system. Little difficulty is encountered in a properly designed sewer system as a result of this practice, and household water consumption increases only 1 to 2 percent with the installation of a grinder. Increases in solids-handling capacities are needed at the sewage treatment

reduction

Waste heat
utilization

plants in cities where large numbers of grinders have been placed in service, however, and for this reason some communities with already overloaded treatment plants have forbidden their use. They have, however, found increasing application in commercial and institutional food-handling establishments.

Ocean disposal. The time-honoured practice by coastal cities of barging garbage and rubbish to sea has come under increasing critical pressure as the lighter material finds its way back to the beaches with the wind and the tides. New York, an early major offender, was prohibited from this practice in 1933 by a ruling of the U.S. Supreme Court. Nevertheless, an estimated 37,000,000 tons of solid wastes, including dredging spoils, ship refuse, waste oil, industrial chemicals and sludges, and sewage sludge were disposed of at sea from the U.S. in 1968. Ten million tons of the wastes were dredging spoil; no dumping of community garbage was recorded. Similar practices on a lesser scale are worldwide; guidelines for the regulation of ocean disposal have become a matter for United Nations action.

Disposal on land. The indiscriminate dumping of refuse on land is an age-old practice; in the late 1960s more than 90 percent of land disposal sites in the U.S. were classified as "dumps." The unsightliness and unavoidable presence of flies, rats, smoke, and odours at dump grounds led to the development of the sanitary landfill method (see Figure 39). The "sanitary landfill" is defined by the Amer-

The sanitary landfill method

Figure 39: Trench method of sanitary landfill used to dispose of refuse in a flat land area.

ican Society of Civil Engineers as a method of disposing of refuse on land without creating nuisances or hazards to public health or safety, engineered to confine the refuse to the smallest practicable area and volume and to cover it with a layer of earth on at least a daily basis. It requires the same careful preliminary and operational planning and design that any engineering construction job must have to be successful. Site selection includes zoning arrangements, accessibility, haul distance from collection routes, availability of cover material, a study of geological formations to assess water pollution hazards, and the ultimate land use plan for the completed site.

The most commonly used equipment on sanitary landfills is the crawler or rubber-tired tractor. It performs the spreading, compacting, covering, trenching, and in many instances even the hauling of the cover material. Other equipment used includes scrapers, graders, and water sprinklers for dust control. Sanitary landfills serving up to 50,000 people, or handling up to 115 tons of solid wastes per day, may operate with one piece of equipment. But suitable land in urban areas is becoming increasingly scarce. Space requirements almost doubled between 1950 and 1970 (0.7 to 1.25 acre-feet [864–1,542 cubic metres] per thousand persons). Intensive work is under way to investigate the economic feasibility of long-distance haul of refuse by rail to large remote disposal sites, such as abandoned strip mines. Reported sanitary landfilling costs range from \$0.75 to \$3.50 per ton of refuse disposed of depending on the size of the operation, land and site preparation costs, operational requirements, and the ultimate land use construction requirements.

Completed sanitary landfill sites are most commonly used for recreational areas, such as parks, playgrounds, and golf courses. An arboretum has been constructed on a Los Angeles County landfill site. Heavy construction on completed sanitary landfill sites, however, has generally been avoided.

Abandoned autos. In the early 1970s the problem of the derelict automobile was beginning to appear in countries outside the U.S., where it was already assuming serious proportions. Large shredders to process auto hulks into scrap were developed in the late 1960s. But despite processing more than 7,000,000 U.S. autos annually, the number of hulks in processing yards or blighting the landscape increased from 6,500,000 in 1965 to about 12,000,000 in 1970. A possible direction for government action was pioneered by the state of Maryland in legislation (1969) providing a bounty for auto hulks brought to regional processing centres.

Shredding autos into scrap

Collection and disposal in rural areas. The collection and disposal of refuse in rural areas presents a special problem because sparse population and small communities mean high unit costs for transportation and disposal. In industrialized countries rural per capita generation of refuse is nearly as great as that in urban areas; often failure to provide services results in promiscuous dumping and littering. A system employing large portable containers has been successfully demonstrated in Chilton County, Alabama. A "mother" truck mechanically picks up and empties the containers and then transports the compacted load of refuse collected from a number of containers to the county's sanitary landfill.

RECLAMATION AND RECYCLING

The removal of salvageable items such as metals and paper from the waste stream for reuse or as raw materials for industrial reuse is termed reclamation and recycling. The amount and kind of refuse salvaged from the solid-waste stream has traditionally followed economic patterns. Before World War II a number of cities operated garbage reduction plants to reclaim grease and produce tankage that was sold to reduce the cost of collection and disposal. Picking belts were operated to remove items such as metals and cardboard for resale. Rising labour costs, difficulty in obtaining labour for the separation process, and lack of markets for grease contributed to the closing of these plants.

Composting is the biochemical alteration of organic refuse from a noxious conglomerate to an innocuous and usable soil humus. A number of anaerobic and aerobic processes have been tried on varying scales in the U.S. None has been successfully employed in U.S. communities on a continuing basis, primarily for economic reasons. Composting has been successfully carried on in Europe, particularly in France, where more favourable economics prevail. Even in The Netherlands, however, the practice of composting refuse has been diminishing as other more economic methods of supplying needed humus to the soil are adopted. While limited markets and related economics have discouraged the salvage of the type and quality materials contained in household refuse, large quantities of industrial and commercial solid waste are recycled.

Composting

A continuing sharp increase in per capita generation of solid wastes is predicted based on materials production forecasts. For example, the 30,000,000,000 beverage containers produced for "consumption" by the U.S. populace in 1965 was more than doubled by 1976. The productive energies of both industry and government are now largely being centred on the goal of increasing the recycle of this waste material through better technology and the development of the economic incentives to encourage reuse of the materials. Research has concentrated on such areas as utilization of fibrous wastes as sources of nutrients, laser-mediated lignin solid-waste fermentation, and the design of a water-disposable packaging container. Major governmental attention is focussed on means of recovering materials and energy from solid waste, the identification of potential markets for recovered resources, and changes in product characteristics and production and packaging practices that would reduce the amount of solid waste.

STREET CLEANING

Sweeping. Until recent times city streets were depositories of garbage and other refuse of every description, a situation that contributed to widespread epidemics. The paved streets of the 20th century, together with the development of mobile-powered cleaning equipment, have led to the establishment of the street-cleaning function as one of the major tax-supported efforts of municipal government. Effective street-cleaning programs not only enhance the appearance of the community, but they protect the public health by reducing disease and injury from dirt entering the eyes, ears, nose, and throat and promote safety by eliminating causes of skidding, fire hazards, and sources of water pollution in storm runoff. Flushing and hand sweeping have long been supplemented by mechanical sweeping; by the 1970s vacuum techniques had been introduced in many European cities.

Vacuum
sweeping

Snow and ice removal. Except in far northern regions, most cities treat snow and ice storms as emergencies, marshalling all forces available until traffic is moving freely along main arteries at least. Many factors affect the impact of a storm on a community; few are controllable. The amount and dryness or wetness of the snow, timing, rate, and duration of the storm, wind conditions, and the temperature—all are important. The emergency nature of snow and ice control work requires careful planning, organization, and operation; reliable weather forecasting service is essential. In combatting snow storms in urban areas, four broad areas of effort are usually required: salting and abrasive spreading, plowing, physical removal (or lifting) of snow from business and commercial areas, and special removal operations such as the cleaning of crosswalks and sidewalks, parking areas, fireplugs, bus stops, etc. Spreading chemicals (most commonly, rock salt) or sand or both is the customary first line of offense against snow and ice. Salt has no effect, however, when the temperature drops below -6°F (-21°C), the temperature at which a concentrated solution of salt water will freeze. Many cities start plowing operations before a depth of $1\frac{1}{2}$ inches (3.8 cm) of snow has fallen, particularly if a severe storm has been forecast. Plows are mounted on various types of vehicles, including dump trucks, wheeled tractors, refuse collection trucks, and motor graders. Where snow must be removed completely, mechanical loading equipment, such as elevating conveyors and front-end loaders, is used. Vehicles equipped with rotary-type plow blades, called snow blowers, are widely used to load hauling vehicles or to remove large accumulations of snow from highways or airport runways. Disposal of snow that is loaded and hauled away is accomplished by dumping it into large bodies of water or large sewers. Unlimited amounts of snow ordinarily can be dumped into large lakes, rivers, or in the ocean without undesirable side effects. Sometimes snow is dumped on vacant land. Snow melting is expensive but is used in some cities where the quantity of snow, haul costs, and other alternatives make it economically attractive. Montreal undertakes to clear all snow within 72 hours of the snowfall and not only maintains a large snow "tip" (dump) but operates several batteries of snow melters capable of melting 560 tons per hour. The method reportedly costs twice that of dumping and four times that of disposing of it into convenient sewers. Effective community snow and ice control programs have been shown to be justified on economic considerations alone.

Snow
blowers

SPECIAL PROBLEMS

Solid wastes include many types of refuse that constitute special and unique problems. Such wastes may be hazardous, for example, radioactive wastes, toxic chemicals, and pathogenic wastes from hospitals or research laboratories, or materials otherwise unique in nature that require special handling. Demolition wastes from urban renewal projects and ash by-products from the energy industry are examples.

Concern over the control of radioactive wastes is worldwide. The U.S. Atomic Energy Commission has maintained control of discharges and of containment of nuclear fission wastes with some delegation of authority to certain state agencies in recent years. The handling and disposing of radioactive solid wastes are not the responsibility of local governments. These originate in all operations of the nuclear energy industry and include such items as contaminated paper, laboratory glassware and equipment, as well as end products, such as chemical slurries and sludges, evaporation solids, and ion-exchange resins. Disposal may be designated in authorized areas on land or into the ocean after processing for volume reduction by compression or incineration. Materials for disposal into the ocean are packaged in 55-gallon (208-litre) concrete-encased drums and transported to designated areas about 150 miles (240 kilometres) at sea in about 7,500 feet (2,300 metres) of water. Abandoned salt mines are being seriously considered as a repository for solid wastes containing radioactive materials.

Radio-
active
wastes

Demolition and construction refuse consists of lumber, pipes, brick masonry, and other materials from buildings and other structures. Some of this material is salvaged for resale (old bricks, lead pipe, copper), but most is hauled away by the contractor for disposal at landfill sites. Explosives and inflammable materials, highly alkaline or acidic sludges, magnesium, manganese, and cyanides are not handled as part of the regular community collection system because of potential injury to workers and special disposal requirements. Other special wastes include large dead animals and quantities of condemned food. Each is subject to special handling procedures before burial or incineration.

(L.We.)

TUNNELS AND UNDERGROUND EXCAVATIONS

A tunnel is an essentially horizontal underground passage-way produced by excavation or occasionally by nature's action in dissolving a soluble rock, such as limestone. A vertical opening is usually called a shaft. Tunnels have many uses: for mining ores, for transportation—including road vehicles, trains, subways, and canals—and for conducting water and sewage. Underground chambers, often associated with a complex of connecting tunnels and shafts, increasingly are being used for such things as underground hydroelectric-power plants, ore-processing plants, pumping stations, vehicle parking, storage of oil and water, water-treatment plants, warehouses, and light manufacturing; also command centres and other special military needs.

True tunnels and chambers are excavated from the inside—with the overlying material left in place—and then lined as necessary to support the adjacent ground. A hillside tunnel entrance is called a portal; tunnels may also be started from the bottom of a vertical shaft or from the end of a horizontal tunnel driven principally for

construction access and called an adit. So-called cut-and-cover tunnels (more correctly called conduits) are built by excavating from the surface, constructing the structure, and then covering with backfill. Tunnels underwater are now commonly built by the use of an immersed tube: long, prefabricated tube sections are floated to the site, sunk in a prepared trench, and covered with backfill. For all underground work, difficulties increase with the size of the opening and are greatly dependent upon weaknesses of the natural ground and the extent of the water inflow.

History**ANCIENT TUNNELS**

It is probable that the first tunnelling was done by prehistoric men seeking to enlarge their caves. All major ancient civilizations developed tunnelling methods. In Babylonia, tunnels were used extensively for irrigation; and a brick-lined pedestrian passage some 3,000 feet (900 metres) long was built around 2180 to 2160 bc under the Euphrates

River, to connect the royal palace with the temple. Construction was accomplished by diverting the river during the dry season. The Egyptians developed techniques for cutting soft rocks with copper saws and hollow reed drills, both surrounded by an abrasive, a technique probably used first for quarrying stone blocks and later in excavating temple rooms inside rock cliffs. Abu Simbel Temple on the Nile, for instance, was built in sandstone about 1250 BC for Ramses II (in the 1960s it was cut apart and moved to higher ground for preservation before flooding from the Aswān High Dam). Even more elaborate temples were later excavated within solid rock in Ethiopia and India.

The Greeks and Romans both made extensive use of tunnels: to reclaim marshes by drainage and for water aqueducts, such as the 6th-century-BC Greek water tunnel on the isle of Samos driven some 3,400 feet (one kilometre) through limestone with a cross section about six feet (two metres) square. Perhaps the largest tunnel in ancient times was a 4,800-foot-long, 25-foot-wide, 30-foot-high (1,500 by eight by nine metres) road tunnel (the Pausilippo) between Naples and Pozzuoli, executed in 36 BC. By that time surveying methods (commonly by string line and plumb bobs) had been introduced, and tunnels were advanced from a succession of closely spaced shafts to provide ventilation. To save the need for a lining, most ancient tunnels were located in reasonably strong rock, which was broken off (spalled) by so-called fire quenching, a method involving heating the rock with fire and suddenly cooling it by dousing with water. Ventilation methods were primitive, often limited to waving a canvas at the mouth of the shaft, and most tunnels claimed the lives of hundreds or even thousands of the slaves used as workers. In AD 41, the Romans used some 30,000 men for 10 years to push a 3.5 mile (six-kilometre) tunnel to drain Lacus Fucinus. They worked from shafts 120 feet (37 metres) apart and up to 400 feet (120 metres) deep. Far more attention was paid to ventilation and safety measures when workers were freemen, as shown by archaeological diggings at Hallstatt, Austria, where salt-mine tunnels have been worked since 2500 BC.

FROM THE MIDDLE AGES TO THE PRESENT

Canal and railroad tunnels. Because the limited tunnelling in the Middle Ages was principally for mining and military engineering, the next major advance was to meet Europe's growing transportation needs in the 17th century. The first of many major canal tunnels was the Canal du Midi (also known as Languedoc) tunnel in France, built in 1666–81 by Pierre Riquet as part of the first canal linking the Atlantic and the Mediterranean. With a length of 515 feet and a cross section of 22 by 27 feet (157 by seven by eight metres), it involved what was probably the first major use of explosives in public-works tunnelling, gunpowder placed in holes drilled by hand-held iron drills. A notable canal tunnel in England was the Bridgewater Canal Tunnel, built in 1761 by James Brindley to carry coal to Manchester from the Worsley mine. Many more canal tunnels were dug in Europe and North America in the 18th and early 19th centuries. Though the canals fell into disuse with the introduction of railroads around 1830, the new form of transport produced a huge increase in tunnelling, which continued for nearly 100 years as railroads expanded over the world. Much pioneer railroad tunnelling developed in England. A 3.5-mile (six-kilometre) tunnel (the Woodhead) of the Manchester–Sheffield Railroad (1839–45) was driven from five shafts up to 600 feet (180 metres) deep. In the United States, the first railroad tunnel was a 701-foot (214-metre) construction on the Allegheny Portage Railroad. Built in 1831–33, it was a combination of canal and railroad systems, carrying canal barges over a summit. Though plans for a transport link from Boston to the Hudson River had first called for a canal tunnel to pass under the Berkshire Mountains, by 1855, when the Hoosac Tunnel was started, railroads had already established their worth, and the plans were changed to a double-track railroad bore 24 by 22 feet and 4.5 miles long (seven by seven metres by seven kilometres). Initial estimates contemplated completion in three years; 21 were actually required, partly

because the rock proved too hard for either hand drilling or a primitive power saw. When the state of Massachusetts finally took over the project, it completed it in 1876 at five times the originally estimated cost. Despite frustrations, the Hoosac Tunnel contributed notable advances in tunnelling, including one of the first uses of dynamite, the first use of electric firing of explosives, and the introduction of power drills, initially steam and later air, from which there ultimately developed a compressed-air industry.

Simultaneously, more spectacular railroad tunnels were being started through the Alps. The first of these, the Mont Cenis Tunnel (also known as Fréjus), required 14 years (1857–71) to complete its 8.5-mile (14-kilometre) length. Its engineer, Germain Sommeiller, introduced many pioneering techniques, including rail-mounted drill carriages, hydraulic ram air compressors, and construction camps for workmen complete with dormitories, family housing, schools, hospitals, a recreation building, and repair shops. Sommeiller also designed an air drill that eventually made it possible to move the tunnel ahead at the rate of 15 feet (4.5 metres) per day and was used in several later European tunnels until replaced by more durable drills developed in the United States by Simon Ingersoll and others on the Hoosac Tunnel. As this long tunnel was driven from two headings separated by 7.5 miles (12 kilometres) of mountainous terrain, surveying techniques had to be refined. Ventilation became a major problem, which was solved by the use of forced air from water-powered fans and a horizontal diaphragm at mid-height, forming an exhaust duct at top of the tunnel. Mont Cenis was soon followed by other notable Alpine railroad tunnels: nine-mile (14-kilometre) St. Gotthard (1872–82), which introduced compressed-air locomotives and suffered major problems with water inflow, weak rock, and bankrupt contractors; the 12-mile (19-kilometre) Simplon (1898–1906); and the nine-mile (14-kilometre) Lötschberg (1906–11), on a northern continuation of the Simplon railroad line.

Nearly 7,000 feet (2,100 metres) below the mountain crest, Simplon encountered major problems from highly stressed rock flying off the walls in rock bursts; high pressure in weak schists and gypsum, requiring 10-foot (three-metre)-thick masonry lining to resist swelling tendencies in local areas; and from high-temperature water (130° F [54° C]), which was partly treated by spraying from cold springs. Driving Simplon as two parallel tunnels with frequent crosscut connections considerably aided ventilation and drainage.

Lötschberg was the site of a major disaster in 1908. When one heading was passing under the Kander River Valley, a sudden inflow of water, gravel, and broken rock filled the tunnel for a length of 4,300 feet (1,300 metres), burying the entire crew of 25 men. Though a geologic panel had predicted that the tunnel here would be in solid bedrock far below the bottom of the valley fill, subsequent investigation showed that bedrock lay at a depth of 940 feet (290 metres), so that at 590 feet (180 metres) the tunnel tapped the Kander River, allowing it and soil of the valley fill to pour into the tunnel, creating a huge depression, or sink, at the surface. After this lesson in the need for improved geological investigation, the tunnel was rerouted about one mile (1.6 kilometres) upstream, where it successfully crossed the Kander Valley in sound rock.

Most long-distance rock tunnels have encountered problems with water inflows. One of the most notorious was the first Japanese Tanna Tunnel, driven through the Takiji Peak in the 1920s. The engineers and crews had to cope with a long succession of extremely large inflows, the first of which killed 16 men and buried 17 others, who were rescued after seven days of tunnelling through the debris. Three years later another major inflow drowned several workers. In the end, Japanese engineers hit on the expedient of digging a parallel drainage tunnel the entire length of the main tunnel. In addition, they resorted to compressed-air tunnelling with shield and air lock (see below), a technique almost unheard of in mountain tunnelling.

Subaqueous tunnels. Tunnelling under rivers was considered impossible until the protective shield was developed in England by Marc Brunel, a French émigré engineer. The first use of the shield, by Brunel and his son Isam-

Greathead technique

bard, was in 1825 on the Wapping–Rotherhithe Tunnel through clay under the Thames River. The tunnel was of horseshoe section $22\frac{1}{4} \times 37\frac{1}{2}$ feet (seven by 12 metres) and brick lined. After several floodings from hitting sand pockets and a seven-year shutdown for refinancing and building a second shield, the Brunels succeeded in completing the world's first true subaqueous tunnel in 1841, essentially nine years' work for a 1,200-foot (370-metre)-long tunnel. In 1869 by reducing to a small size (eight feet [2.4 metres]) and by changing to a circular shield plus a lining of cast-iron segments, Peter W. Barlow and his field engineer, James Henry Greathead, were able to complete a second Thames tunnel in only one year as a pedestrian walkway from Tower Hill. In 1874, Greathead made the subaqueous technique really practical by refinements and mechanization of the Brunel–Barlow shield and by adding of compressed air pressure inside the tunnel to hold back the outside water pressure. Compressed air alone was used to hold back the water in 1880 in a first attempt to tunnel under New York's Hudson River; major difficulties and the loss of 20 lives forced abandonment after only 1,600 feet (480 metres) had been excavated. The first major application of the shield-plus-compressed-air technique occurred in 1886 on the London subway with an 11-foot (3.3-metre) bore, where it accomplished the unheard-of record of seven miles (11 kilometres) of tunnelling without a single fatality. So thoroughly did Greathead develop his procedure that it was used successfully for the next 75 years with no significant change. A modern Greathead shield illustrates his original developments as pictured in Figure 40: miners working under a hood in individual small pockets that can be quickly closed against inflow; shield propelled forward by jacks; permanent lining segments erected under protection of the shield tail; and the whole tunnel pressurized to resist water inflow.

Once subaqueous tunnelling became practical, many railroad and subway crossings were constructed with the Greathead shield, and the technique later proved adaptable for the much larger tunnels required for automobiles. A new problem, noxious gases from internal-combustion engines, was successfully solved by Clifford Holland for the world's first vehicular tunnel, completed in 1927 under the Hudson River and now bearing his name. Holland and his chief engineer, Ole Singstad, solved the ventilation problem with huge-capacity fans in ventilating buildings at each end, forcing air through a supply duct below the roadway, with an exhaust duct above the ceiling. Such ventilation provisions significantly increased the tunnel size, requiring about a 30-foot (nine-metre) diameter for a two-lane vehicular tunnel.

Many similar vehicular tunnels were built by shield-and-compressed-air methods—including Lincoln and Queens tunnels in New York City, Sumner and Callahan in Boston, and Mersey in Liverpool. Since 1950, however, most subaqueous tunnelers preferred the immersed-tube method, in which long tube sections are prefabricated, towed to the site, sunk in a previously dredged trench,

connected to sections already in place, and then covered with backfill. This basic procedure was first used in its present form on the Detroit River Railroad Tunnel between Detroit and Windsor, Ontario (1906–10). A prime advantage is the avoidance of high costs and the risks of operating a shield under high air pressure, since work inside the sunken tube is at atmospheric pressure (free air).

Machine-mined tunnels. Sporadic attempts to realize the tunnel engineer's dream of a mechanical rotary excavator culminated in 1954 at Oahe Dam on the Missouri River near Pierre, South Dakota. With ground conditions being favourable (a readily cuttable clay–shale), success resulted from a team effort: Jerome O. Ackerman as chief engineer, F.K. Mittry as initial contractor, and James S. Robbins as builder of the first machine—the “Mittry Mole.” Later contracts developed three other Oahe-type moles, so that all of the various tunnels here were machine-mined—totaling eight miles (13 kilometres) of 25- to 30-foot (eight- to nine-metre) diameter. These were the first of the modern moles that since 1960 have been rapidly adopted for many of the world's tunnels as a means of increasing speeds from the previous range of 25 to 50 feet (eight to 15 metres) per day to a range of several hundred feet per day. The Oahe mole was partly inspired by work on a pilot tunnel in chalk started under the English Channel for which an air-powered rotary cutting arm, the Beaumont borer, had been invented. A 1947 coal-mining version followed, and in 1949 a coal saw was used to cut a circumferential slot in chalk for 33-foot- (10-metre-) diameter tunnels at Fort Randall Dam, South Dakota. In 1962 a comparable breakthrough for the more difficult excavation of vertical shafts was achieved in the U.S. development of the mechanical raise borer, profiting from earlier trials in Germany.

Tunnelling techniques

BASIC TUNNELLING SYSTEM

Tunnels are generally grouped in four broad categories, depending on the material through which they pass: soft ground, consisting of soil and very weak rock; hard rock; soft rock, such as shale, chalk, and friable sandstone; and subaqueous. While these four broad types of ground condition require very different methods of excavation and ground support, nevertheless, nearly all tunnelling operations involve certain basic procedures: investigation, excavation and materials transport, ground support, and environmental control. Similarly, tunnels for mining and for civil-engineering projects share the basic procedures but differ greatly in the design approach toward permanence, due to their differing purposes. Many mining tunnels have been planned only for minimum-cost temporary use during ore extraction, although the growing desire of surface owners for legal protection against subsequent tunnel collapse may cause this to change. By contrast, most civil-engineering or public-works tunnels involve continued human occupancy plus full protection of adja-

Four categories of tunnels

cent owners and are much more conservatively designed for permanent safety. In all tunnels, geological conditions play the dominant role in governing the acceptability of construction methods and the practicality of different designs. Indeed, tunnelling history is filled with instances in which a sudden encounter with unanticipated conditions caused long stoppages for changes in construction methods, in design, or in both, with resulting great increases in cost and time. At the Awali Tunnel in Lebanon in 1960, for example, a huge flow of water and sand filled over two miles (three kilometres) of the bore and more than doubled construction time to eight years for its 10-mile (16-kilometre) length.

Geological investigation. Thorough geological analysis is essential in order to assess the relative risks of different locations and to reduce the uncertainties of ground and water conditions at the location chosen. In addition to soil and rock types, key factors include the initial defects controlling behaviour of the rock mass; size of rock block between joints; weak beds and zones, including faults, shear zones, and altered areas weakened by weathering or thermal action; groundwater, including flow pattern and pressure; plus several special hazards, such as heat, gas, and earthquake risk. For mountain regions the large cost and long time required for deep borings generally limit their number; but much can be learned from thorough aerial and surface surveys, plus well-logging and geophysical techniques developed in the oil industry. Often the problem is approached with flexibility toward changes in design and in construction methods and with continuous exploration ahead of the tunnel face, done in older tunnels by mining a pilot bore ahead and now by drilling. Japanese engineers have pioneered methods for prelocating troublesome rock and water conditions.

For large rock chambers and also particularly large tunnels, the problems increase so rapidly with increasing opening size that adverse geology can make the project impractical or at least tremendously costly. Hence, the concentrated opening areas of these projects are invariably investigated during the design stage by a series of small exploratory tunnels called drifts, which also provide for in-place field tests to investigate engineering properties of the rock mass and can often be located so their later enlargement affords access for construction.

Since shallow tunnels are more often in soft ground, borings become more practical. Hence, most subways involve borings at intervals of 100–500 feet (30–150 metres) to observe the water table and to obtain undisturbed samples for testing strength, permeability, and other engineering properties of the soil. Portals of rock tunnels are often in soil or in rock weakened by weathering. Being shallow, they are readily investigated by borings, but, unfortunately, portal problems have frequently been treated lightly. Often they are only marginally explored or the design is left to the contractor, with the result that a high percentage of tunnels, especially in the United States, have experienced portal failures. Failure to locate buried valleys has also caused a number of costly surprises. The five-mile (eight-kilometre) Oso Tunnel in New Mexico offers one example. There, in 1967, a mole had begun to progress well in hard shale, until 1,000 feet (300 metres) from the portal it hit a buried valley filled with water-bearing sand and gravel, which buried the mole. After six months' delay for hand mining, the mole was repaired and soon set new world records for advance rate—averaging 240 feet (70 metres) per day with a maximum of 420 feet (130 metres) per day.

Excavation and materials handling. Excavation of the ground within the tunnel bore may be either semicontinuous, as by hand-held power tools or mining machine, or cyclic, as by drilling and blasting methods for harder rock. Here each cycle involves drilling, loading explosive, blasting, ventilating fumes, and excavation of the blasted rock (called mucking). Commonly, the mucker is a type of front-end loader that moves the broken rock onto a belt conveyor that dumps it into a hauling system of cars or trucks. As all operations are concentrated at the heading, congestion is chronic, and much ingenuity has gone into designing equipment able to work in a small space.

Since progress depends on the rate of heading advance, it is often facilitated by mining several headings simultaneously, as opening up intermediate headings from shafts or from adits driven to provide extra points of access for longer tunnels.

For smaller diameters and longer tunnels, a narrow-gauge railroad is commonly employed to take out the muck and bring in men and construction material. For larger size bores of short to moderate length, trucks are generally preferred. For underground use these require diesel engines with scrubbers to eliminate dangerous gases from the exhaust. While existing truck and rail systems are adequate for tunnels progressing in the range of 40–60 feet (12–18 metres) per day, their capacity is inadequate to keep up with fast-moving moles progressing at the rate of several hundred feet per day. Hence, considerable attention is being devoted to developing high-capacity transport systems—continuous-belt conveyors, pipelines, and innovative rail systems (high-capacity cars on high-speed trains). Muck disposal and its transport on the surface can also be a problem in congested urban areas. One solution successfully applied in Japan is to convey it by pipeline to sites where it can be used for reclamation by landfill.

For survey control, high-accuracy transit-level work (from base lines established by mountaintop triangulation) has generally been adequate; long tunnels from opposite sides of the mountain commonly meet with an error of one foot (30 centimetres) or less. Further improvements are likely from the recent introduction of the laser, the pencil-size light beam of which supplies a reference line readily interpreted by workmen. Most moles in the United States now use a laser beam to guide steering; and some experimental machines employ electronic steering actuated by the laser beam.

Ground support. The dominant factor in all phases of the tunnelling system is the extent of support needed to hold the surrounding ground safely. Engineers must consider the type of support, its strength, and how soon it must be installed after excavation. The key factor in timing support installation is so-called stand-up time; *i.e.*, how long the ground will safely stand by itself at the heading, thus providing a period for installing supports. In soft ground, stand-up time can vary from seconds in such soils as loose sand up to hours in such ground as cohesive clay and even drops to zero in flowing ground below the water table, where inward seepage moves loose sand into the tunnel. Stand-up time in rock may vary from minutes in ravelling ground (closely fractured rock where pieces gradually loosen and fall) up to days in moderately jointed rock (joint spacing in feet) and may even be measured in centuries in nearly intact rock, where the rock-block size (between joints) equals or exceeds size of the tunnel opening, thus requiring no support. While a miner generally prefers rock to soft ground, local occurrences of major defects within the rock can effectively produce a soft-ground situation; passage through such areas generally requires radical change to the use of a soft-ground type of support.

Under most conditions, tunnelling causes a transfer of the ground load by arching to sides of the opening, termed the ground-arch effect (Figure 41, top). At the heading the effect is three-dimensional, locally creating a ground dome in which the load is arched not only to the sides but also forward and back. If permanence of the ground arch is completely assured, stand-up time is infinite, and no support is required. Ground-arch strength usually deteriorates with time, however, increasing the load on the support. Thus, the total load is shared between support and ground arch in proportion to their relative stiffness by a physical mechanism termed structure-medium interaction. The support load increases greatly when the inherent ground strength is much reduced by allowing excessive yield to loosen the rock mass. Because this may occur when installation of support is delayed too long, or because it may result from blast damage, good practice is based on the need to preserve the strength of the ground arch as the strongest load-carrying member of the system, by prompt installation of proper support and by preventing blast damage and movement from water inflow that has a tendency to loosen the ground.

material

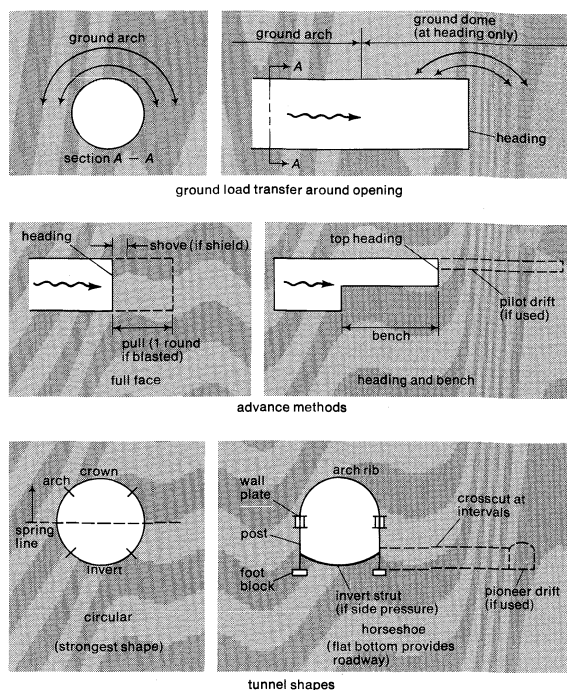

Figure 41: Tunnel terminology (see text).

Because stand-up time drops rapidly as size of the opening increases, the full-face method of advance (see Figure 41, centre), in which the entire diameter of the tunnel is excavated at one time, it is most suitable for strong ground or for smaller tunnels. The effect of weak ground can be offset by decreasing the size of opening initially mined and supported, as in the top heading and bench method of advance. For the extreme case of very soft ground, this approach results in the multiple-drift method of advance (Figure 42), in which the individual drifts are reduced to a small size that is safe for excavation and portions of the support are placed in each drift and progressively connected as the drifts are expanded. The central core is left unexcavated until sides and crown are safely supported, thus providing a convenient central buttress for bracing the temporary support in each individual drift. While this obviously slow multidrift method is an old technique for very weak ground, such conditions still force its adoption as a last resort in some modern tunnels. In 1971, for example, on the Straight Creek interstate highway tunnel in Colorado, a very complex pattern of multiple drifts was found necessary to advance this large horseshoe-shaped tunnel 42 by 45 feet (13 by 14 metres) high through a

Multiple-drift method

Figure 42: Multiple-drift method of excavation.

weak shear zone more than 1,000 feet (300 metres) wide, after unsuccessful trials with full-face operation of a shield.

In early tunnels, timber was used for the initial or temporary support, followed by a permanent lining of brick or stone masonry. Since steel became available, it has been widely used as the first temporary stage or primary support. For protection against corrosion, it is nearly always encased in concrete as a second stage or final lining. Steel-rib support with timber blocking outside has been widely employed in rock tunnels. The horseshoe shape is common for all but weakest rocks, since the flat bottom facilitates hauling. By contrast, the stronger and more structurally efficient circular shape is generally required to support the greater loads from soft ground. Figure 41, bottom, compares these two shapes and indicates a number of terms identifying various parts of the cross section and adjacent members for a steel-rib type of support. Here a wall plate is generally used only with a top heading method, where it serves to support arch ribs both in the top heading and also where the bench is being excavated by spanning over this length until posts can be inserted beneath. Newer types of supports are discussed below with more modern tunnel procedures, in which the trend is away from two stages of support toward a single support system, part installed early and gradually strengthened in increments for conversion to the final complete support system.

Environmental control. In all but the shortest tunnels, control of the environment is essential to provide safe working conditions. Ventilation is vital, both to provide fresh air and to remove explosive gases such as methane and noxious gases, including blast fumes. While the problem is reduced by using diesel engines with exhaust scrubbers and by selecting only low-fume explosives for underground use, long tunnels involve a major ventilating plant that employs a forced draft through lightweight pipes up to three feet (90 centimetres) in diameter and with booster fans at intervals. In smaller tunnels, the fans are frequently reversible, exhausting fumes immediately after blasting, then reversing to supply fresh air to the heading where the work is now concentrated.

High-level noise generated at the heading by drilling equipment and throughout the tunnel by high-velocity air in the vent lines frequently requires the use of earplugs with sign language for communication. In the future, equipment operators may work in sealed cabs, but communication is an unsolved problem. Electronic equipment in tunnels is prohibited, since stray currents may activate blasting circuits. Thunderstorms may also produce stray currents and require special precautions.

Dust is controlled by water sprays, wet drilling, and the use of respirator masks. Since prolonged exposure to dust from rocks containing a high percentage of silica may cause a respiratory ailment known as silicosis, severe conditions require special precautions, such as a vacuum-exhaust hood for each drill.

While excess heat is more common in deep tunnels, it occasionally occurs in fairly shallow tunnels. In 1953, workers in the 6.4-mile (10.3-kilometre) Telecote Tunnel near Santa Barbara, California, were transported immersed in water-filled mine cars through the hot area (117° F [47° C]). In 1970 a complete refrigeration plant was required to progress through a huge inflow of hot water at 150° F (66° C) in the seven-mile (11-kilometre) Graton Tunnel, driven under the Andes to drain a copper mine in Peru.

Control of dust and heat

MODERN SOFT-GROUND TUNNELLING

Settlement damage and lost ground. Soft-ground tunnels most commonly are used for urban services (subways, sewers, and other utilities) for which the need for quick access by passengers or maintenance staff favours a shallow depth. In many cities this means that the tunnels are above bedrock, making tunnelling easier but requiring continuous support. The tunnel structure in such cases is generally designed to support the entire load of the ground above it, in part because the ground arch in soil deteriorates with time and in part as an allowance for load changes resulting from future construction of buildings or tunnels. Soft-ground tunnels are typically circular in shape because of this shape's inherently greater strength

Urban
tunnels

and ability to readjust to future load changes. In locations within street rights-of-way, the dominant concern in urban tunnelling is the need to avoid intolerable settlement damage to adjoining buildings. While this is rarely a problem in the case of modern skyscrapers, which usually have foundations extending to rock and deep basements often extending below the tunnel, it can be a decisive consideration in the presence of moderate-height buildings, whose foundations are usually shallow. In this case the tunnel engineer must choose between underpinning or employing a tunnelling method that is sufficiently foolproof that it will prevent settlement damage.

Surface settlement results from lost ground; *i.e.*, ground that moves into the tunnel in excess of the tunnel's actual volume. All soft-ground tunnelling methods result in a certain amount of lost ground. Some is inevitable, such as the slow lateral squeeze of plastic clay that occurs ahead of the tunnel face as new stresses from doming at the heading cause the clay to move toward the face before the tunnel even reaches its location. Most lost ground, however, results from improper construction methods and careless workmanship. Hence the following emphasizes reasonably conservative tunnelling methods, which offer the best chance for holding lost ground to an acceptable level of approximately 1 percent.

Hand-mined tunnels. The ancient practice of hand mining is still economical for some conditions (shorter and smaller tunnels) and may illustrate particular techniques better than its mechanized counterpart. Examples are forepoling and breasting techniques as developed for the hazardous case of running (unstable) ground. Figure 43

Figure 43: Heading advance by forepoling.

shows the essentials of the process: heading advanced under a roof of forepole planks that are driven ahead at the crown (and at the sides in severe cases) plus continuous planking or breasting at the heading. With careful work the method permits advance with very little lost ground. The top breastboard may be removed, a small advance excavated, this breastboard replaced, and progress continued by working down one board at a time. While solid wall forepoling is nearly a lost art, an adaptation is termed spiling where the forepoles are intermittent with gaps between. Crown spiling is still resorted to for passing bad ground where spiles may consist of rails driven ahead, or even steel bars set in holes drilled into crushed rock.

In ground providing a reasonable stand-up time, a modern support system uses steel liner-plate sections placed against the soil and bolted into a solid sheeted complete circle and, in larger tunnels, strengthened inside by circular steel ribs. Individual liner plates are light in weight and are easily erected by hand. By employing small drifts (horizontal passageways), braced to a central core, liner-plate technique has been successful in larger tunnels—Figure 44 shows 1940 practice on the 20-foot (six-metre) tunnels of the Chicago subway. The top heading is carried ahead,

Figure 44: Soft-ground support by ribs and liner plates.

preceded slightly by a "monkey drift" in which the wall plate is set and serves as a footing for the arch ribs, also to span over as the wall plate is underpinned by erecting posts in small notches at each side of the lower bench. As the ribs and liner plate provide only a light support, they are stiffened by installation of a concrete lining about one day behind the mining. While liner-plate tunnels are more economical than shield tunnels, the risks of lost ground are somewhat greater and require not only very careful workmanship but also thorough soil-mechanics investigation in advance, pioneered in Chicago by Karl V. Terzaghi (founder of modern soil mechanics).

Shield tunnels. The risk of lost ground can also be reduced by using a shield with individual pockets from which men can mine ahead; these can quickly be closed to stop a run-in (Figure 40). In extremely soft ground the shield may be simply shoved ahead with all its pockets closed, completely displacing the soil ahead of it; or it may be shoved with some of the pockets open, through which the soft soil extrudes like a sausage, cut into chunks for removal by a belt conveyor. The first of these methods was used on the Lincoln Tunnel in Hudson River silt.

Support erected inside the tail of the shield consists of large segments, so heavy that they require a power erector arm for positioning while being bolted together. Because of its high resistance to corrosion, cast iron has been the most commonly used material for segments, thus eliminating the need for a secondary lining of concrete. Today, lighter segments are employed. In 1968, for example, the San Francisco subway used welded steel-plate segments, protected outside by a bituminous coating and galvanized inside. British engineers have developed precast concrete segments that are proving popular in Europe.

An inherent problem with the shield method is the existence of a two- to five-inch (five- to 13-centimetre) ring-shaped void left outside the segments as the result of the thickness of the skin plate and the clearance needed for segment erection. Movement of soil into this void could result in up to 5 percent lost ground, an amount intolerable in urban work. Lost ground is held to reasonable levels by promptly blowing small-sized gravel into the void, then injecting cement grout (sand-cement-water mixture).

Water control. A soft-ground tunnel below the water table involves a constant risk of a run-in; *i.e.*, soil and water flowing into the tunnel, which often results in complete loss of the heading. One solution is to lower the water table below the tunnel bottom before construction begins. This can be accomplished by pumping from deep wells ahead and from well points within the tunnel. While this benefits the tunnelling, dropping the water table increases the loading on deeper soil layers. If these are relatively compressible, the result can be a major settlement of adjacent buildings on shallow foundations, an extreme example being a 15- to 20-foot (4.5- to six-metre) subsidence in Mexico City due to overpumping.

Tunnel
blowout

When soil conditions make it undesirable to drop the water table, compressed air inside the tunnel may offset the outside water pressure. In larger tunnels, air pressure is generally set to balance the water pressure in the lower part of the tunnel, with the result that it then exceeds the smaller water pressure at the crown (upper part). Since air tends to escape through the upper part of the tunnel, constant inspection and repair of leaks with straw and mud are required. Otherwise, a blowout could occur, depressurizing the tunnel and possibly losing the heading as soil enters. Compressed air greatly increases operating costs, partly because a large compressor plant is needed, with standby equipment to insure against loss of pressure and partly because of the slow movement of men and muck trains through the air locks. The dominant factor, however, is the huge reduction in productive time and lengthy decompression time required for men working under air to prevent the crippling disease known as the bends (or caisson disease), also encountered by divers. Regulations stiffen as pressure increases up to usual maximum of 45 pounds per square inch (three atmospheres) where daily time is limited to one hour working and six hours for decompression. This, plus higher hazard pay, makes tunnelling under high air pressure very costly. In consequence, many tunnelling operations attempt to lower the operating air pressure, either by partially dropping the water table or, especially in Europe, by strengthening the ground through the injection of solidifying chemical grouts. French and British grouting-specialist companies have developed a number of highly engineered chemical grouts, and these are achieving considerable success in advance cementing of weak soil.

Soft-ground moles. Since their first success in 1954, moles (mining machines) have been rapidly adopted worldwide. Close copies of the Oahe moles were used for similar large-diameter tunnels in clay shale at Gardiner Dam in Canada and at Mangla Dam in Pakistan during the mid-1960s, and subsequent moles have succeeded at many other locations involving soft rocks. Of the several hundred moles built, most have been designed for the more easily excavated soil tunnel and are now beginning to divide into four broad types (all are similar in that they excavate the earth with drag teeth and discharge the muck onto a belt conveyor, and most operate inside a shield).

Four types
of moles

The open-face-wheel type is probably the most common. In Figure 45 a scale model is used to illustrate the operation of the wheel within a shield and the lining of precast concrete segments that are conveyed forward for erection within the tail of the shield. In the wheel in Figure 45 the cutter arm rotates in one direction; in a variant model it oscillates back and forth in a windshield-wiper action that is most suitable in wet, sticky ground. While suitable for firm ground, the open-face mole has sometimes been buried by running or loose ground.

The closed-faced-wheel mole partly offsets this problem, since it can be kept pressed against the face while taking in muck through slots. Since the cutters are changed from the face, changing must be done in firm ground. This kind of mole performed well, beginning in the late 1960s, on the San Francisco subway project in soft to medium clay with some sand layers, averaging 30 feet (nine metres) per day. In this project, mole operation made it cheaper and safer to drive two single-track tunnels than one large

double-track tunnel. When adjacent buildings had deep foundations, a partial lowering of the water table permitted operations under low pressure, which succeeded in limiting surface settlement to about one inch (25 millimetres). In areas of shallow building foundations, dewatering was not permitted; air pressure was then doubled to 28 pounds per square inch, and settlements were slightly smaller.

A third type is the pressure-on-face mole. Here, only the face is pressurized, and the tunnel proper operates in free air—thus avoiding the high costs of labour under pressure. In 1969 a first major attempt used air pressure on the face of a mole operating in sands and silts for the Paris Metro. A 1970 attempt in volcanic clays of Mexico City used a clay-water mixture as a pressurized slurry (liquid mixture); the technique was novel in that the slurry muck was removed by pipeline, a procedure simultaneously also used in Japan with a 23-foot (seven-metre)-diameter pressure-on-face mole. The concept has been further developed in England, where an experimental mole of this type was first constructed in 1971.

The digger-shield type of machine is essentially a hydraulic-powered digger arm excavating ahead of a shield, whose protection can be extended forward by hydraulically operated poling plates, acting as retractable spiles. In 1967–70 in the 26-foot (eight-metre)-diameter Saugus-Castaic Tunnel near Los Angeles, a mole of this type produced daily progress in clayey sandstone averaging 113 feet (34 metres) per day and 202 feet (62 metres) maximum, completing five miles (eight kilometres) of tunnel one-half year ahead of schedule. In 1968 an independently developed device of similar design also worked well in compacted silt for a 12-foot (3.7-metre)-diameter sewer tunnel in Seattle.

Pipe jacking. For small tunnels in a five- to eight-foot (1.5- to 2.5-metre) size range, small moles of the open-face-wheel type have been effectively combined with an older technique known as pipe jacking, in which a final lining of precast concrete pipe is jacked forward in sections. Figure 46 illustrates the system as used in 1969 on two miles (three kilometres) of sewer in Chicago clay with jacking runs up to 1,400 feet (430 metres) between shafts. A laser-aligned wheel mole cut a bore slightly larger than

From Engineering News Record (1969)

Figure 46: Pipe jacking within a tunnel (see text).

the lining pipe. Friction was reduced by bentonite lubricant added outside through holes drilled from the surface, which were later used for grouting any voids outside the pipe lining. The original pipe-jacking technique was developed particularly for crossing under railroads and highways as a means of avoiding traffic interruption from the alternate of construction in open trench. Since the Chicago project showed a potential for progress of a few hundred feet per day, the technique has become attractive for small tunnels.

MODERN ROCK TUNNELLING

Nature of the rock mass. It is important to distinguish between the high strength of a block of solid or intact rock and the much lower strength of the rock mass consisting of strong rock blocks separated by much weaker joints and other rock defects. While the nature of intact rock is significant in quarrying, drilling, and cutting by moles, tunnelling and other areas of rock engineering are concerned with the properties of the rock mass. These properties are controlled by the spacing and nature of the defects, including joints (generally fractures caused by tension and sometimes filled with weaker material), faults (shear fractures frequently filled with claylike material called gouge), shear zones (crushed from shear displacement), altered zones (in which heat or chemical action have largely destroyed the original bond cementing the rock crystals), bedding planes, and weak seams (in shale, often altered to clay). Since these geological details (or hazards) usually can only be generalized in advance predictions, rock-tunnelling methods require flexibility for handling conditions as they are encountered. Any of these defects can convert the rock to the more hazardous soft-ground case.

Also important is the geostress; *i.e.*, the state of stress existing *in situ* prior to tunnelling. Though conditions are fairly simple in soil, geostress in rock has a wide range because it is influenced by the stresses remaining from past geological events: mountain building, crustal movements, or load subsequently removed (melting of glacial ice or erosion of former sediment cover). Evaluation of the geostress effects and the rock mass properties are primary objectives of the relatively new field of rock mechanics and are dealt with below with underground chambers since their significance increases with opening size. This section therefore emphasizes the usual rock tunnel, in the size range of 15 to 25 feet (4.5 to eight metres).

Conventional blasting. Blasting is carried on in a cycle of drilling, loading, blasting, ventilating fumes, and removing muck. Since only one of these five operations can be conducted at a time in the confined space at the heading, concentrated efforts to improve each have resulted in raising the rate of advance to a range of 40–60 feet (12–18 metres) per day, or probably near the limit for such a cyclic system. Drilling, which consumes a major part of the time cycle, has been intensely mechanized in the United States. High-speed drills with renewable bits of hard tungsten carbide are positioned by power-operated jib booms located at each platform level of the drilling jumbo (a mounted platform for carrying drills). Truck-mounted jumbos are used in larger tunnels. When rail-mounted, the drilling jumbo is arranged to straddle the mucker so that drilling can resume during the last phase of the mucking operation.

By experimenting with various drill-hole patterns and the sequence of firing explosives in the holes, Swedish engineers have been able to blast a nearly clean cylinder in each cycle, while minimizing use of explosives.

Dynamite, the usual explosive, is fired by electric blasting caps, energized from a separate firing circuit with locked switches. Cartridges are generally loaded individually and seated with a wooden tamping rod; Swedish efforts to expedite loading often employ a pneumatic cartridge loader. American efforts toward reduced loading time have tended to replace dynamite with a free-running blasting agent, such as a mixture of ammonium nitrate and fuel oil (called AN-FO), which in granular form (prills) can be blown into the drill hole by compressed air. While AN-FO-type agents are cheaper, their lower power increases

the quantity required, and their fumes usually increase ventilating requirements. For wet holes, the prills must be changed to a slurry requiring special processing and pumping equipment.

Rock support. Most common loading on the support of a tunnel in hard rock is due to the weight of loosened rock below the ground arch, where designers rely particularly on experience with Alpine tunnels as evaluated by two Austrians, Karl V. Terzaghi, the founder of soil mechanics, and Josef Stini, a pioneer in engineering geology. The support load is greatly increased by factors weakening the rock mass, particularly blasting damage. Furthermore, if a delay in placing support allows the zone of rock loosening to propagate upward (*i.e.*, rock falls from the tunnel roof), the rock-mass strength is reduced, and the ground arch is raised. Obviously, the loosened rock load can be greatly altered by a change in joint inclination (orientation of rock fractures) or by the presence of one or more of the rock defects previously mentioned. Less frequent but more severe is the case of high geostress, which in hard, brittle rock may result in dangerous rock bursts (explosive spalling off from the tunnel side) or, in a more plastic rock mass, may exhibit a slow squeezing into the tunnel. In extreme cases, squeezing ground has been handled by allowing the rock to yield while keeping the process under control, then remining and resetting initial support several times, plus deferring concrete lining until the ground arch becomes stabilized.

For many years steel rib sets were the usual first-stage support for rock tunnels, with close spacing of the wood blocking against the rock being important to reduce bending stress in the rib. Advantages are increased flexibility in changing rib spacing plus the ability to handle squeezing ground by resetting the ribs after remining. A disadvantage is that in many cases the system yields excessively, thus inviting weakening of the rock mass. Finally, the rib system serves only as a first-stage or temporary support, requiring a second-stage encasement in a concrete lining for corrosion protection.

Concrete lining. Concrete linings aid fluid flow by providing a smooth surface and insure against rock fragment falling on vehicles using the tunnel. While shallow tunnels are often lined by dropping concrete down holes drilled from the surface, the greater depth of most rock tunnels requires concreting entirely within the tunnel. Operations in such congested space involve special equipment, including agitator cars for transport, pumps or compressed-air devices for placing the concrete, and telescoping arch forms that can be collapsed to move forward inside forms remaining in place. The invert is generally concreted first, followed by the arch where forms must be left in place from 14 to 18 hours for the concrete to gain necessary strength. Voids at the crown are minimized by keeping the discharge pipe buried in fresh concrete. The final operation consists of contact grouting, in which a sand-cement grout is injected to fill any voids and to establish full contact between lining and ground. The method usually produces progress in the range of 40 to 120 feet (12 to 36 metres) per day. In the 1960s there was a trend toward an advancing-slope method of continuous concreting, as originally devised for embedding the steel cylinder of a hydropower penstock. In this procedure, several hundred feet of forms are initially set, then collapsed in short sections and moved forward after the concrete has gained necessary strength, thus keeping ahead of the continuously advancing slope of fresh concrete. As a 1968 example, Libby Dam's Flathead Tunnel in Montana attained a concreting rate of 300 feet (90 metres) per day by using the advancing slope method.

Rock bolts. Rock bolts are used to reinforce jointed rock much as reinforcing bars supply tensile resistance in reinforced concrete. After early trials around 1920, they were developed in the 1940s for strengthening laminated roof strata in mines (see INDUSTRIES, EXTRACTION AND PROCESSING). For public works their use has increased rapidly since 1955, as confidence has developed from two independent pioneering applications, both in the early 1950s. One was the successful change from steel rib sets to cheaper rock bolts on major portions of the 85 miles (135

Steel rib sets

Geostress

Reducing explosive-loading time

Pioneering uses of rock bolts

Rock
tendons

kilometres) of tunnels forming New York City's Delaware River Aqueduct. The other was the success of such bolts as the sole rock support in large underground powerhouse chambers of Australia's Snowy Mountains project. Since about 1960, rock bolts have had major success in providing the sole support for large tunnels and rock chambers with spans up to 100 feet (30 metres). Bolts are commonly sized from 0.75 to 1.5 inches (19–38 millimetres) and function to create a compression across rock fissures, both to prevent the joints opening and to create resistance to sliding along the joints. For this they are placed promptly after blasting, anchored at the end, tensioned, and then grouted to resist corrosion and to prevent anchor creep. Rock tendons (prestressed cables or bundled rods, providing higher capacity than rock bolts) up to 250 feet (75 metres) long and prestressed to several hundred tons each have succeeded in stabilizing many sliding rock masses in rock chambers, dam abutments, and high rock slopes. A noted example is their use in reinforcing the abutments of Vaiont Dam in Italy. In 1963 this project experienced disaster when a giant landslide filled the reservoir, causing a huge wave to overtop the dam, with large loss of life. Remarkably, the 875-foot (270-metre)-high arch dam survived this huge overloading; the rock tendons are believed to have supplied a major strengthening.

Shotcrete. Shotcrete is small-aggregate concrete conveyed through a hose and shot from an air gun onto a backup surface on which it is built up in thin layers. Though sand mixes had been so applied for many years, new equipment in the late 1940s made it possible to improve the product by including coarse aggregate up to one inch (25 millimetres); strengths of 6,000 to 10,000 pounds per square inch (400 to 700 kilograms per square centimetre) became common. Following initial success as rock-tunnel support in 1951–55 on the Maggia Hydro Project in Switzerland, the technique was further developed in Austria and Sweden. The remarkable ability of a thin shotcrete layer (one to three inches [25 to 75 millimetres]) to bond to and knit fissured rock into a strong arch and to stop ravelling of loose pieces soon led to shotcrete largely superseding steel rib support in many European rock tunnels. By 1962 the practice had spread to South America. From this experience plus limited trial at the Hecla Mine in Idaho, the first major use of coarse-aggregate shotcrete for tunnel support in North America developed in 1967 on the Vancouver Railroad Tunnel, with its 20- by 29-foot (six- by nine-metre)-high cross section and two-mile (three-kilometre) length. Here an initial two- to four-inch (five- to 10-centimetre) coat proved so successful in stabilizing hard, blocky shale and in preventing ravelling in friable (crumbly) conglomerate and sandstone that the shotcrete was thickened to six inches (15 centimetres) in the arch and four inches (10 centimetres) on the walls to form the permanent support, saving about 75 percent of the cost of the original steel ribs and concrete lining.

Applying
shotcrete

A key to shotcreting's success is its prompt application before loosening starts to reduce the strength of the rock mass. In Swedish practice this is accomplished by applying immediately after blasting and, while mucking is in progress, utilizing the "Swedish robot" shown in Figure 47, which allows the operator to remain under the protection of the previously supported roof. On the Vancouver tunnel, shotcrete was applied from a platform extending forward from the jumbo while the mucking machine op-

Figure 47: "Swedish robot" used for shotcreting.

From Civil Engineering (January 1970), A.S.C.E.

erated below. By taking advantage of several unique properties of shotcrete (flexibility, high bending strength, and ability to increase thickness by successive layers), Swedish practice has developed shotcreting into a single-support system that is strengthened progressively as needed for conversion into the final support.

Preserving rock strength. In rock tunnels, the requirements for support can be significantly decreased to the extent that the construction method can preserve the inherent strength of the rock mass. The opinion has been often expressed that a high percentage of support in United States rock tunnels (perhaps over half) has been needed to stabilize rock damaged by blasting rather than because of an inherently low strength of the rock. As a remedy, two techniques are currently available. First is the Swedish development of sound-wall blasting (to preserve rock strength), treated below under rock chambers, since its importance increases with size of the opening. The second is the American development of rock moles that cut a smooth surface in the tunnel (Figure 48), thus minimiz-

Rock
moles

Figure 48: Workman tightening the nut on a rock bolt that holds a steel strap inside a mole-excavated tunnel. Laser beam target at left is used to guide steering of mole.

ing rock damage and support needs—here limited to rock bolts connected by steel straps for this sandstone tunnel. In stronger rocks (as the 1970 Chicago sewers in dolomite) mole excavation not only largely eliminated need for support but also produced a surface of adequate smoothness for sewer flow, which permitted a major saving by omitting the concrete lining. Since their initial success in clay shale, the use of rock moles has expanded rapidly and has achieved significant success in medium-strength rock such as sandstone, siltstone, limestone, dolomite, rhyolite, and schist. The advance rate has ranged up to 300 to 400 feet (90 to 120 metres) per day and has often outpaced other operations in the tunnelling system. While experimental moles were used successfully to cut hard rock such as granite and quartzite, such devices were not economical, because cutter life was short, and frequent cutter replacement was costly. This was likely to change, however, as mole manufacturers sought to extend the range of application. Improvement in cutters and progress in reducing the time lost from equipment breakages were producing consistent improvements.

American moles have developed two types of cutters: disk cutters that wedge out the rock between initial grooves cut

Continu-
ous-
tunnelling
system

by the hard-faced rolling disks, and roller-bit cutters using bits initially developed for fast drilling of oil wells. As later entrants in the field, European manufacturers have generally tried a different approach—milling-type cutters that mill or plane away part of the rock, then shear off undercut areas. Attention is also focussing on broadening the moles' capabilities to function as the primary machine of the whole tunnelling system. Thus, future moles are expected not only to cut rock but also to explore ahead for dangerous ground; handle and treat bad ground; provide a capability for prompt erection of support, rock bolting, or shotcreting; change cutters from the rear in loose ground; and produce rock fragments of a size appropriate to capability of the muck removal system. As these problems are solved, the continuous-tunnelling system by mole is expected largely to replace the cyclic drilling and blasting system.

Water inflows. Exploring ahead of the path of a tunnel is particularly necessary for location of possible high water inflows and permitting their pretreatment by drainage or grouting. When high-pressure flows occur unexpectedly, they result in long stoppages. When huge flows are encountered, one approach is to drive parallel tunnels, advancing them alternately so that one relieves pressure in front of the other. This was done in 1898 in work on the Simplon Tunnel, and in 1969 on the Graton Tunnel in Peru, where flow reached 60,000 gallons (230,000 litres) per minute. Another technique is to depressurize ahead by drain holes (or small drainage drifts on each side), an extreme example being the 1968 Japanese handling of extraordinarily difficult water and rock conditions on the Rokko Railroad Tunnel, using approximately three-quarters of a mile (1,200 metres) of drainage drifts and five miles (eight kilometres) of drain holes in a 0.25-mile (400-metre) length of the main tunnel.

Heavy ground. The miner's term for very weak or high geostress ground that causes repeated failures and replacement of support is heavy ground. Ingenuity, patience, and large increases of time and funds are invariably required to deal with it. Special techniques have generally been evolved on the job, as indicated by a few of the numerous examples. On the 7.2-mile (11.6-kilometre) Mont Blanc Vehicular Tunnel of 32-foot (10-metre) size under the Alps in 1959–63, a pilot bore ahead helped greatly to reduce rock bursts by relieving the high geostress. The five-mile (eight-kilometre), 14-foot (four-metre) El Colegio Penstock Tunnel in Colombia was completed in 1965 in bituminous shale, requiring the replacement and resetting of more than 2,000 rib sets, which buckled as the invert (bottom supports) and sides gradually squeezed in up to three feet (90 centimetres), and by deferring concreting until the ground arch stabilized.

While the ground arch eventually stabilized in these and numerous similar examples, knowledge is inadequate to establish the point between desirable deformation (to mobilize ground strength) and excessive deformation (which reduces its strength), and improvement is most likely to come from carefully planned and observed field-test sections at prototype scale, but these have been so costly that very few have actually been executed, notably the 1940 test sections in clay on the Chicago subway and the 1950 Garrison Dam test tunnel in the clay-shale of North Dakota. Such prototype field testing has resulted, however, in substantial savings in eventual tunnel cost. For harder rock, reliable results are even more fragmentary.

Unlined tunnels. Numerous modest-size conventionally blasted tunnels have been left unlined if human occupancy was to be rare and the rock was generally good. Initially, only weak zones are lined, and marginal areas are left for later maintenance. Most common is the case of a water tunnel that is built oversized to offset the friction increase from the rough sides and, if a penstock tunnel, is equipped with a rock trap to catch loose rock pieces before they can enter the turbines. Most of these have been successful, particularly if operations could be scheduled for periodic shutdowns for maintenance repair of rockfalls; the Laramie-Poudre Irrigation Tunnel in northern Colorado experienced only two significant rockfalls in 60 years, each easily repaired during a nonirrigation period. In contrast, a

progressive rockfall on the 14-mile (23-kilometre) Kemano penstock tunnel in Canada resulted in shutting down the whole town of Kitimat, British Columbia, and vacationing workers for nine months in 1961 since there were no other electric sources to operate the smelter. Thus, the choice of an unlined tunnel involves a compromise between initial saving and deferred maintenance plus evaluation of the consequences of a tunnel shutdown.

Underground excavations and structures

ROCK CHAMBERS

While chambers in 1971 were being excavated in rock to fulfill a wide variety of functions, the main stimulus to their development had come from hydroelectric-power-plant requirements. Though the basic concept originated in the United States, where the world's first underground hydroplants were built in enlarged tunnels at Snoqualme Falls near Seattle, Washington, in 1898 and at Fairfax Falls, Vermont, in 1904, Swedish engineers developed the idea into excavating large chambers to accommodate hydraulic machinery. After an initial trial in 1910–14 at the Porjus Plant north of the Arctic Circle, many underground power plants were subsequently built by the Swedish State Power Board. Swedish success soon popularized the idea through Europe and over the world, particularly to Australia, Scotland, Canada, Mexico, and Japan, where several hundred underground hydroplants have been built since 1950. Sweden, having a long experience with explosives and rock work, with generally favourable strong rock, and with energetic research and development, has even been able to lower the costs for underground work to approximate those for surface construction of such facilities as power plants, warehouses, pumping plants, oil-storage tanks, and water-treatment plants. With costs in the United States being five to 10 times greater underground, new construction of underground chambers was not significantly resumed there until 1958, when the Haas underground hydroplant was built in California and the Norad underground air force command centre in Colorado. By 1970, the United States had begun to adopt the Swedish concept and had completed three more hydroplants with several more under construction or being planned.

Favourably located, an underground hydroplant can have several advantages over a surface plant, including lower costs, because certain plant elements are built more simply underground: less risk from avalanches, earthquakes, and bombing; cheaper year-round construction and operation (in cold climates); and preservation of a scenic environment—a dominant factor in Scotland's tourist area and now receiving recognition worldwide. A typical layout involves a complex assembly of tunnels, chambers, and shafts. Figure 49 shows the world's largest underground powerhouse, Churchill Falls in the Labrador wilderness of Canada, with a capacity of 5,000,000 kilowatts, under construction since 1967 at a total project cost of about

\$1,000,000,000. By building a dam of modest height well above the falls and by locating the powerhouse at 1,000 feet (300 metres) depth with a one-mile (1,600-metre) tunnel (the tailrace tunnel) to discharge water from the turbines below downstream rapids, the designers have been able to develop a head (water height) of 1,060 feet (320 metres) while at the same time preserving the scenic 250-foot (75-metre)-high waterfall, expected to be a major tourist attraction once several hundred miles of wilderness-road improvement permits public access. Openings here are of impressive size: machine hall (powerhouse proper), 81-foot (25-metre) span by 154 feet (47 metres) high by 972 feet (296 metres) long; surge chamber, 60 feet (18 metres) by 148 feet (45 metres) high by 763 feet (234 metres); and two tailrace tunnels, 45 by 60 feet (14 by 18 metres) high.

Large rock chambers are economical only when the rock can essentially support itself through a durable ground arch with the addition of only a modest amount of artificial support. Otherwise, major structural support for a large opening in weak rock is very costly. The Norad project, for example, included an intersecting grid of chambers in granite 45 by 60 feet (14 by 18 metres) high, supported by rock bolts except in one local area. Here, one of the chamber intersections coincided with the intersection of two curving shear zones of fractured rock—a happening which added \$3,500,000 extra cost for a perforated concrete dome 100 feet (30 metres) in diameter to secure this local area. In some Italian and Portuguese underground powerhouses, weak-rock areas have necessitated comparable costly lining. While significant rock defects are more manageable in the usual 10- to 20-foot (three- to six-metre) rock tunnel, the problem so increases with increasing size of opening that the presence of extensive weak rock can easily place a large-chamber project outside the range of economic practicality. Hence, geological conditions are very carefully investigated for rock-chamber projects, using many borings plus exploratory drifts to locate rock defects, with a three-dimensional geological model to aid in visualizing conditions. A chamber location is selected that offers the least risk of support problems. This objective was largely attained in the granite gneiss at Churchill Falls, where the location and chamber configuration were changed several times to avoid rock defects. Rock-chamber projects, furthermore, rely heavily on the relatively new field of rock mechanics to evaluate the engineering properties of the rock mass, in which exploratory drifts are particularly important in affording access for in-place field testing.

Rock-mechanics investigation. The young field of rock mechanics was beginning, early in the 1970s, to develop a rational basis of design for projects in rock; much is already developed for projects in soil by the older field of soil mechanics. Initially, the discipline had been stimulated by such complex projects as arch dams and underground chambers and then increasingly with similar problems with tunnels, rock slopes, and building foundations. In treating the rock mass with its defects as an engineering material, rock mechanics utilizes numerous techniques such as theoretical analysis, laboratory testing, field testing on site, and instrumentation to monitor performance during construction and operation. Since rock mechanics is a discipline in itself, only the most common field tests are briefly outlined below to give some concept of its role in design, particularly for a rock-chamber project.

Geostress, which can be a significant factor in choice of chamber orientation, shape, and support design, is usually determined in exploratory drifts. Two methods are common, although each is still in the development stage. One is an "overcoring" method (developed in Sweden and South Africa) used for ranges up to around 100 feet (30 metres) out from the drift and employing a cylindrical instrument known as a borehole deformer. A small hole is drilled into the rock and the deformer inserted. Diameter changes of the borehole are measured and recorded by the deformer as the geostress is relieved by overcoring (cutting a circular core around the small hole) with a six-inch (15-centimetre) bit. Measurements at several depths in at least three borings at different orientations furnish the data needed for computing the existing geostress. When

measurement is desired only at the surface of the drift, the so-called French flat-jack method is preferred. In this, a slot is cut at the surface, and its closure is measured as the geostress is relieved by the slot. Next, a flat hydraulic jack is inserted in the rock. The jack pressure necessary to restore closure of the slot (to the condition before its cutting) is considered to equal the original geostress. As these methods require a long drift or shaft for access to the area of measurement, development is under way (particularly in the United States) to extend the range of depth to a few thousand feet. Such will aid in comparing geostress at alternate sites, and hopefully avoid locations with high geostress, which has proven very troublesome in several past chamber projects.

Shear strength of a joint, fault, or other rock defect is a controlling factor in appraising strength of the rock mass in terms of its resistance to sliding along the defect. Although partly determinable in the laboratory, it is best investigated in the field by a direct shear test at the work site. While this test has long been used for soil and soft rock, its adaptation to hard rock is due largely to work performed in Portugal. Shear strength is important in all problems of sliding; at Morrow Point Dam, in Colorado, for example, a large rock wedge between two faults started to move into the underground powerhouse and was stabilized by large tendons anchored back in a drainage tunnel plus strut action provided by the concrete structure that supported the generator machinery.

The modulus of deformation (that is, the stiffness of the rock) is significant in problems involving movement under stress and in sharing of load between rock and structure, as in a tunnel lining, embedded steel penstock, or foundation of a dam or heavy building. The simplest field test is the plate-jacking method, in which the rock in a test drift is loaded by hydraulic jacks acting on a plate two to three feet (60 to 90 centimetres) in diameter. Larger areas can be tested either by radially loading the internal surface of a test tunnel or by pressurizing a membrane-lined chamber.

Analysis methods in rock mechanics have helped in appraising stress conditions around openings—as at Churchill Falls—to identify and then correct zones of tension and stress concentration. Related work with rock block models is contributing to understanding the failure mechanism of the rock mass, notable work being under way in Austria, Yugoslavia, and the United States.

Chamber excavation and support. Excavation for rock chambers generally starts with a horizontal tunnel at the top of the area to be excavated and progresses down in steps. Rock is excavated by drilling and blasting, carried on simultaneously in several headings. This procedure may give way, however, as moles gain in their ability to cut hard rock economically and as a rock saw or other device is developed for squaring up the circular surface normally cut by the mole. High geostress can be a real problem (causing inward movement of the chamber walls) unless handled by a careful sequence of partial excavations designed to relieve it gradually.

Many of the earlier underground hydroplants were roofed with a concrete arch, often designed for a major load, as in some Italian projects in weak rocks or where blast damage was considerable, as at a few projects in Scotland. Since about 1960, however, most have relied solely on rock bolts for support (sometimes supplemented with shotcrete). That such a light support has been widely successful can be attributed to careful investigation resulting in locations with strong rock, employment of techniques to relieve high geostress, and controlled blasting to preserve rock strength.

Sound-wall blasting. Sound-wall blasting is a technique, primarily developed in Sweden, that preserves the finished rock surfaces in sound condition by careful design of the blasting charges to fit the rock conditions. In underground work, Swedish practice has often produced remarkable results almost like rock sculpturing in which the excellent shaping and preservation of the rock surfaces often permit omitting concrete lining at savings greater than the extra cost of the engineered blasting. While Swedish success is due partly to the generally strong rock in that country, it is due even more to energetic research and development

Excavation methods for rock chambers

Swedish work on sound-wall blasting

Techniques of rock mechanics

programs to develop (1) theoretical methods for blasting design plus field blast tests to determine pertinent rock properties, (2) special explosives for different rock conditions, and (3) institutes for the training of specialized blasting engineers to apply these procedures in the field construction.

In the United States, sound-wall blasting has enjoyed only indifferent success underground. Reluctance of the blasting industry to change from its customary empirical approach and the lack of specialized blasting engineers trained in Swedish practices have led to a return to the more costly technique of mining an initial pilot bore to afford stress relief, followed by blasting successively thinner slabs toward the free face of the pilot bore.

For excavation from the ground surface, the requirements of sound-wall blasting largely have been met by the technique of presplitting, developed in the United States in the late 1950s. Basically, this technique consists of creating a continuous crack (or presplit) at a desired finished excavation line by initially firing a line of closely spaced, lightly loaded holes drilled there. Next, the interior rock mass is drilled and blasted by conventional means. If a high horizontal geostress is present, it is important that it first be relieved (as by an initial cut a modest distance from the presplit line); otherwise, the presplit crack is not likely to occur in the direction desired. Stockton Dam, in Missouri, illustrates the benefit of presplitting. Here, vertical faces in dolomite up to 110 feet (34 metres) were successfully presplit and promptly rock bolted; this permitted a major reduction in thickness of the concrete facing, resulting in a net saving of about \$2,500,000.

SHAFTS

The mining industry has been the primary constructor of shafts, because at many locations these are essential for access to ore, for ventilation, and for material transport. Depths of several thousand feet are common. In public-works projects, such as sewer tunnels, shafts are usually only a few hundred feet deep and because of their high cost are avoided in the design stage wherever practical. Shallower shafts find many uses, however, for penstocks and access to underground hydroplants, for dropping aqueduct tunnels beneath rivers, for missile silos, and for oil and liquefied-gas storage. Being essentially vertical tunnels, shafts involve the same problems of different types of ground and water conditions but on an aggravated scale, since vertical transport makes the operation slower, more costly, and even more congested than with horizontal tunneling. Except when there is a high horizontal geostress in rock, the loading on a shaft support is generally less than for a tunnel. Inflowing water, however, is far more dangerous during construction and generally intolerable during operation. Hence, most shafts are concrete lined and waterproofed, and the lining installation usually follows only a short distance behind excavation. The shape is usually circular, although, before present mechanized excavation methods, mining shafts were frequently rectangular. Shafts may be sunk from the surface (or drilled in smaller sizes), or, if an existing tunnel provides access, they may be raised from below.

Shaft sinking and drilling. Mining downward, generally from the surface, although occasionally from an underground chamber, is called shaft sinking. In soil, shallow shafts are frequently supported with interlocking steel sheetpiling held by ring beams (circular rib sets); or a concrete caisson may be built on the surface and sunk by excavating inside as weight is added by extending its walls. More recently, large-diameter shallow shafts have been constructed by the "slurry trench method," in which a circular trench is excavated while filled with a heavy liquid (usually bentonite slurry), which supports its walls until finally displaced by filling the trench with concrete. For greater depth in soil, another method involves freezing a ring of soil around the shaft. In this method, a ring of closely spaced freezing holes is drilled outside the shaft. A refrigerated brine is circulated in double-wall pipes in the holes to freeze the soil before starting the shaft excavation. It is then kept frozen until the shaft is completed and lined with concrete. This freezing method was developed

in Germany and The Netherlands, where it was used successfully to sink shafts through nearly 2,000 feet (600 metres) of alluvial soil to reach coal beds in the underlying rock. It has also been applied under similar conditions in Britain, Poland, and Belgium. Occasionally, the freezing technique has been used in soft rock to solidify a deep aquifer (layer of water-bearing rock). Due to the long time required for drilling the freezing holes and for freezing the ground (18 to 24 months for some deep shafts), the freezing method has not been popular on public-works projects except as a last resort, although it has been used in New York City for shallow shafts through soil to gain access for deep-water tunnels.

More efficient methods for sinking deep shafts in rock were developed in South African gold-mining operations, in which shafts 5,000 to 8,000 feet (1,500 to 2,400 metres) deep are common and generally 20 to 30 feet (six to nine metres) in diameter. South African procedure has produced progress around 30 feet (nine metres) per day by utilizing a sinking stage of multiple platforms, which permits concurrent excavation and concrete lining. Excavation is by drilling and blasting with muck loaded into large buckets, with larger shafts operating four buckets alternately in hoisting wells extending through the platforms. Grouting is carried a few hundred feet ahead to seal out water. Best progress is achieved when the rock is pregrouted from two or three holes drilled from the surface before starting the shaft. Since the shallower shafts on public-works projects cannot justify the investment in the large plant needed to operate a sinking stage, their progress in rock is much slower—in the range of five to 10 feet (1.5 to three metres) per day.

Occasionally, shafts have been sunk through soil by drilling methods. The technique was first used in British practice in 1930 and was subsequently further refined in The Netherlands and Germany. The procedure involves first advancing a pilot hole, then reaming in several stages of enlargement to final diameter, while the walls of the hole are supported by a heavy liquid (called drilling mud), with circulation of the mud serving to remove the cuttings. Then a double-wall steel casing is sunk by displacing the drilling mud, followed by injecting concrete outside the casing and within the annular space between its double walls. One use of this technique was in the 25-foot (eight-metre)-diameter Statemine shaft in The Netherlands, 1,500 feet (460 metres) deep through soil that required about three and one-half years before completion in 1959. For the 1962 construction of some 200 missile shafts in Wyoming in soft rock (clay shale and friable sandstone), a giant auger proved effective for sinking these 65-foot (20-metre)-deep, 15-foot (five-metre)-diameter shafts, generally at the rate of two to three days per shaft. Perhaps the largest drilled shaft is one in the Soviet Union: 2,674 feet (815 metres) deep, which was enlarged in four stages of reaming to a final diameter of 28.7 feet (about nine metres), progressing at a reported rate of 15 feet (4.5 metres) per day.

More dramatic has been the adaptation in the United States of oil-well-drilling methods in a technique called big-hole drilling, used for constructing small shafts in the diameter range of three to six feet (90 to 180 centimetres). Big-hole drilling was developed for deep emplacement in underground testing of nuclear devices, with more than 150 such big holes drilled in the 1960s up to 5,000 feet (1,500 metres) deep in Nevada in rocks ranging from soft tuff to granite. In big-hole drilling the hole is made in one pass only with an array of roller-bit cutters that are pressed against the rock by the weight of an assembly of lead-filled drill collars, sometimes totalling 300,000 pounds (135,000 kilograms). The drill rig must be huge in size to handle such loads. The greatest impediment controlling progress has been the removal of drill cuttings, where an air lift is showing promise.

Shaft raising. Handling cuttings is simplified when the shaft can be raised from an existing tunnel, since the cuttings then merely fall to the tunnel, where they are easily loaded into mine cars or trucks. This advantage has long been recognized in mining; where once an initial shaft has been sunk to provide access to and an opportunity for

Big-hole
drilling

Freezing
method
of shaft
sinking

horizontal tunnels, most subsequent shafts are then raised from these tunnels, often by upward mining with men working from a cage hung from a cable through a small pilot hole drilled downward from above. In 1957 this procedure was improved by Swedish development of the raise climber, whose working cage climbs a rail fastened to the shaft wall and extends backward into the horizontal access tunnel into which the cage is retracted during a blast. Simultaneously in the 1950s Germans began experimenting with several mechanized reamers, including a motor-cutter unit pulled upward by a cable in a previously down-drilled pilot hole. A more significant step toward mechanized shaft raising occurred in 1962 when United States mole manufacturers developed a device called a raise borer, in which the cutting head is rotated and pulled upward by a drill shaft in a down-drilled pilot hole, with the power unit being located at top of the pilot hole. The capacity of this type of borer (or upward reamer) generally ranges from three- to eight-foot (90- to 240-centimetre) diameters in lifts up to 1,000 feet (300 metres) with progress ranging up to 300 feet (90 metres) per day. Furthermore, available cutters when operating on raise borers can cut through rock often almost twice as hard as rock moles can deal with. For larger shafts, bigger diameter reamers may be operated in an inverted position to ream downward, with the cuttings sluiced to the access tunnel below. A 12-foot (3.7-metre)-diameter, 1,600-foot (500-metre)-deep vent shaft was completed by this method in 1969 at the White Pine Copper Mine in Michigan. Starting from a 10-inch (25-centimetre) pilot hole, it was enlarged in three downreaming passes.

The introduction of a workable raise borer in the 1960s represented a breakthrough in shaft construction, cutting construction time to one-third and cost to less than one-half that for an upward-mined shaft. At the beginning of the 1970s, the procedure was being widely adopted for shaft raising, and some projects had been specifically designed to take advantage of this more efficient method. At a Northfield Mountain (Massachusetts) underground hydroplant (completed in 1971), the previously common large surge chamber was replaced by a series of horizontal tunnels at three levels, connected by vertical shafts. This layout permitted significant economy by the use of jumbos already available from other tunnels of the project and the use of a raise borer for starting the shafts. If very large shafts are involved, the raise borer is particularly useful in simplifying the so-called glory-hole method (Figure 50), in which the main shaft is sunk by blasting; the muck is then dumped in the central glory hole, previously

Glory-hole method

Figure 50: Shaft excavation by glory-hole method at the Angeles penstock tunnel near Los Angeles.

constructed by a raise borer. The example is based on the construction of a 133-foot (40-metre)-diameter surge shaft above the Angeles penstock tunnel near Los Angeles. The glory-hole technique was also used in 1944 in constructing a series of 20 underground fuel-oil chambers in Hawaii, working from access tunnels driven initially at both top and bottom of the chambers and later used to house oil and vent piping. The advent of the raise borer should now make this and similar construction more economically attractive. Recently, some deep sewer projects have been redesigned to utilize the raise borer for shaft connections.

IMMERSED-TUBE TUNNELS

Development of method. The immersed-tube, or sunken-tube, method, used principally for underwater crossings, involves prefabricating long tube sections, floating them to the site, sinking each in a previously dredged

From *Civil Engineering* (December 1966)

Figure 51: Immersed-tube tunnel building procedure (see text).

trench, and then covering with backfill (Figure 51). While more correctly classified as a subaqueous adaptation of the dry-land cut-and-cover procedure often used for subways, the immersed-tube method warrants inclusion as a tunnelling technique because it is becoming a preferred alternate to the older method of constructing a subaqueous tunnel under compressed air with a Greathead shield. A major advantage is that, once the new section has been connected, interior work is conducted in free air, thus avoiding the high cost and major risk of operating a large shield under high air pressure. Furthermore, the immersed-tube method is usable in water deeper than is possible with the shield method, which essentially is restricted to less than 100 feet (30 metres) of water by the maximum air pressure at which workmen can safely work.

The procedure was first developed by an American engineer, W.J. Wilgus, for the construction (1906-10) of the Detroit River twin-tube railroad tunnel between Detroit, Michigan, and Windsor, Ontario, where it was successfully used for the 2,665-foot (812-metre) river-crossing portion. A structural assembly of steel tubes was prefabricated in 262-foot (80-metre)-long sections with both ends temporarily bulkheaded or closed. Each section was then towed out and sunk in 60 to 80 feet (18 to 24 metres) of water, onto a grillage of I-beams in sand at the bottom of a trench previously dredged in the river-bottom clay. After being connected to the previous section by locking pins driven by a diver, the section was weighted down by surrounding it with concrete. Next, after removal of the temporary bulkheads at the just-completed connection, the newly placed section was pumped out, permitting completion of an interior concrete lining in free air. With subsequent refinements these basic principles still form the basis of the immersed-tube method.

After use on a four-tube New York subway crossing under the Harlem River in 1912-14, the method was tried for a vehicular tunnel in the 1925-28 construction of the 3,545-foot (1,081-metre)-long, 37-foot (11-metre)-diameter Posey tunnel at Oakland, California. Because these and other experiences have indicated that the problems encountered in building large vehicular tunnels could be better handled by the immersed-tube method, it has been preferred for subaqueous vehicular tunnels since about 1940. While shield tunnelling continued in a transition period (1940-50), subsequently nearly all of the world's large vehicular tunnels have been constructed by the immersed-tube

Advantages of immersed-tube method

method, including such notable examples as the Bankhead tunnel at Mobile, Alabama; two Chesapeake Bay tunnels; the Fraser River tunnel at Vancouver, British Columbia; the Maas River tunnel in The Netherlands; Denmark's Limfjord tunnel; Sweden's Tingstad tunnel; and the Hong Kong Cross Harbor tunnel.

Modern practice. The world's longest and deepest application to date is the twin-tube subway crossing of San Francisco Bay, constructed between 1966 and 1971 with a length of 3.6 miles (5.8 kilometres) in a maximum water depth of 135 feet (41 metres). The 330-foot (100-metre)-long, 48-foot (15-metre)-wide sections were constructed of steel plate and launched by shipbuilding procedures. Each section also had temporary end bulkheads and upper pockets for gravel ballast placed during sinking. After placement of the interior concrete lining at a fitting-out dock, each section was towed to the site and sunk in a trench previously dredged in the mud in the bottom of the bay. With diver guidance, the initial connection was accomplished by hydraulic-jack-powered couplers, similar to those that automatically join railroad cars. By relieving the water pressure within the short compartment between bulkheads at the new joint, the water pressure acting on the forward end of the new section provided a huge force that pushed it into intimate contact with the previously laid tube, compressing the rubber gaskets to provide a watertight seal. Following this, the temporary bulkheads were removed on each side of the new joint and interior concrete placed across the connection.

Most applications of the immersed-tube procedure outside the United States have been by a Danish engineer-constructor firm, Christiani and Nielsen, starting in 1938 with a three-tube highway crossing of the Maas River in Rotterdam. While following United States technique in essence, European engineers have developed a number of innovations, including prestressed concrete in lieu of a steel structure (often consisting of a number of short sections tied together with prestressed tendons to form a single section 300 feet [90 metres] in length); the use of butyl rubber as the waterproofing membrane; and initial support on temporary piles while a sand fill is jetted beneath. An alternate to the last approach has been used in a Swedish experiment on the Tingstad tunnel, in which the precast sections were supported on water-filled nylon sacks and the water later replaced by grout injected into the sacks to form the permanent support. Also, the cross section has been greatly enlarged—the 1969 Schelde River tunnel in Antwerp, Belgium, used precast sections 328 feet (100 metres) long by 33 feet (10 metres) high by 157 feet (48 metres) wide. This unusually large width accommodates two highway tubes of three lanes each, one two-track railroad tube, and one bicycle tube. Particularly unusual was a 1963 use of the immersed-tube technique in subway construction in Rotterdam. Trenches were dug or, in some cases, made out of abandoned canals and filled with water. The tube sections were then floated into position. This technique had been first tried in 1952 for a land approach to the immersed-tube Elizabeth tunnel in Norfolk, Virginia; in low-elevation ground with the water table near the surface, it permits a considerable saving in bracing of the trench because keeping the trench filled eliminates the need for resisting external water pressure.

Thus, the immersed-tube method has become a frequent choice for subaqueous crossings, although some locations pose problems of interference with intensive navigation traffic or the possibility of displacement by severe storms (one tube section of the Chesapeake Bay tunnel was moved out of its trench by a severe storm during construction). The method is being actively considered for many of the world's most difficult underwater crossings, including the long-discussed English Channel Project.

Future trends in underground construction

ENVIRONMENTAL AND ECONOMIC FACTORS

Improvement of surface environment. Unexpectedly rapid increases in urbanization throughout the world, especially since World War II, have brought many problems, including congestion, air pollution, loss of scarce

surface area for vehicular ways, and major traffic disruption during their construction. Some cities relying principally on auto transport have even found that nearly two-thirds of their central land area is devoted to vehicular service (freeways, streets, and parking facilities), leaving only one-third of the surface space for productive or recreational use. During the past decade there has been a growing awareness that this situation could be alleviated by underground placement of a large number of facilities that do not need to be on the surface, such as rapid transit, parking, utilities, sewage and water-treatment plants, fluid storage, warehouses, and light manufacturing. The overriding deterrent, however, has been the greater cost underground—except in Sweden where energetic research has reduced underground costs to nearly equal the surface alternates. Hence planners have rarely dared to propose underground construction except where the surface alternate was widely recognized as intolerable. Underground construction in urban areas has, thus, generally been limited to situations without a viable surface alternate; as a result, additional increases in surface construction have further aggravated the problem. At the same time, the low volume of underground construction has provided insufficient incentive for the development of innovative technology.

A different approach for the United States was crystallized from a 1966–68 study by the National Academy of Sciences and the National Academy of Engineering, which proposed cost reduction from government-stimulated technologic research plus broader evaluation of social impacts. This would often show the underground alternate as the better investment for society. A reduction of at least one-third in cost and one-half in construction time over the next two decades was foreseen, and it was proposed that social and environmental costs be included in estimates as well as construction costs. In 1970 an international meeting of some 20 countries was held in Washington, D.C., under the Organisation for Economic Co-operation and Development (an assembly of NATO countries), to share views and develop recommendations on government policy in this area. The conference recommended that energetic stimulation of underground construction be adopted as national policy in each of the 20 countries represented and in effect visualized the underground as a largely undeveloped natural resource. This resource, it was pointed out, could be used to expand urban areas downward to help preserve the upper environment—for example, by tunnels for transport and inter-basin water transfer, for recovery of minerals increasingly needed by the economy, and in developing presently unreachable resources under ocean areas adjoining the continents. Such international consensus suggests that this is indeed a powerful concept ready for acceptance.

Scope of the tunnelling market. While informed people foresee a great increase in underground construction, numerical estimates are crude at best, particularly since statistics have not been accumulated in the past for underground construction as a separate item either in the public-works or the mining sectors. The 1970 conference mentioned above included a survey suggesting an average annual volume in its 20 member countries of about \$1,000,000,000 in public works for the 1960–69 decade (\$3,000,000,000 including mining). Estimates made at that time of a doubling of volume over the next decade assumed the continuation of the current rate of technological improvement and recognized that the increase would be far greater if stimulated by government support in an energetic research and development program to reduce cost. All estimates were alike in forecasting a huge increase in underground construction during the following two decades. Key factors affecting the actual increase are technological improvements reducing costs and an increasing awareness on the part of society and public-works planners of the many potential applications for better use of the underground.

POTENTIAL APPLICATIONS

Future applications are expected to range from expansion of existing uses to the introduction of entirely new con-

New approach to underground construction

The San Francisco subway tunnel

European innovations

cepts. Several of these are considered below; many others are likely to emerge as innovative planners turn their attention to utilizing the underground space. The largest increase is likely to be in rock tunnelling: partly from the nature of the projects and partly from the expectation that improved moles will make rock tunnelling more attractive than soil tunnels, with their usual requirement for continuous temporary support plus a permanent concrete lining.

Intercity
transit

Deep rock tunnels for rapid transit between cities are beginning to receive very serious consideration. These might include a 425-mile (680-kilometre) system to cover the nearly continuous urban area between Boston and Washington, D.C., probably with an entirely new type of conveyance at speeds of several hundred miles per hour. A forerunner system is the New Tōkaidō Line in Japan, which uses standard railroad equipment at about 150 miles (250 kilometres) per hour. Highway tunnels are beginning to increase in number as well. Urban highway tunnels conceivably may offer a convenient opportunity to reduce pollution by treating the exhaust air that has already been collected by the ventilating system essential for longer vehicular tunnels.

There is increasing recognition that many more inter-basin water transfers will be needed, involving systems of tunnels and canals. Notable projects include the California Aqueduct, which transfers water from the northern mountains some 450 miles (725 kilometres) to the semi-arid Los Angeles area; the Orange-Fish Project in South Africa, which includes a 50-mile (80-kilometre) tunnel; and studies for possible transfer of surplus Canadian water into the southwestern United States. Drainage can also be a problem, as in the old lakebed area occupied by Mexico City, where current expansion of the drainage system involves some 60 miles (100 kilometres) of tunnel.

Urban
tunnels

Shallower tunnels for subways are bound to increase beyond those expansions undertaken in recent years in many cities, including San Francisco, Washington, D.C., Boston, Chicago, New York, London, Paris, Budapest, Munich, and Mexico City. Multiple use is likely to receive further consideration as communication agencies begin to show interest in adding space within the structures for the several types of utilities. Some merchants visualize mechanized movement of pedestrians between stores. One notable example is Montreal's extensive assembly of underground shopping malls, which interconnect most new downtown buildings as well as provide access to the subway and commuter railroads—a project that has relieved the streets from pedestrian traffic, particularly during severe weather. Another example involves utilization of space excavated above subway stations for parking facilities, as on the Toronto subway and more recently on the Paris Metro, where the space above one of the stations in the Champs-Élysées area provides seven levels of parking.

Subaqueous crossings are becoming more ambitious. The world's longest railroad tunnel, for example, currently under way in Japan, is the 34-mile (54-kilometre) Seikan undersea rock tunnel between the islands of Honshu and Hokkaido; the 14.4-mile (23-kilometre) pilot tunnel, completed in 1983 after 19 years of work, was utilized as a proving ground for several new types of moles. Of comparable scope is the more publicized projected English Channel tunnel for a rail connection between France and England, using special cars for auto transport. Studies have concentrated on two alternatives: twin mole-excavated tunnels in chalk plus a service tunnel or an immersed-tube structure providing comparable space. The immersed-tube procedure has also been considered for a number of other difficult crossings; *e.g.*, from Denmark to Sweden and from Sicily to Italy. Immersed tubes are likely to become more attractive with improvement in methods for trench dredging in deeper water and for grading the trench bottom to support the tube structure. The Japanese are experimenting with an underwater bulldozer, robot-manned and television-monitored. One innovative proposal for supplying additional water to Southern California visualizes the immersed-tube method to construct a large pipeline for some 500 miles (800 kilometres) under the shallower ocean along the continental shelf. Subaqueous tunnelling also is likely to be involved as procedures are

developed for utilizing the vast continental-shelf areas of the world; concepts are already being studied for tunnels to service oil wells and for extensive undersea mining such as has been pioneered in Britain and eastern Canada.

Both Norway and Sweden have reduced the direct costs of fluid storage by storing petroleum products in underground chambers, thus eliminating the maintenance cost for frequent repainting of steel tanks in a surface facility. Locating these chambers below the permanent water table (and below any existing wells) ensures that seepage will be toward the chambers rather than outward; thus, the oil is prevented from leaking out of the chamber, and the lining may be omitted. Further economies may result from orienting the chambers vertically to take advantage of the raise borer and glory-hole techniques, previously mentioned. There are a number of underground installations for the storage of highly compressed gas cooled to a liquid state; these may increase once improved types of lining have been developed. Although the method involves only limited tunnelling for access, the United States Atomic Energy Commission has developed an ingenious method for disposal of nuclear waste by injecting it into fissured rock within a cement grout so that hardening of the grout reconverts the nuclear minerals into a stable rocklike state. Other disposal methods involve more tunnelling, such as within salt, which has particularly good ability for shielding against radiation.

Fluid
storage

A good example of an imaginative concept is Chicago's Underflow Tunnel and Reservoir Plan, which is intended to alleviate both pollution and flooding. Like most older cities, Chicago has a combined sewer system that carries both storm runoff and sanitary sewage during wet weather but only sanitary sewage during dry weather. The city's huge growth has so overtaxed older portions of the system that severe storms cause flooding in low areas. While sewage treatment has essentially eliminated sewage pollution of Lake Michigan, making Chicago virtually the only major city on the Great Lakes continuing wide recreational usage of its lake beaches, the treatment plants generally are sized to handle only the dry-weather flow. Thus, overflow during major storms is discharged into streams draining away from the lake as a mixture of sanitary sewage diluted by storm water. Conventional solutions adopted in the past, such as adding a second pipe system to collect only the storm water, discharging it into the streams, or adding plant capacity to treat all combined flow during severe storms, have proved tremendously expensive. An early version of the plan is illustrated in Figure 52; a novel aspect of the plan is temporary storage of excess water in large underground caverns, which after each storm could be pumped out for gradual treatment by the existing sewage plants. Inclusion of the surface reservoir shown in Figure 52 makes practical the use of the diluted sewage in a pumped storage hydroplant; in this type of facility the fluid is pumped up during offpeak-electric-power night periods, when steam power is cheaply

By courtesy of the Metropolitan Sanitary District of Greater Chicago

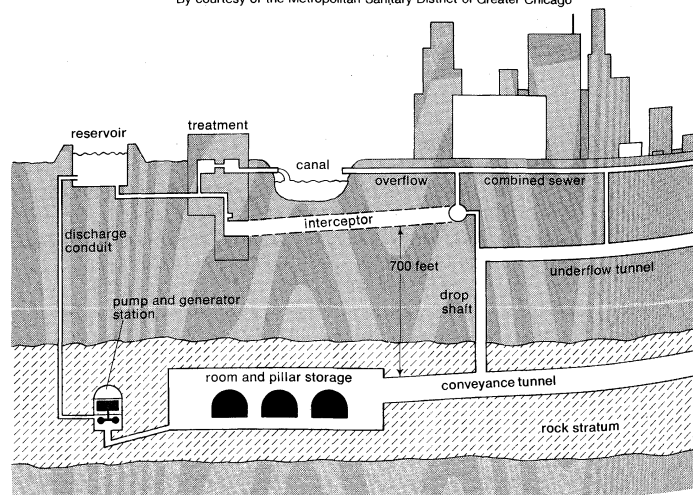

Figure 52: Potential water control plan for Chicago.

available, and then allowed to flow back to generate peak power when demand exceeds economic capacity of the steam plants. A second multiple use is the opportunity to reduce present surface quarrying for crushed stone aggregate by using the dolomitic limestone mined from the deep tunnels and caverns.

The use of rock chambers for underground hydroplants seems certain to increase in most countries, particularly those in which until recently surface plants have been favoured because of their apparently lower cost. Scotland has been one of the first countries to recognize that extra construction cost can often be warranted to preserve the scenic environment, also recognized by choice of an underground location for recent U.S. pump-storage plants—Northfield Mt. in Massachusetts and Raccoon Mt. in Tennessee, plus others being planned. Sweden's use of the underground for plants treating sewage and water, for warehouses, and for light manufacturing is likely to find further application. The relatively small annual temperature range in the underground has made it a desirable environment for facilities requiring close atmospheric control. In the vicinity of Kansas City, Missouri, mined-out space in underground limestone quarries is being used effectively for laboratory space, for dehumidified storage of corrosion-sensitive equipment, and for refrigerated food storage, an application also favoured in Sweden.

Similar environment factors plus the probability of less disturbance during earthquakes have made the underground desirable for a number of scientific installations, including atomic accelerators, earthquake research, nuclear research, and space telescopes. Since earthquake risk is a big factor in locating nuclear powerplants, the merits of an underground location are attracting interest in siting studies for future plants.

IMPROVED TECHNOLOGY

Worldwide efforts are under way to accelerate improvements in the technology of underground construction and are likely to be stimulated as a result of the 1970 OECD International Conference recommending improvement as government policy. The endeavour involves specialists such as geologists, soil- and rock-mechanics engineers, public-works designers, mining engineers, contractors, equipment and materials manufacturers, planners, and also lawyers, who aid in the search for more equitable contractual methods to share the risks of unknown geology and resulting extra costs. Many improvements and their early applications have been previously discussed; others are briefly mentioned here, including several that have not yet moved from the research stage to the pilot, or trial, stage. Projects in rock are emphasized, since the field of rock engineering is less developed than its older counterpart, soils engineering.

Geological prediction and evaluation are universally recognized as deserving a high priority for improvement. Since ground and water conditions are controlling factors in choosing both the design and construction method underground and seem destined to be even more so with greater use of moles, efforts are directed toward improving boring information (as with borehole cameras); faster borings (the Japanese are trying to bore one to three miles [about 1,600 to 4,800 metres] ahead of a tunnelling mole); geophysical methods to estimate rock-mass properties; and techniques to observe pattern of water flows. For evaluation, the new field of rock mechanics is concentrating on measuring geostress and rock-mass properties, failure mechanics of jointed rock, and analytical methods for applying results to design of underground openings.

For rock excavation, improved cutters are generally considered the key for expanding economic ability of moles to include harder rock. Much effort is being devoted to improving current mechanical cutters, including technical advances based upon space metallurgy, geometry of cutter shape and arrangement, mechanics of cutting action, and research in presoftening rock. Concurrently, there is an intensive search for entirely new rock-cutting methods (some nearing a pilot application), including high-pressure water jets, Russian water cannon (operated at high pressures), electron beam, and flame jet (often combined with

abrasive powder). Other methods under research involve lasers and ultrasonics. Most of these have high power requirements and might increase ventilating needs from an already overtaxed system. Though some of these novel methods will eventually reach the stage of economic practicality, it is not possible to predict at present which ones will eventually succeed. Also needed is a means for testing rock in terms of mole drillability plus correlation with mole performance in different rocks, where promising work is under way at several locations.

A decided change in current materials-handling systems seems inevitable to keep up with fast-moving moles by matching the mole's rate of excavation and fragmentation sizing of the muck produced. Schemes now under study include long belt conveyors, high-speed rail with completely new types of equipment, and both hydraulic and pneumatic pipelines. Useful experience is being accumulated with pipeline transport of ore slurries, of coal, and even of such bulky material as canned goods.

For ground support, rock-mechanics engineers are working toward replacing past empirical methods with a more rational basis of design. One key factor is likely to be the tolerable deformation for mobilizing but not destroying the strength of the rock mass. There is wide agreement that progress will best be aided by field-test sections at prototype scale in selected ongoing projects. While several newer types of support have been discussed (rock bolts, shotcrete, and precast-concrete elements), developments are under way toward entirely new types, including lighter material plus yield-controllable types as a corollary to above tolerable deformation concept. For projects using concrete lining, major changes seem inevitable to keep pace with fast-moving moles, probably including some entirely new types of concretes. Current efforts include work with precast elements, plus research into stronger and faster set materials which use resins and other polymers in lieu of portland cement.

Preservation of ground strength is beginning to win acceptance as vital for the safety of large rock chambers and also often a means of cost saving in tunnels. For preserving strength of the rock mass around tunnels, a mole-cut surface provides a solution. For large chambers, consideration is being given to cutting a peripheral slot with a wire saw of the type used to quarry monument stone. Where chambers are blasted, engineered soundwall blasting has provided a solution in Sweden.

Ground strengthening by precementation with chemical grouts is a technique notably developed in France and Britain through extensive research by specialized grouting firms. Figure 53 shows the world's outstanding application at the Auber Station of the Métro Express beneath the Place de L'Opéra traffic centre of Paris—a large chamber

130 feet (40 metres) wide by 60 feet (18 metres) high by 750 feet (230 metres) long in chalky marl below an existing subway, at a depth of 120 feet (40 metres), about 60 feet (18 metres) below water table. This was completed in 1970 without interrupting surface traffic and without underpinning the many old masonry buildings above (including the historic National Opera Building), a truly courageous undertaking made possible by surrounding the chamber with a pregrouted zone to seal out water and to preclude the overlying sand and gravel. Different types of chemical grout were successively injected (totalling about 2,000,000,000 cubic feet [57,000,000 cubic metres]), working from crown and side drifts; then the chamber was mined and supported both top and bottom by prestressed arches of concrete elements. Similar procedure was also successful at the Étoile Station adjacent to the Arc de Triomphe. While this technique of ground strengthening by grout solidification requires highly skilled specialists, it is an instructive example of how a new technology is likely to make economically possible future projects previously considered beyond engineering ability.

Canals and inland waterways: J. PHILLIPS, *A General History of Inland Navigation Foreign and Domestic*, 4th ed. (1803), a general history of foreign and domestic navigation on inland waterways, containing a complete account of the canals built in England up to the end of the 18th century; O. FRANZIUS, *Waterway Engineering* (1936), a standard technical work on engineering methods employed up to the 1930s; H.O. MANCE, *International River and Canal Transport* (1944), a history of the commissions controlling and regulating operations on the international waterways to the end of World War II; A.W. SKEMPTON, "Canals and River Navigations Before 1750," in CHARLES SINGER (ed.), *History of Technology*, vol. 3, ch. 17 (1957, reprinted 1965), a concise history of canal construction and river works from ancient times through the medieval period to the Renaissance; ROGER PILKINGTON, "Canals: Inland Waterways Outside Britain," and CHARLES HADFIELD, "Canals: Inland Waterways of the British Isles," *ibid.*, vol. 4, ch. 18 (1958, reprinted 1965), a useful account of canal development and construction during the Industrial Revolution of the late 18th and early 19th century; D.A. FARNIE, *East and West of Suez: The Suez Canal in History, 1854–1956* (1969), a comprehensive and detailed study of the history of the Suez Canal and of its impact on the foreign policies of the imperial powers in relation to the Middle East; L.T.C. ROLT, *Navigable Waterways* (1969), a descriptive account of inland waterway networks; R. CALVERT, *Inland Waterways of Europe* (1963), a nontechnical account of the principal European inland waterway systems, including interesting diagrams, maps, useful itineraries, and an international bibliography; E.E. BENEST, *Inland Waterways of Belgium* (1960), *Inland Waterways of France*, 2nd ed. (1963, suppl. 1967), and *Inland Waterways of the Netherlands*, 2 vol. (1966–68), three useful compendiums of information on navigation on the inland waterways of the respective countries. See also ANTHONY BURTON, *The Canal Builders*, 2nd ed. (1981); and LANCE E. METZ and JANET CROUSE EPSTEIN (eds.), *Proceedings of the Canal History and Technology Symposium, January 30, 1982*, 2 vol. (1982–83).

Dams: E. WEGMANN, *The Design and Construction of Dams*, 8th ed. (1927), a general textbook on dams containing much information of historical interest; W.P. CREAGER, J.D. JUSTIN, and J. HINDS, *Engineering for Dams*, 3 vol. (1945), a textbook dealing principally, but not exclusively, with American practice; J. HINDS, "Continuous Development of Dams Since 1850," *Trans. Am. Soc. Civ. Engrs.*, CT:489–520 (1953), a history of the development of dam design and construction over 100 years giving some selected examples to illustrate design principles; J. GUTHRIE BROWN (ed.), *Hydro-Electric Engineering Practice*, 3 vol., 2nd rev. ed. (1964), a comprehensive modern textbook dealing principally with British and European practice; J.L. SHERARD et al., *Earth and Earth-Rock Dams* (1963), on the design and construction of foundations and embankments; C.V. DAVIS (ed.), *Handbook of Applied Hydraulics*, 3rd ed. (1969), a classic work on the basic principles of hydraulic engineering and the design of hydraulic structure; INTERNATIONAL COMMISSION ON LARGE DAMS, *World Register of Dams*, 4 vol. (1963, updated to December 1968), a register listing basic statistical data about large dams in countries that are members of the commission; U.S. COMMITTEE OF THE INTERNATIONAL COMMISSION ON LARGE DAMS, *Register of Dams in the United States* (1963), basic statistical details of dams in the U.S., with some photographs; ACADEMY OF SCIENCES OF THE GEORGIAN S.S.R., INSTITUTE OF POWER ENGINEERING, *The High Dams of the World* (Eng. trans. 1967), basic statistical details of world dams, with an extensive bibliography; NORMAN SMITH, *A History of Dams* (1971), an outstanding detailed record of ancient dams. Interesting information can be found in MARIAN MOFFETT and LAWRENCE WODEHOUSE, *Built for the People of the United States* (1983); and *Dams and Earthquake: Proceedings of a Conference Held at the Institution of Civil Engineers, London, 1–2 October 1980* (1981).

Harbours and sea works: The Nautical Charts and the Sailing Directions issued by the Hydrographic Office of the U.S. Navy and the Sailing Directions published by the Hydrographic Department of the Admiralty give full descriptions of the harbours of the world. For U.S. harbours, see the "Port Series" and the "Lake Series" published by the Corps of Engineers, U.S. Army, and the charts issued by the U.S. Coast and Geodetic Survey. The Corps of Engineers, U.S. Army, publishes many manuals and articles concerning particular harbours and problems of harbour design.

The *Proceedings of the Permanent International Association of Navigation Congresses (PIANC)* contain much detailed information on harbours of the world, as well as technical studies on harbour problems.

Books on this subject include: F.M. DU-PLAT TAYLOR, *The Design, Construction and Maintenance of Docks, Wharves and Piers*, 3rd ed. rev. (1949); J.F. BRAHTZ (ed.), *Ocean Engineering: Goals, Environment, Technology* (1968); J. CHAPON, *Travaux*

maritimes, 3rd ed., 2 vol. (1974-75); C.M. TOWNSEND, *The Hydraulic Principles Governing River and Harbour Construction* (1922); and A.M. MUIR WOOD, *Coastal Hydraulics* (1969).

See also the monthly journal, *Dock and Harbour Authority*, which is devoted to problems of dock and harbour operation and construction; and WOLFGANG RUDOLPH, *Harbor and Town: A Maritime Cultural History* (1983).

Lighthouses: F.A. TALBOT, *Lighthips and Lighthouses* (1913), a well-illustrated book describing lighthouses of the world from antiquity to the early part of the 20th century; J.P. BOWEN, *British Lighthouses* (1947), a short but usefully comprehensive summary of British lighthouse practice from the early 19th century to 1947; G.R. PUTNAM, *Lighthouses and Lightships of the United States*, rev. ed. (1933), an historical survey of most of the major lighthouses and lightships of the U.S.; D.A. STEVENSON, *World's Lighthouses before 1830* (1959), and an edited version of a detailed journal kept by Robert Stevenson during a tour of English lighthouses, *English Lighthouse Tours of Robert Stevenson* (1946), classic works by a member of the famous family of Scottish lighthouse engineers; F. MAJDALANY, *The Red Rocks of Eddystone* (1959), a readable description of the building of the four Eddystone lighthouses, emphasizing the human and dramatic aspects of the work rather than the technical; H.P. MEAD, *Trinity House* (1947), a discussion of the origins and history of Trinity House, the lighthouse authority for England and Wales; UNITED STATES COAST GUARD, *Historically Famous Lighthouses* (1950), and *Coast Guard History* (1949), two pamphlets that provide a brief insight into the work of the U.S. Coast Guard and some of its more famous lighthouses. See also CHARLES M. BROWN, *Aids to Navigation in Alaska History* (1974); LOVE DEAN, *Reef Lights: Seaswept Lighthouses of the Florida Keys* (1982); FRANK PERRY, *Lighthouse Point: Reflections on Monterey Bay History* (1982).

Water-supply systems: T. ASHBY, *The Aqueducts of Ancient Rome* (1935), an exhaustive, detailed account of the Roman aqueducts based on modern archaeological findings, with many illustrations showing dimensions and an extensive bibliography; E. COOPER, *Aqueduct Empire* (1968), a history of the development of all major aqueduct systems in California; C. HERSCHEL, *Frontinus on the Water Supply of the City of Rome* (1899), a commentary on the translation of Frontinus, water commissioner of Rome in 98 AD, with a description of the aqueducts and their operation; R. WALKER, *Water Supply, Treatment, and Distribution* (1978), a clear, concise account; F.W. ROBINS, *The Story of Water Supply* (1946), a history of water supply from earliest times to the present with emphasis on practices in England; E.B. VAN DEMAN, *The Building of the Roman Aqueducts* (1934), the most authoritative and extensive historical work in English on the ancient Roman aqueducts; E. WEGMANN, *The Water Supply of the City of New York, 1658-1895* (1896), descriptions of the planning and building of New York City aqueducts through the 19th century. G.M. FAIR *et al.*, *Water and Wastewater Engineering*, 2 vol. (1966), and H.E. BABBITT and J.J. DOLAND, *Water Supply Engineering*, 6th ed. (1962), modern texts covering all aspects of water-supply systems; E.S. HOPKINS and E.L. BEAN, *Water Purification Control*, 4th ed. (1966), a recent detailed treatment of water-purification processes and techniques, with extensive references to periodical literature; F.W. ROBINS, *The Story of Water Supply* (1946),

a world history of water-supply system development with detailed information on British developments; C.V. DAVIS and K.E. SORENSEN (eds.), *Handbook of Applied Hydraulics*, 3rd ed. (1969), authoritative articles on specific areas of water-supply system development. ABRAHAM HOFFMAN, *Vision or Villainy: Origins of the Owens Valley-Los Angeles Water Controversy* (1981), is a historical study.

Waste treatment and disposal systems: M.M. COHN, *Sewers for Growing America* (1966), a modern description of waste-water collection systems, their history, and the water-pollution problem created; G.M. FAIR, J.C. GEYER, and D.A. OKUN, *Water and Wastewater Engineering*, 2 vol. (1966-68), and H.E. BABBITT and E.R. BAUMANN, *Sewerage and Sewage Treatment*, 8th ed. (1958), popular texts in sanitary engineering; *Waste Treatment Proceedings* (1960), a symposium report. Physical descriptions of various city systems are provided by published reports of most municipal sanitary agencies. AMERICAN PUBLIC WORKS ASSOCIATION, COMMITTEE ON SOLID WASTE DISPOSAL, *Municipal Refuse Disposal*, 3rd ed. (1970), a comprehensive text on municipal disposal methods, system selection, and management; *Refuse Collection Practice*, 3rd ed. (1966), a complete text on municipal collection systems and their management; F. FLINTOFF and R. MILLARD, *Public Cleansing* (1968), a modern text treating refuse collection and disposal methods in the United Kingdom; G.G. GOLUEKE, *Solid Waste Management: Abstracts and Excerpts from the Literature, 1970* (1970), an extensive collection of annotated references from 1939 to 1970; AMERICAN PUBLIC WORKS ASSOCIATION, STREET SANITATION COMMITTEE, *Street Cleaning Practice*, 3rd ed. (1978), a comprehensive text on street cleaning, snow and ice control methods, and equipment in use in the United States. Later monographs include MARTIN V. MELOSI, *Garbage in the Cities: Refuse, Reform, and the Environment, 1880-1980* (1981), a well-researched history; ORGANISATION FOR ECONOMIC CO-OPERATION AND DEVELOPMENT, WASTE MANAGEMENT POLICY GROUP, *Economic Instruments in Solid Waste Management* (1981); HARVEY ALTER, *Materials Recovery from Municipal Waste* (1983); JOHN R. HOLMES, *Practical Waste Management* (1983).

Tunnelling and underground excavation: AGRICOLA, *De Re Metallica* (1556; Eng. trans. by H.C. and L.H. HOOVER, 1950), a classic work on early mining in Europe; F.W. SIMMS, *Practical Tunneling*, 3rd ed. rev. 1877), on early public works, with accounts of difficulties overcome by pioneers; H.W. RICHARDSON and R.S. MAYO, *Practical Tunnel Driving* (1941), a history of U.S. practice to 1940, emphasizing tunnel equipment; C.A. PEQUIGNOT (ed.), *Tunnels and Tunneling* (1963), on English practice, with comprehensive tables comparing tunnels of the world; G. E. SANDSTROM, *Tunnels* (British title, *The History of Tunneling*, 1963), a historical survey that summarizes Sweden's contributions to underground engineering; K.G. STAGG and O.C. ZIENKIEWICZ, *Rock Mechanics in Engineering Practice* (1968), an introductory work, with each of its 12 chapters written by a noted authority; A.D. BARTLETT, *Tunnels—Planning, Design, Construction*, 2 vol. (1981-82), is a substantial study.

Publishing

Publishing is the activity that involves the selection, preparation, and marketing of printed matter. It has grown from small and ancient beginnings into a vast and complex industry responsible for the dissemination of all manner of cultural material, from the most lofty to the most trivial; its impact upon civilization is impossible to calculate.

This article treats the history and development of book, newspaper, and magazine publishing in its technical and commercial aspects. The preparation and dissemination of written communication is followed from its beginnings

in the ancient world to the modern period. For additional information on the preparation of early manuscripts, see **WRITING**. A more detailed examination of printing technology can be found in **PRINTING, TYPOGRAPHY, AND PHOTOENGRAVING**. The dissemination of published material via electronic media is treated in **INFORMATION PROCESSING**. For a discussion of reference-book publishing, see **ENCYCLOPAEDIAS AND DICTIONARIES**.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 735.

General considerations

The invention and original function of writing

The history of publishing is characterized by a close interplay of technical innovation and social change, each promoting the other. Publishing as it is known today depends on a series of three major inventions—writing, paper, and printing—and one crucial social development—the spread of literacy. Before the invention of writing, perhaps by the Sumerians in the 4th millennium BC, information could be spread only by word of mouth, with all the accompanying limitations of place and time. Writing was originally regarded not as a means of disseminating information but as a way to fix religious formulations or to secure codes of law, genealogies, and other socially important matters, which had previously been committed to memory. Publishing could begin only after the monopoly of letters, often held by a priestly caste, had been broken, probably in connection with the development of the value of writing in commerce. Scripts of various kinds came to be used throughout most of the ancient world for proclamations, correspondence, transactions, and records; but book production was confined largely to religious centres of learning, as it would be again later in medieval Europe.

Only in Hellenistic Greece, in Rome, and in China, where there were essentially nontheocratic societies, does there seem to have been any publishing in the modern sense—*i.e.*, a copying industry supplying a lay readership.

The invention of printing transformed the possibilities of the written word. Printing seems to have been first invented in China in the 6th century AD in the form of block printing. An earlier version may have been developed at the beginning of the 1st millennium BC, but, if so, it soon fell into disuse. The Chinese invented movable type in the 11th century AD but did not fully exploit it. Other Chinese inventions, including paper (AD 105), were passed on to Europe by the Arabs but not, it seems, printing. The reason may well lie in Arab insistence on hand copying of the Qur'an (Arabic printing of the Qur'an does not appear to have been officially sanctioned until 1825). The invention of printing in Europe is usually attributed to Johannes Gutenberg in Germany about 1440–50, although block printing had been carried out from about 1400. Gutenberg's achievement was not a single invention but a whole new craft involving movable metal type, ink, paper, and press. In less than 50 years it had been carried through most of Europe, largely by German printers.

Gutenberg's achievement

Printing in Europe is inseparable from the Renaissance and Reformation. It grew from the climate and needs of the first, and it fought in the battles of the second. It has been at the heart of the expanding intellectual movement of the past 500 years. Although printing was thought of at first merely as a means of avoiding copying errors, its possibilities for mass-producing written matter soon became evident. In 1498, for instance, 18,000 letters of indulgence were printed at Barcelona. The market for books was still small, but literacy had spread beyond the clergy and had reached the emerging middle classes. The church, the state, universities, reformers, and radicals were all quick to use the press. Not surprisingly, every kind of attempt was made to control and regulate such a "dangerous" new mode of communication. Freedom of the press was pursued and attacked for the next three centuries; but by the end of the 18th century a large measure of freedom had been won in western Europe and North America, and a wide range of printed matter was in circulation. The mechanization of printing in the 19th century and its further development in the 20th, which went hand in hand with increasing literacy and rising standards of education, finally brought the printed word to its powerful position as a means of influencing minds and, hence, societies.

The functions peculiar to the publisher—*i.e.*, selecting, editing, and designing the material; arranging its production and distribution; and bearing the financial risk or the responsibility for the whole operation—often merged in the past with those of the author, the printer, or the bookseller. With increasing specialization, however, publishing became, certainly by the 19th century, an increasingly distinct occupation. Most modern Western publishers purchase printing services in the open market, solicit manuscripts from authors, and distribute their wares to purchasers through shops, mail order, or direct sales.

Published matter falls into two main categories, periodical and nonperiodical; *i.e.*, publications that appear at more or less regular intervals and are members of a series and those that appear on single occasions (except for reissues of essentially the same material).

Of the nonperiodical publications, books constitute by far the largest class; they are also, in one form or another, the oldest of all types of publication and go back to the earliest civilizations. In giving permanence to man's thoughts and records of his achievements, they answer a deep human need. Not every published book is of lasting value; but a nation's books, taken as a whole and winnowed out by the passing years, can be said to be its main cultural storehouse. Conquerors or usurpers wishing to destroy a people's heritage have often burned its books, as did Shih Huang-ti in China in 213 bc, the Spaniards in Mexico in 1520, and the Nazis in the 1930s.

There is no wholly satisfactory definition of a book, as the word covers a variety of publications (for example, some publications that appear periodically, such as *The World Almanac and Book of Facts*, may be considered books). For statistical purposes, however, the United Nations Educational, Social and Cultural Organization defines a book as "a non-periodical printed publication of at least 49 pages excluding covers."

Periodical publications may be further divided into two main classes, newspapers and magazines. Though the boundary between them is not sharp—there are magazines devoted to news, and many newspapers have magazine features—their differences of format, tempo, and function are sufficiently marked: the newspaper (daily or weekly) usually has large, loose pages, a high degree of immediacy, and miscellaneous contents; whereas the magazine (weekly, monthly, or quarterly) has smaller pages, is usually fastened together and sometimes bound, and is less urgent in tone and more specialized in content. Both sprang up after the invention of printing, but both have shown a phenomenal rate of growth to meet the demand for quick information and regular entertainment. Newspapers have long been by far the most widely read published matter; the democratizing process of the 19th and 20th centuries would be unthinkable without them. Magazines, close behind newspapers both historically and in terms of readership, rapidly branched out from their learned origins

into "periodicals of amusement." Today there is probably not a single interest, frivolous or serious, of man, woman, or child, that is not catered to by a magazine.

There are, of course, many other types of publications besides books, newspapers, and magazines. In many cases the same principles of publishing apply, and it is only the nature of the product and the technicalities of its manufacture that are different. There is, for instance, the important business of map and atlas publishing. Another important field is music publishing, which produces a great variety of material, from complete symphonic scores to sheet music of the latest popular hit. A further range of activities might be grouped under the term "utility publishing"; *i.e.*, the issuing of calendars, diaries, timetables, ready reckoners, guide books, and all manner of informational or directional material, not to mention postcards and greeting cards. A great deal of occasional publishing, of pamphlets and booklets, is done by organizations to further particular aims or to spread particular views; *e.g.*, by churches, religious groups, societies, and political parties. This kind of publishing is sometimes subsidized.

Book publishing

The form, content, and provisions for making and distributing books have varied widely during their long history, but in general it may be said that a book is designed to serve as an instrument of communication. The Babylonian clay tablet, the Egyptian papyrus roll, the medieval vellum codex, the printed paper volume, the microfilm, and various other combinations have served as books. The great variety in form is matched by an equal variety in content. Both Shakespeare's collected plays, first published in 1623, and the most ill-conceived and trivial tract published in that or any other year were designed as instruments of communication.

The book is also characterized by its use of writing or some other system of visual symbols (such as pictures or musical notation) to convey a meaning. As a sophisticated medium of communication, it requires mastery of the hard-won skills of reading and writing. Another distinguishing feature is publication for tangible circulation. A temple column with a message carved on it is not a book. Signs and placards that are easy enough to transport are made to attract the eyes of passers-by from a fixed location and thus are not usually considered books. Private documents not intended for circulation also are not considered to be books.

A book, for the purpose of this discussion, is a written (or printed) message of considerable length, meant for public circulation and recorded on materials that are light yet durable enough to afford comparatively easy portability. Its primary purpose is to carry a message between people, depending on the twin faculties of portability and permanence. As such, the book transcends time and space to announce, to expound, and to preserve and transmit knowledge. Books have attended the preservation and dissemination of knowledge in every literate society. The following account, keeping mainly within the scope of civilization as it developed in western Europe and North America, considers the book as it appeared at different times in history, the characteristic content and survival of copies and texts, and the means of production and distribution.

THE ORIGINS OF BOOKS

How soon after the invention of writing men began to make books is uncertain because the books themselves have not survived. The oldest surviving examples of writing are on clay or stone. The more fragile materials used for writing at various times have generally perished. The earliest known books are the clay tablets of Mesopotamia and the papyrus rolls of Egypt. There are examples of both dating from the early 3rd millennium bc.

Books on clay tablets. The ancient Sumerians, Babylonians, Assyrians, and Hittites wrote on tablets made from water-cleaned clay. Although these writing bricks varied in shape and dimension, a common form was a thin quadrilateral tile about five inches long. While the clay was still

wet, the writer used a stylus to inscribe it with cuneiform characters. By writing on every surface in small characters, he could copy a substantial text on a single tablet. For longer texts he used several tablets, linking them together by numbers and catchwords as is done in modern books.

Book production on clay tablets probably continued for 2,000 years. The nature and volume of the surviving records from Mesopotamia and Asia Minor indicate a heavy emphasis on the preservative function of writing and the book. Either dried in the sun or baked in a kiln, clay tablets were almost indestructible. The latter process was used for texts of special value, legal codes, royal annals, and epics to ensure greater preservation. Buried for thousands of years in the mounds of forgotten cities, they have been removed intact in modern archaeological excavations. The number of clay tablets recovered approaches 500,000, but new finds continually add to the total. The largest surviving category consists of private commercial documents and government archives. Of the remainder, many are duplications of texts.

Clay tablets are usually associated with cuneiform writing, a script that takes its modern name from the wedge-shaped (from Latin *cuneus*, "wedge") marks made by the stylus in clay. When the Aramaic language and alphabet arose in the 6th century BC, the clay tablet book declined because clay was less suited than papyrus to the Aramaic characters.

The Egyptian papyrus roll. The papyrus roll of ancient Egypt is more nearly the direct ancestor of the modern book than is the clay tablet. Papyrus as a writing material resembles paper. It was made from a reedy plant of the same name that flourishes in the Nile Valley. Strips of papyrus pith laid at right angles on top of each other and pasted together made cream-coloured papery sheets. Although the sheets varied in size, ordinary ones measured about five to six inches wide. The sheets were pasted together to make a long roll. To make a book, the scribe copied a text on the side of the sheets where the strips of pith ran horizontally, and the finished product was rolled up with the text inside.

The use of papyrus affected the style of writing just as clay tablets had done. Scribes wrote on it with a reed pen or brush and inks of different colours. The result could be very decorative, especially when done in the monumental hieroglyphic style of writing, a style best adapted to stone inscriptions. The Egyptians created two cursive hands, the hieratic (priestly) and the demotic (a simplified form of hieratic suited to popular use), which were better adapted to papyrus.

Compared with tablets, papyrus is fragile, yet an example is extant from 2500 BC; and stone inscriptions that are even older portray scribes with rolls. This amazing survival is partly the result of the dry climate of Egypt, in which some papyrus rolls survived unprotected for centuries while buried in the desert sands. The practice of certain Egyptian funerary customs also contributed to the preservation of many Egyptian books. Obsessed by a concern with life after death, they wrote magical formulas on coffins and on the walls of tombs to guide the dead safely to the gates of the Egyptian underworld. When the space thus provided became insufficient, they entombed papyrus rolls containing the texts. These mortuary texts are now described collectively as the *Book of the Dead*, although the Egyptians never standardized a uniform collection. Such books, when overlooked by grave robbers, survived in good condition in the tomb. Besides mortuary texts, Egyptian texts included scientific writings and a large number of myths, stories, and tales.

Quotations from ancient writings show that scribes were highly regarded in ancient Egypt. They were the priests and government officials employed in the temples, pyramid complexes, and the courts of the pharaohs. The Greek historian Herodotus reported that Egyptian embalmers did a thriving business in copies of the *Book of the Dead*.

Chinese books. The Chinese, though not so early as the Sumerians and the Egyptians, were the third people to produce books on an extensive scale. Although few surviving examples antedate the Christian Era, literary and archaeological evidence indicates that the Chinese had

writing and probably books at least as early as 1300 BC. Those primitive books were made of wood or bamboo strips bound together with cords. Many such books were burned in 213 BC by the Ch'in emperor Shih Huang-ti, who feared the strength of the tradition they embodied. The fragility of materials and the damp climate resulted in the loss of other ancient copies. Some books escaped, however, and these, together with whatever books may have been produced in the intervening period, constituted a large enough body for a Chinese national bibliography to appear in the 1st century BC. This was prepared by a corps of specialists in medicine, military science, philosophy, poetry, divination, and astronomy. A classified list of works on tablets and on silk, it mentioned 677 books. With such a tradition, the survival of Chinese texts was assured by continuous copying and was not dependent on the capacity of a lone example to withstand the wear of the centuries.

BOOKS IN CLASSICAL ANTIQUITY

Greek books. The Greeks adopted the papyrus roll and passed it on to the Romans. Although both Greeks and Romans used other writing materials (waxed wooden tablets, for example), the Greek and Roman words for book show identification with the Egyptian model. Greek *biblos* ("book") can be compared with *byblos* ("papyrus"), while the Latin *volumen* ("book") signified a roll. It has been suggested that papyrus was continuously in use in Greece from the 6th century BC, and evidence has been cited to indicate its use as early as 900 BC. Objects called books are mentioned by ancient Greek writers as having been in use in the 5th century BC. The oldest extant Greek rolls, however, date from the 4th century BC.

The 30,000 extant Greek papyri permit a generalized description of the Greek book. Rolled up, it stood about nine or 10 inches high and was an inch or an inch and a half in diameter. When the book was unrolled it displayed a text written in the Greek alphabet in columns about three inches wide separated by inch-wide margins. In spite of the Greek proficiency in decorative arts, few surviving books are illustrated. Such illustrations as have survived were of the practical sort found in later scientific books.

Practicality was a mark of the Greek book. The alphabet, although not invented by the Greeks, was adapted and stabilized by them as an instrument of verbal communication rather than of decorative purpose. Unlike the monumental Egyptian survivals in a decorative hand that sometimes exceeded 100 feet in length, Greek rolls seldom exceeded 35 feet in length and featured little embellishment. Such a roll was about as large as could be conveniently held in the hands to read, and it was big enough to contain a book of Thucydides or one of the longer New Testament Gospels. The average Greek book was shorter. Two books (here denoting a subdivision of a text) of Homer written in a later small hand fitted a 35-foot roll.

During the golden age of Athens in the 5th century BC, books were known and used but were lightly regarded as avenues of learning. Great tragedies and comedies, speeches, poems, histories, and lectures were produced, but all evidence indicates that the preferred method of publication at that time was oral. The actor, the orator, the rhapsodist, and the lecturer were supreme.

Given the interests and the scope of inquiry of Periclean Greeks, it is noteworthy that they had books and read them at all. Greek readers were general readers. Though it should not be assumed that all who lived in Athens could read, those who could included more than the narrow circle of scribes and scholars who were trained from youth to reverence books and to make a career of the difficult arts of reading and writing. The Greek alphabet reduced this difficulty, and the nonspecialized content of Greek books made them practical instruments of communication to a general public.

With the coming of Alexander the Great, the outlook of the Greeks was broadened into a universal attitude that was reflected in their use of books. As the Alexandrian kingdoms spread throughout the East, the Greeks were forced to extend their interest to alien peoples and the records of the past. Consequently, the range of matters

worth discussing became too extensive for oral transmission and for the solitary speaker. In the important Hellenistic cities, most notably at Pergamum and Alexandria, centres of learning grew up; these aimed at a world synthesis of knowledge. (A noteworthy example of this synthesizing work was the Septuagint, which was a translation of the Hebrew Scriptures into Greek.) Libraries were a distinguishing feature of these centres. The Museum and the Serapeum at Alexandria were reputed at various times to have from 200,000 to 700,000 rolls. The Ptolemies at Alexandria pursued a vigorous collecting policy in an attempt to acquire good copies of all important texts; and scholars were constantly at work on textual scholarship and the writing of new books. The book superseded the oral presentation as a primary means of publication. Greek writers even refer to the market in books and to prices paid for them. The discovery of surviving papyri in the rubbish heaps of provincial towns indicates that the trade was widely diffused. The large libraries maintained scriptoria in which extensive copying was done. However, survivals are scanty and there is no group of extant examples that bears such close resemblance to each other as to indicate that they were the product of the same scribe or scriptorium. Some surviving rolls bear the mark of professional work; others are amateurish.

The volume of surviving Greek texts is so slender that it arouses speculation about the nature of the large book collections of Alexandria. There are various explanations. First, the Alexandrians were doing textual criticism and required many copies of the same text to carry on the work. Second, the record indicates that the volume of Greek literature was much larger than what has survived, a majority of the texts having been lost. Literary and bibliographical references made by ancient writers and bibliographers indicate, for example, that the dramatists Aeschylus, Sophocles, Euripides, and Aristophanes wrote among them about 330 plays; those surviving number 46. Nearly all of Greek lyric poetry has been lost. Only one-fourth of the texts by Stobaeus, an anthologist of the 5th century AD, survived to modern times.

Survival of
works

The survival of Greek texts depended on copying by succeeding generations. No manuscript in the hand of either a Greek or Roman author is extant, and the earliest extant copies of most works date from centuries after the composition. In such circumstances, the greatest factor in survival was the widespread and continuing popularity of a work. The centres of textual criticism fostered the preservation of some texts by establishing a canon of writings to be taught in the schools. This practice proved to be more important for a work's survival than the establishment of the great libraries, because the library collections were destroyed, while the widespread copying of books for use by students ensured that they were physically dispersed over a large area, thus rendering an author's work less vulnerable to local disasters. Finally, the universal interest and application of the content was an important factor that led to the survival of some nonliterary texts through translation into Arabic, Latin, and other foreign languages.

Roman books. Rome was the channel through which the Greek book was introduced to the people of western Europe. When the Romans conquered Greece they carried home Greek libraries to serve as a foundation for similar libraries in Rome. Roman libraries had separate collections of Greek and Latin books; but except for the substitution of the Latin language for Greek, a Roman papyrus roll closely resembled a Greek one in content, and there was much imitation.

The Romans developed a book trade on a fairly large scale. From the time of the 1st-century-BC orator Cicero there is evidence of large scriptoria turning out copies of books for sale. On several occasions Cicero referred to bookshops; the 1st-century-AD poet Martial complained about professional copyists who became careless in their speed; and the 1st-century-AD naturalist Pliny the Elder described the extensive trade in papyrus. The trade decrees of the emperor Diocletian set regulations for determining a price for the copying of books.

Book ownership was widespread among Romans of the upper class. Private libraries were common and were con-

sidered the necessary badge of distinction for anyone who aspired to high position or social importance. On the other hand, books were also within reach of less prosperous people because the use of slave labour to multiply copies kept prices relatively low. From a comparative study of prices, it has been concluded that books were cheap enough for people with only moderate incomes to buy them. As many as 30 copies of a work might be made simultaneously by a reader dictating to slave copyists. In many ways these enterprises were prototypes for modern publishing houses. Roman publishers selected the manuscripts to be reproduced; advanced money to authors for rights to the manuscripts, thus assuming the risks of publication; chose the format, size, and price of each edition; and developed profitable markets for their merchandise.

BOOKS IN THE EARLY CHRISTIAN ERA

The codex. The substitution of the codex for the roll was a revolutionary change in the form of the book. Instead of having leaves fastened together to extend in a long strip, the codex was constructed from folded leaves bound together on one side—either the right or the left, depending on the direction of writing. (Some variant forms were bound at the top of the leaves.) The codex enjoyed several advantages over the roll. A compact pile of pages could be opened instantly to any point in the text, eliminating the cumbersome unrolling and rerolling, and facilitating the binding of many more leaves in a single book. In addition, the codex made feasible writing on both sides of the leaf; this was not practical for the roll. Because of its compactness, its ease of opening, and its use of both sides of the leaf, the codex could conveniently contain longer texts. The difference can be illustrated with copies of the Bible. While the Gospel of Matthew reached the capacity of the roll, a common codex included the four Gospels and Acts bound together; and complete Bibles were not unknown.

The folded note tablets used by the Greeks and the Romans may have suggested the codex form, but its development to the point of eventual supremacy was related to changes in the world of learning and in the materials for making books. The change in the scholarly outlook came from the rise of Christianity; the new material was vellum or parchment.

Vellum and parchment. Vellum and parchment are materials prepared from the skins of animals. Strictly speaking, vellum is a finer quality of parchment prepared from calf skins, but the terms have been used interchangeably since the Middle Ages. The forerunner of parchment as a writing material was leather. Egyptian sources refer to documents written on leather as early as 2450 BC, and a fragmentary Egyptian leather roll of the 24th century BC survives; but leather was rarely used because papyrus was plentiful. The Hebrews also used leather for books. The spectacular discovery of the Dead Sea Scrolls in the 1940s turned up collections of both leather and papyrus rolls that had been stored in earthen jars in caves along the Dead Sea for centuries. These liturgical and biblical books, produced by a Jewish ascetic sect, were written between the mid-2nd century BC and AD 68.

Parchment is a greatly refined form of leather. The skins of various animals—cattle, sheep, and goats being most common—are washed and divested of hair or wool. Then the skin is stretched tight on a frame, scraped thin to remove further traces of hair and flesh, whitened with chalk, and smoothed with pumice. Tradition has it that parchment was invented as the result of book-collecting rivalry between Ptolemy V of Egypt and Eumenes II of Pergamum about 190 BC. Fearing the library at Pergamum might outstrip the collections at Alexandria, Ptolemy placed an embargo on papyrus to prevent his rival from making any more books, whereupon Eumenes made parchment. The fact that both the Greek and Latin words for parchment mean “stuff from Pergamum” offers some support for the tradition.

Although parchment was used to produce book rolls, and although many early codices were made from papyrus, the new writing material facilitated the success of the codex. A sheet of parchment could be cut in a size larger than a sheet of papyrus; it was flexible and durable, and it

Leather as
a writing
material

could better receive writing on both sides. These qualities were important. In making a parchment or vellum codex, a large sheet was folded to form a folio of two leaves, a quaternion (quarto) of four, or even an octavo of eight. Gatherings were made from a number of these folded sheets, which were then stitched together to form a book. Because papyrus was more brittle and could not be made in large enough sheets, the folio collected in quires (*i.e.*, loose sheets) was the limit of its usefulness. At the same time, because of the vertical alignment of the fibres on one side, papyrus was not well adapted for writing on both sides in a horizontal script.

For 400 years the roll and the codex existed side by side. There are contemporary references to the codex book dating from the 1st century BC; actual survivals date from the 2nd century AD, however. In the 4th century AD vellum or parchment as a material and the codex as a form became dominant, although there are later examples of rolls, and papyrus was occasionally used for official documents until the 10th century. There were similarities between the two forms; an example of the influence of the roll on the codex can be seen in the use of multiple columns on the pages of early codices, much like the columnar writing on the rolls.

Christianity and the book. In books surviving from the first four centuries AD, codices more often contained Christian writings, whereas pagan works were usually written on rolls. Several points in the Christian use of books contributed to a preference for vellum and the codex. First, Christianity was rooted in Judaism, which for centuries had revered sacred writings. The Christians retained the Jewish Scriptures and added some writings of their own, collected in a New Testament. There was strong motivation for preserving these unchanging words on the most durable materials, and vellum was more durable than papyrus. Second, in referring to their sacred writings the Christians made comparative studies of sources. The writings were related, and students liked to refer from one source to another. This reference entailed having a comparatively large volume of writings available and increased the attractiveness of the easy turning of pages possible with a codex. In this respect it is noteworthy that Roman legal scholarship, which also required a comparison of sources, likewise showed an early preference for the codex. A third point was the expressed intention of early Christians to shun pagan literature by using an entirely different form of book. Conversely the clinging of the pagan authors to an outmoded form may be ascribed in part to a conservative resistance to the Christian ideas.

The social potential of books was illustrated by the Christian emphasis on their dissemination. Christianity, which aimed at universality, produced a stream of books, whereas the literary remains of pagan religions are scarce. The process of introducing the universal religion throughout the Roman Empire extended over three centuries, covered thousands of miles, and embraced peoples of the most varied backgrounds and individuals of the greatest differences in rank. The worldwide outlook thus led to a greater dependence on books. Biblical texts and translations, commentaries, polemical tracts, and pamphlets were important in the circumstances, not only to record belief but also to disseminate and explain it.

By the 4th century, the same time that the vellum codex had superseded the papyrus roll, the Christian book had replaced the pagan book in every form. Little of importance was written in the classical tradition after AD 100. The greatest writers of the following three centuries were Christian scholars such as Origen, Pamphilus of Caesarea, Tertullian, St. Augustine, and St. Jerome. Of all Christian books, however, the most numerous survivals are New Testament codices and apocryphal New Testament writings.

THE MEDIEVAL BOOK

The monasteries. The dissolution of the western Roman Empire during the 5th century, and the consequent dominance of marauding barbarians, threatened the existence of books. It was the church that withstood the assaults and remained as a stable agency to provide the

security and interest in tradition without which books can be neither disseminated nor wholly enjoyed. Books found refuge in monasteries. The 6th-century Rule of St. Benedict enjoined monks to read books at certain times. The surrounding social chaos placed upon monasteries the responsibility for making books and creating libraries in order to implement the injunction. A more specific model was set by the historian and grammarian Cassiodorus, who, after serving the Ostrogothic kings in high positions, retired from public life in about 540 to found a monastery and establish a scriptorium at Vivarium. The scriptorium was the centre of his interest there. He supervised the copying of books and wrote a guide to learning, the *Institutions of Divine and Human Readings*. He also composed works that presented certain writers as models, discussed rules for editing, and suggested procedures for establishing a scriptorium and a library.

Following the early examples, monastic houses throughout the Middle Ages characteristically had libraries and scriptoria where monks copied books to add to their collections. Arrangements for this activity varied from place to place. Occasionally the scriptorium was a single large

Scriptoria

Bettmann Archives

A medieval monk copying from a text, in a scriptorium.

room. Sometimes the copying was done in carrels, individual cells built in the cloister or library. Fittings for the scriptoria were spare; they lacked heat and artificial light. Work was undertaken only during the daylight hours, because fear of fires that might result from artificial light prevented working after dark. The labour (if contemporary complaints can be believed) was hard, for it was often said, "Two fingers hold the pen, but the whole body toils." The scribe sat at a desk copying in silence a text that was spread before him. The monks did not follow the practice of the Roman commercial scriptorium where a reader dictated a book while several scribes made simultaneous copies of it. Instead, after the scribe's work was finished it was proofread and titles and notes were inserted. The book might then be given to an illuminator, who supplied any needed illustrations or decorative devices. Finally, the book was bound. This procedure closely resembles that of modern book production, except that in the scriptoria each step in the preparation of a manuscript was repeated for each copy of a work. Book production was slowed to a trickle, and a monastic library with as many as 600 volumes was considered fairly large.

The medieval book was a codex written on vellum or parchment, although by the 15th century paper manuscripts were normal. Many medieval manuscripts attained a high perfection of colour and form and are renowned for their beauty. Such examples as the Book of Kells from Ireland, the Lindisfarne Gospels from England, and the many brilliant "books of hours" made in France are world-renowned as examples of art. The customary book was less splendid, however. Written in a neat book hand that developed into the models from which printing

types were designed, the manuscript books of the Middle Ages were the models for the first printed books.

Because the monastic book trade was largely internal, the contents of books are evident from the monastic library catalogs. Generally the catalogs grouped the books in three divisions. First came the Bible and commentaries. Writings of the Church Fathers and contemporary theologians followed. Finally there was a smaller section of worldly books—including at various places some classics, mathematics, medicine, astronomy, law, and historical and philosophical writings. Scriptoria flourished throughout Europe. Books in the Greek language were found only in Byzantine monasteries; in western Europe books were written in Latin. Only with the onset of humanistic scholarship in the 14th century, and the rise of important vernacular writers at about the same time, did books in Greek and various vernacular languages assume any prominence in the catalogs of western European monasteries.

The revival of the secular book trade. For six centuries after Cassiodorus, references to book production outside monasteries are few and hard to interpret. A definite expansion in book production came with the rise of the universities in the 12th century and a revived interest in ancient Greek writings, although these were studied mainly in Latin translation. The universities were located in cities and generated a demand for books. University stationers were established to supply the demand; these were controlled by the universities, which framed regulations about the content and size of books and set prices for sale and for rental. The University of Vercelli in Piedmont, Italy, framed such a regulation in 1228, and many similar acts are recorded for other universities. To satisfy the growing demand, the university stationer, unlike the monastic scriptoria, produced multiple copies of works.

There can be no doubt that books were readily exposed for sale in the 14th century. This is evident in *Philobiblon*, a book finished in 1345 describing the book-collecting activities of Richard de Bury, bishop of Durham. The book relates how the bishop established good relations with stationers and booksellers in England, France, Germany, and Italy by sending advance payments. Evidence from the same century indicates that the stationers were organized in craft guilds in the same way that other trades were organized. A London record of 1357 granted exemption from jury service to writers of text hand (a compressed, angular hand used for the main text of a book). In 1403 the Stationers' Company of London appealed to the city for the right to have their own ordinances.

Humanistic and vernacular books. The manuscript books of the 14th and 15th centuries were affected by the rise of humanism and the increased use of the vernacular languages. The emergence of humanism has long stood as a notable example of the capacity of the book to preserve knowledge through centuries of disinterest and neglect. In the first half of the 14th century the intellectually curious began seeking out texts of classical authors. Many texts were found in monastery libraries, and soon considerable enthusiasm for the style of writing and pagan contents of the classical works developed. Library collections throughout western Europe were searched with the aim of recovering and purifying the classical texts. The restored texts, often with humanistic commentaries, became prized books that were collected by whoever could afford them. The Biblioteca Medicea-Laurenziana Library in Florence, the modern Biblioteca Apostolica Vaticana, and important collections in the Bibliothèque Nationale date from this time period. By 1450 most of the Latin classics had been recovered, and the humanists turned their attention to Greece, even before the fall of Constantinople in 1453 caused the exodus of so many books and scholars from the Eastern capital.

Concurrently with the revived interest in classical literature and language came the production of vernacular books. A vernacular literature had long been growing; and anonymous medieval authors had composed poems and stories of first importance before the 14th century, but their transmission had been largely oral. In the 14th and 15th centuries vernacular books appeared. The anonymous classics were put in writing, and new books by such

creative geniuses as Dante, Petrarch, Boccaccio, Chaucer, and Villon appeared.

The expanded literary production found a much larger audience capable of participating in the use and enjoyment of books. Lay princes as well as churchmen promoted learning and were among the patrons of humanism, although the practicing humanists themselves were for the most part ecclesiastics. An increasing number of books were written in the vernacular, and there is evidence that tradesmen and artisans in the cities were learning to read and write. It was partly to them that John Wycliffe directed his English translation of the Bible.

During the 15th century the manuscript book came to resemble its successor, the printed book, in scope. In the wake of the humanists, the content of books expanded to embrace a large sphere of human activity. New authors wrote in the language of the people. Increasing numbers of people enjoyed the advantage of literacy. Books were recognized as objects in trade, and their production and sale were handled by guilds in the same way as other articles of commerce. Paper, which had come to Europe from China by way of Arab traders, was replacing vellum as the material for books. Creation of the printing press wanted only ingenuity and patience.

THE AGE OF EARLY PRINTING: 1450–1550

Before the invention of printing, the number of manuscript books in Europe could be counted in thousands. By 1500, after only 50 years of printing, there were more than 9,000,000 books. These figures indicate the impact of the press, the rapidity with which it spread, the need for an artificial script, and the vulnerability of written culture up to that time.

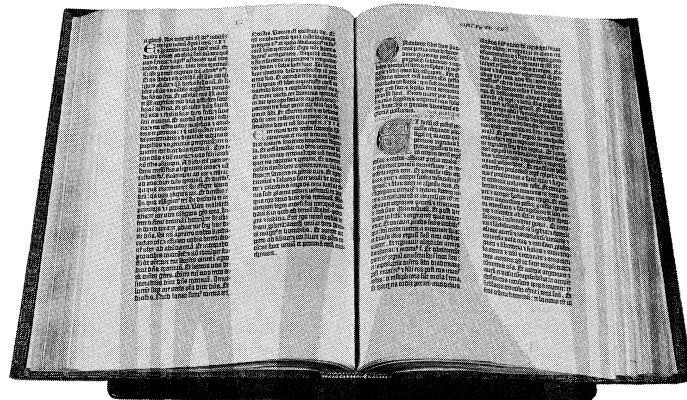

The printed books of this initial period, up to 1500, are known as incunabula; *i.e.*, "swaddling clothes" or "cradle," from a Latin phrase used in 1639 to describe the beginnings of typography. The dividing line, however, is artificial. The initial period of printing, a restless, highly competitive free-for-all, runs well into the 16th century. Printing began to settle down, to become regulated from within and controlled from without, only after about 1550. In this first 100 years, the printer dominated the book trade. The printer was often his own typesetter, editor, publisher, and bookseller; only papermaking and, usually, bookbinding were outside his province.

Early printer-publishers. *Germany.* Printing has been called the great German contribution to civilization; in its early days it was known as the German art. After its invention (about 1440–50) by a goldsmith of Mainz, Johannes Gutenberg, it was disseminated with missionary zeal—and a keen commercial sense—largely by Germans and largely along the trade routes of German merchants. Gutenberg himself is usually credited with what is known as the 42-line Bible (1455); the 36-line Bible; and a popular encyclopaedia called the *Catholicon* (1460); however, he lost control of his assets in collection proceedings brought against him by his business partner in 1455. Gutenberg's partner, Johann Fust, and his employee, Peter Schöffer (later Fust's son-in-law), continued the business together

Books in vernacular languages

after 1455; but Mainz itself never became a major centre of the book trade. It was soon challenged by Strassburg (Strasbourg) where, in 1460–61, Johann Mentelin, with an eye for the lay market, brought out a Bible compressed into fewer pages and followed this with the first printed Bible in German or any other vernacular. A few years later, Cologne had its first press (1464) and became an important centre of printing in the northwest. Cologne's early production was almost entirely in Latin because of the heavy bias of its university toward orthodox Thomist theology. In the south, printing quickly spread to the other great trading centres, Basel (1466), Nürnberg (1470), and Augsburg (1472). Basel became famous for the scholarly editions of Johann Amerbach and Johann Froben, who had the benefit of distinguished advisers, including the Dutch humanist scholar Desiderius Erasmus. In Augsburg, the first press was set up alongside the renowned scriptorium of the Abbey of SS. Ulrich and Afra; and the tradition of the illuminated manuscript was carried over into equally sumptuous editions of illustrated printed books. At Nürnberg, which soon took the lead in the book trade, Anton Koberger operated on a large, international scale. At his peak, he ran 24 presses and had links with Basel, Strassburg, Lyon, Paris, and many other cities. He could be called the first great businessman publisher and the first publisher to rise socially—to membership in the town council. By 1500 there were presses in some 60 German towns, including Lübeck (1475), the head of the Hanseatic League. From there, printing spread to Denmark, Sweden, Rostock, Danzig, and Russia, though the first printer who went to Russia was apparently murdered before he could achieve anything. Printing first began in Russia in 1552, with the help of a printer from Copenhagen.

Italy. It may be said that book printing, after its birth in medieval Germany, was carried to maturity in humanistic Italy. The printing press reached Italy very early (1462–63), via the Benedictine monastery of Subiaco, near Rome, which had strong German connections and a famous scriptorium. Two German printers, Konrad Sweynheim and Arnold Pannartz, who had settled there, soon moved to Rome (1467), where the church encouraged the production of inexpensive books. In Italy as in Germany, however, it was the great commercial towns that became centres of printing and publishing. By 1500, Venice had no fewer than 150 presses; and two Venetian printers exercised a decisive influence on the form of the book: Nicolas Jenson, an outstanding typographer who perfected the roman typeface in 1470, and Aldus Manutius, the greatest printer-publisher of his time. Aldus began printing in 1490 with a series of Greek texts. He then hit on the idea of bringing out inexpensive “pocket editions” for the new readers produced by the humanist movement. Beginning in 1501 and continuing with six titles a year for the next five years, he issued a series of Latin texts that were models of scholarship and elegance. To keep down the cost, Aldus printed editions of 1,000, instead of the more usual 250; and to fill the page economically, he used an italic type designed for him by Francesco Griffo. The Aldine editions were widely copied, by pirating (*i.e.*, without permission from the publisher or payment to him) and other methods, and their dolphin and anchor was one of the first instances of a publisher's device (roughly equivalent to the modern logo).

France. The way in which printing came to France is of special interest because it shows a publisher (rather than a printer-publisher) in command from the start. In Paris in 1470, the rector and librarian of the Sorbonne invited three German printers to set up a press on university premises. The scholars chose the books and supervised the printing, even to specifying the type. Their preference for roman type greatly helped the eventual defeat of black-letter, or Gothic, type. Among the early French printers were Jean Dupré, a businessman publisher of *éditions de luxe* (“luxury editions”), who set up in 1481, and Antoine Vérard, who began printing in 1485. Vérard was the first to print a Book of Hours, a book containing the prayers or offices appointed to be said at canonical hours, and his work set a standard of elegance for French book production. After 1500, when the full force of the Renaissance

began to be felt in France, a brilliant group of scholarly printers, including Josse Bade, Geoffroy Tory, and the Estienne (Stephanus) family, who published without a break for five generations (1502–1674), carried France into the lead in European book production and consolidated the Aldine type of book—compact, inexpensive, and printed in roman and italic types. The golden age of French typography is usually placed in the reign of Francis I (1515–47), one of the few monarchs ever to take a keen personal interest in printing. He was the patron and friend of Robert Estienne. In 1538 he ordered Estienne to give a copy of every Greek book he printed to the royal library, thus founding the first copyright library. In 1539 he laid down a code for printers, which included a prohibition on the use of any device that could be confused with another. Outside Paris, the only significant centre of printing in France was Lyon. While Paris was under the watchful eye of the predominantly Roman Catholic theologians at the Sorbonne, Lyon was able to publish humanist and Protestant works more freely. Among its foremost printers were Johann Trechsel and his sons, Melchior and Caspar; Sebastian Greyff, or Gryphius; and a fine typographer, Robert Granjon. By about 1600, however, religious pressure and the competition of Paris had put an end to printing in Lyon. Thereafter, the French book trade was based entirely in Paris.

Other continental printers. Other parts of Europe established presses quickly; *e.g.*, Utrecht (1470), Budapest (1473), and Cracow (1474), in each case through Germans. In Spain the German connection is particularly evident. The first Spanish press was set up in 1473 at Valencia, where the German trading company of Ravensburg had an important base. Though Madrid became dominant after 1566, publishing flourished in the early period at Barcelona, Burgos, Zaragoza, Seville, and the university towns of Salamanca and Alcalá de Henares. Spain quickly evolved its own distinctive style of book, full of dignity and printed largely in black-letter types. The most remarkable production of the period was the magnificent Complutensian Polyglot Bible (which presented the text in several languages in adjacent columns), sponsored by Cardinal Francisco Jiménez de Cisneros “to revive the hitherto dormant study of the scriptures,” which it effectively did. It was printed at Alcalá de Henares, in Hebrew, Chaldee, Syriac, Greek, and Latin, by Arnaldo Guillermo de Brocar, the first great Spanish printer. Editorial work was begun in 1502, the six volumes were printed in 1514–17, and the book finally was issued in 1521 or 1522. In Lisbon, the first printed book was a Pentateuch (the first five books of the Bible) produced in 1489 by Eliezer Toledano; he was reinforced in 1495 by two printers summoned by the Queen of Portugal. From Spain, printing crossed the Atlantic during this early period. In 1539 Juan Cromberger of Seville, whose father, Jacob, had set up a press there in 1502, secured the privilege for printing in Mexico and sent over one of his men, Juan Pablos. In that year, Pablos published the first printed book in the New World, *Doctrina christiana en la lengua mexicana e castellana* (“Christian Doctrine in the Mexican and Castilian Language”).

England. Compared with the Continent, England in the early days of printing was somewhat backward. Printing only reached England in 1476, and in 1500 there were still only five printers working in England, all in London and all foreigners. Type seems to have been largely imported from the Continent until about 1567, and paper until about 1589 (except for a brief spell during 1495–98). In an Act of 1484 to restrict aliens engaging in trade in England, Richard III deliberately exempted all aliens connected with the book trade in order to encourage its domestic development. In the following year, Henry VII appointed a foreigner, Peter Actors of Savoy, as royal stationer, with complete freedom to import books. For about 40 years, England was a profitable field for continental printers and their agents. This necessary free trade was brought to an end and native stationers protected under Henry VIII, whose acts of 1523, 1529, and 1534 imposed regulations on foreign craftsmen and finally prohibited the free importation of books. It has been estimated that up

First pocket editions

William
Caxton
and
his press

to 1535 two-thirds of those employed in the book trade in England were foreigners.

It is thus all the more remarkable that the man who introduced printing to England was a native, William Caxton. After learning to print at Cologne (1471–72), Caxton set up a press at Bruges (about 1474), where he had long been established in business. His first book, *The Recuyell of the Histories of Troye*, was his own translation from the French, and its production was probably the main reason why this semiretired merchant gentleman took to printing at the age of 50. He then returned to England through the encouragement of Edward IV and continued to receive royal patronage under Richard III and Henry VII. Caxton is important not so much as a printer (he was not a very good one) but because from the first he published in English instead of Latin and so helped to shape the language at a time when it was still in flux. Of the 90-odd books he printed, 74 were in English, of which 22 were his own translations. Some, such as the *Ordre of Chyvalry* and the *Fayttes of Armes*, were for the pleasure of his royal patrons; but his range was wide and included *Dictes and Sayenges of the Philosophers* (1477; his first book in England); two editions of Chaucer's *Canterbury Tales* (the second undertaken because a better manuscript came to hand); *The Fables of Aesop* (in his own translation from the French); Sir Thomas Malory's *Kyng Arthur*; and his largest work, *The Golden Legend*, a compilation of such ecclesiastical lore as lives of the saints, homilies, and commentaries on church services, a considerable editorial labour apart from the printing.

Caxton's press was carried on after his death by his assistant, Wynkyn de Worde of Alsace. In the absence of court connections and also because he was a shrewd businessman, he relied less on the production of expensive books for the rich and more on a wide variety of religious books, grammars and other schoolbooks, and collections of popular tales. He published more than 700 titles, mostly small volumes for the ordinary citizen, and continued Caxton's standardizing of the language, a solid contribution to the native book trade. The best of the early printers was Richard Pynson of Normandy, who began printing in 1492 and became printer to the king in 1508. Pynson, the first to use roman type in England (1509), published the first English book on arithmetic (1522). After his early liturgies and some fine illustrated books, he concentrated mainly on legal works. In 1521 he published Henry VIII's answer to Luther in defense of the papacy, for which the King received the title of *fidei defensor* ("defender of the faith") from the Pope.

Printed illustrations. Although 15th-century printers characteristically were content to exploit the existing book format, their use of printed illustrations in fact produced a new means of expression. Printers used woodcuts to print illustrations by the relief process and experimented with intaglio in copper engravings. Woodcut pictures were produced before metal types, and it was a simple development to make woodcuts in appropriate dimensions for use with type to print illustrated books. Albrecht Pfister of Bamberg was printing books illustrated with woodcuts about 1461. Copper engravings, which were better able to produce fine lines, were especially suitable for the reproduction of maps; among the few incunabula illustrated with engravings is a Ptolemy *Geographia* printed at Rome by Arnoldus Buckinck in 1478. But because engravings required a different press and introduced a separate process into printing, and because experiments with woodcut illustrations were so satisfactory, there was no extensive use of engravings before 1550.

Once a picture was prepared for printing, it could be repeated an indefinite number of times with little loss in detail, accuracy, form, or original vigour. When great artists such as Albrecht Dürer designed woodcuts the result was books of high aesthetic value that could be produced in great numbers. *Hyperotomachia Poliphili*, printed by Aldus Manutius in 1499, is a monument to the early perfection of the woodcut and to book illustration in general. Equally as important as the reproduction of great art was the opportunity that printed illustrations offered for the faithful reproduction of pictures and diagrams in scientific

books. The dawning scientific scholarship profited from the development of printed illustration; it is significant that studies in both anatomy, with its need for precise illustration of the human body, and cartography greatly expanded after development of printed illustrations.

The book trade. The book trade during this early period showed enormous vitality and variety. Competition was fierce and unscrupulous. A printer of Parma in 1473, apologizing for careless work, explained that others were bringing out the same text, and so he had to rush it through the press "more quickly than asparagus could be cooked." Though most of the early firms were small printer-publishers, many different arrangements were made and at least one businessman, Johann Rynmann of Augsburg, published nearly 200 books but printed none of them. Publishing companies, which both financed and guided the printing enterprise, were also tried, as at Milan in 1472 and at Perugia in 1475. Publishers were not slow to promote their books. The medieval scribes had placed their names, the date when they finished their labours, and perhaps a prayer or a note on the book, at the end of their codices. From this grew the printer's colophon, or tailpiece, which gave the title of the book, the date and place of printing, the name and house device of the printer, and a bit of self-advertisement. By about 1480, the information of the colophon began to appear at the front of the book as a title page, along with the title itself and the name of the author. Advertisements for books, in the form of handbills or broadsheets, are known from about 1466 onward, including one of Caxton's of 1477, ending with a polite request not to tear it down, *Supplicio stet cedula* ("Please let the poster stand"). Publisher's lists and catalogs occur almost as early. Distribution of books along the trade routes, with their courier services, appears to have been highly effective. In 1467, for instance, a bookseller in Riga on the Baltic coast had a stock of books issued by Schöffer in Mainz on the Rhine. Another effective channel for the distribution of books was the regular trade fairs, especially those at Frankfurt and at Stourbridge in England. Besides the stationers, who may sometimes have functioned as wholesalers, there were also retailers known as "book-carriers."

Early publishing had a profound effect on national languages and literatures—it began at once to create, standardize, and preserve them. Caxton, in the preface to his translation of the *Aeneid*, after telling a story of confused dialects, ended up "Lo! what should a man in these days now write, eggs or eyren?" By choosing words "understood of common people" and by printing all he could of English literature, he steered the English language along its main line of development. The early printing of great vernacular works, such as those of Dante, Petrarch, and Boccaccio in Italy, or a vernacular Bible, such as that of Luther in Germany, gave many languages their standard modern form. The French language owes much to the early printer-publisher Robert Estienne, who is known not only for his typographical innovations of the 1530s but also for his dictionaries. His work in the latter field caused him to be known as the father of French lexicography. Up to 1500, about three-quarters of all printing was in Latin, but thereafter that proportion steadily declined as books appeared in the vernacular and reached an ever-widening public.

Controls over printing. The church at first had every reason to welcome printing. Bibles (preferably in Latin), missals, breviaries, and general ecclesiastical literature poured from the early presses of Europe; and the first best-seller in print was a devotional work by Thomas à Kempis, *De imitatione Christi* (*Imitation of Christ*), which went through 99 editions between 1471 and 1500. Such sales were matched, however, between 1500 and 1520 by the works of the humanist Erasmus, and, after 1517, by those of the "heretic" Martin Luther. The church had always exercised censorship over written matter, especially through the universities in the late Middle Ages. As the works of the reformers swelled in volume and tone, this censorship became increasingly harsh. The Inquisition was restored, and it was decreed in 1543 that no book might be printed or sold without permission from the church.

lishing's
effect on
languages

The
Index of
Forbidden
Books

Lists of banned books were drawn up, and the first general *Index Librorum Prohibitorum* (Index of Forbidden Books) was issued in 1559. Dutch printers in particular suffered under the Inquisition and a number went to the stake for publishing Protestant books. To avoid such a fate, some resorted to the fake imprint, putting a fictitious printer or place of publication on the title page, or omitting that information.

Censorship also began to be exercised in varying degrees by individual rulers, especially in England, where church and state had been united under Henry VIII after his defection from Rome. The Tudors, with little right under common law, arrogated to themselves authority to control the press. After about 1525, endless proclamations were issued against heretical or seditious books. The most important was that of 1538 against "naughty printed books," which made it necessary to secure a license from the Privy Council or other royal nominees for the printing or distribution of any book in English.

The
Stationers'
Company

In this attempt at control, an increasingly prominent part came to be played by the Stationers' Company. Since its formation in 1403 from the old fraternities of scribes, limners, bookbinders, and stationers, it had sought to protect its members and regulate competition. Its first application for a royal charter in 1542 seems to have gone unheeded; but in 1557, an important date in the English book trade, the interests of the crown (then the Roman Catholic Mary Tudor), which wanted a ready instrument of control, coincided with those of the company (under a Roman Catholic first Master), and it was granted a charter that gave it a virtual monopoly. Thereafter, only those who were members of the company or who otherwise had special privileges or patents might print matter for sale in the kingdom. Under the system of royal privileges begun by Henry VIII, a printer was sometimes given the sole right to print and sell a particular book or class of books for a specified number of years, to enable him to recoup his outlay. This type of regulation now came into the hands of the Stationers' Company. After licensing by the authorities, all books had to be entered in the company's register, on payment of a small fee. The first stationer to enter a book acquired a right to the title or "copy" of it, which could then be transferred as might any other property. As the beginning of a system of copyright, this procedure was an admirable development; but the grip that the company obtained and its self-interested subservience to authority were to stunt the free growth of the English book trade for the next 100 years.

THE FLOURISHING BOOK TRADE: 1550–1800

From the mid-16th through the 18th century, there were virtually no technical changes in the methods of book production, but the organization of the trade moved gradually toward its modern form. The key functions of publishing, selecting the material to be printed and bearing the financial risk of its production, shifted from the printer to the bookseller and from him to the publisher in his own right; the author, too, at last came into his own. The battle with the censor became increasingly fierce before any measure of freedom of the press was allowed. Literacy grew steadily and the book trade expanded, both within and beyond national boundaries.

Advances in Europe and America. *The Netherlands.* After 1550, the lead in book publishing passed for a time to the Netherlands. The business founded at Antwerp in 1549 by Christophe Plantin, a Frenchman by birth, came to dominate the Roman Catholic south of the country, both in quantity and in quality. Its finest production was probably the eight-volume polyglot Bible (1569–72), the *Biblia regia* ("Royal Bible"). The firm was carried on for generations by the descendants of Plantin's son-in-law, Joannes Moretus (Jan Moerentorf). In the Protestant north, the house of Elzevir occupied a similar position. After its founding by Louis Elzevir, who issued his first book in 1593, its publishing endeavours were extended by succeeding generations to The Hague, Utrecht, and Amsterdam, with varying fortunes. A duodecimo (small-format) series of classical Latin texts that the Elzevirs began issuing in 1629 more than matched the earlier Al-

dine editions in excellence at a reasonable standard price. The Dutch, as great seafarers, were preeminent publishers of atlases, a word that was first used when the maps of Gerardus Mercator were published by his son, Rumold, in 1595. The high skill of Dutch engravers also went into their emblem books (books of symbolic pictures with accompanying verse), for which there was a considerable demand between 1580 and 1650.

France. In France, as the monarchy reasserted its authority after the wars of religion, publishing, which was already heavily concentrated in Paris, became increasingly centralized. In 1620, Louis XIII set up a private press in the Louvre, the *Imprimerie Royale*, which the Cardinal de Richelieu turned into a state establishment in 1640. This national press established and continued to maintain a standard of excellence for book production in France.

Louis XIII also tried to regulate the trade in books. By an ordinance of 1618, a body called the *Chambre des Syndicats* was established. It was organized along lines similar to the Stationers' Company in England, but because it contained two royal nominees, its control was even more absolute. The power of censorship, though it remained for a time with the Sorbonne, also passed eventually to officials of the crown. Under these conditions, publishers were inclined to exercise caution; as in other strictly regulated areas, more controversial works first appeared outside the country (often in Holland or Geneva) or under a false imprint. But French books fully upheld the influence of French taste in Europe. The vernacular made strong inroads (even as the language of scholarship) when Descartes published his *Discours de la méthode* (*Discourse on Method*) in French in 1637. A remarkable publishing feat of the 18th century was the 70-volume collected edition of Voltaire's works (1784–89) produced at Kehl, in Baden, by Pierre-Augustin Caron de Beaumarchais, the author of *The Barber of Seville* and *The Marriage of Figaro*. Beaumarchais bought the printing equipment (especially for the purpose) from the widow of the great English typographer John Baskerville.

Publishing
the works
of Voltaire

Germany. After the Reformation, the intellectual life of Germany was predominantly Protestant and the book trade almost entirely so. Through its book fairs, Frankfurt had become the centre of German publishing and even a kind of European clearinghouse. In 1579, however, the fair came under the supervision of the imperial censorship commission (Frankfurt being a free imperial city), and this action gradually killed it. After about 1650, though Frankfurt continued to be important for the production of type and illustrated books, the centre of the trade shifted decisively to Leipzig. There, an enlightened government and a celebrated university favoured cultural life and patronized book publishing. Two Leipzig firms dating from the 17th century survive to the present day: that founded by Johann Friedrich Gleditsch in 1694, which was taken over by the firm of F.A. Brockhaus in 1830, and that founded by Moritz Georg Weidmann in 1682. A Weidmann partner, Philipp Erasmus Reich, was known in the 18th century as "the prince of the German book trade." He could be said to have invented the net price principle (see below *Price regulation*) and the idea of a booksellers' association (1765), which in 1825 became the *Börsenverein der Deutschen Buchhändler*, a unique organization of publishers, wholesalers, and retailers. Toward the end of the 18th century, three publishers were outstanding—Georg Joachim Göschen in Leipzig; Johann Friedrich Cotta in Tübingen and Stuttgart; and Johann Friedrich Unger in Berlin, all of whom had a share in publishing Schiller and Goethe. Unger also published the magnificent translation of Shakespeare by August von Schlegel (8 vol., 1797–1810).

England. In the golden age of Elizabeth I, publishing in England was probably at its most turbulent. Through her Injunctions of 1559, Elizabeth confirmed the charter of the Stationers' Company and the system of licensing by the crown or its nominees, which now included church dignitaries. Controls were tightened in 1586 by a decree of the Star Chamber, which confined printing to London, except for one press each in the universities of Oxford and Cambridge. The Stationers' Company was given powers

The Biblia
regia

to inspect printing offices and to seize and destroy offending material or presses, which it zealously did, as much in defense of its monopoly as in support of the crown. But despite stern measures, the great religious question, in which Elizabeth steered a precarious course between Papists and Puritans, continued to be fought out with secret presses on both sides.

Within the legitimate trade, the booksellers had begun to get the upper hand. The incorporation of the Stationers' Company, like that of other London companies, was in itself an indication of the ascendancy of the trader over the craftsman. During the reign of Elizabeth, as part of a developing system of monopolies, the former short-term privileges for publishing certain works or classes of works (called "copies") were granted, for a consideration, as life patents with rights of reversion, such as those enjoyed by Richard Tottel for law books or John Day for alphabet books and catechisms. The printers had already been driven by high costs to make arrangements with the booksellers, to their own disadvantage. Gradually, the very best copies came into the hands of a rich few, who ruled the company and who, in the words of a report of 1582, "keepe no printing howse, neither beare any charge of letter, or other furniture but onlie paye for the workmanship." In 1577 an abortive revolt was led by John Wolfe, who maintained his right to print whatever he pleased. Wolfe was twice imprisoned, but he was finally bought off by admission to the Stationers' Company. In 1584 to still the discontent, some of the rich patentees surrendered a number of copies to the company for the benefit of its poorer members. These were supplemented in 1603, when King James I withdrew some patents from individuals and sold them to the company, again for "the poore of the same."

In this way the Stationers' Company itself became a publishing organization; and having tasted the advantages, it bought up more and more copies on its own account. These came to be divided into "stocks," the English Stock, Bible Stock, Irish Stock, Latin Stock, and Ballad Stock, with shares allocated among its members. By 1640, through leasing the patents at its discretion, the company controlled most of the printing offices in London. The benefit to the poor stationers was somewhat marginal and the monopoly and lack of foreign stimulus caused England to lag behind the Continent in standards of production.

For all that, the privileged men were sometimes good publishers; a few even supported authors during their labours. Some landmarks of the period were John Lyly's *Euphues*, published by Gabriel Cawood (1578); Sir Thomas North's translation of Plutarch's *Lives*, so important for Shakespeare, by Thomas Vautroullier (1579); Edmund Spenser's *Faerie Queene*, by William Ponsonbie (1589–96), and the Authorised (or King James) Version of the Bible (1611), which was completed in a room at Stationers' Hall and printed at the expense of Robert Barker, the king's printer.

Publication of drama was left, along with much of the poetry and the popular literature, to publishers who were not members of the Stationers' Company and to the outright pirates, who scrambled for what they could get and but for whom much would never have been printed. To join this fringe, the would-be publisher had only to get hold of a manuscript, by fair means or foul, enter it as his copy (or dispense with the formality), and have it printed. Just such a man was Thomas Thorpe, the publisher of Shakespeare's sonnets (1609); the mysterious "Mr. W.H." in the dedication is thought by some to be the person who procured him his copy. The first Shakespeare play to be published (*Titus Andronicus*, 1594) was printed by a notorious pirate, John Danter, who also brought out, anonymously, a defective *Romeo and Juliet* (1597), largely from shorthand notes made during performance. Eighteen of the plays appeared in "good" and "bad" quartos before the great First Folio in 1623. A typical imprint of the time, of the "good" second quarto of *Hamlet* (1604), reads: "Printed by I.R. for N.L. and are to be sold at his shoppe under Saint Dunston's Church in Fleetstreet"; i.e., printed by James Roberts for Nicholas Ling. For the First Folio, a large undertaking of more than 900 pages, a syndicate of five was formed, headed by Edward Blount and

William Jaggard; the Folio was printed, none too well, by William's son, Isaac.

Attempts to control the publishing business continued through most of the 17th century. In 1637 the Star Chamber issued its most drastic decree, which confirmed previous enactments, laid down detailed licensing procedures, reduced the total number of printers to 23, and prescribed severe penalties for offenses. Four years later, however, the Star Chamber itself was swept away by Parliament, and in the ensuing uncertainty the book trade had a taste of freedom. This new situation quickly alarmed not only the Stationers' Company, which saw its privileges vanishing, but also Parliament, which proved to be as reactionary as the royalists. In 1643 it passed an ordinance restoring both licensing and the powers of the company. It was this act that prompted John Milton to write his *Areopagitica*, a noble and powerful plea for freedom of the press, which vigorously argued against every claim of justification for censorship. After the Restoration, the Licensing Act of 1662 was ruthlessly enforced until after the Great Plague of 1664–65, when its rigours were mitigated; it lapsed in 1679. James II revived licensing in 1685, but Parliament refused to renew it in 1694. Thereafter, restraint, harassment, and persecution continued, but by other means, under a broad interpretation of the meaning of libel. With the end of licensing and the gradual breakdown of the whole guild system, the Stationers' Company declined in importance; but it remained useful in connection with copyright.

In the latter part of the 17th century, publishing expanded rapidly, partly through the rise of the periodical press (see below *Magazine publishing*), with its growing body of writers and readers. Successful books became highly profitable, and the author's right to a proper share was more widely recognized. The poet John Dryden is said to have received a total of £1,200 for his *Virgil* (1697), at a time when a shopkeeper might receive £50 a year and a labourer £15. Patronage continued, with all its political implications; but dedications became increasingly cut-and-dried, costing five guineas for a poem, perhaps, or 20 for a play; royalty was naturally expected to pay more. By the 1750s it was virtually at an end; "We have done with patronage," said Dr. Johnson. In its place came the public at large, to whom Henry Fielding dedicated his satirical piece for the theatre, *The Historical Register for the Year 1736*, on its publication in the following year. In the expanding literary market, the enterprising publisher tried to collect all the most promising authors to write for him. Through his personal inclinations, his sense of public taste, and his readiness to risk novelty, he began to play a part of his own in the course of literary development. As this side of the business absorbed more and more of his energies, the final separation of publisher and bookseller came about, though never so decisively as that between bookseller and printer.

In Britain this transition was marked—and fostered—by the passing of the Copyright Act of 1709, the first of its kind in any country. It was "An Act for the encouragement of Learning, by vesting the copies of printed books in the authors or purchasers of such copies during the times therein mentioned." For books printed before the act, the time was 21 years, "and no longer" (from April 10, 1710, when the act came into force). For works not yet published, the copyright was 14 years, "and no longer," though if the author was still living at the end of that time period, the copyright returned to him for a further period of 14 years. Penalties were also laid down, and registration at Stationers' Hall was made a condition for their enforcement.

The Copyright Act of 1709, like all subsequent measures, tried to strike a balance between the needs of those who make a living from books—writers, printers, and publishers—and the interests of the reading public, which are far from identical; it tried, in other words, to limit privilege as well as piracy. The terms it set were amended when they came to be regarded as too short; but in setting any term at all, and in focusing attention on the author as prime producer, it was revolutionary.

The fathers of modern publishing in Britain, which may

be said to date from this time, were Jacob Tonson, who acquired the copyright of Milton's *Paradise Lost* and published works by Dryden, Joseph Addison, Sir Richard Steele, and Alexander Pope, among others; and Barnaby Bernard Lintot, who also published Pope, paying him some £5,300 in all for his verse translation of the *Iliad*. Charles Rivington began publishing in 1711, and Longmans, Green & Co. was begun in 1724 by Thomas Longman when he bought the business of William Taylor, the publisher of Daniel Defoe's *Robinson Crusoe*. At mid-century the best-known figure in the trade was Robert Dodsley, the footman-poet who was befriended by Pope. Among "his" authors were Pope himself, Oliver Goldsmith, Laurence Sterne, and Samuel Johnson. He is credited with suggesting the idea of the *Dictionary* to Dr. Johnson, and his name heads the list of "gentlemen partners" who financed it. Such cooperative associations were popular as a means of financing longer works. They were known as congers and developed into a system of shares in individual books, which could be bought and sold at will.

America. During the 18th century, the book trade in the American colonies began to flourish. Printing had begun there in 1639, when the first printers, Stephen Day (also spelled Daye) and his two sons, left Cambridge, Eng., for Cambridge, Mass. After printing *The Oath of a Free-Man* (1638) and *An Almanack for the Year of Our Lord 1639*, the Days produced their first book, *The Whole Booke of Psalmes*, in 1640. In the early years of the Colonies, Cambridge, Mass., had the sole privilege of printing, but the monopoly was broken in 1674, when Marmaduke Johnson, who had come over to print an Indian Bible (1663), moved his press to Boston. Gradually others followed—Philadelphia had a press in 1685; New York City, in 1693. It was difficult for the colonial printer, as for any small printer, to produce large works because of a shortage of type; but patronage by the government helped to give his products a dignified style. Almanacs, primers, and law books were the staples of book production; works of theology formed the leading category. Until 1769 American printers bought their presses from England, but thereafter they acquired their equipment and supplies, including ink and paper, domestically. Books were sold in various ways—by subscription, by the printer himself, by hawkers, and through shopkeepers. Though Massachusetts passed a law against hawkers in 1713, it carefully excluded book peddlers, who had a valuable function in rural areas. The first bookseller seems to have been Hezekiah Usher of Boston, who added books to his general merchandise in about 1647.

Spread of education and literacy. The great increase in available reading matter after about 1650 both resulted from and promoted the spread of education to the middle classes, especially to women. The wider readership is reflected among the middle classes by the rich development of the prose novel in the 18th century and, among the less well-to-do, by the large sales of almanacs and chapbooks. The almanacs, such as Benjamin Franklin's *Poor Richard's Almanack* (Philadelphia, 1732–64), usually consisted of miscellaneous information and homiletic matter (collections of religious and moral sayings), while the chapbooks, consisting of a few pages cheaply produced, contained a popular story or ballad illustrated by a crude woodcut; a well-known example is *The famous and remarkable History of Sir Richard Whittington, three times Lord Mayor of London* (1656).

Growth of libraries. Growth in the book trade led naturally to growth in libraries. Some of the oldest collections of books developed into national "copyright libraries," of immense value for bibliographical purposes. Sir Thomas Bodley opened his famous library at Oxford in 1602, and in 1610 the Stationers' Company undertook to give it a copy of every book printed in England. Later, Acts of Parliament required the delivery of copies of every book to a varying number of libraries, the most important being the library of the British Museum, founded in 1759. This idea of a definitive collection was adopted elsewhere; e.g., in the United States, where the Librarian of the Library of Congress (founded in 1800) was appointed copyright officer in 1870.

In the 18th century a characteristic development was the commercial lending library, and in the 19th the free public library. Despite the fears of publishers and booksellers that the availability of books in library collections would discourage people from purchasing copies for their own use, circulating libraries have promoted rather than diminished the sale of books, besides being a steady market in themselves.

Decline of censorship. From the 18th century censorship in most Western countries diminished. It was abolished in Sweden in 1766, in Denmark in 1770, and in Germany in 1848. The clearest statement, to which lip service, at least, is now almost universally paid, came from the French National Assembly in 1789: "The free communication of thought and opinion is one of the most precious rights of man; every citizen may therefore speak, write and print freely." In the United States, no formal censorship has ever been established; control over printed matter has always been exercised through the courts under the law of libel. This was also the case in Britain after the lapsing of the Licensing Act in 1694; but two important steps had yet to be taken: in 1766, Parliament put an end to general warrants (i.e., for the arrest of unnamed persons and for the seizure of unspecified papers); and in 1792, Charles James Fox's Libel Act finally gave the jury the right to decide the issue, which had previously depended mainly on the judge. Subsequent efforts to suppress printed matter have centred on questions of libel, obscenity, or national security.

MODERN PUBLISHING:

FROM THE 19TH CENTURY TO THE PRESENT

The 19th century. In the 19th century a whole new era in publishing began. A series of technical developments, in the book trade as in other industries, dramatically raised output and lowered costs. Stereotyping, the iron press, the application of steam power, mechanical typesetting and typesetting, new methods of reproducing illustrations—these inventions, developed through the century and often resisted by the printer, amounted to a revolution in book production. Paper, made by hand up to 1800, formed more than 20 percent of the cost of a book in 1740; by 1910 it had fallen to a little more than 7 percent. Bindings, too, became less expensive. After 1820 cloth cases began to be used in place of leather, and increasingly the publisher issued his books already bound. Previously, he had done so only with less expensive books; the bindings of others had been left to the bookseller or private buyer. In Europe and America, expansion and competition were the essence of the century, and the book trade had a full share of both. While the population of Europe doubled, that of the United States increased fifteenfold. Improved means of communication led to wider distribution, and a thirst for self-improvement and entertainment greatly expanded readership, leading to a rapid growth in every category of book from the scholarly to the juvenile. The interplay of technical innovation and social change was never closer. As the development of the railways encouraged people to travel, a demand arose for reading material to lessen the tedium of the long journeys. The only victim in the book trade was design, part of the price that was paid almost universally in the first phase of machine production.

Publishing was now well established, with its characteristic blend of commerce and idealism. Their tendency to specialize made French and German publishers more vulnerable to change than their British colleagues, who aimed as a rule at greater flexibility. Literary and intellectual currents were flowing strongly and the number of new books rose by leaps and bounds. Rough figures for Britain indicate 100 new titles per year up to about 1750, rising to 600 by 1825, and to 6,000 before the end of the century. Equally characteristic was the appearance of popular series at low prices, "literature for the millions," as Archibald Constable was the first to call it. The forerunner was the publisher John Bell's *The Poets of Great Britain* (rivaling Dr. Johnson's), which appeared in 1777–83, in 109 volumes at six shillings each, when even a slim volume usually cost a guinea or more.

By the 1850s the application of the new techniques of

Revolu-
tionary
inventions

The

series in
England

mass production had brought down the price of an inexpensive reprint to one shilling, as in the Railway Library of novels (George Routledge, 1,300 vol., 1848–98), for instance, or in the three series of classics issued by H.G. Bohn in 1846, 1850, and 1853. Later reprints were cheaper still. Least expensive was Cassell's National Library (209 vol., 1886–90), bound in paper for threepence and in cloth for sixpence, that is, a 12th the price of the Bell set. On the Continent, two German series were outstanding. The Tauchnitz Collection of British and American Authors (1841–1939) became known to thousands of travelers. Tauchnitz voluntarily paid royalties and forbade the sale of his editions in Britain. Even more successful was Reclams Universal-Bibliothek, begun in 1867. An important factor in this series, as in others later, was the release of works through the expiration of copyright.

Book piracy. In the United States, publishing gradually became centralized in a few cities—Philadelphia, Boston, and New York City. Although American literature put down strong roots during the 19th century, piracy from Britain rose to great heights. There was sharp competition to be the first to secure proofs of any important new book. Publishers waiting at the dockside for new British books could produce an American edition almost within hours, as they did in 1823 with Sir Walter Scott's *Pepper of the Peak*. In the absence of international copyright agreements, the British author usually received nothing, but there were honourable exceptions; Harper Brothers, for instance, paid considerable royalties to Charles Dickens and Thomas Macaulay, among others. There was also at least one famous case of piracy in reverse. When Harriet Beecher Stowe's antislavery novel *Uncle Tom's Cabin* came out in the United States in 1852, 1,500,000 copies rapidly appeared in England, some editions selling for sixpence. Though it can be argued by some people that piracy is not only inevitable but possibly even desirable for the sake of cultural diffusion in some circumstances, the availability of inexpensive foreign books, if prolonged as it almost certainly was in the United States, can damage the prospects for home-produced literature. Though there were some household names, such as Washington Irving, James Fenimore Cooper, Ralph Waldo Emerson, and Henry Wadsworth Longfellow, American writers in general had a lean time; and the strong development of the magazine short story and the lecture tour in the United States has been attributed in part to their difficulties. Toward the end of the century American publishing was further enriched by translations of many foreign works, as a result of the flood of immigrants into New York City.

Price regulation. While 19th-century publishing was competitive and individualistic, its growing volume pointed increasingly to the need for greater organization. A major problem, once booksellers had become distinct from publishers, was suicidal price-cutting in the retail trade. Though price regulation ran counter to accepted notions of free competition and met with fierce opposition, in the general interest of the industry it was inevitable. Like copyright, it helped to provide a firm structure within which fair prices could be calculated. The net price principle, first raised in the previous century by the German publisher Reich, was adopted in Germany in 1887 through the work of the Börsenverein, the trade organization founded in 1825. Under this principle, the publisher allows a trade discount to the bookseller only on condition that the book is sold to the public at not less than its "net published price" as fixed by the publisher. In England a first attempt to introduce it by the booksellers in the 1850s was condemned to failure by the Free Traders; but toward the end of the century some publishers, led by Alexander Macmillan, began to replace the variable discounts by fixed prices. To press for the new system, the Associated Booksellers of Great Britain and Ireland was formed in 1895, and the Publishers Association was created in 1896. These two organizations then worked out the Net Book Agreement (1901), primarily through the efforts of Frederick (later Sir Frederick) Macmillan. The principle has since been generally adopted, although only to a limited extent in the United States. At roughly the same time, the founding of the Society of Authors (1884) in England and

the Authors' League (1912) in the United States helped to standardize fair dealing over contracts and the payment of royalties to authors.

Trade catalogs. The trade also became better organized in the provision of comprehensive catalogs of current books. These began as early as the twice-yearly book fairs at Frankfurt (first catalog 1564) and Leipzig (first catalog 1594). So great was the value of the Frankfurt catalog that an English edition was published in 1617–28. Eventually, all such semiprivate ventures, as *A Catalogue of all the Books Printed in the United States* (1804) or English catalogs deriving from *The Publishers' Circular* (1837) or *Whitaker's* (1874), became national lists, such as the *Bibliographie de la France* (from 1811), the U.S. *Cumulative Book List* (from 1898), the *Deutsche Nationalbibliographie* (from 1931), and the *British National Bibliography* (from 1950).

Development of copyright law. Copyright, too, underwent considerable development. By the end of the century, most countries had some provision, and various terms of protection were tried, running from publication or from the date of the author's death. The United States first legislated in 1790, France in 1793, and Germany in 1839. Moves toward an international code began in 1828 in Denmark. They took the form of reciprocal treaty arrangements between individual countries by which foreign authors received the same protection as did native authors. Britain joined the movement in several arrangements between 1844 and 1886. In 1885 a uniform international system of copyright was initiated by the Berne Convention. The customary term of protection is the author's lifetime plus 50 years. Most countries subscribed to the Convention, but not the United States or Russia. The United States continued to protect its domestic printing industry up to 1955, when it joined the Universal Copyright Convention (Unesco 1952). While the Berne Convention prescribed a minimum level of protection, the Universal Convention was based on the concept of "national treatment"—each member country treating works by citizens of other member countries as it would those of its own citizens. Thus the United States was able to enter into an international agreement without the necessity of immediately revising its own copyright law. Since the Universal Convention contained a provision that the Convention would not be applicable between any two countries that belonged to the Berne Union, it served primarily as a treaty between the United States and the countries that recognized international copyright. The Soviet Union became a party to the Berne Convention in 1973.

The 20th century. In the 20th century the effects of state education in the more advanced countries became increasingly apparent. Standards of living rose, and as in earlier times, these two conditions brought increased use and publication of books. During the late 1890s and the early years of the 1900s, many new publishing houses were founded. In the industrialized countries, though wages were rising, a small business could be staffed economically, and printing costs were such that it was economically feasible to print as few as 1,000 copies of a new book. It was thus comparatively easy to make a start, especially because the long-term credit that printers were prepared to grant made a minimum of capital necessary.

Book publishing grew to a substantial industry, consisting mostly of small units in the Western world but also embracing a number of large concerns, many of which were public corporations employing staffs of 1,000 or more. Specialization became frequent, particularly in educational books, as the needs of the new school populations were realized. Some companies, such as Macmillan, in both their British and American houses, had begun to issue schoolbooks almost by chance; then, as their sales grew most profitably, they developed separate departments for school and college textbooks. Others, such as The American Book Company, and Methuen in London, had begun specifically with educational books in mind. For more than one leading London firm, India, despite its high illiteracy rate, began to grow strongly as a market and to repay the care and expense involved in setting up separate Indian branches.

The net
price
principle

The first literary agents. A new factor at this time, which was to change the financial climate for fiction publishers in particular, was the advent of the literary agent. The first agent began business in 1875, and between 1900 and 1914 many more appeared. Reasonable though it was that authors who were unable themselves to handle their business with publishers satisfactorily should employ a professional to bargain for them, the higher rates of royalty and larger advance payments thus secured cut seriously into a publisher's profit. The increased cost made it considerably more difficult to finance the most speculative part of the business, the encouragement of new talent. The system of literary agents began in Britain but spread rapidly to the United States and also to the Continent, though in the latter it did not assume so great an importance. Keenly resented at first, the literary agent, by pressing for higher payment to authors he represented, may have been indirectly responsible for the greater selling efforts that some publishers began to make early in the century.

Sales methods. The discreet sales methods of the 19th century, whereby the sales representative merely showed his samples and the publisher took small spaces in newspapers for the bare announcement of title and author of his new books, were replaced by more forceful techniques. In this effort American publishers took a prominent part. Less hampered by inhibitions over the more blatant forms of salesmanship than their European colleagues, publishing houses in New York City began to take large advertisements, make extravagant claims for the qualities of their books, and thus build up bigger sales for new books than was customary in other countries. The existence of a prosperous middle class with fast-growing incomes was one factor; the vast spread of the population across the continent was another. These factors, combined with the development of the railroad, led to the successful development of mail-order advertising and selling. The sale of books, such as works of reference, by subscription was another technique that rapidly developed and grew into a business worth millions of dollars in the United States and elsewhere. It involved securing an undertaking to buy on installments over many months an already published set of books; it could also be used to secure advance orders for an expensive work, probably in several volumes, that the publisher was planning to issue, as was sometimes done in the 18th century. Continental countries also exploited the method, and considerable use was made of the door-to-door canvasser.

Effects of World War I. The coming of war in 1914 naturally had a disrupting, though not wholly destructive, effect upon book publishing in European countries. Shortage of paper necessitated rationing to two-thirds of prewar consumption in the case of Britain, while from hundreds of thousands of those in the armed forces came a tremendous demand for light reading. Although at one time the cost of paper rose to eight times its prewar level, sales of books increased sharply. The extra quantities could be supplied only at the expense of quality, and the standards of paper and binding were appalling. It would have been disastrous for a publisher to be left with large stocks of these books since paper supplies quickly returned to normal after the war, and the poorly produced books became unsalable. Of continental countries, Germany suffered the worst shortages, though the principal publishers were able to stay in business; in many respects a worse ordeal awaited them in the postwar inflation. In Britain, there was reluctance to recognize books as of any special importance to the national effort; virtually no direct use of them was made by the government, and it was not until the last four months of the war that a small proportion of publishers' staffs were granted any relief from compulsory national service.

An immediate aftereffect of the war in Europe was a sharp reduction in the purchasing power of the middle class. Whereas before, in most European countries, a proportion of the educated and professional classes bought new books regularly, high taxation, inflation, and trade depression in the postwar years cut down on spare money. Those publishers who continued to cater only to that public found it increasingly difficult to trade profitably, and many went

out of business or were absorbed into larger firms. In the United States, on the other hand, boom conditions in the postwar years produced a still more prosperous and enlarged middle class ready to absorb an increasing supply of books. The number of publishing houses grew; and more American authors, such as Sinclair Lewis and Ernest Hemingway, found a world market. British and continental publishers turned more readily than before to New York City in search of fresh talent. Universities also increased in number more rapidly in the United States than elsewhere, producing a larger demand for college textbooks. Publishing them became an immensely important part of the business for many U.S. firms, which in some cases depended upon their profitable college departments to finance other parts of their operation, such as the fiction side.

The book club. A new development of vast potential at this time was the book club, an association of members who undertook to purchase, usually each month, a book selected for them by a committee, the advantage being that the book in question was supplied at a lower price than that at which it could be bought in a bookshop. The scheme, of which an early forerunner was the Swiss Co-operative Movement in about 1900, had obvious attractions for the part of the reading public that had no direct access to a bookseller. The pioneer Book-of-the-Month Club in America (1926) developed a membership that ran into hundreds of thousands, followed by The Literary Guild, its great rival, and specialized book clubs that covered a variety of special reader interests. These clubs were strongly opposed at first by both publishers and booksellers, who disliked the additional emphasis placed upon the potential best-seller, but they came to supply a genuine need. They also helped to offset the enormous amount of book borrowing from libraries. From the 1950s onward, however, their popularity was somewhat affected by the availability of inexpensive paperbound books sold in thousands of outlets outside the regular book channels.

Design standards. As noted above, machine production had lowered standards of design. The English designer William Morris and his Kelmscott Press, however, had begun to work for better typography and book design in the 1890s; and his example had led to the establishment of other private presses, such as The Doves Press and the Ashendene Press, which produced editions (usually limited) of exceptional beauty, printed on handmade paper. Though aimed essentially at the collector and issued at high prices, such books began to influence the more discerning publisher; and by the 1920s a few firms, such as Alfred Knopf in New York City, Chatto and Windus and Jonathan Cape in London, and the Insel Verlag in Leipzig, were seen to be far ahead of their competitors in their standards of design. With careful planning, skillful selection of typeface, and provision of layouts to guide the printer, more and more publishers managed to achieve typographically handsome books at a commercial price. These efforts were part of the Design in Industry movement, which sought to demonstrate that mass production need not preclude beauty. It should be noted, however, that responsibility for design was passing from the printer to the publisher; as the former, with the growth of his business, became more the industrialist and less the craftsman, the latter realized that he must himself take charge of this aspect of the book.

The Great Depression. The great trade slump that began in October 1929 brought a swift decline in the prosperity of American publishing. By 1931 British publishers could no longer depend upon selling a high proportion of their books to the United States, either in the form of physical copies or by way of a contract conceding the U.S. rights. Though the book trade of Europe proved a little more resilient than some other industries, it passed through a difficult period. Sales declined, profits were negligible, and there were many bankruptcies. Attempts were made to find new outlets for books and fresh ways to attract the public to them. In London an annual Book Exhibition was run by *The Sunday Times* from 1933 to 1938; and *The New York Times* tried a similar venture in its city. The Germans continued to hold their annual

Installment

class

Book Fair in Leipzig, but this was primarily a trade function. Some British newspapers, striving for higher circulations, approached publishers to supply them with huge numbers of their popular books, specially printed, to be given away or sold very cheaply, in exchange for coupons from the papers. Booksellers resented the practice, but for hard-pressed publishers it was financially attractive. In the rather desperate climate of the times, some publishers also spent inordinate amounts on newspaper advertising. Reprint book clubs proliferated too, again to the benefit of the few publishers and authors fortunate enough to secure a choice. In 1932 a valuable innovation that stimulated sales was the Book Token, a form of gift certificate. The invention of an English publisher, Harold Raymond, the Book Token could be exchanged for a book of specified value at any participating bookshop. It was at first opposed by many booksellers; but it went on to become a major factor in Christmas sales, and the system was adopted in other countries and by other trades.

Appearance of
paperbacks

Even in the depressed conditions, publishers still dreamed of tapping a wider readership. This began to become a reality in 1935, when Allen Lane launched his pioneer Penguin series of paperbacks. It was a risky operation, involving speculatively high initial printings to keep down the unit cost. But despite the strongly held belief that paperbacks would not appeal outside the Continent, where they had sold freely, and the resistance of booksellers, who feared a sharp reduction in their receipts, the new series quickly caught on. They represented remarkable value at the original price of sixpence, equivalent to the cost of a small item in a variety store. Though printed on cheap paper the books employed good typography—far superior to that of any earlier attempts at paperbacks—and the original cover design was attractive in the bold simplicity of its orange and white stripes. A U.S. agency was arranged shortly before World War II and was later taken over by Victor Weybright, who subsequently established the highly successful New American Library for the mass promotion of paperbacks in the world market.

Nazi persecution of the Jews in the immediate prewar years and the impact of the war itself caused a wave of emigration, from Germany and Austria in particular, which brought fresh publishing talent to both Britain and the United States, as well as to other countries, including Australia. Some of the striking developments in the production of art books, with beautiful coloured illustrations, were a direct result of this movement, which bore its fullest fruit after the war.

Effects of World War II. The war that in 1939 European publishers had feared would utterly destroy their business proved in many respects less terrible in its effects on books than had been imagined. While the destruction of buildings, plants, and vast stocks of books, most notably in London and later in Leipzig, brought publishing to a standstill for individual firms, the activity as a whole continued. As in 1914, but to an even greater extent, the demand for reading matter, for both instruction and entertainment, grew enormously. The nature of the war, with its long periods of waiting alternating with intense bouts of frenzied activity, both induced the need and provided the opportunity for reading. As a result, book sales in the "free" countries rose to fresh heights. The occupied countries of Europe endured censorship and a tight control of materials; but most publishers survived and were swift to renew contacts with London and New York City colleagues immediately after the war.

Wartime
paper
shortages

In the United States, though they were subject to some shortages and inconvenience, publishers were comparatively untouched by the war, and their business expanded rapidly. In Britain, however, because of the acute pressure on shipping, the import of esparto grass, an essential ingredient for good book papers, was strictly limited; and a publisher's paper ration was reduced to 37½ percent of his prewar annual consumption. By closer setting of type and the use of much thinner paper, the ration was stretched to produce the maximum number of copies; but the final appearance of British books inevitably suffered, and they began to compare very unfavourably with those of the United States.

In countries that suffered severe paper shortage there was, of course, a sharp reduction in the number of new books and in the size of editions; consequently, with the increase in demand, the available books were rapidly sold out. The result was an enormous, if illusory, increase of profitability for publishers; and despite heavy wartime taxation they found themselves in far better shape financially than ever before. Instead of holding large, and often very slow-selling, stocks with insufficient cash resources, publishers had little stock but ample cash. There was, too, the marginal advantage that those new authors who were able to secure publication in the war years could be virtually certain that their books would be quickly sold out. In these artificial conditions, many publishers were more prepared to risk the work of an untried author. Against this, however, was the very serious shortage of standard works of every kind, classics and educational and reference books; at one time the cry went up that "Shakespeare is out of print!" While a small extra tonnage of paper was released in Britain in 1942 for the reprinting of books that were considered "nationally important" in wartime, no one could possibly pretend that there was not a real book famine in most European countries. After the war it took about five years for paper to become reasonably plentiful again. Despite the disruption brought by the war, however, interest in books had increased enormously; and sales were furthered by the total disappearance or severe rationing in most of the warring countries of so many consumer articles that normally compete with books. Contrary to the fears of many publishers, a new reading public was emerging, and it was not lost in the postwar world.

The postwar period. After the end of the war, there was an awkward year or so of reorganization and anticlimax, when many wartime publications suddenly became unsalable; but then publishing, in almost every country, once more expanded rapidly. People who had been cut off entirely from the rest of the world displayed an immense hunger for the books that had appeared during the previous six years. Much new business developed in the sale of the actual books and in translation rights. Such conditions continued at a higher level than they had attained in the 1930s, and they were to be further stimulated with the rise of the Frankfurt Book Fair. Social change came to many countries, bringing a broader spread of purchasing power and above all wider educational opportunity for much of the population. The change was to set book publishing upon a bolder and more adventurous course, turning it from a minor industry into one of sufficient growth and profitability to attract professional investors.

A feature of the early postwar years was the remarkable phoenixlike rise of the German book trade, literally from the ashes of the Allied air raids, which had destroyed the principal cities with their publishing offices and printing works. Because Leipzig was in the Soviet-controlled zone of Germany, however, the centre of the trade moved to Frankfurt for the first time since about 1650. As part of its drive to become the commercial capital of West Germany, Frankfurt developed its exhibition facilities rapidly. Thus, the book trade fair had ideal conditions in which to thrive. Before 1939 it had been largely a domestic affair at which German publishers displayed their new works to booksellers, with only a small number of foreign publishers participating and those almost entirely continental; but it steadily grew to be the greatest meeting place for publishers from throughout the world.

Revival of
German
publishing

In the nations that formed the Soviet bloc following World War II, publishing was subjected to a state control similar to that initiated in Soviet Russia in 1917. Very few of the famous publishing houses of Poland and Czechoslovakia survived, and the houses that did survive came under the ownership and control of the state. The normal pattern is for all books upon a particular group of subjects to be issued from one publishing house. Thus in Hungary, for example, the principal houses deal with science, political history, agriculture, music, belles-lettres, or military or technical subjects. The organization in Rumania is similar; but in East Germany it is significant that many of the prewar firms remain, though all are subject to government control.

Rise of
photocom-
position

Besides the economic and social changes that favoured publishing after 1945, an outburst of knowledge, particularly in science and technology, produced many new subjects, many of them subdivided into the highest degree of specialization, all of which called for new books. The many new universities and colleges of technology that sprang up throughout the world formed a strong market for the thousands of college books, which came to make up such a large part of many a publisher's list. At the same time there was a major advance in printing, a break away from the traditional letterpress system dependent upon lead type. Photocomposition (composing of printed matter by photographic means rather than by hand), coupled with offset printing technique, obviated much of the handwork of the earlier methods, improved working speeds, and prevented costs from rising as steeply as they would otherwise have done. The trend was toward giant machines for mass production, giving a favourable price for cases in which 100,000 or more copies were needed. Such giant machines became essential for the printing of paperbacks, but the problem remained of printing economically those "short runs" of 3,000 or so in which the works of new authors, from whom many of the important books of the future must come, are normally tried out.

The paperback revolution. By the early 1950s the paperback revolution was well under way. Growing from the prewar Penguins and spreading to many other firms, paperbacks began to proliferate into well-printed, inexpensive books on every conceivable subject. Generally known as pocket books on the Continent, they swept the world, converting book borrowers into buyers and creating new book readers on a scale never known before. Their use has been particularly widespread in the developing countries, notably those of Africa. Besides their cheapness, putting books for the first time into the area of impulse buying, and the wide range of first-class literature available, the new paperbacks had remarkable ubiquity, being found not only in bookshops but also in drugstores, street kiosks, and newsstands in railway stations, airports, and hotel lobbies. The cheapness of the paperback is due essentially to the large number printed, seldom fewer than 30,000 and frequently far more, and not, as is often supposed, to the use of paper instead of a hard cover for the binding.

By far the greater number of paperbacks have been reprints of books that have had some success in their original clothbound form. Normally the paperback publisher makes an offer to buy the paperback rights from the publisher of the hardcover edition and the paperback royalties are shared between the author and the hardcover publisher. While many of the big paperback houses have produced a certain number of new, hitherto unpublished books, the paperback operation is dependent in the main upon books originating with the conventional publishers. It is a fallacy therefore to suppose that, for all their seeming dominance, the paperback is likely to oust the hardcover book.

Scholarly
paper-
backs

A smaller selling type of paperback has sprung from the enormous growth in the number of university students throughout the world. This is the reissue of works of scholarship, science, religion, literature, and art. Many had been out of print for years, and they had often been issued originally in small editions of no more than 2,000 copies by university presses or other specialized publishers. This great extension of the market began in the United States in the 1950s, with prices ranging from 65 cents to \$1.95, at that time unusually high levels for paperbacks; the idea soon spread to Britain and the Continent. This operation has usually remained in the hands of the original publishers of the books, who have developed their own series of "university paperback books." It became customary for many new academic books to be issued simultaneously in both cloth (hardcover) editions and as paperbacks, the usual price of the latter being a little more than half that of the cloth edition.

University and government presses. The increase in the number of universities was accompanied by an increase in the number of university presses. The purpose of these presses is to serve the needs of scholarship, to publish specialized material that a purely commercial firm would

find impracticable to handle. Their freedom from the more acute profit-making pressures, often a result of direct subsidies, coupled with their assured, if limited, market, enables many to reach high standards of production and commercial viability. Some of the older establishments, such as the Oxford University Press, are, of course, large, profitable organizations with worldwide connections and a long list of more general publications.

Another type of publishing house not usually in direct competition with ordinary firms is the state printing office, which is responsible in many countries for issuing public and official material. In England, Her Majesty's Stationery Office, originally created in 1786 to coordinate office supplies for government departments, has come to issue a wide range of excellent books and pamphlets in connection with museums, galleries, and the advisory function of ministries, besides official papers. In the United States, the Government Printing Office in Washington, D.C., was set up by Congress in 1860 for similar purposes; it too has steadily widened its field of operations. The Soviet Union and China have similar organizations to issue their publications.

Publishing practice. Every publishing house has manufacturing, marketing, and accounts departments, but the heart of the business lies in the editorial function. This has changed in its mode of operation through the years and still varies from one country to another and between firms, but not in essentials. The editor, or sponsor as he is sometimes called, who is often a director, selects the books to be published, deals with the author, and is responsible for the critical reading of the typescript (and its revision if necessary) and for seeing the book through the press, in consultation with the manufacturing and marketing departments. So vital can the editor's part be that his presence in a firm, or his transfer to another, can be a major factor in attracting authors. Besides the editor, there is also an editorial department, which is responsible for the detailed preparation of the typescript before it is printed. This receives more attention today than in the past. Facts, figures, and references are checked, and inelegancies of style are polished where necessary. Careful attention by a skilled editor at this stage can contribute greatly to the quality of many books.

Role of the
editor

Educational publishing. A particular branch of editorial work that has grown to be of cardinal importance since World War II concerns the conception, planning, and publication of the hundreds of books needed for educational programs at every level. Throughout the world editors specializing in school and college books visit teachers and lecturers to promote the writing of the required textbooks. The educational editor must concentrate almost wholly upon the commissioning of books to fit a particular syllabus in a school or university. Rarely, if ever, does the editor receive an unsolicited typescript that can be accepted at once. The editor must seek material by regular visits, either personally or by one of his assistants, to schools or colleges to find the teachers who have the makings of authorship. Outlines or drafts of texts are evaluated by editors who develop the central themes into a usable form. Much time must then be spent on revision and production before the book is completed. In the United States, the boards of education in some of the larger states review the available textbooks and approve a selection for use in their school districts. This selection process is called adoption, and publishers compete to have their books adopted for use because of the large volume of sales that are thus guaranteed. The schoolbook that is widely adopted may sell for a generation and reward author and publisher on a scale beyond the dreams of those concerned only with general books. Equally, nothing can fail so completely as the schoolbook that gets no adoptions.

Forms of copyright. Book publishing depends fundamentally on copyright, which is the sole right to copy or to produce a work, conceded to the publisher by the author through a mutual agreement. Without this element of monopoly it would be impossible for a publisher to trade. It is also the guarantee for an author that he has legal rights to prevent the use of his material without fair com-

Subsidiary rights

pensation. On the expiration of copyright, anyone is free to publish the work in question without payment to the author or his heirs. Copyright at one time was simple and indivisible; many alternative forms of text reproduction have developed, however. Their exploitation is governed by individual clauses in the agreement. These subsidiary rights may be briefly summarized. American rights for a British book and British rights for a book of American origin can prove to be exceptionally profitable. Though a book normally has its greatest sale in its country of origin, there are cases in which it does even better abroad. The richness of the American market gives it a particular attraction for publishers and authors of almost every other country. Translation rights have become a valuable source of additional revenue, particularly since the establishment of the Berne Convention.

All the signatory countries agreed to copyright protection for the unpublished works of nationals of other member countries and for all the work first published in the Convention countries. While many books may earn no more than a few hundred dollars from the rights of translation in a single country, some world best-sellers, by authors of international stature, have a demand in almost every country, new or old, for a translation, and the aggregate earnings are then immense. Paperback rights for the more salable books, whether fiction or fact, are customarily offered to one of the major paperback houses, which flourish in most larger countries. For a best-seller there can be keen competition between the paperback houses, and advances well into seven figures may be offered to the original publisher, who normally controls the reprint rights. The original publisher also stipulates the earliest date at which the paperback may appear; as a rule, this is not less than 12 months after first publication. Rights for serial publication may be sold in several divisions: first serial rights, for which the best price can be obtained from a large-circulation newspaper or magazine in the capital city, may allow the publication of a number of installments appearing several weeks ahead of the issue of the book, or the serialization may "straddle" the appearance of the book, some installments before, the rest after. Second serial rights, for which much less is paid, can still yield useful sums: after first serialization has taken place, lesser papers in other parts of the country, or in other countries where the same language is spoken, can use the book. Digest rights, and their allied condensed book rights, represent another lucrative subsidiary use for books of wide general appeal.

Broadcast and television rights

Book club rights are also among those the publisher can exploit; the fees received from the clubs are also shared with the author. Broadcast and television rights in books interest a publisher primarily for the possibility of bringing a book and its author to the attention of a large segment of the public, rather than for the amounts paid. As a rule, there must be direct quotation from the text if a broadcasting company is to pay anything to the publisher. A television interview with the author, including sight of a copy of the book, is of great publicity value, and the author may even receive a fee for the appearance, but this is not part of the book's earnings. If the author can show a film relating to the book, it would be paid for at the appropriate rates for television use. In radio broadcasting, the reading of a book as a serial is one most remunerative possibility; the other is its full dramatization as a serial. The latter is, of course, still more valuable on television. Such use of new books has become more frequent; in the past this treatment was more often accorded to works of classic status. Dramatic and film rights can have importance for fiction, biography, and other general books, but only a small fraction of 1 percent of those published can be exploited by these means. From the publisher's standpoint, it is reasonable to share in the proceeds from the sale of these rights, for they result from the publisher's efforts.

Remote copying

The last group of subsidiary rights, rights for mechanical reproduction by film micrography, xerography, tape or disc recording, or any other technique of sight or sound, are of increasing concern to publishers. Dry-copying machines, easily operated, are to be found throughout the world in public, university, and school libraries, and while

ordinarily only single copies can legally be made solely for the purposes of private study, it is a simple matter, though illegal, to run off a number of copies of long extracts, which then make it unnecessary to buy more than one copy of the book. Similarly, microfilm enables a single copy to satisfy many users and reduces the number of copies of the book that must be kept available in a library. Wherever material originates in the form of a book, however, the publisher must retain an interest in all forms of reproduction as part of his resources for promoting experimental and imaginative work.

Publisher's agreement. A publisher's agreement with an author normally specifies that in consideration of certain payments the former shall, during the legal term of copyright, have the exclusive right to produce or reproduce the said work in any material legible form throughout the world. In many cases, however, this agreement is modified to exclude some of the subsidiary rights named above, depending on the bargaining power of the author or his agent. After clauses specifying the extent of the rights conferred, the basic clause of a royalty agreement is that which states the rate of royalty to be paid. A typical wording is as follows: "On all copies of the said work sold on the normal terms a royalty of ten percent shall be paid on the published price rising to twelve percent after the sale of 5,000 copies and to fifteen percent after 10,000 copies." Other clauses provide for somewhat lower royalty rates on export sales and on cheap editions, on which the publisher's margin of profit is considerably less. Provision is also made for division between author and publisher of any payments received for such subsidiary rights as are included in the agreement. A publisher can fairly claim a share in them if they arise from the fact of book publication. Proofreading is another important matter covered by the agreement, the author being responsible for this. If the cost of making his corrections exceeds a stated figure he must pay for the excess. Lastly, in the majority of publishing agreements there is an option clause under which the author undertakes to give the publisher the first offer of his "next literary work suitable for publication in book form," usually with the addition that if, after a stipulated time, no terms shall have been agreed on for its publication the author is free to submit it elsewhere. The exact form of the legal instrument varies in detail; it is possibly drawn up in the greatest detail by U.S. firms because of the complexities of their system of selling: e.g., by mail order, subscription, and similar means, in which the publisher must incur abnormal costs in order to secure the business. The vital condition for this publisher-author relationship, in the past often conducted with complete informality, is that there must be a legal document, a contract, setting out the rights and obligations of the two parties.

Literary agents and scouts. Literary agents have become increasingly important and prominent as publishing has grown more complex. A high proportion of the more successful authors of novels and general books now employ literary agents to place their books with publishers and to handle negotiations with them, the author being charged a commission of 10 percent. Besides negotiating and drawing up the contract with the firm, the good agency is equipped to handle the many subsidiary rights. Because an important element in the agent's value to an author is his capacity to extract better terms than the author would himself, it is not surprising that publishers have resented the agent's intrusion into the personal, and often very friendly, relationships between themselves and their authors. There can be no doubt, however, that agents do perform a valuable service in relieving an author of the considerable amount of routine work that his literary affairs may involve. Advice on possible new books to be written and occasionally, for the author of exceptional promise, an advance on anticipated earnings are also part of the assistance that the agent may offer. It must be emphasized, however, that agents are interested mainly in general books; they are seldom equipped to handle specialized and technical works.

Another publishing auxiliary who became significant in the 1950s and 1960s is the literary scout. Though a few had been employed earlier, mainly by U.S. publishers, who

Literary scouts

had their "lookouts" in one or two European cities, the practice is now more widespread. Many European publishers employ residents in London, Paris, and New York City to alert them at once to any promising new book, either written or just published. The scout, who may be connected with a newspaper or literary agency, is usually paid some modest amount as a retainer, probably with a commission of 1 or 2 percent on the published price of the books he recommends, in effect a small royalty on sales. On occasion a valuable find can be quite lucrative to the scout; frequently everything depends upon the speed with which a copy of the work can be got into the hands of his principal.

Selling and promotion. The publisher's techniques for book promotion have become increasingly sophisticated in all advanced countries. The typical traveler or book salesman is likely to hold a college degree, certainly in the United States; he receives a careful briefing from the home office, with elaborate samples and sales aids, and perhaps a car provided, or partly provided, by the firm. The itinerary for calls on bookshops (or in the case of the educational representative, schools and colleges) is prescribed by a supervisor, who usually checks the resulting orders against a quota. A well-run publishing house issues two or three seasonal announcement lists with details of its forthcoming books, as well as an annual catalog of its present and past books still in print, which are sent to the principal booksellers and librarians. For many books, a prospectus may be issued, both for the use of booksellers and for direct mailing by the publisher. The distribution of review copies to the press is the last item in the normal program. These three steps, traveling, catalogs, and reviews, are the vital elements in the machinery of book distribution, which it is virtually impossible to accomplish without the professional work of a publisher. The capacity of some authors to produce a quite presentable book with the help of a printer still leaves them far from their objective unless they can find a publisher to undertake its distribution.

Book
advertising

Newspaper and periodical advertising is the publisher's principal means of reaching the public, and standards here have also risen considerably since World War II. Originally handled entirely by the publisher's own staff, it is now not uncommon for the larger houses, especially in the United States and in some European countries, to employ advertising agencies to prepare the copy and the general details of the campaign for any important book. While few authors consider that their books are advertised adequately and most publishers are highly doubtful whether press advertising does in fact sell books, the amounts spent in relation to sales revenue are much higher than for most other commodities, seldom less than 5 percent for new books. Without their receipts from publishers' advertising, some periodicals would find it impossible to devote so much space to book reviews, which are in themselves a most valuable aid to sales. The news value of many new books also enables them to secure free publicity through references in the general, as distinct from the literary, pages of a newspaper. A publisher with imagination, or the firm's press officer if there is one, can often suggest aspects of a book susceptible to such treatment. Broadcasting and television services, too, can sometimes be interested in books and their authors, and the resultant publicity may then be extremely effective.

Over the whole field of sales promotion, as publishing houses have grown in size and profitability, there has been a marked tendency for the more commercial methods of general business to be applied to books, which are aggressively promoted to retailers and the public in the same manner as are many other commodities. Though this may increase sales, at least in the short term, it may be doubted whether it is in the interests of the public and to the long-term advantage of good publishing. (P.U./G.U./Ed.)

Newspaper publishing

"A community needs news," said the British author Dame Rebecca West, "for the same reason that a man needs eyes. It has to see where it is going." For William Ran-

dolph Hearst, one of America's most important newspaper publishers, news was "what someone wants to stop you printing: all the rest is ads." Both idealistic and mercenary motives have contributed to the development of modern newspapers, which continue to attract millions of regular readers throughout the world despite stern competition from radio and television. Modern electronics, which has put a television set in almost every home in the Western world, has also revolutionized the newspaper publishing process, allowing many more newspapers to be born. An increasing number of these new newspapers are given away free, their production costs being borne entirely by the revenue from advertisements, which are of much greater importance than they were in Hearst's day.

Newspapers can be published daily or weekly, in the morning or in the afternoon; they may be published for the few hundred inhabitants of a small town, for a whole country, or even for an international market. A newspaper differs from other types of publication by its immediacy, characteristic headlines, and coverage of a miscellany of topical issues and events. According to the Royal Commission on the Press in Great Britain, to qualify as news "an event must first be interesting to the public, and the public for this purpose means for each paper the people who read that paper." But the importance of newspapers stretches far beyond a passing human interest in events. In the 19th century the first independent newspapers contributed significantly to the spread of literacy and of the concepts of human rights and democratic freedoms. Newspapers continue to shape opinions in the "global village" of the late 20th century, where international preoccupations are frequently of concern to the individual, and where individual tragedies are often played out on an international stage. Since it is commonly held that individuals have a right to know enough about what is happening to be able to participate in public life, the newspaper journalist is deemed to have a duty to inform. Whenever this public right to know comes under attack, a heavy responsibility falls on the journalist.

ORIGINS AND EARLY EVIDENCES

The daily newspaper is essentially the product of an industrialized society. In its independent form, the newspaper is usually integral to the development of democracy. The newspaper thus defined was fairly late in emerging, since it depended on a certain basic freedom of speech and relatively widespread literacy.

The Roman Empire. The urge to inform the public of official developments and pronouncements has been a characteristic of most autocratic rulers. This urge was fulfilled in ancient Rome by the *Acta Diurna* ("Daily Events"), a daily gazette dating from 59 BC and attributed in origin to Julius Caesar. Handwritten copies of this early journal were posted in prominent places in Rome and in the provinces with the clear intention of feeding the populace official information. The *Acta Diurna* was not, however, restricted to proclamations, edicts, or even to political decisions taken in the Roman Senate, the actions of which were reported separately in the *Acta Senatus* (literally "Proceedings of the Senate"). The typical *Acta Diurna* might contain news of gladiatorial contests, astrological omens, notable marriages, births and deaths, public appointments, and trials and executions. Such reading matter complemented the usual fare of military news and plebiscite results also given in the *Acta Diurna* and presaged the future popularity of such newspaper fillers as horoscopes, the obituary column, and the sports pages.

China. If the *Acta Diurna* was the forerunner of the modern newspaper in terms of content, it was, nevertheless, a government publication: the authorities decided what qualified as news for public consumption. The same applied to the regular *pao*, or reports of court affairs, circulated among the educated civil servants of Peking for more than a thousand years (AD 618–1911). The *pao* changed in format and title under the various dynasties, and technological change brought a shift from hand copying to printing from wooden type in the 17th century, but the durability of the *pao* was a testament to the stability of the civil servant class.

Medieval Europe. In Europe, the impetus for regular publication of news was lacking for several centuries after the breakup of the Roman Empire. The increased output of books and pamphlets made possible by the development of the printing press in the 16th century did not include any newspapers, properly defined. The nearest form was the newsheet, which was not printed but handwritten by official scribes and read aloud by town criers. News was also contained in the newsbook, or news pamphlet, which flourished in the 16th century as a means of disseminating information on particular topics of interest. One such pamphlet, printed in England by Richard Fawkes, and dated September 1513, was a description of the Battle of Flodden Field. Titled *The Trew Encountre*, this four-leaved pamphlet gave an eyewitness account of the battle together with a list of the English heroes involved. By the final decade of the 15th century, publication of newsbooks was running at more than 20 a year in England alone, matching a regular supply on the Continent. Authors and printers escaped official censorship or penalties by remaining anonymous or cultivating a certain obscurity, for it took a long time before the pamphlets came to the attention of the authorities. In any case the topics most frequently chosen for coverage—scandals, feats of heroism, or marvelous occurrences—were mainly nonpolitical and could not be regarded as a threat to the powerful. Governments in various countries were already in the vanguard of news publishing for propaganda purposes. The Venetian republic set a precedent by charging an admission fee of one *gazeta* (approximately three-fourths of a penny) to public readings of the latest news concerning the war with Turkey (1563), thus recognizing a commercial demand for news, even on the part of the illiterate. The term *gazette* was to become common among later newspapers sold commercially. Another popular title was to be Mercury (the messenger of the gods). The *Mercurius Gallobelgicus* (1588–1638) was among the earliest of a number of periodical summaries of the news that began to appear in Europe in the late 16th century. Newspaper names like *Mercury*, *Herald*, and *Express* have always been popular, suggesting the immediacy or freshness of the reading matter. Other names, such as *Observer*, *Guardian*, *Standard*, and *Argus* (a vigilant watcher), stress the social role played by newspapers in a democratic society.

THE FIRST NEWSPAPERS

Newspaper development can be seen in three phases: first, the sporadic forerunners, gradually moving toward regular publication; second, more or less regular journals but liable to suppression and subject to censorship and licensing; and, third, a phase in which direct censorship is abandoned but attempts at control continue through taxation, bribery, and prosecution. Thereafter, some degree of independence has followed.

Commercial newsletters in continental Europe. The newsletter had been accepted as a conventional form of correspondence between officials or friends in Roman times, and in the late Middle Ages newsletters between the important trading families began to cross frontiers regularly. One family, the Fuggers, were owners of an important financial house in the German city of Augsburg; their regular newsletters were well-known even to outsiders. Traders' newsletters contained commercial information on the availability and prices of various goods and services, but they could include political news, just as the financial editor of today must consider the broader sweep of events likely to influence economic transactions. The commercial newsletter thus became the first vehicle of "serious" news, with its attempt at regular, frequent publication and concern with topical events generally.

The newsletter usually accorded primacy as a definite newspaper is the *Relation* of Strasbourg, first printed in 1609 by Johann Carolus. A close rival is the *Avisa Relation oder Zeitung* (*Zeitung* is the German word for "newspaper"), founded in the same year by Heinrich Julius, duke of Brunswick-Wolfenbützel. In 1605, in the Low Countries, Abraham Verhoeven of Antwerp had begun publication of the *Nieuwe Tijdingen*, although the earliest surviving copy is dated 1621. In any case, this historical rivalry is

evidence of a fairly sudden demand for newspapers at the start of the 17th century, and the continuous publication of the *Nieuwe Tijdingen* indicates that this demand soon became well-established. Although these publications were emerging throughout western Europe, it was the Dutch, with their advantageous geographical and trading position, who pioneered the international coverage of news through their "corantos," or "current news." The *Courante uyt Italien, Duytsland, & C.*, began to appear weekly or twice-weekly in 1618.

Similar rudimentary newspapers soon appeared in other European countries: Switzerland (1610), the Habsburg domains in central Europe (1620), England (1621), France (1631), Denmark (1634), Italy (1636), Sweden (1645), and Poland (1661). English and French translations of Dutch corantos were also available. But signs of official intolerance emerged fairly soon, and censorship stifled newspaper development in the late 17th century and into the 18th century in continental Europe. In Paris in 1631, the *Nouvelles Ordinaires de Divers Endroits*, a publishing venture by the booksellers Louis Vendosme and Jean Martin, was immediately replaced by an officially authorized publication, *La Gazette*, published under the name of Théophraste Renaudot but with influential backing by Cardinal de Richelieu. The new publication was to continue (as *La Gazette de France*) until 1917, casting the shadow of authority over nonofficial newspapers throughout its life. The first French daily—*Le Journal de Paris*—was not started until 1777; and although the Revolution of 1789 brought a temporary upsurge in newspaper publishing, with 350 papers being issued in Paris alone, the return to monarchy brought another clampdown. Napoleon I had his own official organ—*Le Moniteur Universel*, first published by Charles-Joseph Panckoucke (one of a family of booksellers and writers) in 1789 and lasting until 1869—and there were only three other French newspapers.

In Germany, early newsletter development was soon hampered by the Thirty Years' War (1618–48), with its restrictions on trade, shortage of paper, and strict censorship. Even in peacetime censorship and parochialism inhibited the German press. Among the important regional newspapers were the *Augsburger Zeitung* (1689), the *Vossische Zeitung* in Berlin (1705), and the *Hamburgische Correspondent* (1714). In Austria the *Wiener Zeitung* was started in 1703 and is considered to be the oldest surviving daily newspaper in the world. The oldest continuously published weekly paper is the official Swedish *gazette*, the *Post-och inrikes tidningar*, begun in 1645. Sweden is also notable for having introduced the first law (in 1766) guaranteeing freedom of the press, but the concept of an independent press barely existed in most of Europe until the middle of the 19th century, and until then publishers were constantly subject to state authority.

Early newspapers in Britain and America. *Britain.* The British press made its debut—an inauspicious one—in the early 17th century. News coverage was restricted to foreign affairs for a long time, and even the first so-called English newspaper was a translation by Nathaniel Butter, a printer, of a Dutch coranto called *Corante, or neues from Italy, Germany, Hungarie, Spaine and France*, dated Sept. 24, 1621. Together with two London stationers, Nicholas Bourne and Thomas Archer, Butter published a stream of corantos and avisos, including a numbered and dated series of *Weekley Newes*, beginning in 1622. But a number of difficulties confronted a prospective publisher: a license to publish was needed; regular censorship of reporting was in operation from the earliest days; and foreign news no longer appeared because of a Star Chamber decree (in force from 1632 to 1638) completely banning the publication of accounts of the Thirty Years' War.

Between the abolition of the Star Chamber in 1641 and the establishment of the Commonwealth in 1649 publishers enjoyed a short spell of freedom from strict official control. Publication of domestic news began to appear more regularly, shedding the original book form. News and headlines increasingly replaced the old title page. The Civil Wars (1642–51) acted as a stimulus to reporters and publishers, and 300 distinct news publications were brought out between 1640 and 1660, although

Newspaper
names

Censorship

many of these were only occasional reports from the battle front, such as *Truths from York* or *News from Hull*. The names of some contemporary publications, like the *Intelligencers*, *Scouts*, *Spys*, and *Posts*, reflected the bellicosity of the times, but the *Mercurys* still abounded, including the propaganda papers *Mercurius Academicus* (Royalist) and *Mercurius Britannicus* (Parliamentarian). The Parliamentarian victory brought strict control of the press from 1649 to 1658, and the restored monarchy was even more absolute, with the press being restricted to just two official papers. During the period of the Licensing Act (1662–94), an official surveyor of the press was given the sole privilege of publishing newspapers. The Revolution of 1688 produced a return to more permissive publishing laws and the first provincial presses were set up, starting with the *Worcester Post Man* (1690) and, in Scotland, the first *Edinburgh Gazette* (1699), although the British press was to remain principally a national one, centred on Fleet Street in London. Appearing briefly was *Lloyd's News* (1696), issuing from Edward Lloyd's coffeehouse, which had become a centre of marine insurance. The subsequent *Lloyd's List and Shipping Gazette* (from 1734), with its combination of general and shipping news, exemplified both the importance of the City of London's financial activities to the newspapers and the importance of a reliable and regular financial press to business.

Daily
publication

In the early years of the 18th century the British newspaper was approaching its first stage of maturity. After 1691, improvements in the postal system made daily publication practical, the first attempt at doing so being the single-sheet *Daily Courant* (1702–35), which consisted largely of extracts from foreign corantos. A more radical departure was the triweekly *Review* (1704–13), produced by Daniel Defoe, in which the writer's opinion on current political topics was given, introducing the editorial, or leading article. Defoe had been imprisoned, in 1702, for his pamphlet "The Shortest Way with Dissenters," but many eminent British writers were being attracted to the newspapers. Henry Muddiman had gained eminence as the "journalist" who edited the *London Gazette* (from 1666). John Milton had edited the *Mercurius Politicus* under Oliver Cromwell, and Sir Richard Steele and Joseph Addison, *The Spectator* (published daily 1711–12). *The Spectator* and *The Tatler* (triweekly, 1709–11, also written by Steele) are commemorated in the modern magazines of the same name (see below *Magazine publishing*), but their incorporation of social and artistic news and comment influenced the content of the contemporary newspaper permanently. Sales of the popular *Spectator* sometimes ran as high as 3,000 copies, and already this circulation level was enough to attract advertising. An excise duty on advertisements was introduced by the Stamp Act (1712), along with other so-called taxes on knowledge aimed at curbing the nascent power of the press. The rate of duty, at one penny on a whole sheet (four sides of print), was the same as the cover price of *The Spectator*, and this effective doubling of the price killed it, along with many other newspapers. But the newspaper had already become a permanent part of the social and literary life in London, and not even higher duties could prevent the proliferation of newspaper titles throughout the century.

Typical of the new breed of English papers was *The Daily Advertiser* (1730–1807), which offered advertising space along with news of a political, commercial, and social nature. An important gap in the political pages was filled from 1771, when the right to publish proceedings in Parliament had been granted. This right was not won lightly, for illicit accounts of debates in the House had appeared in the monthly *Political State of Great Britain* (1711–40) and every effort had been made to stop them. But campaigners such as the political reformer John Wilkes (with the *North Briton*, 1762) eventually won out. Politicians of both Whig and Tory sympathies ran their own often scurrilous newspapers or simply bribed journalists with occasional handouts and annual stipends, but later in the century there emerged a more sophisticated reader who demanded, and received, an independent viewpoint. Eminent newspapers of the time included the *Morning Post* (1772), *The Times* (from 1788, but started as the *Daily*

Universal Register in 1785), and *The Observer* (1791), each of which is still published (although the *Morning Post* was later merged with the *Daily Telegraph*). Censorship continued in the guise of frequent libel prosecutions, and as late as 1810 the radical political essayist William Cobbett was imprisoned and fined for denouncing flogging in the army, but the principle of a free press, at least in peacetime conditions, had been firmly established.

North America. In North America, publication of newspapers was deterred during colonial times by the long arm of the British law, but after independence the United States could boast one of the world's least restrictive sets of laws on publication. A first attempt at publishing, albeit abortive, was made in Boston by a radical from London, Benjamin Harris, in 1690. His *Publick Occurrences, Both Foreign and Domestick*, intended as a monthly series, was immediately stopped by the Governor of Massachusetts. It was clear that free speech and a nonofficial press were not to be tolerated in the colonies. Boston was also the site of the first official newspaper, the *Boston Newsletter* (1704), with which the authorities replaced the proclamations, pamphlets, and newsletters previously used to convey news from London. In 1719 the original title was replaced by the *Boston Gazette*, printed by Benjamin Franklin's elder brother, James, who soon produced the first independent American newspaper, the *New-England Courant* of 1721. William Bradford founded the first New York City newspaper, the *New-York Gazette*, in 1725, and his son Andrew was the first newspaper proprietor in Philadelphia. Further expansion of the colonies created 37 different titles by the outbreak of the War of Independence.

Colonial editors were aware of their responsibilities in creating a historical record of what was to be the new nation, and they cooperated in passing news to one another. In the absence of municipal offices, the printing office and newspaper headquarters often became a vital centre of community life. But frontier tensions led to passionate arguments, and newspapers became closely involved with political change. The Boston Tea Party (1773) itself is said to have been planned in a backroom of the *Boston Gazette*, already nicknamed "Monday's Dung Barge" by Loyalists. After independence the burning issues created with the new republic were aired in many new papers, most of which took up highly partisan stances. Thomas Jefferson and the first Republicans (later Democrats) were supported by the *Philadelphia Aurora* (1790), while Alexander Hamilton and the Federalists benefited from the support of the *Gazette of the United States* (1789–1818). Many city papers moved from weekly to daily publication, the first of these being the *Pennsylvania Evening Post* in 1783. The *Pennsylvania Packet* changed its name to *Pennsylvania Packet and Daily Advertiser* when it became a daily in 1784, indicating a new source of revenue for newspapers; and this was confirmed by the *New-York Daily Advertiser* (1785), the first to be published as a daily from the beginning.

The First Amendment to the U.S. Constitution specifically guaranteed "the freedom of speech or of the press." The right to criticize the government had been established as early as 1735, however, when John Peter Zenger, the publisher of the *New-York Weekly Journal*, was acquitted of criminal libel. After the temporary Alien and Sedition Acts (1798–1801), which included censorship clauses, were repealed, newspapers in the United States returned to polemics and public campaigns and set off on a course that was to help shape the modern character of the popular newspaper worldwide.

Early newspapers in Japan. A long tradition of news publication existed in Japan in the form of *yomiuri* ("sell and read," as the papers were sold by reading them aloud) or *kawara-ban* ("tile-block printing," the method of production). The *kawara-ban* broadsheets appeared continuously throughout the Tokugawa period (1603–1867), reporting popular festivals, personal scandals—notably the double suicides fashionable during the Genroku era (1608–1709)—natural disasters, and important events, such as the siege of Osaka Castle in 1615. Although much reporting concerned fairly innocuous occurrences, most writers preferred to remain anonymous for fear of the

punishments that could be imposed by the shogunate officials for unauthorized public discussion of political and social problems.

ERA OF THE INDUSTRIAL REVOLUTION

By 1800 educated citizens of most countries in Europe and in the United States could expect some access to independent news coverage and political comment, even if it was only to be found in clandestinely published newsheets. The basic formulas for serious newspapers and commercially successful, if sensational, popular newspapers had been worked out by shrewd writers and editors—members of the new profession of journalism. These formulas were to be elaborated throughout the 19th century, and by the end of the century the modern pattern of newspaper ownership and production had already been set in the United States and Britain, with newspapers passing from the realm of literature to that of big business.

Technological advances. New technology influenced newspapers both directly, through the revolution in printing techniques, and indirectly, through the rapid developments in transport and communications. In printing technology, necessity determined invention when the demand for newspapers exceeded the few thousand weekly copies required of the most popular titles. In 1814, the steam-driven “double-press” was introduced at *The Times* in London, allowing an output of 5,000 copies per hour. The higher output was a contributory factor in the rise of *The Times*’ circulation from 5,000 to 50,000 by the middle of the century. The hand-operated wooden press used for books, newspapers, and single sheets alike was further pushed into obsolescence by the invention of mechanical lead type, the Fourdrinier machine (which produced cheap cellulose paper in rolls), curved printing plates, automatic ink-feeds, and, in 1865, the cylindrical rotary press.

The main breakthrough, however, did not take place until the end of the century, with the introduction of automatic typesetting on Ottmar Mergenthaler’s Linotype machine. Until then, each line of words to be printed had to be lined up and justified (made to fill exactly the allotted space between margins) by hand. After printing, the letters were replaced in alphabetical order by hand for reuse. The new machines were operated by a keyboard which selected a matrix for the correct letter from a channel in the magazine; the line of text was automatically justified (made to fill the line exactly by adjusting the space between words); the line of lead type was cast; and the matrices were automatically returned to the correct channels, thus saving the need for the lengthy process of manual distribution. The first Linotype machines were introduced at the *New York Tribune* in 1886 and in Britain at the *Newcastle Chronicle* in 1889. By 1895 every publisher in Fleet Street (then the centre of London newspaper publishing) was using the new machines. Linotype keyboard operators could set copy six times faster than the hand compositor. Electricity, introduced in 1884, was also a spur to the printing industry, as were machines that could not only print but could also cut, fold, and bind together newspapers of any size.

Newspaper production was also transformed by the speeding up of communication, which allowed news to be gathered instantly from distant cities via the telephone or even from foreign countries through the seabed cables laid between Dover, Eng., and Calais, Fr., in 1851 and across the Atlantic in 1866. In 1815, when the mounted courier was the chief means of getting news, it ordinarily took four days before news of an event as near as Brussels could be reported in London. The railway and other improvements in communications, such as the telegraph, revolutionized the newsman’s conception of time and space. The railway networks not only moved reporters rapidly to and from their destinations but also helped to distribute newspapers, thus making them a more urgent and attractive commodity. Rapid and widespread delivery, especially in Britain and France, gave the larger newspapers based in capital cities a national status.

Foundations of modern journalism. The creation of new industrial occupations in society as a whole was reported by a new set of newspapermen who had far more specific jobs than their 18th-century predecessors. Earlier journal-

ists might write, edit, and print each copy of the paper by themselves. With the expansion of newspapers, full-time reporters, whose job was to go and get the news, were recruited, and they replaced many occasional correspondents, although there was always room for the stringer, a part-time reporter based in a small town or a remote region. William Howard Russell, a reporter for the London *Times* during the Crimean War (1853–56), became famous as one of the first war correspondents, and his writings inspired Florence Nightingale to take up her mission to the Crimea. More than 150 war correspondents reported on the U.S. Civil War (1861–65). The reporter could become as celebrated as the soldier, and vigilant reporting could perhaps prevent some of the atrocities perpetrated in wartime. In peacetime the fearless on-the-spot reporter hoping to “scoop” rival papers for a big story also became a folk hero, and his byline (the name or nom de plume published with the article) could become better known than that of the editor.

The expense of employing a large team of reporters, some of whom could be out of the office for months, proved impossible for smaller papers, thus paving the way for the news agency. The French businessman Charles Havas had begun this development in 1835 by turning a translation company into an agency offering the French press translated items from the chief European papers. His carrier-pigeon service between London, Paris, and Brussels followed, turning the company into an international concern that sold news items and that, eventually, also dealt in advertising space. Paul Julius Reuter, a former Havas employee, was among the first to exploit the new telegraphic cable lines in Germany, but his real success came in London, where he set up shop in 1851 as a supplier of overseas commercial information. Expansion soon led to the creation of the Reuters service of foreign telegrams to the press, an organization that grew with the spread of the British Empire to cover a large part of the world. In the United States, meanwhile, a very different type of agency—the newspaper cooperative—had arisen. Six New York City papers were the founding members; they suspended their traditional rivalries to share the cost of reporting the war with Mexico (1846–48) by establishing the New York Associated Press agency. Between 1870 and 1934, a series of agency treaties divided the world into exclusive territories for each major agency, but thereafter freedom of international operation was reinstated. The press agencies ensured a continuous supply of international “spot news”—i.e., the bare facts about events as they occur—and raised standards of objective news reporting. For their feature pages, American newspaper editors came to rely on the feature syndicates, which supplied ready-to-use material from medical columns and book reviews to astrological forecasts and crossword puzzles.

Growth of the newspaper business. Advances in newspaper production matched a quickening in the pace of life for the millions of people who read newspapers in the late 19th century. The railways, which transported newspapers rapidly from town to town, contributed to the breakdown of rural isolation, while the steamship and the telegraph brought nations closer together. Mass-produced newspapers with a broad appeal became available for the newly literate or semiliterate industrial worker. Circulations of some popular papers were climbing toward 1,000,000 by the end of the century, and newspaper publishing and advertising had become big business.

The United States. The movement toward a popular and politically independent press was spearheaded in the United States, where many potential readers were refugees from European political and religious persecution. The teeming immigrant population of New York City was the seedbed for several of the newspapers that were to shape the character of modern journalism. In 1835 the *New York Herald* was founded as the first American newspaper to proclaim and to maintain complete political independence. Its publisher, James Gordon Bennett, announced that the *Herald* would endeavour to record news, “with comments suitable, just, independent, fearless and good-tempered,” while supporting no political party. The popularity of the *Herald*, with its exciting amalgam of news and

The
reporter

News
agencies

Linotype

views presented in brief, easily digestible articles, was soon represented by a print run of more than 30,000 copies. The New Yorker's appetite for news was a substantial one, and in 1841 Horace Greeley introduced the *New York Tribune*. Whereas Bennett was an entertainer, Greeley was a campaigner, the first of the many idealists and crusaders who were to occupy American newspaper offices. "Go West, young man!" was a phrase coined in the *Tribune*, which also reflected its proprietor's fierce opposition to slavery and which influenced opinion well beyond the bounds of New York City. In the rough-and-ready frontier territories of the Midwest, crude sensationalism was a characteristic of the new popular press under editors such as Wilbur F. Storey of the *Chicago Times* (founded 1854), while painstaking investigation and exposure of political corruption was used by Rockhill Nelson of the *Kansas City Star* (1880) as new evidence of the independence of the press. In the South newspapers helped in rebuilding civic consciousness after the desolation of the Civil War through the efforts of men like Henry W. Grady at the *Atlanta Constitution* (after 1880) in Georgia and Henry Watterson at the *Louisville Courier-Journal* in Kentucky (after 1868).

The character of a newspaper could change radically under a new owner or editor. In New York City, an individual stamp was put on the influential *Evening Post* by its scholarly editor, Parke Godwin. The *New York Sun* had started life in 1833 as the first of the inexpensive popular papers known as the "penny press," with its founder, Benjamin H. Day, successfully exploiting a vein of demand for inconsequential "human-interest" stories. Later, under Charles A. Dana (after 1868), the *Sun* rose in style and prominence. The *New York Times* (1851), long in the shadow of the more vigorous *Herald* and *Tribune*, struck an important and lasting blow for the independence of the press by exposing an attempted bribe of the *Times*' editor by Tammany Hall politician William Marcy ("Boss") Tweed; the reported \$5,000,000 sum offered and rejected was an ample indication of the growing power of the press.

Great Britain. In Europe, Britain alone could boast the presence of an independent press in the first half of the 19th century. The London *Times* demonstrated the value of journalistic objectivity and the need to criticize governments if hard-won rights were to be preserved. Under the consistent management of John Walter II and John Walter III, son and grandson of the founder, and with enlightened editorial control from outstanding journalists, such as Thomas Barnes and John Thaddeus Delane, *The Times* became a model for most serious British newspapers. In 1819 its reporting of the Peterloo Massacre by government troops at a political rally in Manchester was uncompromising; it campaigned for Parliamentary reform (achieved in 1832) and exposed the horrors of the Crimean War. From a technical standpoint *The Times* led the way in the introduction of advanced printing machinery and provided a fast and reliable news service as early as the Napoleonic Wars.

In 1836 the Stamp Tax was reduced to one penny, and in 1855 it was abolished entirely. This gradual relaxation of an impost on newspapers produced higher circulations for existing newspapers and encouraged the publication of new titles. Many were cheap, lurid crime sheets that disappeared as fast as they emerged. One exception was the sensational Sunday paper, the *News of the World* (1843), which attracted more readers than any other Sunday paper in Britain for more than a century. More characteristic of the age was the *Daily Telegraph* (1855), a penny paper, but one that competed directly with *The Times* by covering serious news stories and including thoughtful editorial comment on four sides of print, but at a quarter of the price of the fourpenny *Times*.

Continental Europe. During much of the 19th century, fear of popular insurgence led the European monarchies to keep a watchful eye on the newspaper presses. At the same time, prior to the unification of the modern states of Germany and Italy, newspapers covering national affairs were of limited interest. The first signs of a popular press appeared with the founding in Paris of *La Presse* (1836) by Émile de Girardin, who might be called one of the

first press barons. He introduced new features and serials to raise circulation as high as 20,000 and thus to enable him to lower the price of his newspapers. A prominent contemporary of Girardin was Louis-Désiré Véron, who founded the *Revue de Paris* (1829) and revived the liberal daily *Le Constitutionnel* (1835). Aspiring French authors could gain publicity for their literary talents in these papers, especially when the Tanguy Law (1850) made it compulsory for them to sign the articles they wrote. But this literary slant to French newspapers, which persists to some degree in the modern era, could not disguise their paucity of hard news.

Disunity and political censorship continued to restrict the German press, although one independent daily, the *Allgemeine Zeitung* (Tübingen, 1798), managed to achieve wide influence. Farther north in Sweden, despite the freedom of speech granted to the press in 1766, the first notable newspaper (the *Aftonbladet*, founded by Lars Johan Hierta) was not begun until 1830.

Toward the middle of the century, censorship was abolished or relaxed in many other countries, including Switzerland (1848) and Denmark (1849). The new freedoms, together with the spread of literacy, gave birth to important newspapers, many of which still survive, including *Le Figaro* (Paris, 1854, daily from 1866), *Frankfurter Zeitung* (1856), *Le Peuple* (Brussels, date unknown), and the *Corriere della Sera* (Milan, 1876). In Spain and Portugal, censorship continued to prevent the development of true journalistic independence; any periods of comparative freedom were quickly followed by the reimposition of controls. In Russia strict censorship remained in force under the tsars, apart from a single decade (1855–65) of tolerance under Alexander II, when many new papers appeared. But limitations on publication were reimposed when it was found that greater freedom allowed radical ideas to be voiced, and the Russian press, like that in much of Europe, was forced to concentrate on literary rather than journalistic achievements.

Japan. The arrival of the U.S. naval officer Commodore Perry in Japan in 1853 was announced to the public in *kawara-bans*, which continued to be published for some years, though they began to be superseded by English-language newspapers. The first of these, the *Nagasaki Shipping List and Advertiser* (1861), was followed in the next five years by numerous periodicals, mainly translations produced by the shogunate Office for Reviewing Barbarian Papers. The office translated items from newspapers of China, Hong Kong, and the United States, as did Joseph Heko, a naturalized U.S. citizen and an interpreter at the American Embassy, in his monthly *Kaigai shimbun* (1865–66). The news items were therefore out of date, of little concern to the average Japanese, and too much resembling official announcements to be regarded as true newspapers. In 1867, however, the overthrow of the shogunate and the restoration of the Meiji led to the publication of more than a dozen newspapers concerned with domestic issues. Mainly issued by shogunate sympathizers, they included the *Koko shimbun*, whose publisher, the dramatist and educator Fukuchi Genichiro, had studied Western newspapers on his official travels abroad for the Japanese government (and who was later, in 1874, to preside over the *Nichi-Nichi shimbun*, which was closer to Western newspapers in style). The government soon suppressed these publications and promulgated the Newspaper Ordinance, which, in its 1871 version, decreed that the contents of a newspaper should always be "in the interest of governing the nation," a principle that was already anathema to many European and North American publishers.

Arrests of journalists and the suppression of newspapers were common in the 1870s, but the decade nevertheless saw the birth of several giants of contemporary Japanese journalism. In 1870 the *Yokohama Mainichi*, the first daily in Japan, was started; it was also one of the first to use lead type. Two years later the *Tokyo Nichi-Nichi* appeared as one of the first truly modern Japanese newspapers, although it regarded itself as virtually an official gazette. The *Yomiuri shimbun*, one of the three leading national dailies in modern Japan, was founded in Tokyo

The Times

The French press

The first Japanese daily

in 1874, and it soon gained a reputation as a “literary” newspaper. The other two principal papers—the *Osaka Nippo* (1876) and the *Osaka Asahi* (1879)—were to become, respectively, the *Osaka Mainichi* and the *Asahi shimbun* (created in the early 1940s by a merger with the *Tokyo Asahi*, founded in 1888). They are associated with two of the fathers of modern Japanese newspaper publishing, Murayama Ryuhei (*Asahi*) and Motoyama Hikochi (*Mainichi*). Motoyama took full control of the *Mainichi* in 1903 and three years later added the *Tokyo Nichi-Nichi* to his publishing empire.

Other countries. In other parts of the world a familiar cycle took place, with prohibition or strict censorship gradually giving way to the demand for a free press, although colonial governments long exercised an especially tight control on political publications. Canada had its first newspapers as early as the 18th century. These developed regionally and catered to both English and French speakers in Montreal, Quebec, and Toronto. Fine standards of journalism were later set by the *Winnipeg Free Press* (1872).

Parts of India also had an early service, with newsletters being circulated from the 16th century. Under British rule, both English- and vernacular-language papers flourished—the latter under government control—and enviable standards were set by *The Times of India* (1838, formerly the *Bombay Times*) and *The Hindu* (1878).

Several Australian titles date to the early years of settlement, notable ones being the *Sydney Morning Herald* (1831), the Melbourne *Argus* (1846), and *The Age* (1854). Full censorship lasted until 1824 and the stamp tax until 1830, but one title (*The Sydney Gazette and New South Wales Advertiser*) was being published as early as 1803. The first issue of New Zealand’s earliest newspaper, the *New Zealand Gazette*, was printed by emigrants even before their departure from London. The second issue awaited the installation of printing facilities in Wellington in 1840, when large-scale colonization was begun, but in the same year the *New Zealand Advertiser* was added to the list. The *Taranaki Herald* began publication in 1852.

In South Africa a press law was passed in 1828 to secure a modicum of publishing freedom, mainly through the efforts of the editor of the country’s first paper, the *South African Commercial Advertiser*. Later papers, such as the *Cape Argus* (1857), were often tied to commercial and mining interests at first, but later their editors began to insist on freer commentary. The racially divided nature of the country has prevented, however, absolute freedom even in modern times. Similar restrictions continue to be applied to publishers in many other African and Asian countries, in eastern Europe, and in Latin America, although the political complexion of the various regimes may differ.

ERA OF THE POPULAR PRESS

The introduction of the Linotype machine in 1886 allowed production of the vast numbers of newspapers then in circulation in the industrialized countries, led as before by Britain and the United States. In the latter country new standards of sensationalism were set—and new sales records frequently announced—with the birth of the ruthless “yellow” journalism (an expression derived from a cartoon character called the “Yellow Kid,” whose creator worked for the American newspaper publishers William Randolph Hearst and Joseph Pulitzer). In Britain the print runs of papers like *The Times* and the *Daily Telegraph* quickly reached the 100,000 mark in the second half of the 19th century. Newspapers were becoming part of mass-market industry, and in so doing they were shaking off many of their former ties with the literary world. This was evidenced in the revolutionary 1890s by the emergence of the “press baron,” a businessman who owned chains of newspapers, by the increasing importance of advertising revenue, and by the use of unorthodox methods of winning more readers.

The United States. The number of American newspaper titles more than doubled between 1880 and 1900, from 850 to nearly 2,000. In addition to the weekly newspaper serving the smaller community, every major city

had its own daily newspaper, and the metropolis had become the site of circulation battles between several titles. In New York City the newspaper business was shaken up by the arrival of Joseph Pulitzer, who is often credited with changing the course of American journalism. An immigrant from Hungary, Pulitzer had proved his ability in St. Louis, Mo., where he had bought and merged two local papers, the *Post* and the *Dispatch*. In New York City Pulitzer bought the failing *New York World* and in three years raised its circulation from 15,000 to 250,000, at that time the highest figure achieved by any newspaper in the world. With a series of stunts and campaigns, Pulitzer revitalized the established formulas of sensationalism and idealism, taking one step further the qualities of editorial independence and exciting journalism that had been introduced to an earlier generation of New Yorkers by Bennett’s *Herald* and Greeley’s *Tribune* (see above).

Whereas Pulitzer was never afraid to unearth public wrongdoing and to crusade against it, the next press baron to influence New York City newspapers, William Randolph Hearst, was prepared to go to much further extremes in creating a headline story. Like Pulitzer, Hearst had learned about newspaper proprietorship in the brash, tough frontier West. His *San Francisco Examiner* (from 1880) had gained a reputation for exposing and cleaning up political corruption. By the time he came to New York City in 1895, however, Hearst was interested in circulation-building sensation at any price, even if it meant dressing up complete fabrications as news. This approach was revealed all too clearly in 1898, when Hearst’s *Morning Journal* was challenging Pulitzer’s *World* in the New York circulation battle. The *Journal* published exaggerated stories and editorials about the political tensions between the United States and Spain that stirred the country to a pitch of hysteria. Eventually, war—over Cuba—was triggered by the sinking of the U.S. battleship *Maine* in Havana harbour, but Hearst nevertheless claimed credit for the war in a banner headline: “How Do You Like the *Journal’s* War?” Hearst is reported to have cabled his illustrator in Cuba, demanding pictures of atrocities for the *Journal*. The illustrator found no atrocities to illustrate and informed Hearst, who replied, “You furnish the pictures and I’ll furnish the war.” Scare headlines and attention-grabbing campaigns were only one of the tactics introduced by Hearst. Equally important in yellow journalism were a strong emphasis on the pictorial—photographs, cartoons, graphic illustrations—and the new Sunday supplements, which focused on human-interest stories and comic strips.

It was inevitable that some newspapers, and especially those that refrained from irresponsible tactics, would suffer circulation losses. One of these was *The New York Times*, which only recovered after its position as the city’s leading serious journal was reestablished after the paper was taken over by the tycoon Adolph S. Ochs in 1896. The paper’s slogans, “All the news that’s fit to print” and “It will not soil the breakfast cloth,” indicated its commitment to serious news reporting.

By 1900 there were half a dozen well-known newspaper barons in the United States. Hearst, whose collections at one time ran to 42 papers, was the most acquisitive of the early owners. Another early chain-builder was Edward Scripps, who began collecting newspapers in 1878. Scripps bought small, financially insecure newspapers and set them on their feet by installing capable young editors, who were given a share of the profits as an incentive to improve circulation. The editors were always urged “to serve that class of people and only that class of people from whom you cannot even hope to derive any other income than the one cent a day that they pay for your newspaper.” Scripps wanted his papers to be of genuine service to the public, and though he succeeded in making money from them his motive was never exclusively profit. But the commercial advantage of owning newspaper chains soon became obvious, as it allowed newsprint to be bought on favourable terms and syndicated articles to be used to the fullest. Scripps’s methods were adopted by his rivals and by newspaper proprietors in other countries as the idea of the chain spread. Inevitably, the profitable newspapers at-

tracted outside investors whose motives were commercial, not journalistic. This new type of proprietor was exemplified by Frank A. Munsey, who bought and merged many newspapers between 1916 and 1924, including the *Sun* and the *Herald* in New York City. In describing Munsey and others like him, the American author and editor William Allen White wrote that he possessed "the talent of a meat packer, the morals of a money changer, and the manners of an undertaker."

Commercial consolidation into larger publishing groups continued immediately after World War I, when the struggle for circulation intensified. First published in 1919, the *New York Daily News* was written to a ruthless recipe of sex and sensationalism by Joseph Medill Patterson, and it sparked off a war with Hearst's *Daily Mirror* and Bernarr Macfadden's *Daily Graphic*, both launched in 1924. The *Graphic* closed in 1932, and the *Daily News* survived to take over the *Mirror* in 1963 before itself becoming a part of the international media empire of the Australian-born Rupert Murdoch. Takeovers often led to title mergers or the complete disappearance of titles. In 1931 the *New York Morning, Evening, and Sunday World* titles were bought by the Scripps-Howard chain; the morning and Sunday editions were dropped, and the *Evening World* was merged with the *New York Evening Telegram*, an action that fitted in well with the popularity of afternoon papers in the United States. Newspapers with extensive circulations could command the attention of the larger advertisers, and this reinforced the disappearance of smaller titles in favour of a few high-circulation papers.

One outcome of the new ownership pattern was the gradual disappearance of the old press baron, who, as editor-proprietor, had tended to combine the roles of professional editor and management executive. Even the editor was to suffer a loss of personal impact as fame was increasingly won by columnists—men and women who were given regular columns to express forceful points of view or divulge society secrets. Among the most important political columnists of the 1920s were David Lawrence of the *United States News*, Frank Kent of the *Baltimore Sun*, Mark Sullivan of the *New York Herald-Tribune*, and Walter Lippmann of the *New York World*. Such writers could gain considerable national followings when their columns or articles were syndicated by major chains.

Great Britain. The British press was slower to emerge as a popular, sensational medium, but a major turning point came in 1855 when the stamp tax was abolished. This was preceded in 1853 by the abolition of the duty on advertisements, and the more liberal climate exposed a remarkable national appetite for newspapers of all kinds. The abolition of taxes and duties, including that on paper in 1861, brought down the prices of newspapers, and this alone was enough to create what were, for the time, very high circulations. By 1861 sales of the *Daily Telegraph* had risen to a daily average of 130,000, double that of *The Times*. Abolition of the tax on paper was said to have brought an additional £12,000 a year to the *Telegraph*. The *Telegraph's* circulation had risen to more than 240,000 copies by 1877, then the highest in the world. The *Telegraph* could not be compared, however, with the more colourful New York papers. It was a worthy newspaper, more than half of it being taken up with reports of proceedings in Parliament, but its readers and those of *The Times* came almost exclusively from the growing mercantile middle class, for whom the two papers provided the writings of many of the best authors of the day at a comfortably affordable price. Journalistic independence was usually upheld, but as the party political hostility between Gladstone and Disraeli grew sharper, each paper became more partisan, a development that in turn stimulated sales.

Later in the century the British press began to adapt to the demand for less exacting reading matter. In 1888 the halfpenny evening *Star* was launched by the Irish nationalist politician T.P. O'Connor. Aiming at a wider public than any previous newspaper, the *Star* incorporated short, lively news items of human interest in a bold, attractive display. The new paper also gave good racing tips, thus endearing it to a group of men who have always con-

tributed substantially to the circulation of what are known as the "populars." Another contemporary evening paper, the *Pall Mall Gazette*, adopted American tactics for some of its crusades. In a series of articles entitled "The Maiden Tribute to Modern Babylon," W.T. Stead exposed the prostitution of young girls in London by himself procuring one. (Indeed as a result he served a term in jail.) This early example of investigative journalism—in which the reporter creates hard news stories by investigating (sometimes clandestinely and by direct experience from inside) illegal or scandalous activities—led to the passing of the Criminal Law Amendment Act in 1885, which improved protection of minors. It also highlighted the power of the press to define what is unacceptable to society.

At the turn of the century, popular journalism came into its own in Britain with the rise of Alfred Harmsworth (later Lord Northcliffe), who can be called the first of the British press barons both for his title and for his enduring influence on the press. During his lifetime he owned, at various times, the *Daily Mail*, *Mirror*, *The Times*, and the *Observer*. As his first effort he launched a cheap weekly magazine in 1888, when he was only 23. Using short sentences, short paragraphs, and short articles, the new style of editing was aimed at attracting a large following among those who had learned to read as a result of the 1870 Education Act making school compulsory for all British children. In 1894 Harmsworth bought the *Evening News*, and by combining his editing style with some of the methods of the American yellow press he quadrupled its circulation within a year. In 1896 came Harmsworth's main innovation, the *Daily Mail*, which within three years was selling more than 500,000 copies a day. This was more than twice the figure reached by any other paper thitherto. The *Daily Mail* went on to sell more than 1,000,000 copies a day during the Boer War (1899–1902).

As "A Penny Paper for One Halfpenny" the *Daily Mail* was sold to the reader at a low price only made possible by the paper's lucrative revenue from advertising. It was the first British paper to be based deliberately on advertising revenue rather than on sales revenue and the first to publish circulation figures audited independently by a chartered accountant. These figures gave advertisers evidence that the *Daily Mail* was reaching the public in sufficient numbers to warrant increasingly expensive advertising space. Another *Mail* slogan, "The Busy Man's Daily Journal," emphasized the snappy editorial style that followed the Harmsworth dictum of "Explain, simplify, clarify." This approach guided the new type of journalists known as subeditors, whose job was to rewrite stories in the "house" style, to compose headlines, and, if necessary, to add a little seasoning to the original story.

Another Harmsworth innovation was the tabloid newspaper, which was to revolutionize the popular press in the 20th century. The term tabloid was coined by Harmsworth when he designed and edited an experimental issue of the *New York World*, produced for New Year's Day, 1900. The tabloid halved the size of the newspaper page, which allowed easier handling by the reader, but it also suited the new, curtailed size of articles and the more numerous pages required per issue. In the long run, however, the term tabloid has come to define the popular newspaper more in style than in physical characteristics. The first successful tabloid was Harmsworth's *Daily Mirror* (1903). Originally launched as a newspaper for "gentlewomen," the *Mirror* had been a failure, but the tabloid format, together with a halfpenny cover price and numerous photographs, made the new picture paper an immediate success, with circulation running at more than 1,000,000 copies by 1914. Lord Northcliffe sold the *Mirror* to his brother Lord Rothermere in 1913. Meanwhile, the equally successful tabloid *Daily Sketch* had been begun in Manchester in 1909 by Sir Edward Hulton.

Like the American press barons, Northcliffe constantly intervened in the production of his newspapers, sending orders under his preferred epithet of "Chief" to the editors not only of the *Mail* and the *Mirror* but also of *The Times* (from 1908) and the *Observer* (from 1905), both of which he owned until his death in 1922. This was never more apparent than during World War I, when the British

The first
British
press baron

The
tabloids

Official Press Bureau was set up to control the amount of war information available to the public through the newspapers. Though accepting that a certain degree of censorship was necessary to conceal military intelligence from the enemy, Northcliffe nevertheless boldly defied the bureau over its cover-up of an ammunition shortage. Such defiance confirmed the independence of the press from government, but the influence of proprietors was itself to become an important issue in press freedom. This was typified after World War I by the intensive campaign for Empire Free Trade in Lord Beaverbrook's *Daily Express*. The preservation of the British Empire was the guiding passion of Max Aitken, who was raised to the peerage as Lord Beaverbrook in 1917. A Canadian-born journalist who took the *Express* into second place in national circulation behind the *Daily Mirror*, Beaverbrook continued to thrust his viewpoint on the editors of his papers for many years, although his campaigns for free trade within the empire and, after World War II, commonwealth trade preference were unsuccessful. Through the *Daily Express*, the *Sunday Express* (started in 1918), and the London *Evening Standard* (acquired 1923), Beaverbrook's opposition to Britain's attempts to join the European Community was given a regular airing. Beaverbrook admitted to the first Royal Commission on the Press that if an editor took a divergent view on, for example, the empire, he would be "talked out of it." So talented was Beaverbrook as a publisher and journalist that the *Express* newspapers gained and kept many readers for life, even though it is doubtful whether the issues of empire and Common Market membership were of passionate concern to them.

The circulation "war of the tabs" that struck New York City in the 1920s was copied in Britain in the 1930s, bringing with it numerous circulation-boosting stunts. Prizes for readers had been introduced as early as the 1890s, when Harmsworth offered a pound a week for life for the reader who could guess the value of gold in the Bank of England on a given day. In the 1920s one paper offered free insurance to subscribers, but this soon proved too costly to maintain. In 1930 the *Daily Herald* offered gifts to woo new readers. Although they were condemned by the Newspaper Proprietors' Association (now known as the Newspaper Publishers Association), gift schemes proliferated among other newspapers, with the *Herald* eventually achieving a circulation of 2,000,000, the highest in the world. Many of the new readers were stolen from other papers—the *Daily Mirror* saw its figure drop from more than 1,000,000 to 700,000 by 1934—but newspapers in general acquired 1,500,000 new readers, so that by the end of the decade there was a national newspaper aimed at every socioeconomic class. The *Daily Mirror* was revived by its editor, Harry Bartholomew, to become a true working-class paper with a radical political voice, although the winning of new readers—circulation eventually topped 4,000,000—was mostly due to the shameless use of the techniques of yellow journalism.

THE MODERN ERA

Since World War II, there have been radical changes in newspaper production on a par with those brought by the Industrial Revolution. Electronic technology has revolutionized the ways in which newspapers are written, edited, and printed, while radio and television have developed into serious competitors as sources of news, official information, and entertainment and as a vehicle for advertising.

Technological developments. Computers and telecommunications have transformed the production process for the modern newspaper. They have also led to changes in the quality of the newspaper itself, but their real impact has been on the finances of the newspaper industry and on the relevance of the traditional print workers. One of the first signs of technology's potential for change came in the 1930s, when Walter Morey developed the Teletypesetter (first demonstrated in 1928). This machine was an improvement on the telegraph, which was widely used by reporters in the field and by the wire services, such as Reuters and Associated Press, to send news items in draft form to editorial offices miles away. With the Teletypesetter, the impulses sent over the wire included encoded

instructions to Linotype machines. The machines could then decode the instructions and automatically prepare whole pages ready for printing. It was therefore envisaged that the reporter would have the facility for "direct input" into the printing room, which would eliminate the need for retyping by a Linotype operator and thus save newspapers both time and money.

But direct input had to await the development of sophisticated computers and computer programs, which did not materialize until after World War II. In 1946 the first techniques of photocomposition were developed. With this method of typesetting, the images of pages are prepared for the printer photographically, as on a photocopier, instead of in lines of metal type. The new method was introduced gradually in newspapers, where the Linotype machines had worked well enough for more than half a century and where union opposition to the new technology was deeply entrenched. Technological advances were accelerated in the 1970s, introducing computers and computer programs that were tailor-made for the newspaper publisher, and many newspaper companies replaced their 19th-century printing systems with the new technology almost overnight.

In a modern newspaper office each journalist has a desktop terminal—i.e., a keyboard and a visual display screen connected to the main computer. The visual display shows the current article or, in the case of a copy editor, the whole of the page being composed from various articles and pictures. While writing, the reporter can retrieve information stored in the computer, such as any previous articles on the same subject, which can be displayed on the screen alongside the new copy. This split-screen technology also allows the copy editor to move copy around the screen on special page-layout terminals until the copy fits the page. Once it is ready, a push of a button sends the complete page to the main computer for eventual transformation into an aluminum printing plate.

By this direct-input process the production of a page of news is accelerated. But the new technology can serve other production purposes. On some papers it is possible for an advertiser to send copy via the telephone to the newspaper office, where the computer automatically finds a suitable space for it and transmits it to the copy editor's screen. The reporter in the field, equipped with a portable terminal, can also input a story to the newspaper's computer directly and can gain access to the computer's library of information in the same way. If necessary, the editor can discuss the article with the reporter over the telephone as they both look at it on their screens. Similarly, items from press agencies can be located instantly; these may be transmitted to the computer terminal via cables or over the air by satellite, enabling news to reach the other side of the world within minutes. The electronic transmission of whole pages of news between remote locations also means that the printing plant does not have to be situated near the editorial offices. This can decrease real estate or rental costs, and it allows simultaneous editions of the same newspaper to be printed in different cities and even on different continents, an advantage that has been exploited by the British-based *Financial Times* and U.S.-based *Wall Street Journal*.

Financial developments. The introduction of new technology brought forth strong resistance from the unions of printing workers, which were traditionally among the most powerful labour unions. At first the operators of the obsolete Linotype machines were "brought upstairs" from the hot-metal shop to the newspaper offices, where they were retrained to compose copy on computer keyboards. But eventually even this function was no longer necessary as computers became more sophisticated, featuring word processing for journalists, graphics programs for illustrators, and editing programs designed specifically for newspaper editors. As the computer has taken over more and more of the basic functions of newspaper production, the proprietor has been able to cut down on highly skilled workers and take on a less qualified and lower-paid staff to do necessary jobs such as typing.

Even before the introduction of the Linotype machine, however, the manual craft unions had been jealous

Photo-
composition

New tech-
nology and
the unions

guardians of their trade as hand compositors. The compositors, together with the other craftsmen involved in printing, were well paid for their skills and for the night shifts they were obliged to work on morning papers. Overstaffing became common in newspaper printing departments when the unions laid down strict rules on the demarcation of labour (jobs that would be done only by particular employees), and working hours and conditions were precisely defined. The strike was used as a powerful weapon against the newspaper proprietor, since the loss of even one day's circulation might drive the reader to another paper. It was also feared that the regular reader might find that he did not miss his newspaper enough to start buying it again after the strike, especially when radio and television made news so readily available.

In the 1960s rising costs forced many newspapers to cease publication. The company owning the newspaper was often a conglomerate with various industrial interests. When this was the case, it was often not committed to maintaining an unprofitable title, regardless of the newspapers' history and tradition or its number of loyal readers. High circulation levels meant nothing if the paper did not attract advertising revenue and if inflated production costs prevented it from making any sort of profit. However, some well-known newspapers have been supported financially from the profits made by other parts of the conglomerate. Owning a venerable title can be a mark of prestige for a business enterprise, and there are still business tycoons who hope to emulate the press barons of earlier years—especially so in Britain, where a high percentage of newspaper proprietors have been raised to the peerage. It is not unusual, however, for prestigious papers to change ownership fairly frequently.

In Britain, for example, *The Times* was bought by a Canadian conglomerate, The Thomson Organisation, in 1966. Following a self-imposed closedown lasting nearly a year in 1979, Thomson sold *The Times* to News International, an Australian-based media company run by Rupert Murdoch, a businessman from a newspaper-owning family and who had a reputation for toughness. In a major attempt to break the power of the print unions, Murdoch moved *The Times* away from its headquarters near Fleet Street to new premises at Wapping in the London docklands, where he started to produce and print it using new technology. Another British newspaper proprietor, Eddie Shah, had already challenged the print unions in the provinces, and in 1986 he began *Today*, the first national British paper produced entirely on the new technology and without co-operation from the traditional print unions. *Today* used a production system similar to those of certain American papers and magazines. One of these, *USA Today*, was a success from its beginning in the early 1980s.

Newspaper
popularity

Despite earlier fears of possible damage from competition by radio and, later, television, many newspapers have proved to be still attractive to consumers and hence profitable. Newspapers have, for instance, retained their importance as vehicles for advertising. The total amount of money that advertisers are willing to spend has continued to grow, which means that television has not greatly impinged on the value of the space offered by newspapers. In many countries radio and television are limited in the amount of advertising they may carry, which leaves a gap to be filled by newspapers and magazines. The press also offers classified space for the small advertiser, while regional and local papers are essential for small business wishing to advertise, especially in job recruitment, real estate, and automobile sales. One of the main developments of the 1970s and '80s has been the spread of free newspapers, or freesheets, which are delivered door-to-door or are distributed in public places. The free newspapers are usually printed by small newspaper enterprises using computerized technology and are entirely financed by advertising revenue. They pose a more serious threat to the existence of newspapers—particularly local ones—than do either radio or television. Because colour pictures are often essential to advertisers, many newspapers have come to offer occasional colour pages or, more commonly, to include colour magazines—Sunday supplements; by 1985 every British national Sunday newspaper included a free

colour magazine. The costs of producing such a magazine are clearly worth the advertising revenue they generate.

Besides retaining their share of advertising, newspapers have had to compete for the attention of the consumer who can get the main points of the news from radio or television. Newspapers have done well to survive amid the proliferation of portable radios and radios in automobiles and of cable and satellite-broadcast television channels. The modern reader, in fact, is more likely to buy a newspaper to consult a special section than to read it from cover to cover. Readers may be attracted by the paper's sports reporting, racing tips, horoscopes, job advertisements, gossip columns, or, ironically, the daily listings of radio and television programming.

Another social change that has proved advantageous for newspapers is the increase in leisure time in developed countries. Shorter workweeks and longer vacations offer two opportunities for newspapers to exploit. First, there is simply more time to spend reading, encouraging sales to the individual of more than one newspaper or of a larger newspaper. Second, and of more importance for newspapers from the economic point of view, has been the growth of a diversity of leisure activities such as home improvement, gardening, and food and wine. Newspapers devote special features to these activities, particularly in their weekend editions. Foreign travel has also become more common, creating a demand for informative articles on popular tourist destinations. Even the sports pages, an essential part of the modern newspaper, have been affected by the changing leisure patterns—there has been an increase in the number of sports of general interest, allowing the expansion of the sports section to cover less popular sports. The economic advantage of covering more leisure activities and interests comes from the ability of newspapers to attract advertising revenue from commercial suppliers of leisure goods and services. The addition of new leisure pages does not normally lead to any reduction of editorial space, including the usual news and features, and so there is a tendency for newspapers to add more pages. Technological advances are allowing these larger newspapers to be printed. In expanding their coverage to include modern leisure interests, newspapers can be seen to continue to reflect the society of which they are a part.

Coverage
of leisure
activities

The role of the press. In the years leading up to World War II, newspapers had reflected the socially gloomy atmosphere engendered by economic and political restrictions. In Britain, *The Times* supported government policy, and only the *Daily Mirror* was prepared to investigate in depth European political, diplomatic, and economic events. The continental press reflected all too faithfully the unhappy state of affairs. In Germany, Italy, Spain, and Portugal the press was subject to the rigid censorship associated with Fascism, while in the Soviet Union a different political system induced the same controls. During the war, there was an expected clampdown on news coverage, although in the United States and Britain a greater flow of information was allowed than had been the case during World War I. The British Ministry of Information and the U.S. Office of War Information issued vast amounts of official news and propaganda. In the United States, the Office of Censorship defined a "Code of Wartime Practices for the American Press," while in Britain, newspapers voluntarily submitted any doubtful material for censorship, and an air of cooperative self-censorship thus prevailed. As in any modern war, journalist heroes were created, the standards of photography reached great heights, and the horror and tragedy of the war frequently inspired excellence in writing and editing.

In the developing countries of the Third World, newspapers have a vital role to play in disseminating a balanced picture of national affairs and in contributing to the growth of literacy. Repression of independent opinion is common in such countries, however. The freedom of the press is by no means universal even in the industrialized West.

Apart from constraints to do with defamation and national security, news blackouts or restrictions on information have occurred during military crises. Of even more concern is the growing number of threats made to journalists reporting from areas of political or military tension,

where at one time the press card gave the right to independent reporting. For more than half the world's population an independent press is still an unattainable goal. The Communist view in the Soviet bloc and the People's Republic of China is that Western press freedom is illusory, because a wealthy minority controls what is to be printed, whereas access to the press is truly free in Communist countries. Distortion of the truth can be said to arise wherever newspaper ownership approaches monopoly or even, as in some Western countries, it is controlled by a small number of organizations. New technology does offer escape from this impasse, because it makes possible the commercial production of far more newspapers. Many of these new titles could publicize the views of minorities who at present often go unheard.

Above all, the serious newspaper has moved toward providing in-depth detail, analysis, and opinion on many current events. The quality of newspaper coverage of business affairs, the arts, and social issues is increasingly important as publishers deal with more sophisticated readers. The newspaper can still be a forum for thoughtful debate, a medium for creative expression, and a safeguard of the written language. (P.U./G.U./D.H.T.)

Magazine publishing

BEGINNINGS IN THE 17TH CENTURY

Though there may have been published material similar to a magazine in antiquity, especially perhaps in China, the magazine as it is now known began only after the invention of printing in the West. It had its roots in the spate of pamphlets, broadsides, ballads, chapbooks, and almanacs that printing made possible. Much of the energy that went into these gradually became channeled into publications that appeared regularly and collected a variety of material designed to appeal to particular interests. The magazine thus came to occupy the large middle ground, incapable of sharp definition, between the book and the newspaper.

The earliest magazine appears to have been the German *Erbauliche Monats-Unterredungen* (1663–68; "Edifying Monthly Discussions"), started by Johann Rist, a theologian and poet of Hamburg. Soon after, there appeared a group of learned periodicals; the *Journal des Sçavans* (later *Journal des Savants*; 1665), started in France by the author Denis de Sallo; the *Philosophical Transactions* (1665), of the Royal Society in England; and the *Giornale de' letterati* (1668) published in Italy, issued by the scholar and ecclesiastic Francesco Nazzari. A similar journal was started in Germany a little later, the *Acta eruditorum Lipsiensium* (Leipzig; 1682); and mention may also be made of the exile-French *Nouvelles de la République des Lettres* (1684), published by the philosopher Pierre Bayle mainly in Holland to escape censorship. These sprang from the revival of learning, the need to review its fruits, and the wish to diffuse its spirit as widely as possible.

The learned journals summarized important new books, but there were as yet no literary reviews. Book advertisements, by about 1650 a regular feature of the newsheets, sometimes had brief comments added, and regular catalogs began to appear, such as the English quarterly *Mercurius librarius, or A Catalogue of Books* (1668–70). But in the 17th century the only periodicals devoted to books were short-lived: the *Weekly Memorials for the Ingenious* (1682–83), which offered some critical notes on books, and the *Universal Historical Bibliothèque* (January–March 1686). The latter invited scholarly contributions and could thus be regarded as the true forerunner of the literary review.

The lighter type of magazine, or "periodical of amusement," may be dated from 1672, which saw the first appearance of *Le Mercure Galant* (renamed *Mercure de France* in 1714). It was founded by the writer Jean Donneau de Vizé and contained court news, anecdotes, and short pieces of verse—a recipe that was to prove endlessly popular and become widely imitated. This was followed in 1688 by a German periodical with an unwieldy title but one that well expressed the intention behind many a subsequent magazine: "Entertaining and Serious, Rational and Unsophisticated Ideas on All Kinds of Agreeable

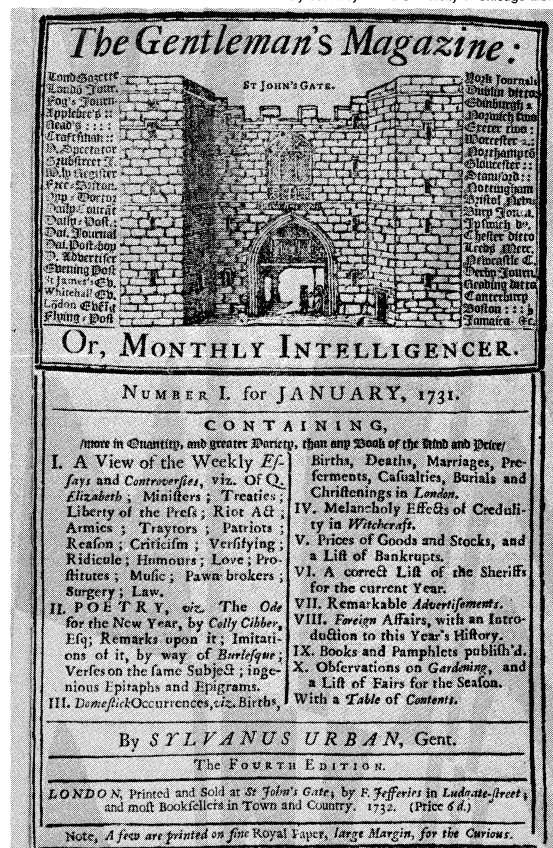

and Useful Books and Subjects." It was issued in Leipzig by the jurist Christian Thomasius, who made a point of encouraging women readers. England was next in the field, with a penny weekly, the *Athenian Gazette* (better known later as the *Athenian Mercury*; 1690–97), run by a London publisher, John Dunton, to resolve "all the most Nice and Curious Questions." Soon after came the *Gentleman's Journal* (1692–94), started by the French-born Peter Anthony Motteux, with a monthly blend of news, prose, and poetry; and in 1693, after devoting some experimental numbers of the *Athenian Mercury* to "the Fair Sex," Dunton brought out the first magazine specifically for women, the *Ladies' Mercury*. Finally, another note, taken up time and again later, was struck by *The London Spy* (1698–1700), issued by a tavern keeper, Ned Ward, and containing a running narrative of the sights and sounds of London.

DEVELOPMENTS IN THE 18TH CENTURY

Great Britain. With increasing literacy, especially among women, and a quickening interest in new ideas, the magazine filled out and became better established. In Britain, three early "essay periodicals" had enormous influence: Daniel Defoe's *The Review* (1704–13; thrice weekly), Sir Richard Steele's *The Tatler* (1709–11; thrice weekly), to which Joseph Addison soon contributed, and Addison and Steele's *The Spectator* (1711–12, briefly revived in 1714; daily). Though they resembled newspapers in the frequency of their appearance, they were more like magazines in content. *The Review* introduced the opinion-forming political article on domestic and foreign affairs; while the cultivated essays of *The Tatler* and *The Spectator*, designed "to enliven morality with wit, and to temper wit with morality," did much to shape the manners and taste of the age. The latter had countless imitators, not only in Britain, where there were in addition the *Female Tatler* (1709–10) and the *Female Spectator* (1744–46), but also on the Continent and later in America. The Stamp Tax of 1712 had a damping effect, as intended, but mag-

azines proved endlessly resilient, easy to start and easy to fail, then as now.

So far various themes had been tried out; they were first brought together convincingly by the English printer Edward Cave, who began to publish *The Gentleman's Magazine* in 1731. It was originally a monthly collection of essays and articles culled from elsewhere, hence the term magazine—the first use of the word in this context. Cave was joined in 1738 by Dr. Johnson, who was later to publish his own *Rambler* (1750–52); thereafter *The Gentleman's Magazine* contained mostly original matter, including parliamentary reports. Rivals and imitators quickly followed, notably the *London Magazine* (1732–85) and the *Scots Magazine* (1739–1817; to 1826 published as the *Edinburgh Magazine*); and, among the increasing number of women's periodicals, there were a *Ladies' Magazine* (1749–53) and a *Lady's Magazine* (1770–1832). Their progenitor, however, outlived them all and perished only in 1907.

The literary and political rivalries of the day produced numerous short-lived periodicals, from which the critical review emerged as an established form. Robert Dodsley, a London publisher, started the *Museum* (1746–47), devoted mainly to books, and Ralph Griffiths, a Nonconformist bookseller, founded *The Monthly Review* (1749–1845), which had the novelist and poet Oliver Goldsmith as a contributor. To oppose the latter on behalf of the Tories and the Church of England, *The Critical Review* (1756–1817) was started by an Edinburgh printer, Archibald Hamilton, with the novelist Tobias Smollett as its first editor. Book reviews tended to be long and fulsome, with copious quotations; a more astringent note came in only with the founding of the *Edinburgh Review* in 1802 (see below).

Continental Europe. On the Continent development was similar but was hampered by censorship. French magazines containing new ideas had to appear in exile, such as the philosopher Pierre Bayle's *Nouvelles de la République des Lettres*, which was published largely in Holland; some 30 titles were published in Holland up to the time of the French Revolution. Within France, there were the short-lived *Spectateur Français* (1722–23) and *Spectateur Suisse* (1723); and *Le Pour et le Contre* (1733–40; "For and Against"), issued by the Abbé Prévost (author of *Manon Lescaut*). Of more literary interest were the *Gazette Littéraire de l'Europe* (1764–84) and *La Décade Philosophique, Littéraire et Politique* (1794–1804).

In Leipzig the poet and philosopher Johann Christoph Gottsched issued a periodical for women, *Die vernünftigen Tadelrinnen* (1725–26; "The Rational Woman-Critics"), and the first German literary review, *Beiträge zur kritischen Historie der deutschen Sprache* (1732–44; "Contributions to the History of the German Language"). German literary movements were connected with the production of new magazines to a greater extent than in Britain. Examples of such vehicles include Friedrich von Schiller's *Horen* (1795–97) and Johann Wolfgang von Goethe's *Propyläen* (1798–1800), the influence of which was often greater than their duration. Of more general and lasting influence was the *Allgemeine Literatur-zeitung* (1785–1849), founded by Friedrich Justin Bertuch, "the father of the German periodical."

The first Russian periodical, published by the Academy of Sciences, was a learned journal called "Monthly Works" (1755–64). The first privately published Russian magazine, a critical periodical with essays and translations from the British *Spectator*, was called "Industrious Bee" and began in 1759. Catherine II used her *Vsiakaia Vsiachina* (1769–70), also modeled on the *Spectator*, to attack opponents, among them Nikolay Novikov, whose "Drone" (1769–70) and "Windbag" (1770) were suspended and whose "Painter" (1770–72) escaped only by being dedicated to the Empress.

America. In America the first magazines were published in 1741. In that year appeared Andrew Bradford's *American Magazine*, the first publication of its kind in the colonies. It was joined, a mere three days later, by Benjamin Franklin's *General Magazine*. Both magazines appeared in Philadelphia; neither lasted very long, how-

ever—Bradford's magazine survived only three months and Franklin's six. Franklin was more widely known for another of his publications, *Poor Richard's Almanack* (1732–57), which contained maxims and proverbs. Before the end of the 18th century, some 100 magazines had appeared, offering miscellaneous entertainment, uplift, or information, mostly on a very shaky, local, and brief basis. Among the more important were, in Philadelphia, the *Pennsylvania Magazine* (1775–76), edited by Thomas Paine, and the *American Museum* (1787–92) of the bookseller Mathew Carey; the *Massachusetts Magazine* (1789–96), published in Boston; and the *New-York (City) Magazine* (1790–97).

THE 19TH CENTURY AND THE START OF MASS CIRCULATION

General periodicals. Most of the early periodicals were designed for the few who could afford them and can be fairly called "quality" magazines. In the 1830s, however, less expensive magazines, aimed at a wider public, began to appear. At first these magazines emphasized features that promoted improvement, enlightenment, and family entertainment, but, toward the end of the century, they evolved into popular versions that aimed at providing amusement.

The pioneers of the new type of magazine in Britain were Charles Knight, publisher for the Society for the Diffusion of Useful Knowledge, with his weekly *Penny Magazine* (1832–46) and *Penny Cyclopaedia* (1833–58); the Chambers brothers, William and Robert, with *Chambers's (Edinburgh) Journal* (1832–1956), which reached a circulation of 90,000 in 1845; and teetotaler John Cassell, with his *Working Man's Friend and Family Instructor* (1850–53) and the *Quiver* (1861). Besides popular magazines, many standard works appeared serially, often with illustrations. Typical of family entertainment were Charles Dickens' *Household Words* (1850), followed in 1859 by *All the Year Round*; several similar periodicals such as *Good Words* (1860); and, for young people, the *Boy's Own Paper* (1879) and the *Girl's Own Paper* (1880). Germany had its *Pfennigmagazin* (1833), edited by Johann Jakob Weber, and a family magazine modeled on that of Dickens. One example was the *Gartenlaube* (1853–1937; "Arbour"), which enjoyed great popular influence and a circulation of 400,000 in the 1870s. There were no national magazines in the United States before about 1850, but two of its best-known early periodicals were the *Saturday Evening Post* (1821–1969; revived 1971) and *Youth's Companion* (1827–1929). The latter, published in Boston, was typically wholesome in content, intended to "warn against the ways of transgression" and to encourage "virtue and piety."

By the last quarter of the century, largely as a result of compulsory education, the potential market for magazines had greatly increased, and the public was avid for miscellaneous information and light entertainment. The first man in Britain to discover this was George Newnes, who liked snipping out any paragraph that appealed to him. In 1881 he turned his hobby to advantage by publishing a penny magazine, *Tit-Bits from all the Most Interesting Books, Periodicals and Contributors in the World*, soon shortened to *Tit-Bits* (in 1968 restyled *Titbits*). It was a great success and formed the beginning of a publishing empire that was to include *Country Life* (founded 1897), *Wide World Magazine* (1898), and, above all, *The Strand Magazine* (1891–1950), one of the first monthly magazines of light literature with plenty of illustrations. *The Strand* became enormously popular and is perhaps most famous for its Sherlock Holmes stories by Arthur Conan Doyle. Among the early contributors to *Tit-Bits* was Alfred Harmsworth (later Lord Northcliffe), who had an appetite for odd bits of information similar to that of Newnes. In 1888, after editing *Youth* and *Bicycling News*, Harmsworth launched a rival to *Tit-Bits* called *Answers to Correspondents*, or *Answers*, which he successfully promoted by contests. Within five years he produced a string of inexpensive magazines for the same popular market, including *Comic Cuts* and *Home Chat*. A similar empire was built up by Arthur Pearson, another former *Tit-Bits* employee, with *Pearson's Weekly* and *Home Notes*, among others.

Family
magazines

Early popular monthly magazines in the United States

In the United States, magazine publishing boomed as part of the general expansion after the Civil War. It was also helped by favourable postal rates for periodicals (1879). But a gulf remained between expensive magazines aimed at the genteel, such as *Harper's* and *Scribner's* (see below *Literary and scientific magazines*), and cheaper weeklies and miscellanies. The first person to produce a popular monthly to fill this gap and thus spark off a revolution in the industry was Samuel Sidney McClure, who began publishing *McClure's Magazine* in 1893, which he sold for 15 cents an issue instead of the usual 25 or 35 cents. John Brisben Walker, who was building up *Cosmopolitan* (founded 1886) after acquiring it in 1889, cut his price to 12½ cents, and in October 1893 Frank A. Munsey reduced the price of *Munsey's Magazine* (1889–1929) to 10 cents. All three saw that, by keeping down the price and gearing contents to the interests and problems of the average reader, high circulations were attainable. Munsey estimated that, between 1893 and 1899, “the ten-cent magazine increased the magazine-buying public from 250,000 to 750,000 persons.” This increase in circulation in turn led to high advertising revenue, making it possible to sell a magazine, like a newspaper, for less than its cost of production, a practice that was to become common in the next century. Technical development was also important; mass-production methods and the use of photoengraving processes for illustration enabled attractive magazines to be produced at ever lower unit costs.

The first magazine published in Australia was the *Australian Magazine*, which began in 1821 and lasted for 13 monthly issues. The *South Asian Register* began as a quarterly in 1827 but only four issues appeared. The *Hobart Town Magazine* (1833–34) survived a bit longer and contained stories, poems, and essays by Australian writers. The *Sydney Literary News* (1837) was the first to contain serial fiction and advertisements. Illustrations were introduced in the 1840s; the *Australian Gold Digger's Monthly Magazine* and *Colonial Family Visitor* (1852–53) was followed by the *Melbourne Punch* (1855–1925; incorporated in *Table Talk*, 1885–1937).

In India the first magazines were published by the British. The earliest to appear was the *Oriental Magazine; or, Calcutta Amusement* (1785–86); it was followed by a number of short-lived missionary publications. The first periodical founded and edited by an Indian was the *Hindustan Review*, which commenced in 1900.

Magazines in China

Missionaries founded the first periodical in China; printed in Malacca, the *Chinese Monthly Magazine* lasted from 1815 to 1822. It was followed by the *East-West Monthly Magazine*, printed in Canton from 1833 to 1837 and in Singapore from 1837 until its end in 1847.

Illustrated magazines. The first man in Britain to notice the effect of illustrations on sales and grasp their possibilities was a newsagent in Nottingham, Herbert Ingram, who moved to London in 1842 and began publishing *The Illustrated London News*, a weekly consisting of 16 pages of letterpress and 32 woodcuts. It was successful from the start, winning the approval of the Archbishop of Canterbury and hence that of the clerical public. Though it suffered at first from the defect that its pictures were by well-known artists but were not taken from life, it later sent artists all over the world. Drawings made on the spot during the South African War, sometimes at considerable risk, were a great popular feature. Among its competitors was the monthly *English Illustrated Magazine* (1883–1913).

News in pictures

The idea of presenting the news largely in pictures was quickly taken up in France by *L'Illustration* (1843–1944) and in Germany by the *Leipziger illustrierte Zeitung* (1843) and *Die Woche* (1899–1940).

In the United States, the main early illustrated magazines were *Leslie's Weekly* (1855–1922) and *Harper's Weekly* (1857). Soon after its founding, *Leslie's* had a circulation of 100,000, which doubled or trebled whenever there was something sensational to portray. During the Civil War, of which it gave a good pictorial record, it had as many as 12 correspondents at the front.

The invention of photography and the development of the halftone block began to transform this type of mag-

azine from the 1890s, with the artist increasingly being displaced by the camera.

Women's magazines. Women's magazines frequently reflect the changing view of women's role in society. In the 18th century, when women were expected to participate in social and political life, those magazines aimed primarily at women were relatively robust and stimulating in content; in the 19th, when domesticity became the ideal, they were inclined to be insipid and humourless. After about 1880, magazines began to widen their horizons again.

Typical of the late Georgian and Regency magazines in Britain were *The Lady's Magazine* (1770), a sixpenny monthly that, along with its literary contributions and fashion notes, gave away embroidery patterns and sheet music; *The Lady's Monthly Museum* (1798), which had a half-yearly “Cabinet of Fashion” illustrated by coloured engravings, the first to appear in a women's periodical; and *La Belle Assemblée* (1806), which encouraged its readers to unburden themselves in its correspondence columns. These three merged in 1832, the first instance of what was to become a common occurrence, but ceased publication in 1847. Later women's magazines included *The Ladies' Pocket Magazine* (1824–40), *The Ladies' Cabinet* (1832–52), *The New Monthly Belle Assemblée* (1847–70), and *The Ladies' Treasury* (1857–95). All contained verse, fiction, and articles of high moral tone but low intellectual content. There were attempts to swim against the tide, such as *The Female's Friend* (1846), which was one of the first periodicals to espouse women's rights, but they seldom lasted long.

In 1852 a wider market began to be tapped by *The Englishwoman's Domestic Magazine*, a monthly issued by Samuel Beeton at twopence instead of the usual one shilling; it was also the first women's periodical to concentrate on home management and offer practical advice to women rather than provide entertainment for the idle. Beeton's wife (author of the classic *Book of Household Management*, 1861) visited Paris regularly and acquired fashion plates from Adolphe Goubaud's *Moniteur de la Mode*. A feature of Beeton's magazine was the “Practical Dress Instructor,” a forerunner of the paper dressmaking pattern. In 1861, Beeton followed up his success with *The Queen*, a weekly newspaper of more topical character.

The great expansion of women's magazines into a major industry may be dated in Britain from *Myra's Journal of Dress and Fashion* (1875–1912) and *Weldon's Ladies' Journal* (1875–1954), both of which supplied dressmaking patterns and met the needs of a mass readership. Several new quality magazines were started, such as *The Lady* (founded 1885) and *The Gentlewoman* (1890–1926), one of the first to acknowledge the financial necessity of advertisements, but there were many more cheap weeklies, such as *Home Notes* (1894–1957), *Home Chat* (1895–1958), and *Home Companion* (1897–1956); these were of great help in teaching women about hygiene, nutrition, and child care.

Among the earliest women's magazines in the United States was a monthly published in Philadelphia called *Godey's Lady's Book* (1830–98), which employed up to 150 women to hand-tint its fashion plates. Of the early national magazines, one of the best and hardiest was *Harper's Bazar* (1867; *Harper's Bazaar* after 1929), modeled on a Berlin women's periodical, *Der Bazar*, from which it obtained its fashion material. The practical trend was begun in 1863 by Ebenezer Butterick, who devised the tissue-paper clothing pattern and, to popularize it, brought out the *Ladies' Quarterly Review of Broadway Fashions* and, later, *Metropolitan*. These merged in 1873 into the *Delineator*, which had a highly successful career until 1937. The field of women's magazines was finally transformed, however, by Cyrus Curtis with his *Ladies' Home Journal* (founded 1883), edited by his wife, Louisa Knapp Curtis. This soon reached a circulation of 400,000 and, under the editorship of Edward W. Bok, from 1889, broke with sentimentality and piety to become a stimulating journal of real service to women. Other popular magazines were *Ladies' Home Companion* (1886; called *Woman's Home Companion*, 1897–1957), *McCall's Magazine* (founded 1897), and *Pictorial Review* (1899–1939).

Two requiring special mention were *Good Housekeeping* (founded 1885), which established a testing station for consumer goods early in the 20th century, and *Vogue* (founded 1892), a fashion weekly (later a monthly) dedicated to "the ceremonial side of life," which was designed for the elite of New York City and had Cornelius Vanderbilt among its backers.

Literary and scientific magazines. The critical review developed strongly in the 19th century, often as an adjunct to a book-publishing business. It became a forum for the questions of the day—political, literary, and artistic—to which many great figures contributed. There were also many magazines with a literary flavour, and these serialized some of the best fiction of the period. A few marked the beginning of specialization—e.g., in science.

Britain was particularly rich in reviews, beginning with the *Edinburgh Review* (1802–1929), founded by a trio of gifted young critics: Francis Jeffrey, Henry Brougham, and Sydney Smith. The high and independent tone they adopted was said by Samuel Taylor Coleridge to mark an "epoch in periodical criticism." Though Tories, including at first Sir Walter Scott, wrote for it, the *Edinburgh Review* gradually became increasingly Whig in attitude. Scott accordingly transferred his allegiance to the *Quarterly Review* (1809–1967), the *Edinburgh Review's* Tory rival, founded by the London publisher John Murray and first edited by William Gifford. Gifford had previously edited *The Anti-Jacobin* (1797–98), with which such figures as the Tory statesman George Canning were associated. In opposition to these, and more political than any of them, was the *Westminster Review* (1824–1914), started by Jeremy Bentham and James Mill as an organ of the philosophical radicals. Two other early reviews were the *Athenaeum* (1828–1921), an independent literary weekly, and the *Spectator* (founded 1828), a nonpartisan but conservative-leaning political weekly that nonetheless supported parliamentary reform and the cause of the North in the American Civil War. Later reviews included the *Saturday Review* (1855–1938), which had George Bernard Shaw and Max Beerbohm as drama critics (1895–1910); the *Fortnightly Review* (1865–1954), which had the Liberal statesman John Morley as editor (1867–83); the *Contemporary Review* (founded 1866); the *Nineteenth Century* (1877; later the *Twentieth Century*, until it closed in 1974); and W.T. Stead's *Review of Reviews* (1890–1936), a more limited version of *Reader's Digest*.

Of the closely related literary magazines, one of the earliest and best was *Blackwood's Edinburgh Magazine* (1817–1981), founded by a book publisher, William Blackwood, as a rival to the *Edinburgh Review*, but a less ponderous one than the *Quarterly*. It provoked in turn the founding of the *London Magazine* (1820–29), in which Charles Lamb's *Essays* first appeared. The rivalry between these two publications led to a duel in which John Scott, the first editor of the *London Magazine*, was mortally wounded. Other literary periodicals included the *Examiner* (1808–80), edited by the radical essayist Leigh Hunt, who introduced the poetry of Shelley and Keats to the public through its columns; the *New Monthly Magazine* (1814–84); *Bentley's Miscellany* (1837), which had Dickens as its first editor and *Oliver Twist* as one of its serials; and the *Cornhill* (1860–1975), first edited by William Thackeray and the first magazine of its kind to reach a circulation of 100,000. Finally, two rather different periodicals must be mentioned: *Nature* (founded 1869), which began to make scientific ideas more widely known and to which Charles Darwin and Thomas Huxley contributed; and *Punch* (founded 1841), which provided a weekly humorous comment on British life illustrated by many distinguished draftsmen.

Continental European reviews tended to be more literary than political, perhaps because of the persistence of censorship. The most notable in France were the *Revue des Deux Mondes* (founded 1829; later *La Nouvelle Revue des Deux Mondes*), with such contributors as Victor Hugo and the critic Charles-Augustin Sainte-Beuve, and its rival the (*Nouvelle*) *Revue de Paris* (founded 1829), which published authors disapproved of by the other, notably Gustave Flaubert. In Germany, F.A. Brockhaus, the

book publisher, tried to emulate the *Edinburgh Review* with *Hermes* (1819–31) but had more success with *Literarisches Wochenblatt* (1820–98). Two later reviews were the conservative *Deutsche Rundschau* (founded 1874) and the liberal *Freie Bühne* (1890). Two influential Italian reviews were the *Nuova Antologia* (founded 1866) and *La Cultura* (1881–1935).

The early literary magazines in the United States included, among many others often of more local interest, the *Philadelphia Literary Magazine* (1803–08); the *Monthly Anthology* (Boston, 1803–11), which became the quarterly *North American Review* (1815–1940), with a host of famous contributors; the *New York Monthly Magazine* (1824); *Dial* (1840–44), the organ of the New England essayist Ralph Waldo Emerson's Transcendental Club (there was a second, literary *Dial*, 1880–1929); and *De Bow's Review* (New Orleans, 1846–80). The cultured weekly *Home Journal* (1846–1901; then continuing as *Town and Country*) introduced Swinburne and Balzac to Americans, while *Harper's New Monthly Magazine* (New York City, 1850; later called *Harper's Magazine*), founded by the book-publishing Harper brothers, serialized many of the great British novels and became one of America's finest quality magazines. It was rivaled only by the *Atlantic* (Boston, 1857; later called *Atlantic Monthly*), which had a long line of distinguished editors, beginning with James Russell Lowell, and published most of the great American writers, from Ralph Waldo Emerson, Henry Wadsworth Longfellow, and Oliver Wendell Holmes onward; it seemed to enjoy "a perpetual state of literary grace." Similar in quality was *Scribner's Monthly* (1870), which became the *Century* (1881–1930) but was restarted as *Scribner's Magazine* (1887–1939). A fine magazine in the Far West was *Overland Monthly* (San Francisco, 1868–1935), first edited by Bret Harte. Non-literary specialized magazines included *Scientific American*, which was founded in 1845 by Alfred Ely Beach, a talented inventor whose magazine encouraged other inventors; *Popular Science Monthly*, which was founded in 1872, to spread scientific knowledge and which had the philosophers William James and John Dewey among its contributors; and the ever-popular *National Geographic Magazine*, founded in 1888 and published ever since by the National Geographic Society, which used some of the proceeds to sponsor scientific expeditions.

Scholarly journals. The publishing of scholarly journals, begun in the 17th century, expanded greatly in the 19th as fresh fields of inquiry opened up or old ones were further divided into specialties. Numerous learned societies were formed in such fields as classical studies, biblical studies, archaeology, philology, Egyptology, the Orient, and all the branches into which science was dividing, and each society published a regular bulletin, proceedings, or "transactions," which enabled scholars to keep in touch with what others were doing. In the sober pages of these journals, seldom read by the general public, some of the most far-reaching discoveries were first made known. Among the many notable publications were *Annali del Istituto di Corrispondenza Archeologica* (1829), the *Revue Archéologique* (founded 1844), *Philologus* (1846), *Mind* (founded 1876), the *Journal of Hellenic Studies* (founded 1880), the *American Journal of Philology* (founded 1880), the *Asiatic Quarterly* (1886; later called *South Asian Review*), the *Geographical Journal* (1893), and an interesting informal aid to scholars, *Notes and Queries* (1849), with the motto: "When found, make a note of." In every advanced country the professions too began to have journals, such as medicine's *Lancet* (founded 1823), in Britain, originally started to attack abuses in hospital administration; the *Mining Journal* (founded 1835); the *British Medical Journal* (founded 1840); *The Engineer* (founded 1856); and the *Solicitors' Journal* (founded 1857), to cite only a few examples. In the course of time, these developed endless technical ramifications. The economics of all such journals are based on necessity. Though their circulation is small, anyone working in a particular field generally subscribes to them or at least has access to them in appropriate libraries. They can be described as reference books in installments.

*Edinburgh
Review*

THE 20TH CENTURY

The advertising revolution in popular magazines. There was a certain resistance to advertising in magazines, in keeping with their literary affinities. When the advertisement tax in Britain was repealed in 1853 and more advertising began to appear, the *Athenaeum* thought fit to say: "It is the duty of an independent journal to protect as far as possible the credulous, confiding and unwary from the wily arts of the insidious advertiser." In the United States many magazines, such as *Harper's*, took a high line with would-be advertisers until the 1880s; and *Reader's Digest*, with its mammoth circulation, admitted advertisements to its American edition only in 1955. Yet today some sectors of the magazine industry are dominated by advertising, and few are wholly free from its influence.

Magazine advertising economics. In the United States Cyrus Curtis showed what could be achieved in attracting advertising revenue with the *Saturday Evening Post*. He bought the magazine for \$1,000 in 1897, when it was on its last legs, and invested \$1,250,000 of his profits from the *Ladies' Home Journal* before it finally caught on. But when it did, through an appeal based on well-founded stories and articles about the business world, a prime interest at the time, its success was enormous; by 1922 it had a circulation of more than 2,000,000 and an advertising revenue in excess of \$28,000,000. It was a classic demonstration of modern magazine economics: as circulation rose in the initial phase of low advertising rates, money had to be poured in to meet the cost of producing more copies; but, as soon as high advertising rates could be justified by a high circulation, profitability was assured. Conversely, when high rates are maintained on a falling circulation, it is the advertisers who lose, until they withdraw their support.

Once circulation figures became all-important, advertisers naturally asserted their right to verify them. The first attempt, made in 1899 by the Association of American Advertisers, only lasted until 1913, but fresh initiatives in 1914 created the Audit Bureau of Circulation. Though resented at first by publishers, it was eventually seen as a guarantee of their claims. Interest in circulation led publishers into market research. The first organization for this purpose was set up by the Curtis Publishing Company in 1911; but such research did not become general until the 1930s. Reader research, to ascertain what readers wanted from magazines, was also developed in the 1930s and proved to be a useful tool, though no substitute for editorial flair. As was once observed by the features editor of *Vogue*: "If we find out what people want, it's already too late."

Thus the popular magazine in the United States, expanding with the economy, became part of the marketing system. By 1900 advertisements might form up to 50 percent of its contents; by 1947, the proportion was more often 65 percent. A proprietor was no longer just selling attractive editorial matter to a segment of the public; he was also selling a well-charted segment of the public to the advertiser. Though the process was most pronounced in the United States, a vast country where, in the absence of national newspapers, national magazines had a special function, the same principles came to apply, in varying degrees, in Europe.

The effects of advertising on the appearance of the magazine have been, on the whole, stimulating. At the turn of the century, advertisements began to move forward from the back pages into greater prominence among the editorial matter, and this was often regretted by readers. At the same time, advertising agencies were developing from mere space sellers into copywriters and designers; their efforts to produce work of high visual appeal forced editors to make their own editorial typography and layout more attractive. The use of colour, in particular, was greatly fostered by advertisers once they discovered its effectiveness. In the 1880s colour printing was rare, but, after the development of the multicolour rotary press in the 1890s, it steadily became more common. By 1948 nearly half the advertising pages of the leading American magazines were in two or more colours.

The effect of advertising on editorial content is harder

to analyze. Advertisers have not been slow to exercise financial pressure and have often succeeded in suppressing material or modifying policy. In 1940, for instance, *Esquire* lost its piano advertisements after publishing an article recommending the guitar for musical accompaniment; six months later it tried to win them back with a rueful editorial apology. Yet many magazines, notably the *Saturday Evening Post*, *Time*, and *The New Yorker*, have persistently asserted editorial independence. Something like a balance of power has come into being, which can tip either way. What can safely be said is that advertising pressure as a whole has been a socially conservative force, playing on conformity, inclining magazines to work on the principle of "minimum offense," and holding them back from radical editorial departures until they are clearly indicated by changes in public taste. This has tended to make the large-circulation magazine an exploiter rather than a discoverer of fresh talent or new ideas. Yet in the last analysis, advertisers have been forced to recognize that magazines, like newspapers, cannot forgo too much of their independence without forfeiting the loyalty of their readers and hence their value as an advertising medium.

Women's magazines in the United States. The bond with advertising is probably most evident in magazines for women, since they are the greatest buyers of consumer goods. In the United States, up to the mid-1930s, such magazines were largely "trade-papers for home-makers." There were exceptions, such as *True Story* (founded 1919), which concentrated on entertainment, and *Vogue*, which introduced readers to a wider world, but more typical was *Better Homes and Gardens* (founded 1922), which gave fresh impetus to the trend toward "service" by helping both men and women in the running of their homes. In this area, of course, advertising pressure can be considerable—e.g., for editorial support of a new product—but editors have usually contained it within some limits.

An innovation in the 1930s was the store-distributed magazine. One of the first and most successful was *Family Circle* (founded 1932), given away in Piggly Wiggly supermarkets until 1946, when it was sold as a family monthly. Equally successful were *Woman's Day* (founded 1937), published by a subsidiary of the Great Atlantic and Pacific Tea Company, and *Better Living* (founded 1951), sponsored by the Super Market Institute. During the 1930s women's magazines broadened their base to combat falling circulations and to meet changes in taste, as they did again in the 1950s, in a similar crisis.

By the late 1980s scores of political and literary magazines of broadly feminist sympathies had been established, one of the most prominent being *Ms.* (founded 1972), a nonprofit magazine with a circulation of about 500,000. Another general trend has been to direct appeal toward younger women, not only in the old magazines but also in such newer ones as *Seventeen* (founded 1944), *Ingenue* (founded 1959), and *Teen* (founded 1957).

Advertising in Britain and Europe. Though the advertising revolution began in Britain at much the same time as in the United States, its course has been less explosive. By 1898, *The Gentlewoman* was pointing out in its first issue that every copy cost "nearly double the price for which it is sold." Yet Britain's Audit Bureau of Circulations was not set up until 1931, and membership remained small until the 1960s; for it was only then that consumer spending in Britain (and hence advertising) really began to soar, to be reflected in a boom in women's magazines. In the early part of the century, the old general magazines continued to flourish, with such additions as the *Wind-sor Magazine* (1895–1939), *Pearson's Magazine* (1896–1909), *Argosy* (founded 1926), which published only fiction, and the popular weekly *John Bull* (1906–64), which thrived on "revelations." Several American magazines, especially women's, began to come out in British editions, such as *Vogue* (1916), *Good Housekeeping* (1922), and *Harper's Bazaar* (1929; in 1970 amalgamated with *Queen* as *Harpers & Queen*). Society periodicals lost ground after World War I to those catering to the so-called new poor and new rich, although snobbery still proved a lucrative element in magazine publishing, notably with the *Tatler*, which became highly successful under a new edi-

circulation

Youth
magazines

tor in the early 1980s. The fortnightly *Queen*, *Woman's Weekly* (founded 1911), and the monthly *Woman and Home* (founded 1926) and *Woman's Journal* (founded 1927) were joined by such popular weeklies as *Woman's Own* (founded 1932), *Woman's Illustrated* (1936–61), and, above all, *Woman* (founded 1937), the first to be printed by colourgravure. During World War II some of these magazines gave valuable practical advice on how to cope with shortages. In postwar Britain magazines began to be distributed through retail outlets—mostly supermarkets—other than bookshops or newsagents. The chief examples were *Family Circle* (founded 1964), an Anglo-American production, and its sister publication, *Living* (founded 1967). The trend toward youthful markets was indicated by *She* (founded 1955), broad and robust in outlook; *Honey* (founded 1960); *Annabel* (founded 1966), for younger married women in particular; *Petticoat* (1966–75), for 14–19 year olds; and *19* (1968), a market leader. The death of many of the old general magazines, under the pressure of paperbacks and television, and the dearth of illustrated weeklies (see below *Picture magazines*) left room for a new advertising vehicle. The first to perceive this was Lord Thomson, who in 1962 brought out a colour magazine as supplement to the *Sunday Times* (London). Its eventual success forced the *Observer* and the *Daily Telegraph* to follow suit (the colour supplement was eventually removed from the latter paper and issued instead with its sister publication, the *Sunday Telegraph*). In the early 1980s the popular Sunday papers also started supplements.

In the rest of Europe the impact of advertising on magazines has been more delayed and less pronounced, partly because market prices of continental magazines tend to be closer to the production cost. General magazines were fairly limited before World War II, but since then, as part of the economic expansion, there has been a rich crop, including many newsmagazines similar to *Time* and *Life* and also a number of magazines for women. France has several of the latter with large circulations, including *Nous Deux*, *Elle*, and *Intimité*, while those in Germany include entries for all age groups, such as *Jasmin* for newlyweds and *Eltern* for parents. Though the northern European countries have fewer periodicals, it is worth noting that in Finland, *Pirkka*, a giveaway distributed through grocery stores, achieved one of the largest magazine circulations.

Publications outside Europe and the United States. *Japan.* The outstanding early 20th-century personality in Japanese magazine publication was Noma Seiji, who published nine magazines, nearly all with six-figure circulations. World War II did not seriously affect periodicals; and, at the end of occupation in 1952, there were more than 2,000 of all kinds, including *Shufu No Tomo* (1917–56; “Woman’s Friend”), *Yoiko No Tomo* (1924–57; “Child’s Friend”), and *Le-no-Hikari* (founded 1925; “Light of Home”).

Africa. Important publications in Africa have included the quarterly East African *Africana* (founded 1962); the Zimbabwean *Africa Calls* (1960), published every two months; the quarterly *Nigeria Magazine* (1933–66); the quarterly *Pan African Journal* (1967), published in Kenya; and, in South Africa, journals in Afrikaans. Elsewhere, magazines in African languages have increased, as have those in English and French—e.g., the Nigerian *Black Orpheus* (founded 1957), containing creative writing by Africans and West Indians.

India, Bangladesh, and Pakistan. Important 20th-century magazines in India include the *Illustrated Weekly of India* (founded 1880), a topical review for educated readers; the *Statesman Weekly* (founded 1924), an illustrated digest of Indian news and views; the monthly general review *Current Events* (founded 1955); *Thought* (New Delhi, 1949–1978/79), a political and economic weekly; the monthly *Akhand Anand* (founded 1947); and the weekly *Akashvani* (founded 1936), *Dharmayug* (founded 1950), and *Mukhabir-I-Alam* (1903). *Sport and Pastime* (1947), with offices in several cities, is well-illustrated. *Eve's Weekly* (founded 1947), in English, Urdu, and Hindi, is a popular women's magazine. Bangladesh weeklies include *Bangladesh Sangbad* (founded 1972). Pakistani periodicals

include the monthly *Subrang Digest* (1970) and the weekly *Muslim World* (1961).

South America. Argentina had a greater magazine circulation than any other nation in South America until the mid-1970s, when total circulation decreased by almost one-half (it later began to recover slowly). The weekly rotogravure *Maribel* (1932–56) long had the highest periodical circulation in that country, closely followed by that of the women's weekly *Para ti* (founded 1922). Mexico's leading magazine in the early 1980s was the weekly *Selecciones del Reader's Digest*; others included the weeklies *El Libro Semanal* (1954) and *Alarma* (1963). Venezuelan periodicals include the weekly *Resumen* (founded 1973) and *Elite* (1925).

News and photo magazines. The accelerated tempo of life in the 20th century, coupled with the bewildering amount of information appearing in print, suggested the need for more concise ways of presenting it. The first to show how it could be done and so give rise to a whole new class of periodical was the U.S. newsmagazine *Time*, founded in 1923 by Briton Hadden and Henry Luce.

Time magazine. There had, of course, been newsmagazines before, in both Europe and the United States. *Time* magazine's immediate forerunner was the *Pathfinder* (1894–1954), a weekly rewriting of the news for rural readers. There had also been attempts at compression of the digest type (see below *Digests and pocket magazines*). But *Time* was the first to aim at a brief and systematic presentation of the whole of the world's news. It was based on the proposition that “People are uninformed because no publication has adapted itself to the time which busy men are able to spend simply keeping informed.” Its beginning was amateurish and precarious; neither Hadden nor Luce had much experience when they started summarizing the news from bundles of daily papers (copyright provisions on newspapers allowing this use). But after 1928 it grew steadily, finding its market chiefly among the rising number of college graduates. What came to be known as the *Time* style was characterized, in the words of a later critic, by two great democratic ideals, disrespect for authority and reverence for success. *Time* presented the news in tightly packed sentences, well researched and checked, and with a general air of omniscience. In the 1930s, to ensure adequate sources of information, Time Inc. built up a large news-gathering organization of its own. It also branched out into other publications, including *Fortune* (1930), summarizing business news, *Life* (see below), and *People*, a weekly begun in 1974.

Among the direct followers of *Time* in the United States were *Business Week* (founded 1929), *United States News* (founded 1933), and *Newsweek* (founded 1933), its nearest rival. Similar magazines appeared in Shanghai (*East*, 1933), and in Britain (the *News Review*, 1936), though the latter did not have a comparable success, partly because Britain was so well supplied with national dailies. After World War II the United States had several newsmagazines of a regional nature, such as *Fortnight* (1946) in California and *Texas Week* (1946). *Time* has had its greatest influence, however, in postwar Europe, where such magazines as *L'Express* (founded 1953) in France, *Der Spiegel* (founded 1947) in West Germany, and *Panorama* (founded 1962) in Italy derived directly from it. Such magazines did not always develop in exactly the direction that *Time* had taken, but *L'Express* was radically changed at least twice by its owners; the first time it followed *Time* fairly closely. *Der Spiegel* (“The Mirror”) became famous for its aggressive, antiauthoritarian exposures of scandal and malpractice, while *Panorama* achieved a high standing and a reputation for reliability. The influence of *Time* can probably be traced in most newsmagazines, as in *Tiempo* (founded 1942) in Mexico or *Primera Plana* (founded 1962) in Argentina.

Picture magazines. Conciseness can also be achieved through pictures, which obviate the need for description. Illustrated newsmagazines began in the 19th century, but they took an altogether new form as photography developed. The most influential, though by no means the first of the modern type, was undoubtedly the American weekly *Life* (1936–72), started by Henry Luce.

The Luce
magazines

Pictorial journalism grew up alongside advertising techniques, the tabloid, and the documentary film. Modern cameras enabled top-grade photographs to be taken quickly under almost any conditions. Photojournalists were particularly active in Germany, until many had to flee the Nazis. One of them was the Hungarian Stefan Lorant, who developed the photo essay (a story reported through pictures) with *Bilder Courier* in Berlin in 1926 and with the *Münchener illustrierte Presse* in the period 1927–33. He then went to Britain, where he started a pocket picture magazine, *Lilliput* (1937–60), and was the first editor of *Picture Post* (1938–57). Another pioneer was a German, Erich Salomon, who became celebrated for his photographs of the famous, particularly politicians, in unguarded moments. Salomon's pictures in the London *Tatler* in 1928 prompted *Fortune* to invite him to the United States, where he inspired the *Life* photographer Thomas McAvoy.

In November 1936, therefore, when *Life* first appeared, picture magazines were already fairly common. Only a month before, *Mid-Week Pictorial* (1914–37), an American weekly of news pictures, had been restyled along the lines *Life* was to take, but *Life* quickly overwhelmed it. Though expected to have a circulation of well under 500,000 copies, *Life* was running at 1,000,000 within weeks. Its first issue, 96 large pages of pictures on glossy paper for 10 cents, was a sellout, the opening picture brilliant: an obstetrician holding a newborn baby, with the caption "Life begins." Over the years, it kept the promise of its prospectus: "To see life; to see the world; to witness great events; to watch the faces of the poor and the gestures of the proud; to see strange things. . . ." During World War II, which it covered with great accomplishment, it enlarged its operations with a fortnightly international edition, and in 1952 a Spanish-language edition was added for Latin America, *Life en Español*. In 1971 *Life* magazine's circulation was about 7,000,000, but its high costs were no longer being met by advertising income, and it ceased publication in December 1972; it was revived as a monthly in October 1978.

Imitators
of *Life*
magazine

Of the countless imitators of *Life*, many were American, such as *Focus*, *Peek*, *Foto*, and two of longer duration, *Pic* (1937–48) and *Click* (1938–44). Best known was *Look* (1937–71; briefly revived 1979), a popular biweekly. It was founded by Gardner Cowles, Jr., who also started *Quick* (1949–53), a miniature magazine. Britain had two news picture magazines, *Picture Post* (1938–57), which acquired much prestige through its social conscience, and *Illustrated* (1939–58); their place was taken to some extent by the Sunday colour supplements. The French *Paris-Match* (founded 1949), exceptionally well-produced and well-supplied with photographers, gained preeminence throughout Europe; while West Germany produced *Stern* (founded 1948), a glossy blend of light and serious material, and Italy, where magazines are read more than newspapers, produced *Oggi Illustrato* (founded 1945), thriving on not-too-sensational disclosures, and the elegant *Epoca* (founded 1950). Magazines similar to *Life* appeared in a number of other countries, such as *Cruzeiro* (founded about 1908) in Brazil and *Perspektywy* (founded 1969) in Poland, and still more that follow the style of *Look*, such as *Manchete Esportiva* (founded 1952) in Brazil, *Caretas* (founded 1950) in Peru, or the Australian *Pix-People*.

Digests and pocket magazines. *Reader's Digest* magazine. The need for concise reading matter, so well met by *Time* and *Life*, was met even more successfully, in terms of circulation, by an American magazine that reprinted in condensed form articles from other periodicals. This was the pocket-size *Reader's Digest*, founded in 1922 by DeWitt Wallace.

Its forerunners in the United States were the *Literary Digest* (1890–1938), started by two former Lutheran ministers, Isaac K. Funk and Adam W. Wagnalls; the *Review of Reviews* (1890–1937), founded by Albert Shaw to condense material about world affairs; and Frank Munsey's *Scrap Book* (1906–12), "a granary for the gleanings of literature." The *Literary Digest*, in particular, with a circulation of more than 1,000,000 in the early 1920s, was something of an American institution. Its famous straw

votes successfully predicted the result of the presidential elections after 1920, and its highly publicized wrong prediction of the outcome of the 1936 election played a decisive part in its collapse. *Reader's Digest*, however, was more specific in content and more universal in appeal. It aimed to supply "An article a day from leading magazines in condensed, permanent, booklet form." Each article, moreover, satisfied three criteria: "applicability" (it had to be of concern to the average reader); "lasting interest" (it had to be readable a year later); and "constructiveness" (it had to be on the side of optimism and good works).

After three years' preparation, Wallace began to produce the magazine (first issue February 1922) from a basement office in New York City. After a year, subscriptions were running at about 7,000. In 1939, when circulation had reached 3,000,000, *Reader's Digest* moved into large premises at nearby Chappaqua. Until 1930 it was produced entirely by amateurs. Condensed books began to be added at the end of the magazine in 1934, and from this grew the Reader's Digest Condensed Book Club, with 2,500,000 members four years later. Overseas editions were started in 1939 (British), and foreign-language editions in 1940 (Spanish), others being steadily added over the following 10 years. In the late 1980s, *Reader's Digest* had one of the largest circulations of any magazine in the world.

This success was not achieved entirely without setbacks and criticism. At first, permission to reprint was easy to obtain and was without charge; but after a while, and especially after competitors entered the field and sometimes reprinted without permission, magazines began to regard the digests as parasitic. Payments were required, which rose steadily, and the major proprietors withheld their permission at various times. To guard against this and because articles of the sort he wanted were in short supply, Wallace began to print original material in the *Digest* in 1933. To keep up the appearance of a digest, articles were commissioned and then offered to other magazines in exchange for the right to "condense" and reprint them. Such articles, "cooperatively planned" according to the *Digest*, "planted" according to critics, were naturally welcome to many magazines with slender budgets, but they did lead to controversy. In 1944 *The New Yorker*, fearing that *Reader's Digest* was generating too big a fraction of magazine articles in the United States, attacked the system as "a threat to the free flow of ideas and to the independent spirit"; but, in the more general view, the matter was regarded as a private one for the parties concerned. Internationally, too, the *Digest* was attacked by some after World War II for its part in "American cultural imperialism"; but it has continued to find favour with the magazine public.

The digest idea was soon taken up by others, often in direct competition but also in more limited areas, such as *Science Digest*, *Catholic Digest*, *Negro Digest*, and *Children's Digest*. There was also a *Cartoon Digest* (1939), an *Editorial Digest* (1947), and a *Column Digest* (1949). Most of the general digests used original articles, since competition for the limited amount of highly popular reprinted material became too keen, and *Reader's Digest*, as first in the field, was always able to outbid its competitors. One of the more successful was *Magazine Digest* (founded 1930), which was based in Canada and contained a good deal of scientific and technical matter. One that tried a new formula, based on timeliness and a liberal slant, was *Reader's Scope* (1943–48). The most successful book digest was probably *Omnibook* (1938–57), each issue of which contained abridgments of several popular works of fiction and nonfiction. The digests originally carried no advertising, but after World War II they were gradually driven to it by rising costs. One of the last to capitulate was *Reader's Digest* in 1955; the proportion of advertising was restricted, however, to 20 percent.

Types of pocket magazines. The success of *Reader's Digest* also had an influence through its format; it popularized the pocket magazine as a type. Several of the self-improving variety, such as *Your Life* (founded 1937) and *Success Today* (1946–50), were started by Wilfred J. Funk on the proceeds from his father's *Literary Digest* (sold to *Time* in 1938). Of those more directly inspired by *Read-*

Problems
of condens-
ing
articles

er's Digest, *Coronet* (1936–61), an offshoot of *Esquire* Inc., built up a large circulation during World War II, and when it closed, a victim of the promotion race, it was still running at more than 3,000,000. Somewhat livelier and glossier was *Pageant*, first published in 1944. Britain had several pocket magazines, such as *London Opinion*, *Men Only*, and *Lilliput*, but these owed rather less to *Reader's Digest*. Finally, there have been a few "superdigests," miniature newsmagazines with pictures and a minimum of text, such as *Tempo* (1950), *People Today* (founded 1950), and *Jet* (founded 1951).

Specialized magazines. Though general magazines have the largest circulations, most magazines cater to specialist interests or pursuits. Circulation varies, but, even where it is small, it is usually stable over the short term and offers an advertiser a well-defined market. Such magazines may be broadly classified into professional (including trade and technical) and nonprofessional journals.

Professional types. The professional magazine, often the organ of an association, keeps members informed of the latest developments, helps them to maintain standards, and defends their interests. Some were started in the 19th century, but specialization and different viewpoints within specialties have encouraged proliferation. Instead of two or three medical journals, for instance, there are now likely to be dozens, besides those in specialized areas such as dentistry, ophthalmology, and psychiatry. Though most of these magazines are of little interest to the general public, a few print authoritative articles of broader scope.

Trade and technical journals serve those working in industry and commerce. They too have grown enormously in numbers. Major discoveries in science, manufacturing methods, or business practice tend to create a new subdivision of technology, with its own practitioners and, more often than not, its own magazine. Articles in these magazines tend to be highly factual and accurately written, by people deeply immersed in their subjects. Most are well produced, often on art paper for the sake of the illustrations, and heavily dependent on advertising. Indeed, many are issued for a controlled circulation; i.e., a publisher undertakes to distribute a magazine free of charge to a given number of specialist concerns, which can be relied upon to want a certain range of products. The manufacturers of these products, for their part, are naturally glad to have an advertising medium guaranteed to reach their particular market. The business papers may lack glamour, but they play a vital and highly influential part in economic life.

Nonprofessional types. Of the nonprofessional magazines, quite a number serve broad interest groups, religious, political, or social. Most religious denominations have journals, often more than one. Though some of these magazines are subsidized as part of a drive to spread their message, most of them merely aim to foster corporate feeling among coreligionists. Much the same applies to political magazines in the narrow sense—i.e., where they are issued by political organizations: they discuss doctrine, give news of activities, and forge links among members. Political discussion on less partisan matters and in a less partisan tone tends to take place in more general magazines. Certain periodicals spring from the needs of particular groups, an example being student magazines.

Specialized magazines for the layman may fall into the hobby category. Very often a professional magazine has an amateur counterpart, as, for instance, in electronics, where the amateur finds a wide range of technical magazines on radio, television, hi-fi, and tape recording. Other popular subjects are photography (the British *Amateur Photographer* was founded in 1884) and motoring (Hearst's *Motor* was founded, as *Motor Cycling and Motoring*, in 1902); specialization even extends to types of camera and makes of car. Virtually no hobby or sport is without its magazine. As soon as any activity becomes sufficiently popular, a magazine appears to cater to its adherents and to provide an advertising medium, not only for manufacturers and suppliers but also for readers, to help them buy and sell secondhand equipment, for instance.

Some special tastes in entertainment are met by the "pulp" and "comic" magazines. In 1896 Frank Munsey turned his *Argosy* into an all-fiction magazine using rough

wood-pulp paper. The "dime novel" did not qualify for inexpensive postal rates in the United States, but the pulp magazine did, and so an industry was born. Pulp began as adventure magazines but soon split up into further categories: love, detective, and western. Such magazines sold in the millions up to the mid-1930s, when they gradually lost ground to the comics. These began as collections reprinted from the comic strips in newspapers; the first to appear regularly was *Famous Funnies* (1934). After 1937, however, with *Detective Comics*, they came into their own as original publications, and, like the pulps, they grew into a major industry, dividing up into much the same types. They may be seen, in effect, as pictorial condensations of the pulps. Though mainly for children, they were widely read by adults. "Comic" rapidly became a misnomer, as they played increasingly on horror and violence. While some defended them as harmless and even cathartic, others condemned them as incitements to imitation. Attempts at control were made through legislation in the United States and elsewhere, and the industry itself tried to set standards. Television has since drawn much of the criticism, and the demand, to itself, but comics remain big business. One type of magazine, originally classed as pulp but attaining with the years a certain respectability, is the science-fiction magazine, the first example of which was Hugo Gernsback's *Amazing Stories*, first published in 1926.

The "fan" magazines offer glimpses of life behind the scenes in the world of entertainment and sport. In the heyday of motion pictures, many magazines on films and their stars appeared, beginning with *Photoplay* (1911–77) and *Picture Play* (1915) and later others, such as *Movie Mirror* (1930) and *Movieland* (1942). When radio and television became popular, similar magazines sprang up centring on programs and their personalities. One of their functions was to provide a weekly timetable of programs.

Finally, there are a number of "special service" magazines—e.g., financial magazines to help the private investor, magazines of advice issued by consumer associations, magazines specifically for house hunters, racegoers, or for trading in secondhand goods, and so on.

Scholarly, cultural, and literary magazines. As the 20th century progressed, the old critical review lost some of its former glory, but it often wielded an influence quite out of proportion to its circulation. One may distinguish broadly between the scholarly type of review, the more widely read politico-cultural periodical, and the purely literary magazine.

Britain. Many of the British reviews founded in the 19th century have continued to flourish. Among additions of the scholarly type were the *Hibbert Journal* (1902–70), a nonsectarian quarterly for the discussion of religion, philosophy, sociology, and the arts; the *Times Literary Supplement* (founded 1902), important for the completeness of its coverage of all aspects of books and bibliographical matters; *International Affairs* (founded 1922), the journal of Chatham House, the Royal Institute of International Affairs; and *The Political Quarterly* (founded 1930), for the discussion of social and political questions from a progressive but nonparty point of view. Of the weekly political reviews, the *Spectator* (founded 1828), was representative of the right, and the *New Statesman* (founded 1913), founded by Sidney and Beatrice Webb, of the left, though both in a broad context; while *Time and Tide* (1920–79), originally founded by Lady Rhondda as an independent journal, was an influential newsmagazine. Several other periodicals met the need for serious articles on current questions; among them are *The Economist* (founded 1843); *The Listener* (founded 1929), published by the British Broadcasting Corporation and consisting mainly of radio talks in printed form; the *New Scientist* (founded 1956), drawing attention to current scientific work; and *New Society* (founded 1962), concentrating on sociology. Literary magazines came and went, but not without leaving their mark. They included the *Egoist* (1914–19), associated with Ezra Pound and the Imagists; the *London Mercury* (1919–39), started by J.C. (later Sir John) Squire, one of the Georgian poets; the *Criterion* (1922–39), founded and edited by T.S. Eliot; the *Adelphi* (1923–55), of John Middleton Murry; *New Writing*

(1936–46), edited by John Lehmann, who also later revived the old *London Magazine* (from 1954); and *Horizon* (1940–50; revived 1958), which Cyril Connolly started as a medium for literature during the war years. Later, *Encounter* (founded 1953), an international review originally sponsored by the Congress for Cultural Freedom, proved to be an intellectual magazine of value and distinction. In addition, many “little magazines” have struggled along, as always, providing essential seedbeds for new writers.

The United States. American counterparts to British scholarly journals include the *Political Science Quarterly* (founded 1886), edited by the political science faculty of Columbia University; the *American Scholar* (founded 1932), “a quarterly for the independent thinker” edited by the united chapters of Phi Beta Kappa; *Foreign Affairs* (founded 1922), a quarterly dealing with the international aspects of America’s political and economic problems; and *Arts in Society* (founded 1958), a forum for the discussion of the role of art, which also publishes poetry and reviews. Of general political journals, the oldest still in publication in the 1980s was *The Nation*, founded in 1865 by E.L. Godkin and edited in the period 1918–34 by Oswald Garrison Villard. By tradition it adopted a critical stand on most matters, disdaining approval by the majority; it was notable for the “casual brilliance” of its literary reviews. When the muckraking phase in the popular magazines died down, zeal for reform was left to a succession of little magazines that led precarious lives, often needing extra support from loyal readers or rich individuals. Such were the *Progressive* (founded 1909), of the La Follette family; *The Masses* (1911–17), run by the Greenwich Village Socialists; and *The New Republic* (founded 1914), which was started by Herbert Croly with the backing of the Straight family as “frankly an experiment” and “a journal of opinion to meet the challenge of the new time” and which survived as a liberal organ, after many triumphs and vicissitudes. Between the wars came the Marxist *Liberator* (1918–24); the *Freeman* (1920–24 and 1950–54), founded to recommend the single-tax principle of Henry George and later revived as a Republican journal; the *New Leader* (founded 1927), for 10 years the organ of the American Socialist Party; and the extreme left *New Masses* (1926–48). Postwar foundations included the anti-Communist *Plain Talk* (1946–50); the fortnightly *Reporter* (1949–68), strong on “facts and ideas”; and the conservative *National Review* (founded 1955). Of the literary magazines, the *Atlantic* and *Harper’s* were joined by the *American Mercury* (founded 1924), which had a brilliant initial period under H.L. Mencken and George Jean Nathan, when it published work by many distinguished writers of the time; and the *Saturday Review* (founded 1924), which began as a purely literary magazine but broadened its scope in the 1940s. In 1972 a new ownership brought more changes. A powerful influence on American writing has been exerted by *The New Yorker* (founded 1925), mainly through its founder Harold Ross, a perfectionist among editors. It became famous for its cartoons and biographical studies. Finally, there has been no lack of “little magazines” to foster talent.

Continental Europe. Among the numerous literary magazines in Europe, several in France and Germany in particular may be mentioned. The *Mercure de France* was revived in 1890 as an organ of the Symbolists; the influential *Nouvelle Revue Française* (1909) aimed at a fresh examination of literary and intellectual values; and the *Nouvelles Littéraires* (1922) was founded by André Gillon as a weekly of information, criticism, and bibliography. After World War II appeared Jean-Paul Sartre’s left-wing monthly *Les Temps Modernes* (founded 1945); *La Table Ronde* (1948); and *Les Lettres Nouvelles* (1953). In Germany, political magazines included the radical *Die Fackel* (1899; “The Torch”) and *Die neue Gesellschaft* (1903–07; “The New Society”) of the Social Democrats. An important literary influence was *Blätter für die Kunst*, associated with the Neoromantic movement of Stefan George. The Nazi period imposed a break in development, but since the war the liberal weekly *Die Zeit* and a number of literary journals, such as *Westermanns Monatshefte*, *Neue deutsche Hefte*, and *Akzente*, have appeared.

The political involvement of the literary review has been especially marked in the Soviet Union and Soviet-bloc countries. The *Literaturnaya Gazeta* (founded 1929) and the influential *Novy Mir* (founded 1925; “New World”) often became the centre of controversy in the Soviet Union when writers were condemned for their views or denied the opportunity to publish. This has led to a strong underground press. In Czechoslovakia the *Literárne Listy* played a prominent part in the freedom movement of 1968 and was later suppressed at Soviet insistence, along with the *Reportér* and *Student*, leading to the start of several underground magazines. *Sinn und Form* (founded 1949), a Marxist critical journal in East Germany, was subject to temporary suspensions for publishing such banned authors as Sartre, Kafka, and Hemingway. (P.U./G.U./Ed.)

Puppetry

A puppet is an inanimate object moved by human agency in some kind of theatrical show, and the puppet theatre includes any kind of theatrical show that is presented through the medium of puppets. These definitions are wide enough to include an enormous variety of shows and an enormous variety of puppet types, but they do exclude certain related activities and figures. A doll, for instance, is not a puppet, and a girl playing with her doll as if it were a living baby is not giving a puppet show; but, if before an audience of her mother and father she makes the doll walk along the top of a table and act the part of a baby, she is then presenting a primitive puppet show. Similarly, automaton figures moved by clockwork that appear when a clock strikes are not puppets, and such elaborate displays of automatons as those that perform at the cathedral clock in Strasbourg, Fr., or the town hall clock in Munich, W.Ger., must be excluded from consideration.

Puppet shows seem to have existed in almost all civilizations and in almost all periods. In Europe, written records of them go back to the 5th century BC (e.g., the *Symposium* of the Greek historian Xenophon). Written records in other civilizations are less ancient, but in China, in India, in Java, and elsewhere in Asia there are ancient traditions of puppet theatre, the origins of which cannot now be determined. Among the American Indians, there are traditions of puppetlike figures used in ritual magic. In Africa, records of puppets are meagre, but the mask is an important feature in almost all African magical ceremonies, and the dividing line between the puppet and the masked actor, as will be seen, is not always easily drawn. It may certainly be said that puppet theatre has everywhere antedated written drama and, indeed, writing of any kind. It represents one of the most primitive instincts of the human race.

This article discusses the various types of puppets as well as historical and contemporary styles of puppet theatre around the world. Some specific national styles of puppetry are treated in the articles EAST ASIAN ARTS and SOUTHEAST ASIAN ARTS.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 622, and the Index.

The article is divided into the following sections:

CHARACTER OF PUPPET THEATRE

It may well be asked why such an artificial and often complicated form of dramatic art should possess a universal appeal. The claim has, indeed, been made that puppet theatre is the most ancient form of theatre, the origin of the drama itself. Claims of this nature cannot be substantiated, nor can they be refuted; it is improbable that all human dramatic forms were directly inspired by puppets, but it seems certain that from a very early period in man's development puppet theatre and human theatre grew side by side, each perhaps influencing the other. Both find their origins in sympathetic magic, in fertility rituals, in the human instinct to act out that which one wishes to

take place in reality. As it has developed, these magical origins of the puppet theatre have been forgotten, to be replaced by a mere childlike sense of wonder or by more sophisticated theories of art and drama, but the appeal of the puppet even for modern audiences lies nearer a primitive sense of magic than most spectators realize.

Granted the common origin of human and puppet theatre, one may still wonder about the particular features of puppet theatre that have given it its special appeal and that have ensured its survival over so many centuries. It is not, for instance, simpler to perform than human theatre; it is more complicated, less direct, and more expensive in time and labour to create. Once a show has been created, however, it can provide the advantage of economy in personnel and of portability; one man can carry a whole theatre (of certain types of puppet) on his back, and a cast of puppet actors will survive almost indefinitely. These are clear advantages, but it would be a mistake to imagine that they can explain the whole popularity of puppet theatre. They do not apply to every kind of puppet—some puppets need two or even three manipulators for each figure, and many puppets need one manipulator for each figure. The company employed by a major puppet theatre, whether it be a traditional puppet theatre from Japan or a modern one from eastern Europe, will not be fewer than for an equivalent human theatre. The appeal of the puppet must be sought at a deeper level.

The essence of a puppet is its impersonality. It is a type rather than a person. It shares this characteristic with masked actors or with actors whose makeup is so heavy that it constitutes a mask. Thus, the puppets have an affinity with the stock characters of ancient Greek and Roman drama, with the masked characters of the Renaissance commedia dell'arte, with the circus clown, with the ballerina, with the mummers, and with the witch doctor and the priest.

In an impersonal theatre, where the projection of an actor's personality is lacking, the essential rapport between the player and his audience must be established by other means. The audience must work harder. The spectators must no longer be mere spectators; they must bring their sympathetic imagination to bear and project upon the impersonal mask of the player the emotions of the drama. Spectators at a puppet show will often swear that they saw the expression of a puppet change. They saw nothing of the kind; but they were so wrapped up in the passion of the piece that their imaginations lent to the puppets their own fears and laughter and tears. The union between the actor and the audience is the very heart and soul of the theatre, and this union is possible in a special way, indeed in a specially heightened way, when the actor is a puppet.

The impersonality of the puppet carries other characteristics. There is the sense of unreality. In the traditional English Punch-and-Judy puppet shows, for instance, no one minds when Punch throws the Baby out of the window or beats Judy until she is dead; everyone knows that it is not real and laughs at things that would horrify him if they were enacted by human actors. Psychologists agree that the effect is cathartic—one's innate aggressive instincts are released through the medium of these little inanimate figures.

The puppet also carries a sense of universality. This, too, springs from its impersonality. A puppet Charlemagne in a Sicilian puppet theatre is not merely an 8th-century Frankish king but a symbol of royal nobility; and the leader of his rear guard dying on the pass of Roncesvalles is not merely a petty knight ambushed in a skirmish but a type representing heroism and chivalry. Similarly, in the Javanese puppet theatre, a grotesque giant is a personification of the destructive principle, while an elegantly elongated local deity is a personification of the construc-

The unreality and universality of puppets

The appeal of puppetry

An English Punch-and-Judy show. Detail from "Punch or May Day," oil painting by Benjamin Robert Haydon, 1829. In the Tate Gallery, London.

time principle. Here the puppet theatre reveals its close relationship with the whole spirit of folklore and legend. The puppet achieves its elemental qualities of impersonality, unreality, and universality through the stylizations imposed upon it by its own limitations. It is a mistake to imagine that the more lifelike or natural a puppet can be, the more effective it is. Indeed, the opposite is often the case. A puppet that merely imitates nature inevitably fails to equal nature; the puppet only justifies itself when it adds something to nature—by selection, by elimination, or by caricature. Some of the most effective puppets are the crudest: at Liège, Belg., for instance, there is a tradition of puppets whose arm and leg movements are not controlled but purely accidental. The Rājasthāni puppets of India have no legs at all. Even less naturalistic are the hunchbacked grotesques of the European tradition, the birdlike profiles of the Indonesian shadow figures, and the intricately shaped leather cutouts of Thailand, but it is precisely among these most highly stylized types of puppets that the art reaches its highest manifestations.

While these puppets that exist furthest from nature can be admired, it cannot be denied that there is a charm and a fascination in the miniaturization of life. Much of the appeal of the puppet theatre has come from the spectators' delight in watching a world in miniature. This can be appreciated best of all in a toy theatre, in which a tiny stage on a drawing room table can be filled with choruses of peasants, troops of banditti, or armies locked in combat, while the scenery behind them depicts far vistas of beetling cliffs or winding rivers.

And to the appreciation, often instinctive, of these characteristics that mark the puppet theatre, there must be added admiration for the sheer human skill that has gone into the making and manipulation of the figures. The manipulator is usually unseen; his art lies in hiding his art, but the audience is aware of it, and this knowledge adds an element to the dramatic whole. In some kinds of

presentation—for instance, in a type of cabaret floor show that became popular in the mid-20th century—the manipulator works in full view of the audience, who may, if they wish, study his methods of manipulation. This is a far cry from the philosophy of the traditional European puppet players of earlier generations, who guarded the secrets of their craft as if they were conjuring tricks. It is, indeed, fair to say that any presentation that deliberately draws attention to the mechanics of how it is done is distorting the art of puppetry, but the realization, nevertheless, of the expertise involved in a performance and some knowledge of the technical means by which it is achieved do add an extra dimension to the appreciation of this difficult and highly skilled art.

TYPES OF PUPPETS

There are many different types of puppets. Each type has its own individual characteristics, and for each there are certain kinds of suitable dramatic material. Certain types have developed only under specific cultural or geographic conditions. The most important types may be classified as follows:

Hand or glove puppets. These have a hollow cloth body that fits over the manipulator's hand; his fingers fit into the head and the arms and give them motion. The figure is seen from the waist upward, and there are normally no legs. The head is usually of wood, papier-mâché, or rubber material, the hands of wood or felt. One of the most common ways to fit the puppet on the hand is for the first finger to go into the head, and the thumb and second finger to go into the arms. There are, however, many variants of this. The "two-fingers-and-thumb" method is used for Punch-type figures; it allows the puppet to pick up and grasp small props very well and is obviously useful when wielding the stick that plays a big part in the show, but it tends to produce a lopsided effect, with one arm higher than the other. The performer normally holds his hands above his head and stands in a narrow booth with an opening just above head height. Most of the traditional puppet folk heroes of Europe are hand puppets; the booth is fairly easily portable, and the entire show can be presented by one person. This is the typical kind of puppet show presented in the open air all over Europe and also found in China. But it need not be limited to one manipulator; large booths with three or four manipulators provide excellent scope for the use of these figures. The virtue of the hand puppet is its agility and quickness; the limitation is small size and ineffective arm gestures.

Rod puppets. These figures are also manipulated from below, but they are full-length, supported by a rod running inside the body to the head. Separate thin rods may move the hands and, if necessary, the legs. Figures of this type are traditional on the Indonesian islands of Java and Bali, where they are known as *wayang golek*. In Europe they were for a long time confined to the Rhineland; but in the early 20th century Richard Teschner in Vienna developed the artistic potentialities of this type of figure. In Moscow Nina Efimova carried out similar experimental productions, and these may have inspired the State Central Puppet Theatre in Moscow, directed by Sergey Obraztsov, to develop this type of puppet during the 1930s. After World War II Obraztsov's theatre made many tours, especially in eastern Europe, and a number of puppet theatres using rod puppets were founded as a result. Today the rod puppet is the usual type of figure in the large state-supported puppet theatres of eastern Europe. In a similar movement in the United States, largely inspired by Marjorie Batchelder, the use of rod puppets was greatly developed in school and college theatres, and the hand-rod puppet was found to be of particular value. In this figure the hand passes inside the puppet's body to grasp a short rod to the head, the arms being manipulated by rods in the usual way. One great advantage of this technique is that it permits bending of the body, the manipulator's wrist corresponding to the puppet's waist. Although in general the rod puppet is suitable for slow and dignified types of drama, its potentialities are many and of great variety. It is, however, extravagant in its demands on manipulators, requiring always one person, and sometimes two or three, for each figure on stage.

Marionettes or string puppets. These are full-length figures controlled from above. Normally they are moved by strings or more often threads, leading from the limbs to a control or crutch held by the manipulator. Movement is imparted to a large extent by tilting or rocking the control, but individual strings are plucked when a decided movement is required. A simple marionette may have nine strings—one to each leg, one to each hand, one to each shoulder, one to each ear (for head movements), and one to the base of the spine (for bowing); but special effects will require special strings that may double or treble this number. The manipulation of a many-stringed marionette is a highly skilled operation. Controls are of two main types—horizontal (or aeroplane) and vertical—and the choice is largely a matter of personal preference.

The string marionette does not seem to have been fully developed until the mid-19th century, when the English marionettist Thomas Holden created a sensation with his ingenious figures and was followed by many imitators. Before that time, the control of marionettes seems to have

been by a stout wire to the crown of the head, with subsidiary strings to the hands and feet; even more primitive methods of control may still be observed in certain traditional folk theatres. In Sicily there is an iron rod to the head, another rod to the sword arm, and a string to the other arm; the legs hang free and a distinctive walking gait is imparted to the figures by a twisting and swinging of the main rod; in Antwerp, Belg., there are just rods to the head and to one arm; in Liège there are no hand rods at all, merely one rod to the head. Distinctive forms of marionette control are found in India: in Rājasthān a single string passes from the puppet's head over the manipulator's hand and down to the puppet's waist (a second loop of string is sometimes used to control the arms); in southern India there are marionettes whose weight is supported by strings attached to a ring on the manipulator's head, rods controlling the hands.

In European history the marionette represents the most advanced type of puppet; it is capable of imitating almost every human or animal gesture. By the early 20th century, however, there was a danger that it had achieved a sterile naturalism that allowed no further artistic development; some puppeteers found that the control of the marionette figure through strings was too indirect and uncertain to give the firm dramatic effects that they required, and they turned to the rod puppet to achieve this drama. But, in the hands of a sensitive performer, the marionette remains the most delicate, if the most difficult, medium for the puppeteer's art.

Flat figures. Hitherto, all the types of puppets that have been considered have been three-dimensional rounded figures. But there is a whole family of two-dimensional flat figures. Flat figures, worked from above like marionettes, with hinged flaps that could be raised or lowered, were sometimes used for trick transformations; flat jointed figures, operated by piston-type arms attached to revolving wheels below, were used in displays that featured processions. But the greatest use of flat figures was in toy theatres. These seem to have originated in England by a printseller in about 1811 as a kind of theatrical souvenir; one bought engraved sheets of characters and scenery for popular plays of the time, mounted them and cut them out, and performed the play at home. The sheets were sold, in a phrase that has entered the language, for "a penny plain or twopence coloured," the colouring by hand in rapid, vivid strokes of the brush. During a period of about 50 years some 300 plays—all originally performed in the London theatres—were adapted and published for toy-theatre performance in what came to be called the "Juvenile Drama," and a hundred small printsellers were engaged in publishing the plays and the theatrical portraits for tinseling that often went with them. It was always a home activity, never a professional entertainment, and

provided one of the most popular and creative fireside activities for Regency and Victorian families. Although few new plays adapted for the toy theatre were issued after the middle of the 19th century, a handful of publishers kept the old stock in print until the 20th century. After World War II this peculiarly English toy was revived. Toy theatres also flourished in other European countries during the 19th century: Germany published many plays; Austria published some extremely impressive model-theatre scenery; in France toy-theatre sheets were issued; in Denmark a line of plays for the toy theatre remains in print. The interest of these toy-theatre plays is largely social, as a form of domestic amusement, and theatrical, as a record of scenery, costume, and even dramatic gesture in a particular period of stage history.

Shadow figures. These are a special type of flat figure, in which the shadow is seen through a translucent screen. They may be cut from leather or some other opaque material, as in the traditional theatres of Java, Bali, and Thailand, in the so-called ombres chinoises (French: literally "Chinese shadows") of 18th-century Europe, and in the art theatres of 19th-century Paris; or they may be cut

from coloured fish skins or some other translucent material, as in the traditional theatres of China, India, Turkey, and Greece, and in the recent work of several European theatres. They may be operated by rods from below, as in the Javanese theatres; by rods held at right angles to the screen, as in the Chinese and Greek theatres; or by threads concealed behind the figures, as in the ombres chinoises and in its successor that came to be known as the English galanty show. Shadow figures need not be limited to two dimensions; rounded figures may also be used effectively. A particular type of shadow show that was conceived in terms of film is the silhouette films first made by the German filmmaker Lotte Reiniger in the 1920s; for these films, the screen was placed horizontally, like a tabletop, a light was placed beneath it, the camera was above it, looking downward, and the figures were moved by hand on the screen, being photographed by the stop-action technique. The shadow theatre is a medium of great delicacy, and the insubstantial character of shadow puppets exemplifies all the truest features of puppetry as an art form.

Other types. These five types by no means exhaust every kind of figure or every method of manipulation. There are, for instance, the puppets carried by their manipulators in full view of the audience. The most interesting of these are the Japanese bunraku puppets, which are named for a Japanese puppet master, Uemura Bunrakuken, of the 18th century. These figures, which are one-half to two-thirds life size, may be operated by as many as three manipulators: the chief manipulator controls head movements with one hand by means of strings inside the body, which may raise the eyebrows or swivel the eyes, while using the other hand to move the right arm of the puppet; the second manipulator moves the left arm of the puppet; and the third moves the legs; the coordination of movement between these three artists requires long and devoted training. The magnificent costumes and stylized carving of the bunraku puppets establish them as among the most striking figures of their kind in the world.

Somewhat similar figures, though artistically altogether inferior, are the dummies used by ventriloquists; ventriloquism, as such, has no relation to puppetry, but the ventriloquists' figures, with their ingenious facial movements, are true puppets. The technique of the human actor carrying the puppet actor onto the stage and sometimes speaking for it is one that has been developed a great deal in some experimental puppet theatres in recent years. The human actor is sometimes invisible, through the lighting technique of "black theatre," but is sometimes fully visible. This represents a total rejection of much of

Bunraku puppets

the traditional thinking about the nature of puppetry, but it has become increasingly accepted.

Another minor form of puppet representation is provided by the jiggling puppets, or *marionnettes à la planchette*, that were, during the 18th and 19th centuries, frequently performed at street corners throughout Europe. These small figures were made to dance, more or less accidentally, by the slight variations in the tension of a thread passing through their chests horizontally from the performer's knee to an upright post. Similar were puppets held by short rods projecting from the figures' backs, which were made to dance by bouncing them on a springy board on the end of which the performer sat. The unrehearsed movements of figures like these, when loosely jointed, have a spontaneous vitality that more sophisticated puppets often miss. Another interesting, if elemental, type of puppet, the "scarecrow puppets," or *lileki*, of Slovenia, is constructed from two crossed sticks draped with old clothes; two of these figures are held up on either side of a bench draped with a cloth, under which the manipulator lies. The puppets talk with each other and with a human musician who always joins in the proceedings. The playlets usually end with a fight between the two puppets.

Still another minor puppet form is the finger puppet, in which the manipulator's two fingers constitute the limbs of a puppet, whose body is attached over the manipulator's hand. An even simpler finger puppet is a small, hollow figure that fits over a single finger.

The giant figures that process through the streets of some European towns in traditional festivities are puppets of a kind, though they do not normally enact any plays. The same applies to the dragons that are a feature of street processions in China and are to be found in some places in Europe—as, for example, at Tarascon, Fr. Indeed, when a man hides himself within any external frame or mask, the result may be called a puppet. Many of the puppet theatres in Poland today also present plays acted by actors in masks; the Bread and Puppet Theatre in the United States is another example of the same tendency. The divisions between human actors and puppet actors are becoming increasingly blurred; if, in the past, many puppets tried to look and act like humans, today many human actors are trying to look and act like puppets. Clearly, puppetry is being recognized not merely as a particular form of dramatic craft but as one manifestation of total theatre.

STYLES OF PUPPET THEATRE

Puppet theatre has been presented in many diverse styles and for many different kinds of audience. Throughout history, the chief of these has been the performance of folk or traditional plays to popular audiences. The most familiar examples are the puppet shows that have grown up around a number of national or regional comic heroes

who appear in a whole repertory of little plays. Pulcinella, for example, was a human character in the Italian *commedia dell'arte* who began to appear on the puppet stages early in the 17th century; he was carried around Europe by Italian puppet showmen and everywhere became adopted as a new character, hunchbacked and hook-nosed, in the native puppet plays. In France he became Polichinelle, in England Punch, in Russia Petrushka, and so on. In England alone did this wide repertory of plays based on popular legend become limited to the one basic pattern of the Punch-and-Judy show. At about the time of the French Revolution, at the end of the 18th century, a great many local puppet heroes displaced the descendants of Pulcinella throughout Europe: in France it was Guignol, in Germany Kasperl, in the Netherlands Jan Klaassen, in Spain Christovita, and so on. All these characters are glove puppets; many speak through a squeaker in the mouth of the performer that gives a piercing and unhuman timbre to their voices; and all indulge in the fights and other business typical of glove-puppet shows. It is a mistake, however, to regard them all as the same character; they are distinct national types. In Greece the comic puppet hero is Kararkiózis, a shadow puppet, who originally came from Turkey, where he is known as Karagöz.

The dramatic material in which these popular puppets play is sometimes biblical, sometimes based on folk tales, and sometimes from heroic sagas. A play on the Passion of Christ, for instance, is still presented by the Théâtre Toone in Brussels; the Faust legend has provided the classic theme for the German puppet theatre, and the Temptation of St. Anthony for the French; and the poems of the Italian Renaissance poet Ariosto, handed on through many popular sources, provide the themes of crusading chivalry for the puppet theatres of Sicily and Liège. More specifically dramatic or literary sources were used by the traveling marionette theatres of England and the United States in the 19th century, when popular plays such as *East Lynne* and *Uncle Tom's Cabin* were played to village audiences almost everywhere.

In Asia the same tradition of partly religious and partly legendary sources provides the repertory for the puppet theatres. The chief of these are the Hindu epics *Rāmāyana* and *Mahābhārata*, which provide the basic plots for the puppet theatres of southern India and of Indonesia.

In distinction to these essentially popular shows, the puppet theatre has, at certain periods of history, provided a highly fashionable entertainment. In England, for instance, Punch's Theatre at Covent Garden, London, directed by Martin Powell from 1711 to 1713, was a popular attraction for high society and received many mentions in the letters and journalism of the day. From the 1770s to the 1790s several Italian companies attracted fashionable

audiences and the commendation of Samuel Johnson. In Italy a magnificent puppet theatre was established in the Palace of the Chancery in Rome in 1708, for which Alessandro Scarlatti, with other eminent composers, composed operas. In Austria-Hungary Josef Haydn was the resident composer of operas for a puppet theatre erected by Prince Esterházy about 1770. In France the ombres chinoises of François-Dominique Seraphin had been established at the Palais-Royal, in the heart of fashionable Paris, by 1781. The Italian scene designer Antonio Bibiena painted the scenery for a marionette theatre belonging to a young Bolognese prince, which performed in London in 1780. Exquisite Venetian marionette theatres preserved in the Bethnal Green Museum in London and the Cooper-Hewitt Museum in New York City indicate the elegance of these fashionable puppet theatres of the 18th century.

During the 18th century English writers began to turn to the puppet theatre as a medium, chiefly for satire. The novelist Henry Fielding presented a satiric puppet show, under the pseudonym of Madame de la Nash, in 1748. The caustic playwright and actor Samuel Foote used puppets to burlesque heroic tragedy in 1758 and sentimental comedy in 1773. In a similar vein, the dramatist Charles Dibdin presented a satiric puppet revue in 1775, and a group of Irish wits ran the Patagonian Theatre in London from 1776 to 1781 with a program of ballad operas and literary burlesques. In France there was a great vogue for the puppet theatre among literary men during the second half of the 19th century. This seems to have begun with the theatre created in 1847 at Nohant by George Sand and her son Maurice, who wrote the plays; well over a hundred plays were produced during a period of 30 years. These productions were purely for guests at the house; they are witty, graceful, and whimsical. Some years later another artistic dilettante conceived the idea of presenting a literary puppet show, but this time for the public; Louis Duranty opened his theatre in the Tuileries Gardens in Paris in 1861, but it lacked popular appeal and did not survive in its original form for very long. The next year Duranty's experiment inspired a group of literary and artistic friends to found the Theatron Erotikon, a tiny private puppet theatre, which only ran for two years, presenting seven plays to invited audiences. The moving spirit, however, was Lemerrier de Neuville, who went on to create a personal puppet theatre that played in drawing rooms all over France until nearly the end of the century.

All these literary puppet theatres in France had made use of hand puppets, while the English literary puppeteers of the previous century had used marionettes. In 1887

a French artist, Henri Rivière, created a shadow theatre that enjoyed considerable success for a decade at the Chat Noir café in Paris; Rivière was joined by Caran d'Ache and other artists, and the delicacy of the silhouettes was matched by especially composed music and a spoken commentary. Another type of puppet was introduced to Paris in 1888 when Henri Signoret founded the Little Theatre; this theatre used rod puppets mounted on a base that ran on rails below the stage, the movement of the limbs being controlled by strings attached to pedals. The plays presented were pieces by classic authors—Cervantes, Aristophanes, Shakespeare—and new plays by French poets. The Little Theatre, like all the 19th-century French literary puppet theatres, performed infrequently to small audiences in a bohemian milieu; as a movement, this literary enthusiasm for the puppet theatre had little popular influence, but it served as a witness to the potential qualities of puppet theatre.

The puppet theatre in Japan entered literature with the plays of Chikamatsu Monzaemon (1653–1725). This writer, known as the Shakespeare of Japan, took the form of the existing crude Japanese puppet dramas and developed it into a great art form with over a hundred pieces, many of which remain in the repertoire of the bunraku theatre today. In this form of theatre the text, or *jōruri*, is chanted by a *tayū* who is accompanied by a musician on a three-stringed instrument called a *samisen*.

In Europe the art-puppet movement was continued into the 20th century by writers and artists associated with the Bauhaus, the highly influential German school of design, which advocated a "total" or "organic" theatre. One of its most illustrious teachers, the Swiss painter Paul Klee, created figures of great interest for a home puppet theatre, and others designed marionettes that reflected the ideas of Cubism. The eminent English man of the theatre Gordon Craig campaigned vigorously for the puppet as a medium for the thoughts of the artist. Between World Wars I and II and through the 1950s and '60s, a number of artists endeavoured in difficult economic conditions to demonstrate that puppets could present entertainment of high artistic quality for adult audiences. The marionettes of the Art Puppet Theatre in Munich, for instance, were striking exemplars of the German tradition in deeply cut wood carving. In Austria the Salzburg Marionette Theatre specializes in Mozart operas and has achieved a high degree of naturalism and technical expertise. In Czechoslovakia—a country with a fine puppet tradition—Josef Skupa's marionette theatre presented musical turns interspersed with witty satiric sketches introducing the two characters who gave their names to the theatre: Hurvínek, a precocious boy, and Špejbl, his slow-witted father. In France the prominent artists who designed for Les Comédiens de Bois included the painter Fernand Léger. Yves Joly stripped the art of the puppet to its bare essentials by performing hand puppet acts with his bare hands, without any puppets. The same effect was achieved by the Russian

National preferences

puppeteer Sergey Obraztsov with a performance of charm and wit that was quite different from those of the great rod-puppet theatre that he founded. In England the fine craftsman Waldo Lanchester played an important part in the marionette revival; his productions included the early madrigal opera *L'Amfiparnaso*. Jan Bussell, with the Hogarth Puppets, achieved an international reputation with his marionette ballets and light operas. In London a permanent marionette theatre, the Little Angel, was opened by John Wright in 1961. Other permanent puppet theatres have been established in Birmingham and Norwich and at Biggar near Edinburgh.

In the United States the artistic puppet revival was largely inspired by Ellen Van Volkenburg at the Chicago Little Theatre with productions that included *A Midsummer Night's Dream* in 1916. She later directed plays for Tony Sarg, who became the most important influence in American puppetry, with such large-scale marionette plays as *Rip Van Winkle*, *The Rose and the Ring*, and *Alice in Wonderland*. A small group, the Yale Puppeteers, created a theatre in Hollywood, the Turnabout Theatre, that combined human and puppet stages at opposite ends of the auditorium and attracted fashionable audiences for its songs and sketches from 1941 to 1956. Bil Baird ran a puppet theatre in Greenwich Village, New York City, for some years from 1967 and made a great contribution to every aspect of puppetry. But the lack of the kind of state subsidy that is taken for granted in eastern Europe has made the development of large touring puppet theatres impossible in the United States. Professional puppetry there has developed in three main ways: in large, commercially supported productions for television (see below); in socially involved groups, such as the Bread and Puppet Theatre, which uses giant puppets to carry a political or idealistic message; and—at the other end of the scale—as a medium for intimate tabletop presentations by artists such as Bruce Schwartz, who makes no attempt to conceal himself as he handles a single figure with great delicacy.

Meanwhile, the puppet theatre was continuing on a less exalted plane to demonstrate that it could still provide enjoyable entertainment for popular audiences. From the 1870s a number of English marionette companies had developed the technique of their art to an extraordinarily high level, and their influence was widely spread through Europe, Asia, and America by a series of world tours. Their performances made a great feature of trick effects: there was the dissecting skeleton, whose limbs came apart and then came together again; the Grand Turk, whose arms and legs dropped off to turn into a brood of children while his body turned into their mother; the crinolined lady, who turned into a balloon; the Scaramouch, with three heads; and a host of jugglers and acrobats. The last of the great touring marionette theatres in this tradition was the Theatre of the Little Ones of Vittorio Podrecca, which introduced the marionette pianist and the soprano with heaving bosom that have been widely copied ever since.

During the 20th century there has been an increasing tendency to regard the puppet theatre as an entertainment for children. One of the first people to encourage this development was Count Franz Pocci, a Bavarian court official of the mid-19th century, who wrote a large number of children's plays for the traditional marionette theatre of Papa Schmid in Munich. Important also was Max Jacob, who developed the traditional folk repertoire of the German Kasperltheater, between the 1920s and '50s, into something more suited to modern ideas of what befits children's entertainment. Almost all contemporary puppeteers have created programs for audiences of children.

In this survey of the various styles of puppet theatre in different countries and in different cultures, there are certain features that are common to many otherwise differing forms. In many forms of puppet theatre, for instance, the dialogue is not conducted as if through the mouths of the puppets, but instead the story is recited or explained by a person who stands outside the puppet stage to serve as a link with the audience. This technique was certainly in use in England in Elizabethan times, when the "interpreter" of the puppets is frequently referred to; this character is well illustrated in Ben Jonson's *Bartholomew Fair*, in which

one of the puppets leans out of the booth (they were hand puppets) and hits the interpreter on the head because it does not like the way he is telling the story. The same technique of the reciter is found in the Japanese bunraku theatre, in which the chanter contributes enormously to the full effect and is, indeed, regarded as one of the stars of the company. The technique is also found in the French shadow theatre at the Chat Noir, and its imitators and successors, which depended to a great extent upon the chansonnier. Many recent puppet productions utilize this technique as well. Elsewhere, such as in traditional puppet theatres of Java, Greece, and Sicily, all the speaking is done by the manipulator. The plays consist of a mixture of narration and dialogue, and, though the performer's voice will certainly vary for the different characters, the whole inevitably acquires a certain unity that is one of the most precious attributes of the puppet theatre.

Musical accompaniment is an important feature of many puppet shows. The gamelan gong and cymbal orchestra that accompanies a Javanese wayang performance is an essential part of the show; it establishes the mood, provides the cadence of the puppets' movements, and gives respite between major actions. Similarly, the Japanese samisen supports and complements the chanter. In the operatic puppet theatre of 18th-century Rome, the refined musical scores of Scarlatti and the stilted conventions and long-held gestures of the opera of that time must have been admirably matched by the slow, contrived but strangely impressive movements of the rod puppets. When in 1662 Samuel Pepys visited the first theatre to present Punch in England, he noted in his famous diary that "here among the fiddlers I first saw a dulcimer played on with sticks knocking of the strings, and it is very pretty." Even an old-fashioned Punch-and-Judy show had a drum and panpipes as an overture. Puppets without music can seem rather bald. At one time the gramophone was used extensively by puppeteers, and more recently the tape recorder has provided a more adaptable means of accompanying a puppet performance with music and other sound effects.

Lighting effects can also play an important part in a puppet production. The flickering oil lamp of the Javanese wayang enhances the shadows of the figures on the screen; as long ago as 1781, the scene painter Philip James de Loutherbourg used a large model theatre called the Eidophusikon to demonstrate the range of lighting effects that could be achieved with lamps. Modern methods using ultraviolet lighting have enabled directors of puppet productions to achieve astonishing and spectacular effects.

PUPPETRY IN THE CONTEMPORARY WORLD

The puppet theatre in the contemporary world faces great difficulties and great opportunities. The audiences for the traditional folk theatres have almost disappeared. Punch and Judy on the English beaches and Guignol in the parks of Paris still draw a crowd, but the indoor theatres that once attracted humble audiences survive with difficulty, usually with the aid of a sympathetic town council or a local museum. Puppets are increasingly regarded as an entertainment only for children. They certainly do provide a kind of theatre to which children respond with enthusiasm, and, in the general development of children's theatre, the puppet theatre has a part to play. Some puppeteers are happy to play only for children. But others are eager to play also on an adult level; and, for these, audiences are few. No professional puppet theatre can exist in the West on a purely adult repertoire. Even those theatres that do play for children face great economic difficulties from the small size of audience to which puppets can play and from the modest admission fees that can be charged to children. If a few companies do continue to present performances of quality, this is a tribute to their dedication to their art.

There are some possible means of performance beyond the children's theatre. There are cruise ships and night-clubs, which provide an opportunity for short turns but obviously no scope for serious drama. And there is television. At first sight, television would seem an ideal medium for puppetry, and many puppet shows have in fact appeared on it, but initially the great possibilities that it seemed to offer were not fully realized. A straight transference of

Music and lighting

Opportunities and problems

The "interpreter"

a puppet production to the television screen proved not to be effective, and puppet acts on television were often limited to short presentations on variety shows. Several programs designed for television, sometimes combining puppets with human performers, did, however, gain great success. In England, for instance, Muffin the Mule and his animal friends, manipulated by Ann Hogarth, appeared from 1946 on the top of a piano at which Annette Mills played and sang. In the United States a series featuring the Kuklapolitans, created by Burr Tillstrom, began airing in 1947; Kukla, a small boy, had a host of friends, including Ollie the Dragon, who exchanged repartee with Fran, a human actress standing outside the booth. In 1969, puppets were introduced on the educational program "Sesame Street"; these were created by Jim Henson and represented a type of figure that reached its full potential in "The Muppet Show," which attracted enormous audiences in more than a hundred countries between 1976 and 1981. Henson went on to create puppet films in which fantastic puppet characters were manipulated by radio-controlled mechanisms of extraordinary ingenuity. Another type of television puppetry could be seen in "Spitting Image," a program introduced in 1984 with caricatured puppets designed by Roger Law and Peter Fluck. It consisted of satiric sketches, originally of English politicians and personalities, and represented a revival of the 18th-century tradition of adult satiric puppet theatre.

State
subsidies

The economic difficulties facing puppet companies in western Europe and the United States have been lifted in eastern Europe and China, where the state provides generous subsidies for puppet theatres. Whereas in the West a puppet theatre is lucky if it can afford to pay a company of 5 or 6 performers, it is not unusual for a puppet theatre in the East to employ 50 or 60 performers, artists, and technicians. Interest in the puppet theatre has surged in eastern Europe since World War II, and, while the state supports these theatres, there is very little sign of any direct political propaganda in their programs. The results of all this aid have often been impressive in the sheer weight of numbers and scenic effects, and the productions have often been experimental and imaginative. Mere size, however, does not necessarily guarantee artistic success, and some of the best of these theatres would seem to feel a lack of confidence in their medium by their restless searching for new methods of presentation through "black theatre," mask theatre, and other techniques.

Puppetry
in schools

A great feature of education during the 20th century has been the introduction of puppet making into schools as a craft activity. The difficulties facing professional puppet theatre are entirely absent here, and a puppet performance can synthesize many of the arts and skills of a group of children in making, costuming, and manipulating puppets, in writing plays for them, and in acting them. When this activity was first introduced, undue importance was often placed upon the mere construction of figures according to certain set methods and upon the painstaking preparation of a showing, so that the creative release of the performance was long delayed and sometimes never reached. Today the tendency is to create puppets quickly

Fran Allison with Kukla and Ollie, two puppets created by Burr Tillstrom for the series "Kukla, Fran and Ollie."

Jim Henson (centre) and other puppeteers on the set of "The Muppet Show" watching their performance on video monitors as the television program is taped.

© Henson Associates, 1978

from scrap materials or from natural objects and to perform them impromptu, without rehearsal, as a form of dramatic self-expression. It is from such activities that the therapeutic potentialities of puppets have been utilized by psychiatrists working with disturbed children.

The future of the puppet theatre will certainly be greatly influenced by the cross-fertilization between different traditions in puppetry that will result from puppeteers meeting each other and seeing each other's performances at international festivals of the puppet theatre. These festivals now take place almost every year and are usually sponsored by UNIMA, the Union Internationale de la Marionnette, an international society of puppeteers. Originally founded in 1929 and reconstituted in 1957, UNIMA has members in more than 50 countries and provides a common meeting ground for professional and amateur performers, critics, and enthusiasts. In the meantime traditional styles of puppetry will not be neglected. Many countries now boast national organizations—the Puppeteers of America in the United States and Canada or The Puppet Centre in Great Britain, for example—which promote the differing local traditions of this minor but fascinating art.

Radar

Radar is an electromagnetic sensor used for detecting, locating, tracking, and identifying objects of various kinds at considerable distances. It operates by transmitting electromagnetic energy toward objects, commonly referred to as targets, and observing the echoes returned from them. The targets may be aircraft, ships, spacecraft, automotive vehicles, and astronomical bodies, or even birds, insects, and raindrops. Radar can not only determine the presence, location, and velocity of such objects but can sometimes obtain their size and shape as well. What distinguishes radar from optical and infrared sensing devices is its ability to detect faraway objects under all weather conditions and to determine their range with precision.

Radar is an "active" sensing device in that it has its own source of illumination (a transmitter) for locating targets. In certain respects, it resembles active sonar, which is used chiefly for detecting submarines and other objects underwater; however, the acoustic waves of sonar propagate differently from electromagnetic waves and have different properties. Radar typically operates in the microwave region of the electromagnetic spectrum—namely, at frequencies extending from about 400 megahertz (MHz) to 40 gigahertz (GHz). It has, however, been used at lower

frequencies for long-range applications (frequencies as low as several megahertz, which is the HF, or short-wave, band) and at optical and infrared frequencies (those of laser radar, or lidar). The circuit components and other hardware of radar systems vary with the frequency used, and systems range in size from those small enough to fit in the palm of the hand to those so enormous as to take up several football fields. These differences notwithstanding, the basic principles of operation of all radar systems remain the same.

Radar underwent rapid development during the 1930s and '40s to meet the needs of the military. It is still widely employed by the armed forces, and many advances in radar technology have in fact been subsidized by the military. At the same time, radar has found an increasing number of important civilian applications, notably air traffic control, remote sensing of the environment, aircraft and ship navigation, speed measurement for industrial applications and for law enforcement, space surveillance, and planetary observation.

FUNDAMENTALS OF RADAR

Basic principle. A typical radar operates by radiating a narrow beam of electromagnetic energy into space from an antenna (Figure 1). The narrow antenna beam is scanned to search a region where targets are expected. When a target is illuminated by the beam, it intercepts some of the radiated energy and reflects a portion back toward the radar system. Since most radar systems do not transmit and receive at the same time, a single antenna can be used on a time-shared basis for both transmitting and receiving.

A receiver attached to the output element of the antenna extracts the desired reflected signals and (ideally) rejects those that are of no interest. For example, a signal of interest might be the echo from an aircraft. Signals that are not of interest might be echoes from the ground or rain, which can mask and interfere with the detection of the desired echo from the aircraft. The radar measures the location of the target in range and angular direction. Range is determined by measuring the total time it takes for the radar signal to make the round trip to the target and back (see below). The angular direction of a target is usually found from the direction in which the antenna points at the time the echo signal is received. Through measurement of the location of a target at successive instants of time, its track can be determined. Once this information has been

established, the target's location at a time in the future can be predicted. In many surveillance radar applications, the target is not considered to be "detected" until its track has been established.

Pulse radar. The most common type of radar signal consists of a repetitive train of short-duration pulses. Figure 2 is a simple representation of a sine-wave pulse that might be generated by the transmitter of a medium-range radar designed for aircraft detection. The sine wave in the figure represents the variation with time of the output voltage of the transmitter. The numbers given in brackets in the figure are only meant to be illustrative and are not necessarily those of any particular radar. They are, however, similar to what might be expected for a ground-based radar system with a range of about 50 to 60 nautical miles (or 90 to 110 kilometres), such as the kind used for air traffic control at airports. The pulse width is given in the figure as one millionth of a second (one microsecond). It should be noted that the pulse is shown as containing only a few cycles of the sine wave; however, in a radar system having the values indicated, there would be 1,000 cycles within the pulse. In Figure 2 the time between successive pulses is given as one thousandth of a second (one millisecond), which corresponds to a pulse repetition frequency of 1,000 hertz (Hz; cycles per second). The

Measuring target location in terms of range and angle

Figure 1: Principle of radar operation.

The transmitted pulse has already passed the target, which has reflected a portion of the radiated energy back toward the radar unit.

power of the pulse, called the peak power, is taken here to be 1,000,000 watts (1 megawatt). Since pulse radar does not radiate continually, the average power is much less than the peak power. In this example, the average power is 1,000 watts (1 kilowatt). The average power, rather than the peak power, is the measure of the capability of a radar system. Radars have average powers from a few milliwatts to as much as one or more megawatts, depending on the application.

A weak echo signal from a target might be as low as one trillionth of a watt (10^{-12} watt). In short, the power levels in a radar system can be very large (at the transmitter) and very small (at the receiver).

Another example of the extremes encountered in a radar system is the timing. An air-surveillance radar (one that is used to search for aircraft) might scan its antenna 360 degrees in azimuth in a few seconds, but the pulse width might be about one microsecond in duration. (Some radar pulse widths are 1,000 times smaller—i.e., of nanosecond duration.)

The range to a target is determined by measuring the time that a radar signal takes to travel out to the target and back. Radar waves travel at the same speed as light—roughly 300,000,000 metres per second (or 186,000 miles per second). The range to the target is equal to $cT/2$, where c = velocity of propagation of radar energy, and T = round-trip time as measured by the radar. From this expression, the round-trip travel of the radar signal is at a rate of 150 metres per microsecond. For example, if the time that it takes the signal to travel out to the target and back were measured by the radar to be 600 microseconds (0.0006 second), then the range of the target would be 90 kilometres.

Component parts of a radar system. Figure 3 shows the basic parts of a typical radar system. The transmitter generates the high-power signal that is radiated by the antenna. The antenna is often in the shape of a parabolic reflector, similar in concept to an automobile headlight but much different in construction and size. It also might consist of a collection of individual antennas operating together as a phased-array antenna (see below *Radar subsystems: Antennas*). In a sense, an antenna acts as a “transducer” to couple electromagnetic energy from the transmission line to radiation in space, and vice versa. The duplexer permits alternate transmission and reception with the same antenna; in effect, it is a fast-acting switch that protects the sensitive receiver from the high power of the transmitter.

Figure 2: A typical pulse waveform transmitted by radar.

The receiver selects and amplifies the weak radar echoes so that they can be displayed on a television-like screen for the human operator or be processed by a computer. The signal processor separates the signals reflected by the target (e.g., echoes from an aircraft) from unwanted echo signals (the clutter from land, sea, rain, etc.). It is not unusual for these undesired reflections to be much larger than desired target echoes, in some cases more than one million times larger. Large clutter echoes from stationary objects can be differentiated from small echoes from a moving target by noting the shift in the observed frequency produced by the moving target. This phenomenon is called the Doppler frequency shift (see below).

At the output of the receiver a decision is made (either by the human operator or automatically by a computer circuit) as to whether or not a target echo is present. If the output of the receiver is larger than a predetermined value, a target is assumed to be present.

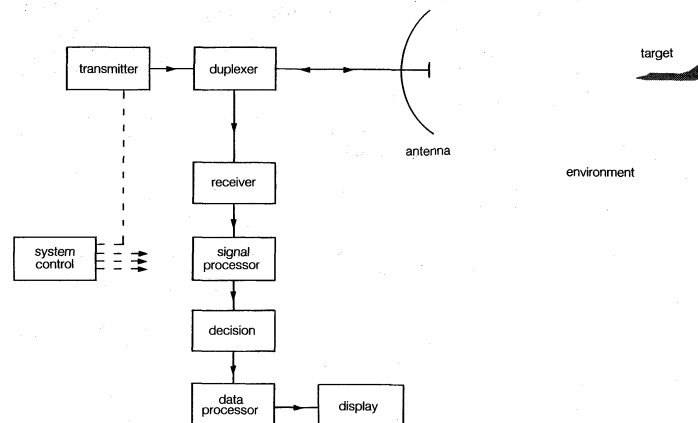

Figure 3: Basic parts of a radar system.

Once it has been decided that a target is present and its location (in range and angle) has been determined, the track of the target can be obtained by measuring the target location at different times. During the early days of radar, target tracking was performed by an operator marking the location of the target “blip” on the face of a cathode-ray tube (CRT) display with a grease pencil. Manual tracking has been largely replaced by automatic electronic tracking, which can process a much greater number of target tracks (many hundreds or even thousands) than can an operator, who can handle only a few simultaneous tracks. Automatic tracking is an example of an operation performed by a data processor.

An example of a radar display is shown in Figure 4. At the left is the unprocessed output of a conventional air-surveillance radar system. This is sometimes called “raw video.” At the right is the processed output with the clutter eliminated and only the moving targets displayed.

The type of signal waveform transmitted and the associated received-signal processing in a radar system might be different depending on the type of target involved and the environment in which it is located. An operator can select the parameters of the radar to maximize performance in a particular environment. Alternatively, electronic circuitry in the radar system can automatically analyze the environment (determine which portions are land, sea, or rain) and select the proper transmitted signal, signal processing, and other radar parameters to optimize performance. The box labeled “system control” in Figure 3 is intended to represent this function. The system control also can provide the timing and reference signals needed to permit the various parts of the radar to operate effectively as an integrated system. (Further descriptions of the major parts of a radar system are given below in the section *Radar subsystems*.)

Target information obtained by radar. The ability to measure the range to a target accurately at long distances and to operate under adverse weather conditions are radar’s most distinctive attributes. There are no other devices that can compete with radar in the measurement of range.

Signal processor

Figure 4: Plan position indicator (PPI) display for an aircraft-surveillance radar system. The radar is located at the centre. The radial direction represents range. The inner ring has a radius of 20 nautical miles, and the outer ring a radius of 40 nautical miles. On the left (A) is the unprocessed output of the radar showing large unwanted clutter echoes as well as the targets beyond the clutter. On the right (B) is the processed output, in which clutter is eliminated by means of an MTI. In (B) the camera shutter remained open for five rotations of the antenna (about one minute) to show the movement of the aircraft detected by the radar. (A) and (B) were not taken at the same time, and so targets seen on one are not the same as on the other.

Courtesy of George Linde, U.S. Naval Research Laboratory

The range accuracy of a simple pulse radar depends on the width of the pulse: the shorter the pulse, the better the accuracy. Short pulses, however, require wide bandwidths in the receiver and transmitter (since bandwidth is equal to the reciprocal of the pulse width). A radar with a pulse width of one microsecond can measure the range to an accuracy of a few tens of metres or better. Some special radars can measure to an accuracy of a few centimetres. The ultimate range accuracy of the best radars is limited not by the radar system itself, but rather by the known accuracy of the velocity at which electromagnetic waves travel. (The calculation of range involves the velocity of the electromagnetic energy transmitted as well as the round-trip time.)

Almost all radars use a directive antenna—*i.e.*, one that directs its energy in a narrow beam. The direction of a target can be found from the direction in which the antenna is pointing when the received echo is at a maximum. (There are other more precise means for determining the direction of a target, of which the monopulse method is probably the most important.) A dedicated tracking radar—one that follows automatically a single target so as to determine its trajectory—generally has a narrow symmetrical “pencil” beam. (A typical beamwidth might be about 1 degree.) Such a radar system can determine the location of the target in both azimuth angle and elevation angle. An aircraft-surveillance radar generally employs an antenna that radiates a “fan” beam, one that is narrow in azimuth (about 1 or 2 degrees) and broad in elevation (elevation beamwidths of from 20 to 40 degrees, or more). A fan beam allows only the measurement of the azimuth angle.

Radar can extract the Doppler frequency shift of the echo produced by a moving target by noting how much the frequency of the received signal differs from the frequency of the signal that was transmitted. (The Doppler frequency shift in radar is similar to the change in audible pitch experienced when listening to a train whistle or the siren of an emergency vehicle when the train or emergency vehicle is moving either toward or away from the listener.) A moving target will cause the frequency of the echo signal to increase if it is approaching the radar or to decrease if it is receding from the radar. For example, if a radar system operates at a frequency of 3,000 megahertz and an aircraft is moving toward it at a speed of 400 knots (740 kilometres per hour), the frequency of the received echo signal will be greater than that of the transmitted signal by about 4.1 kilohertz. The Doppler frequency shift in hertz is equal to $3.4 f_0 v_r$, where f_0 is the radar frequency in gigahertz and v_r is the radial velocity (the rate of change of range) in knots.

Since the Doppler frequency shift is proportional to radial velocity, a radar system that measures such a shift in

frequency can provide the radial velocity of a target. The Doppler frequency shift also is used to separate moving targets (such as aircraft) from stationary ones (land or sea clutter) even when the undesired clutter power might be much greater than the power of the echo from the targets. A form of pulse radar that uses the Doppler frequency shift to eliminate stationary clutter is called either a moving-target indication (MTI) radar or a pulse Doppler radar, depending on the particular parameters of the signal waveform.

The above measurements of range, angle, and radial velocity assume that the target is like a point. Actual targets, however, are of finite size and can have distinctive shapes. The range profile of a finite-sized target can be determined if the range resolution of the radar is small compared to the target's size in the range dimension. (The range resolution of a radar, given in units of distance, is a measure of the ability of a radar to separate two closely spaced echoes.) Some radars can have resolutions smaller than one metre, which is quite suitable for determining the radial size and profile of many targets of interest.

The resolution in angle that can be obtained with conventional antennas is poor compared to that which can be obtained in range. It is possible, however, to achieve good resolution in angle, or cross range, by resolving in Doppler frequency (*i.e.*, separating one Doppler frequency from another). If the radar is moving relative to the target (as when the radar unit is on an aircraft and the target is the ground), the Doppler frequency shift will be different for different parts of the target. Thus the Doppler frequency shift can allow the various parts of the target to be resolved. The resolution in cross range derived from the Doppler frequency shift is far better than that achieved with a narrow-beam antenna. It is not unusual for the cross-range resolution obtained from Doppler frequency to be comparable to that obtained in the range dimension.

Cross-range resolution obtained from Doppler frequency, along with range resolution, is the basis for synthetic aperture radar (SAR). SAR produces an image of a scene that is similar to, but not identical with, an optical photograph. One should not expect the image seen by radar “eyes” to be the same as that observed by optical ones. Each provides different information. Radar and optical images differ because of the large difference in the frequencies involved; optical frequencies are approximately 100,000 times higher than radar frequencies.

The SAR can operate from long range and through clouds or other atmospheric effects that limit optical and infrared imaging sensors. The resolution of a SAR image can be made independent of range, an advantage over passive optical imaging, where the resolution worsens with increasing range. Synthetic aperture radars that map areas of the Earth's surface with resolutions of a few metres can

Doppler
frequency
shift

Synthetic
aperture
radar

provide information about the nature of the terrain and what is on the surface.

A SAR operates on a moving vehicle, such as an aircraft or spacecraft, to image stationary objects or planetary surfaces. Since relative motion is the basis for the Doppler resolution, high resolution (in cross range) also can be accomplished if the radar is stationary and the target is moving. This is called inverse synthetic aperture radar (ISAR). Both the target and the radar can be in motion with ISAR.

Target recognition. Radar can distinguish one kind of target from another (such as a bird from an aircraft), and some systems are able to recognize specific classes of targets (for example, a commercial airliner as opposed to a military jet fighter). Target recognition is accomplished by measuring the size and speed of the target and by observing the target with high resolution in one or more dimensions. Propeller or jet engines modify the radar echo from aircraft and can assist in target recognition. The flapping of the wings of a bird in flight produces a characteristic modulation which can be used to recognize that a bird is present or even to identify one type of bird from another.

DEVELOPMENT OF RADAR

Early experiments. Serious developmental work on radar began in the 1930s, but the basic idea of radar had its origins in the classical experiments on electromagnetic radiation conducted by the German physicist Heinrich Hertz during the late 1880s. Hertz set out to verify experimentally the earlier theoretical work of the Scottish physicist James Clerk Maxwell. Maxwell had formulated the general equations of the electromagnetic field, determining that both light and radio waves are examples of electromagnetic waves governed by the same fundamental laws but having widely different frequencies. Maxwell's work led to the conclusion that radio waves can be reflected from metallic objects and refracted by a dielectric medium just like light waves. Hertz demonstrated these properties in 1888, using radio waves at a wavelength of 66 centimetres (which corresponds to a frequency of about 455 MHz).

The potential utility of Hertz's work as the basis for the detection of targets of practical interest did not go unnoticed at the time. In 1904 a patent for "an obstacle detector and ship navigation device," based on the principles demonstrated by Hertz, was issued in several countries to Christian Hülsmeyer, a German engineer. Hülsmeyer built his invention and demonstrated it to the German navy, but failed to arouse any interest. There was simply no economic, societal, or military need for radar until the early 1930s, when a long-range military bomber capable of carrying large payloads was developed. This prompted the major countries of the world to look for a means with which to detect the approach of hostile aircraft.

Most of the countries that developed radar prior to World War II first experimented with other methods of aircraft detection. These included listening for the acoustic noise of aircraft engines and detecting the electrical noise from their ignition. Researchers also experimented with infrared sensors. None of these, however, proved effective.

First military radars. During the 1930s, efforts to use radio echo for aircraft detection were initiated independently and almost simultaneously in several countries that were concerned with the prevailing military situation and that already had practical experience with radio technology. The United States, Great Britain, Germany, France, the Soviet Union, Italy, and Japan all began experimenting with radar within about two years of one another and embarked, with varying degrees of motivation and success, on its development for military purposes. Most of these countries had some form of operational radar equipment in military service at the start of World War II in 1939.

The first observation of the radar effect at the U.S. Naval Research Laboratory (NRL) in Washington, D.C., was made in 1922. NRL researchers positioned a radio transmitter on one shore of the Potomac River and a receiver on the other. A ship sailing on the river caused fluctuations in the intensity of the received signals when it passed between the transmitter and receiver. (Today, such

a configuration would be called bistatic radar.) In spite of the promising results of this experiment, U.S. Navy officials were unwilling to sponsor further work.

The principle of radar was "rediscovered" at the NRL in 1930 when L.A. Hyland observed that an aircraft flying through the beam of a transmitting antenna caused a fluctuation in the received signal. Although Hyland and his associates at the NRL were enthusiastic about the prospect of detecting targets by radio means and were anxious to pursue its development in earnest, little interest was shown by higher authorities in the navy. Not until it was learned how to use a single antenna for both transmitting and receiving (now termed monostatic radar) was the value of radar for detecting and tracking aircraft and ships fully recognized. Such a system was demonstrated at sea on the battleship USS *New York* in early 1939.

The first radars developed by the U.S. Army were the SCR-268 (at a frequency of 205 MHz) for controlling antiaircraft gunfire and the SCR-270 (at a frequency of 100 MHz) for detecting aircraft. Both of these radars were available at the start of World War II, as was the navy's CXAM shipboard surveillance radar (at a frequency of 200 MHz). It was an SCR-270, one of six available in Hawaii at the time, that detected the approach of Japanese warplanes toward Pearl Harbor, near Honolulu, on Dec. 7, 1941; however, the significance of the radar observations was not appreciated until bombs began to fall.

Britain commenced radar research for aircraft detection in 1935. The British government encouraged engineers to proceed rapidly because they were quite concerned about the growing possibility of war. By September 1938, the first British radar system, the Chain Home, went into 24-hour operation and remained operational throughout the war. The Chain Home radars allowed Britain to successfully deploy its limited air defenses against the heavy German air attacks conducted during the early part of the war. They operated at about 30 MHz—in what is called the short-wave, or high-frequency (HF), band—which is actually quite a low frequency for radar. It might not have been the optimum solution, but the inventor of British radar, Sir Robert Watson-Watt, believed that something that worked and was available was better than an ideal solution that was only a promise or might arrive too late.

The Soviet Union also started working on radar during the 1930s. At the time of the German attack on their country in June 1941, the Soviets had developed several different types of radars and had in production an aircraft-detection radar that operated at 75 MHz (in the very-high-frequency [VHF] band). Their development and manufacture of radar equipment was disrupted by the German invasion, and the work had to be relocated.

At the beginning of World War II, Germany had progressed further in the development of radar than any other country. The Germans employed radar on the ground and in the air for defense against Allied bombers. Radar was installed on a German pocket battleship as early as 1936. Radar development was halted by the Germans in late 1940 because they believed the war was almost over. The United States and Britain, however, accelerated their efforts. By the time the Germans realized their mistake, it was too late to catch up.

Except for some German radars that operated at 375 and 560 MHz, all of the successful radar systems developed prior to the start of World War II were in the VHF band, below about 200 MHz. The use of VHF frequencies posed several problems. First, beamwidths are broad. (Narrow beamwidths yield greater accuracy, better resolution, and the exclusion of unwanted echoes from the ground or other clutter.) Second, the VHF portion of the electromagnetic spectrum does not permit the wide bandwidths required for the short pulses that allow for greater accuracy in range determination (see above *Fundamentals of radar: Target information obtained by radar*). Third, VHF frequencies are subject to atmospheric noise, which limits receiver sensitivity. In spite of these drawbacks, VHF represented the frontier of radio technology in the 1930s, and radar development at this frequency range constituted a genuine pioneering accomplishment. It was well understood by the early developers of radar that operation at

Contributions of Maxwell and Hertz

British Chain Home radar system

Invention
of the
magnetron

even higher frequencies was desirable, particularly since narrow beamwidths could be achieved without excessively large antennas. (The beamwidth of an antenna of fixed size is inversely proportional to the radar frequency.)

Advances during World War II. The opening of higher frequencies (those of the microwave region) to radar, with its attendant advantages, came about in late 1939 when the cavity magnetron oscillator was invented by British physicists at the University of Birmingham. In 1940 the British generously disclosed to the United States the concept of the magnetron, which then became the basis for the work undertaken by the newly formed Massachusetts Institute of Technology (MIT) Radiation Laboratory at Cambridge, Mass. It was the magnetron that made microwave radar a reality in World War II. (For a description of the magnetron, see the article *ELECTRONICS: Principal devices and components: Electron tubes.*)

The successful development of innovative and important microwave radars at the MIT Radiation Laboratory has been attributed to the urgency for meeting new military capabilities as well as to the enlightened and effective scientific management of the laboratory and the recruiting of talented, dedicated scientists. Approximately 150 different radar systems were developed as a result of the laboratory's program during the five years of its existence (1940–45).

One of the most notable microwave radars developed by the MIT Radiation Laboratory was the SCR-584, a widely used gunfire-control system. It employed conical scan tracking, and, with its four-degree beamwidth, it had sufficient angular accuracy to place antiaircraft guns on target without the need for searchlights or optics, as was required with the older VHF SCR-268 gun-laying radar, which had very wide beamwidths. The SCR-584 operated in the frequency range from 2.7 to 2.9 GHz (in the S band) and had a parabolic reflector antenna with a diameter of nearly two metres (six feet). It was first used in combat early in 1944 on the Anzio beachhead in Italy. Its introduction was timely, since the Germans by that time had learned how to jam its predecessor, the SCR-268. The introduction of the SCR-584 microwave radar caught the Germans unprepared.

Radar technology since the mid-1940s. After the war, progress in radar technology slowed considerably. The last half of the 1940s was devoted principally to developments initiated during the war. Two of these were the monopulse tracking radar and the MTI radar (see above). It required many more years of developmental work to bring these two radar techniques to full capability.

New and better radar systems emerged during the 1950s. One of these was a highly accurate monopulse tracking radar designated the AN/FPS-16, which was capable of an angular accuracy of about 0.1 milliradian (roughly 0.006 degree). There also appeared large, high-powered radars designed to operate at 220 MHz (VHF) and 450 MHz (UHF [ultrahigh frequency]). These systems, equipped with large mechanically rotating antennas (more than 120 feet [36 metres] in horizontal dimension), could reliably detect aircraft at very long ranges. Another notable development was the klystron amplifier, which provided a source of stable high power for very long-range radars. Synthetic aperture radar first appeared in the early 1950s, but took almost 30 more years to reach a high state of development with the introduction of digital processing and other advances. The airborne pulse Doppler radar also was introduced in the late 1950s in the Bomarc air-to-air missile.

The decade of the 1950s also saw the publication of important theoretical concepts that helped put radar design on a more quantitative basis. These included the statistical theory of detection of signals in noise; the so-called matched filter theory, which showed how to configure a radar receiver to maximize detection of weak signals; the Woodward ambiguity diagram, which made clear the trade-offs in waveform design for good range and radial velocity measurement and resolution; and the basic methods for Doppler filtering in MTI radars, which later became important when digital technology allowed the theoretical concepts to become a practical reality.

The Doppler frequency shift and its utility for radar were

known before World War II, but it took years of developmental work to achieve the technology necessary for wide-scale adoption. Serious application of the Doppler principle to radar began in the 1950s, and today the principle has become vital in the operation of many radar systems. As previously explained, the Doppler frequency shift of the reflected signal results from the relative motion between the target and the radar. Doppler frequency is indispensable in continuous wave (CW; see below), MTI, and pulse Doppler radars, which all must detect moving targets in the presence of large clutter echoes. The detection of the Doppler frequency shift is the basis for the police speed meter. SAR and ISAR imaging radars make use of Doppler frequency to generate high-resolution images of terrain and targets. The Doppler frequency shift also has been used to measure the velocity of the aircraft carrying the radar system. The extraction of the Doppler shift in weather radars, moreover, allows the identification of severe storms not possible by other techniques.

The first large electronically steered phased-array radars were put into operation in the 1960s. Airborne MTI radar for aircraft detection was developed for the U.S. Navy's Grumman E-2A airborne-early-warning (AEW) aircraft at this time. Many of the attributes of HF over-the-horizon radar (see below *Examples of radar systems*) were demonstrated during the 1960s, as were the first radars designed for detecting ballistic missiles and satellites.

During the 1970s digital technology underwent a tremendous advance, which made practical the signal and data processing required for modern radar. Digital processing allowed radar to achieve what was known to be theoretically possible but difficult to realize by other methods. Significant advances also were made in airborne pulse Doppler radar, greatly enhancing its ability to detect aircraft in the midst of heavy ground clutter. The U.S. Air Force's airborne warning and control system (AWACS) radar and military airborne intercept radar depend on the pulse Doppler principle. It might be noted too that radar began to be used in spacecraft for remote sensing of the environment during the 1970s.

Over the next decade radar methods evolved to a point where they were able to distinguish one type of target from another. Serial production of phased-array radars for air defense (the Patriot and Aegis systems), airborne bomber radar (B-1B aircraft), and ballistic missile detection (Pave Paws) also became feasible during the 1980s. Advances in remote sensing made it possible to measure winds at sea, the geoid (the Earth's figure that corresponds to mean sea level), ocean roughness, ice conditions, and other environmental effects. Solid-state technology, including very large-scale integration (VLSI) and integrated microwave circuitry, permitted new radar capabilities that were only academic curiosities a decade or two earlier.

Continued advances in computer technology in the 1990s allowed increased information about the nature of targets and the environment to be obtained from radar echoes. The introduction of Doppler weather radar systems (as, for example, Nexrad), which measure the radial component of wind speed as well as the rate of precipitation, provided new hazardous weather warning capability. Unattended radar operation with little downtime for repairs was demanded of manufacturers for such applications as air traffic control. HF over-the-horizon radar systems were operated by several countries, primarily for the detection of aircraft at very long ranges over large areas of the oceans. Space-based radars continued to gather information about the Earth's land and sea surfaces on a global basis. Improved imaging radar systems were carried by space probes to obtain higher-resolution pictures of the surface of Venus.

RADAR SUBSYSTEMS

Figure 3 (see above) shows the major subsystems that make up a typical radar system. These subsystems are described in greater detail here.

Antennas. A widely used form of radar antenna is the parabolic reflector, the principle of which is shown in cross section in Figure 5 (A). A horn antenna or other small antenna is placed at the focus of the parabola to illuminate

Impact
of digital
technology

The
klystron

Satellite-
borne
radar
systems

the parabolic surface of the reflector. After being reflected by this surface, the electromagnetic energy is radiated as a narrow beam. A paraboloid, which is generated by rotating a parabola about its axis, forms a symmetrical beam called a pencil beam. A fan beam, one with a narrow beamwidth in azimuth and a broad beamwidth in elevation, can be obtained by illuminating an asymmetrical section of the paraboloid. An example of an antenna that produces a fan beam is shown below in Figure 6.

The half-wave dipole (Figure 5 [B]), whose dimension is one-half of the radar wavelength, is the classic type of electromagnetic antenna. A single dipole is not of much use for radar, since it produces a beamwidth too wide for most applications. Radar requires a narrow beam (a beamwidth of only a few degrees) in order to concentrate its energy on the target and to determine the target location with accuracy. Such narrow beams can be formed by combining many individual dipole antennas so that the signals radiated or received by each elemental dipole are in unison, or in step. (The radar engineer would say that the signals are "in phase" with one another or that they are coherently added together.) This is called a phased-array antenna, the basic principle of which is shown in Figure 5 (C).

The phase shifters at each radiating antenna-element shift the phase of the signal, so that all signals received from a particular direction will be in step with one another. (As a result of this, the power radiated from the elements adds together.) Similarly, all signals radiated by the individual elements of the antenna will be in step with one another in some specific direction. Changing the phase shift at each element alters the direction of the antenna beam. An antenna of this kind is called an electronically steered phased-array. It allows rapid changes in the position of the beam without moving large mechanical structures. In some systems, the beam can be changed from one direction to another within microseconds.

The individual radiating elements of a phased-array antenna need not be dipoles; various other types of antenna elements also can be used. For example, slots cut in the side of a waveguide are common, especially at the higher microwave frequencies. In a radar that requires a one-degree, pencil-beam antenna, there might be about 5,000 individual radiating elements (the actual number depends on the particular design). The phased-array radar is more complex than radar systems that employ reflector antennas, but it provides capabilities not otherwise available.

Since there are many control points (each individual antenna element) in a phased-array, the radiated beam can be shaped to give a desired pattern to the beam. Controlling the shape of the radiated beam is important when the beam has to illuminate the air space where aircraft are found but not illuminate the ground, where clutter echoes are produced. Another example is when the stray radiation (called antenna sidelobes) outside the main beam of the antenna pattern must be minimized.

The electronically steered phased-array is attractive for applications that require large antennas or when the beam must be rapidly changed from one direction to another. Satellite surveillance radars and ballistic missile detection

radars (such as the system shown below in Figure 8) are examples that usually require phased-arrays. The U.S. Army's Patriot battlefield air-defense system and the U.S. Navy's Aegis system for ship air-defense also depend on the electronically steered phased-array antenna.

The phased-array antenna is also used without the phase shifters in Figure 5 (C). The beam is steered by the mechanical movement of the entire antenna. Antennas of this sort are preferred over the parabolic reflector for airborne applications (see Figure 7), in land-based air-surveillance radars requiring multiple beams (as in the so-called 3D radars, which measure elevation angle in addition to azimuth and range), and in applications that require ultralow antenna sidelobe radiation.

Transmitters. The transmitter of a radar system must be efficient, reliable, not too large in size and weight, and easily maintained, as well as have the wide bandwidths and high power that are characteristic of radar applications. In MTI, pulse Doppler, and CW applications, the transmitter must generate noise-free, stable transmissions so that extraneous (unwanted) signals from the transmitter do not interfere with the detection of the small Doppler frequency shift produced by weak moving targets.

It was observed earlier that the invention of the magnetron transmitter in the late 1930s resulted in radar systems that could operate at the higher frequencies known as microwaves. The magnetron transmitter has certain limitations, but it continues to be widely used—generally in low-average-power applications such as ship navigation radar and airborne weather-avoidance radar. The magnetron is a power oscillator in that it self-oscillates (*i.e.*, generates microwave energy) when voltage is applied. Other radar transmitters usually are power amplifiers in that they take low-power signals at the input and amplify them to high power at the output. This provides stable high-power signals, as the signals to be radiated can be generated with precision at low power.

The klystron amplifier is capable of some of the highest power levels used in radar. It has good efficiency and good stability. The disadvantages of the klystron are that it is usually large and it requires high voltages (*e.g.*, about 90 kilovolts for one megawatt of peak power). At low power the instantaneous bandwidth of the klystron is small, but the klystron is capable of large bandwidth at high peak powers of a few megawatts.

The traveling-wave tube (TWT) is related to the klystron. It has very wide bandwidths at low peak power, but, as the peak power levels are increased to those needed for radar, its bandwidth decreases. As peak power increases, the bandwidths of the TWT and the klystron approach one another.

Solid-state transmitters, such as the silicon bipolar transistor, are attractive because of their potential for long life, ease of maintenance, and relatively wide bandwidth. An individual solid-state device generates relatively low power and can be used only when the radar application can be accomplished with low power (as in short-range applications or in the radar altimeter). High power can be achieved, however, by combining the outputs of many individual solid-state devices.

While the solid-state transmitter is easy to maintain and is capable of wide-band operation, it has certain disadvantages. It is much better suited for long pulses (milliseconds) than for the short pulses (microseconds). Long pulses can complicate radar operation because signal processing (such as pulse compression) is needed to achieve the desired range resolution. Furthermore, a long-pulse radar generally requires several different pulse widths: a long pulse for long range and one or more shorter pulses to observe targets at the ranges masked when the long pulse is transmitting. (A one-millisecond pulse, for example, masks echoes from 0 to about 80 nautical miles.)

Every kind of transmitter has its disadvantages as well as advantages. In any particular application, the radar engineer must continually search for compromises that give the results desired without too many negative effects that cannot be adequately accommodated.

Receivers. Like most other receivers, the radar receiver is a classic superheterodyne. It has to filter the desired

Electronically steered phased-array

Solid-state transmitters

Figure 5: Radar antennas.

(A) A parabolic reflector antenna in which the energy radiated from the focus is reflected from the parabolic surface as a narrow beam. (B) A dipole antenna. (C) A phased-array antenna composed of many individual radiating elements.

echo signals from unwanted clutter signals and receiver noise that interfere with detection. It also must amplify the weak received signals to a level where the receiver output is large enough to actuate a display or a computer. The technology of the radar receiver is well established and seldom sets a limit on radar performance.

The receiver must have a large dynamic range in situations where it is necessary to detect weak signals in the presence of very large clutter echoes by recognizing the Doppler frequency shift of the desired moving targets. Dynamic range can be loosely described as the ratio of the largest to the smallest signals that can be handled adequately by a receiver without distortion. A radar receiver might be required to detect signals that vary in power by a million to one—and sometimes much more.

In most cases, the sensitivity of a radar receiver is determined by the noise generated internally at its input. Because it does not generate much noise of its own, a transistor is usually used as the first stage of a receiver.

Signal and data processors. The signal processor is the part of the receiver that extracts the desired signal and rejects clutter. Doppler filtering in an MTI radar or in a pulse Doppler system is an example. Most signal processing is performed digitally with computer technology. Digital processing has significant capabilities in signal processing not previously available with analog methods. Without digital methods many of the signal processing techniques found in today's high-performance radars would not be possible. Digital processing also has made practical data processing, such as required for automatic tracking.

Pulse compression (described below) is sometimes included under signal processing. It too benefits from digital technology, but analog processors (*e.g.*, surface acoustic wave delay-lines) are used rather than digital methods when pulse compression must achieve resolutions of a few metres or less.

Displays. The cathode-ray tube has been the traditional means of displaying the output of a radar system. Although it has its limitations, the CRT has been the preferred technology ever since the early days of radar. The CRT has undergone continual improvement that has made it even more versatile.

The radar display shown in Figure 4 is an example of a plan position indicator, or PPI. It is a maplike presentation in polar coordinates of range and angle. The CRT screen is dark (other than for slight noise background) except when echo signals are present. The PPI is called an intensity-modulated display because the intensity of the electron beam of the CRT is increased sufficiently to excite the phosphor of the screen whenever an echo signal is present. The PPI is the most common form of display in use with radar. Another variety, the B-scope, is also an intensity-modulated display that presents the same information and the same coordinates as the PPI but in rectangular rather than polar format. In still another format, the A-scope, the received signal amplitude is displayed as the vertical coordinate and the range as the horizontal coordinate. The A-scope is called an amplitude-modulated display because echo signals are indicated by the increased amplitude (the vertical coordinate) on the CRT. The A-scope is not a suitable display for a surveillance radar that must search 360 degrees in azimuth, but it is used for tracking radars and in experimental radars when examining the nature of the echo signal is important.

All practical radar displays have been two dimensional (*i.e.*, they use a flat screen), yet most radars provide more information than can be displayed on the two coordinates of a flat screen. Colour coding of the intensity-modulated signal on the PPI is sometimes used to provide additional information about the echo signal. Colour has been employed, for example, to indicate the strength of the echo. Doppler weather radars make good use of colour coding to indicate on a two-dimensional display the rain intensity associated with each echo shown. They also utilize colour to indicate the radial speed of the wind, the wind shear, and other information relating to severe storms. The PPI displays targets as if seen in a horizontal plane. On the other hand, a range-height indicator, or RHI, is an intensity-modulated display that presents the echoes that

appear in a vertical plane—*e.g.*, a vertical cut through the cloud of a severe storm.

The radar display has benefited from the availability of digital technology. Digital memory allows the radar to store data from an entire scan period (usually one rotation of the radar antenna) and present the information to the operator all at once (as in the case of a television-type monitor) rather than display targets only when they are actually within the antenna beam. This allows the operator to view the entire scene all the time and to manipulate the output to display the type of target information of most interest.

Modern surveillance radars rarely display the output of a radar receiver without further processing (raw video). When automatic detection of targets is employed in a radar system, the rejection of unwanted echoes such as land or sea clutter, the addition of the radar pulses received from a target, and the decision as to whether a target is present or not are all performed electronically without assistance from a human operator. The display then shows only detected targets without the background noise. This has been called a "cleaned-up" display or processed video. When automatic tracking is performed electronically (in a digital data processor), only processed target tracks are displayed and no individual target detections are indicated. The speed of a target and its direction of travel can be indicated on the CRT by the length of the line defining the track and its orientation. Near each target track on the display, alphanumeric information can be entered automatically to indicate information that is known about the target. For example, when the air-traffic-control radar-beacon system (ATCRBS) is used in conjunction with an air-surveillance radar, the alphanumeric data on the display can indicate the flight number of the aircraft and its altitude.

TYPES OF RADAR

Radar systems may be categorized according to the function they perform—*e.g.*, aircraft surveillance, surface (ground or sea) surveillance, space surveillance, tracking, weapon control, missile guidance, instrumentation, remote sensing of the environment, intruder detection, or underground probing. They also may be classified, as in the listing below, on the basis of the particular radar technique they employ. It is difficult to give in only a few words precise and readily understandable descriptions of the many types of radar available. The following survey is necessarily brief and qualitative. Additional information about each radar type can be found in the books listed in the *Bibliography*.

Simple pulse radar. This is by far the most widely used technique and constitutes what might be termed "conventional" radar. (For a discussion of its fundamentals, see above *Fundamentals of radar: Pulse radar*.) All but the last two techniques outlined below employ a pulse waveform; however, they have additional features that give an enhanced performance as compared to simple pulse radar.

Moving-target indication (MTI) radar. This is a form of pulse radar that uses the Doppler frequency shift of the received signal to detect moving targets, such as aircraft, and to reject the large unwanted echoes from stationary clutter that do not have a Doppler shift. Almost all ground-based aircraft surveillance radar systems use some form of MTI.

Airborne moving-target indication (AMTI) radar. An MTI radar in an aircraft encounters problems not found in a ground-based system of the same kind because the large undesired clutter echoes from the ground and the sea have a Doppler frequency shift introduced by the motion of the aircraft carrying the radar. The AMTI radar, however, compensates for the Doppler frequency shift of the clutter, making it possible to detect moving targets even though the radar unit itself is in motion.

Pulse Doppler radar (with high pulse-repetition frequency). As with the MTI system, the pulse Doppler radar is a type of pulse radar that utilizes the Doppler frequency shift of the echo signal to reject clutter and detect moving aircraft. However, it operates with a much higher pulse-repetition frequency (prf) than the MTI radar. (A high-prf pulse Doppler radar, for example, might have a prf of 100

Digital
processing

Colour
coding

Radars
with high
resolution

kHz, as compared to an MTI radar with prf of perhaps 300 Hz.) The difference of prfs gives rise to distinctly different behaviour. The MTI radar uses a low prf in order to obtain an unambiguous range measurement. This causes the measurement of the target's radial velocity (as derived from the Doppler frequency shift) to be highly ambiguous and can result in missing some target detections. On the other hand, the pulse Doppler radar operates with a high prf so as to have no ambiguities in the measurement of radial velocity. A high prf, however, causes a highly ambiguous range measurement. The true range is resolved by transmitting multiple waveforms with different prfs.

Pulse Doppler radar (with medium pulse-repetition frequency). A modified form of pulse Doppler radar that operates at a lower prf (10 kHz, for example) than the above-mentioned high-prf pulse Doppler system has both range and Doppler shift ambiguities. It is, however, better for detecting aircraft with low closing speeds than high-prf pulse Doppler radar (which is better for detecting aircraft with high closing speeds). An airborne medium-prf pulse Doppler radar might have to use seven or eight different prfs in order to extract the target information without ambiguities.

High-range-resolution radar. This type of radar uses a very short pulse with range resolution from several metres to a fraction of a metre. Such a radar can profile a target and measure its projected length in the range dimension.

Pulse-compression radar. The ability to generate very short pulses with high peak power (and high energy) is limited for practical reasons by voltage breakdown, or arcing. Thus, conventional high-range-resolution radars with short pulses often are limited in peak power and are not capable of operating at long ranges. Pulse compression overcomes this limitation by obtaining the resolution of a short pulse but with the energy of a long pulse. It does this by modulating either the frequency or the phase of a long, high-energy pulse. The frequency or phase modulation allows the long pulse to be compressed in the receiver by an amount equal to the reciprocal of the signal bandwidth.

Synthetic aperture radar (SAR). The SAR was described above as utilizing resolution in Doppler frequency to provide the equivalent of cross-range (or angle) resolution. More often, it is regarded as a synthetic antenna generated by a moving radar. The effect of a large antenna is obtained by storing the echo signals in a storage medium, or memory, and processing a substantial number of the previously received echoes just as if they were received by a large antenna. This kind of radar is primarily used for mapping the Earth's surface. Although it is not obvious, the two different models used for describing a SAR—a synthetic antenna and Doppler-frequency resolution—are equivalent and produce the same results.

Inverse synthetic aperture radar (ISAR). As previously noted, an ISAR depends on target motion to provide the Doppler frequency shift between various parts of the target and the radar unit so as to obtain high resolution in cross range. A two-dimensional high-resolution image of a target can be obtained by using ISAR for cross-range resolution in conjunction with either a short pulse or pulse-compression radar for resolution in the range dimension.

Side-looking airborne radar (SLAR). This variety of airborne radar employs a large side-looking antenna (*i.e.*, one whose beam is perpendicular to the aircraft's line of flight) and is capable of high range resolution. (The resolution in cross range is not as good as can be obtained with SAR, but it is simpler than the latter and is acceptable for some applications.) SLAR generates maplike images of the ground and permits detection of ground targets.

Imaging radar. Synthetic aperture, inverse synthetic aperture, and side-looking airborne radar techniques are sometimes referred to as imaging radars.

Tracking radar. This kind of radar continuously follows a single target in angle and range to determine its path, or trajectory, and to predict its future position. There are two classes of tracking radars: conical scan and monopulse. The conical scan tracker is simpler but not as accurate as the monopulse variety. Furthermore, monopulse tracking is not as susceptible to some forms of electronic countermeasure as the conical scan. The single-target tracking

radar provides target location almost continuously. A typical tracking radar might measure the target location at a rate of 10 times per second.

Track-while-scan radar. This form of surveillance radar can provide tracks of all targets within its area of coverage by measuring the location of targets on each rotation of the antenna. Though called track-while-scan radar, it is more often known as automatic detection and tracking, or ADT. The output on a visual display from such a radar usually consists of the tracks of the targets (vectors showing direction and speed) rather than individual detections (blips). This type of tracking is suitable for surveillance radars, while continuous tracking is more appropriate for weapon control and instrumentation-radar applications (see below *Major applications of radar*).

3D radar. Conventional air-surveillance radar measures the location of a target in two dimensions—range and azimuth. The elevation angle, from which target height can be derived, also can be determined. The so-called 3D radar is an air-surveillance radar that measures range in a conventional manner but that has an antenna which is mechanically rotated about a vertical axis to obtain the azimuth angle of a target and which has either fixed multiple beams in elevation or a scanned pencil beam to measure its elevation angle. There are other types of radar (such as electronically scanned phased arrays and tracking radars) that measure the target location in three dimensions, but a radar that is properly called 3D is an air-surveillance system that measures the azimuth and elevation angles as just described.

Electronically scanned phased-array radar. An electronically scanned phased-array antenna can position its beam rapidly from one direction to another without mechanical movement of large antenna structures. Agile, rapid beam switching permits the radar to track many targets simultaneously and to perform other functions as required.

Continuous-wave (CW) radar. Since a CW radar transmits and receives at the same time, it must depend on the Doppler frequency shift produced by a moving target to separate the weak echo signal from the strong transmitted signal. A simple CW radar can detect targets, measure their radial velocity (from the Doppler frequency shift), and determine the direction of arrival of the received signal. However, a more complicated waveform is required for finding the range of the target.

Frequency-modulated continuous-wave (FM-CW) radar. If the frequency of a CW radar is continually changed with time, the frequency of the echo signal will differ from that transmitted and the difference will be proportional to the range of the target. Accordingly, measuring the difference between the transmitted and received frequencies gives the range to the target. In such a frequency-modulated continuous-wave radar, the frequency is generally changed in a linear fashion, so that there is an up-and-down alternation in frequency. The most common form of FM-CW radar is the radar altimeter used on aircraft to determine height above the ground. Phase modulation, rather than frequency modulation, of the CW signal has also been used to obtain range measurement.

FACTORS AFFECTING RADAR PERFORMANCE

The performance of a radar system can be judged by the following: (1) the maximum range at which it can see a target of a specified size, (2) the accuracy of its measurement of target location in range and angle, (3) its ability to distinguish one target from another, (4) its ability to detect the desired target echo when masked by large clutter echoes, unintentional interfering signals from other "friendly" transmitters, or intentional radiation from hostile jamming (if a military radar), (5) its ability to recognize the type of target, and (6) its availability (ability to operate when needed), reliability, and maintainability. Some of the major factors that affect performance are discussed in this section.

Transmitter power and antenna size. The maximum range of a radar system depends in large part on the average power of its transmitter and the physical size of its antenna. (In technical terms, this is the power-aperture product.) There are practical limits to each. As noted

before, some radar systems have an average power of roughly one megawatt. Phased-array radars about 100 feet in diameter are not uncommon; some are much larger. Likewise, mechanically scanned reflector antennas about 100 feet or larger in size can be found. There are specialized radars with (fixed) antennas, such as some HF over-the-horizon radars and the U.S. Space Surveillance System (SPASUR), that extend more than one mile.

Receiver noise. The sensitivity of a radar receiver is determined by the unavoidable noise that appears at its input. At microwave radar frequencies, the noise that limits its detectability is usually generated by the receiver itself (*i.e.*, by the random motion of electrons at the input of the receiver) rather than by external noise that enters the receiver via the antenna. The radar engineer often employs a transistor amplifier as the first stage of the receiver even though lower noise can be obtained with more sophisticated devices. This is an example of the application of the basic engineering principle that the "best" performance that can be obtained might not necessarily be the solution that best meets the needs of the user.

The receiver is designed to enhance the desired signals and to reduce the noise and other undesired signals that interfere with detection. The designer attempts to maximize the detectability of weak signals by using what radar engineers call a "matched filter," which is a filter that maximizes the signal-to-noise ratio at the receiver output. The matched filter has a precise mathematical formulation that depends on the shape of the input signal and the character of the receiver noise. A suitable approximation to the matched filter for the ordinary pulse radar, however, is one whose bandwidth in hertz is the reciprocal of the pulse width in seconds.

Target size. The size of a target as "seen" by radar is not always related to the physical size of the object. The measure of the target size as observed by radar is called the radar cross section and is given in units of area (square metres). It is possible for two targets with the same physical cross sectional area to differ considerably in radar size, or radar cross section. For example, a flat plate one square metre in area will produce a radar cross section of about 1,000 square metres at a frequency of 3,000 megahertz (S band; see below) when viewed perpendicular to the surface. A cone-sphere (an object resembling an ice-cream cone) when viewed in the direction of the cone rather than the sphere could have a radar cross section one thousandth of a square metre even though its projected area is also one square metre. In theory, this value does not depend to a great extent on the size of the cone or the cone angle. Thus the flat plate and the cone-sphere can have radar cross sections that differ by a million to one even though their physical projected areas are the same.

The sphere is an unusual target in that its radar cross section is the same as its physical cross section area (when its circumference is large compared to the radar wavelength). That is to say, a sphere with a projected area of one square metre has a radar cross section of one square metre.

Commercial aircraft might have radar cross sections from about 10 to 100 square metres, except when viewed broadside, where it is much larger. (This is an aspect that is seldom of interest, however.) Most air-traffic-control radars are required to detect aircraft with a radar cross section as low as two square metres, since some small general-aviation aircraft can be of this value. For comparison, the radar cross section of a man has been measured at microwave frequencies to be about one square metre. A bird can have a cross section of 0.01 square metre. Although this is a small value, a bird can be readily detected at ranges of several tens of miles by long-range radar. In general, many birds can be picked up by radar so that special measures must usually be taken to insure that echoes from birds do not interfere with the detection of desired targets.

The radar cross section of an aircraft and most other targets of practical interest is not a constant but, rather, fluctuates rapidly as the aspect of the target changes with respect to the radar unit. It would not be unusual for a slight change in aspect to cause the radar cross section to change by a factor of 10 to 1,000. (Radar engineers have

to take this fluctuation in the radar cross section of targets into account in their design.)

Clutter. Echoes from land, sea, rain, snow, hail, birds, insects, auroras, and meteors are of interest to those who observe and study the environment, but they are a nuisance to those who want to detect and follow aircraft, ships, missiles, or other similar targets. Clutter echoes can seriously limit the capability of a radar system; thus a significant part of radar design is devoted to minimizing the effects of clutter without reducing the echoes from desired targets. The Doppler frequency shift is the usual means by which moving targets are distinguished from the clutter of stationary objects. Detection of targets in rain is less of a problem at the lower frequencies, since the radar echo from rain decreases rapidly with decreasing frequency and the average cross section of aircraft is relatively independent of frequency in the microwave region. Because raindrops are more or less spherical (symmetrical) and aircraft are asymmetrical, the use of circular polarization can enhance the detection of aircraft in rain. With circular polarization, the electric field rotates at the radar frequency. Because of this, the electromagnetic energy reflected by the rain and the aircraft will be affected differently, thereby making it easier to distinguish between the two. (In fair weather, most radars use linear polarization—*i.e.*, the direction of the field is fixed.)

Atmospheric effects. As was mentioned, rain and other forms of precipitation can cause echo signals that mask the desired target echoes. There are other atmospheric phenomena that can affect radar performance as well. The decrease in density of the Earth's atmosphere with increasing altitude causes radar waves to bend as they propagate through the atmosphere. This usually increases the detection range at low angles to a slight extent. The atmosphere can form "ducts" that trap and guide radar energy around the curvature of the Earth and allow detection at ranges beyond the normal horizon. Ducting over water is more likely to occur in tropical climates than in colder regions. Ducts can sometimes extend the range of an airborne radar, but on other occasions they may cause the radar energy to be diverted and not illuminate regions below the ducts. This results in the formation of what are called radar holes in the coverage. Since it is not predictable or reliable, ducting can in some instances be more of a nuisance than a help.

Loss of radar energy, when propagation is through the clear atmosphere or rain, is usually insignificant for systems operating at microwave frequencies.

Interference. Signals from nearby radars and other transmitters can be strong enough to enter a radar receiver and produce spurious responses. Well-trained operators are not often deceived by interference, though they may find it a nuisance. Interference is not as easily ignored by automatic detection and tracking systems, however, and so some method is usually needed to recognize and remove interference pulses before they enter the automatic detector and tracker of a radar.

Electronic countermeasures. The purpose of hostile electronic countermeasures (ECM) is to deliberately degrade the effectiveness of military radar. ECM can consist of (1) noise jamming that enters the receiver via the antenna and increases the noise level at the input of the receiver, (2) false target generation, or repeater jamming, by which hostile jammers introduce additional signals into the radar receiver in an attempt to confuse the receiver into thinking they are real target echoes, (3) chaff, which is an artificial cloud consisting of a large number of tiny metallic reflecting strips that create strong echoes over a large area to mask the presence of real target echoes or to create confusion, and (4) decoys, which are small, inexpensive air vehicles or other objects designed to appear to the radar as if they were real targets. Military radars are also subject to direct attack by conventional weapons or by antiradiation missiles (ARMs) that use radar transmissions to find the target and home on it.

Military radar engineers have developed various ways of countering hostile ECM and maintaining the ability of a radar system to perform its mission. It might be noted that a military radar system can often accomplish its

Detecting
targets
during
rainfall

Radar
cross
section

mission satisfactorily even though its performance in the presence of ECM is not what it would be if such measures were absent.

MAJOR APPLICATIONS OF RADAR

Areas of application. Over the years, radar has found many and varied uses for both civilian and military purposes. A sampling of some of the more significant applications is given here.

Military. Radar originally was developed to meet the needs of the military, and it continues to have significant application for military purposes. It is used to detect aircraft, missiles, artillery and mortar projectiles, ships, land vehicles, and satellites. In addition, radar controls, guides, and fuzes weapons; allows one class of target to be distinguished from another; aids in the navigation of aircraft and ships; performs reconnaissance; and determines the damage caused by weapons to targets. The importance of radar in modern warfare is borne out by the many measures designed to negate its effectiveness (in addition to direct attack, which is an option for any military target of value). Attempts to degrade military radar capability include electronic warfare (jamming, deception, chaff, decoys, and interception of radar signals), antiradiation missiles that home on radar transmissions, reduced radar cross-section targets to make detection more difficult (stealth), and high-power microwave energy transmissions to degrade or burn out sensitive receivers. A major objective of military radar development is to insure that a radar system can continue to perform its mission in spite of the various measures that attempt to degrade it.

Air traffic control. Radar supports air traffic control by providing surveillance of aircraft and weather in the vicinity of airports as well as en route between airports. In the United States and elsewhere, airport surveillance radar (ASR) is employed at most major airports. It is designed to detect both commercial aircraft and general aviation aircraft, as well as precipitation, in the area around an air terminal. A larger system, the air route surveillance radar (ARSR), tracks aircraft en route. It has a range of about 200 nautical miles. Many major airports also employ airport surface detection equipment (ASDE), which is a high-resolution radar that provides the airport controller with the location and movement of ground targets within the airport, including service vehicles and taxiing aircraft. The location of dangerous weather phenomena such as "downbursts" (downward blasts of air associated with storms that have been identified as a major cause of fatal weather-related aircraft accidents) can be pinpointed with a specially configured terminal Doppler weather radar (TDWR) located near airports. Radar also has been used to "talk down" pilots to safe landings in adverse weather conditions. This is called ground-controlled approach (GCA) by the military.

Remote sensing. One of the early applications of remote sensing involved the observation of rainfall. The radar measurement of the radial velocity of precipitation (from the Doppler frequency shift) in conjunction with the strength of the reflected signals (reflectivity) can indicate the severity of storms, as well as provide other important information for reliable weather forecasting (see also CLIMATE AND WEATHER: *Meteorological measurement and weather forecasting: History of weather forecasting: Modern trends and developments: Application of radar*).

Astronomers have made radar observations of meteors, auroras, and certain planets. Synthetic aperture radars on orbiting spacecraft have mapped the surface of Venus beneath the ever-present cloud cover that blocks observation at optical wavelengths. Space-based radar systems have measured the Earth's geoid and ocean roughness. An important application of imaging radar from either aircraft or spacecraft is the surveillance of sea ice; information about pack ice distribution and concentration is used to route shipping in cold-weather regions.

Radar has even been used to study the movement of birds and insects at distances and under conditions where visual observation would not be possible.

Aircraft navigation. The radar altimeter measures the height of an airplane above the local terrain, Doppler

navigation radar determines the plane's own speed and direction, and high-resolution radar mapping of the ground contributes to its navigation. Radars carried aboard aircraft also provide information about the location of dangerous weather so that it can be avoided. Military aircraft can fly at low altitudes with the aid of terrain-avoidance and terrain-following radars that warn of obstacles.

Ship safety. Small, relatively simple radar systems on board ships aid in piloting and collision avoidance. Similar radars on land provide harbour surveillance.

Space applications. Radars have been used in space for rendezvous, docking, and landing of spacecraft. Since size and weight are important in space, the same equipment is used on a time-shared basis aboard the U.S. Space Shuttle both as radar to allow rendezvous with (and sometimes retrieve) other spacecraft and as a two-way data link to relay satellites that communicate with ground stations. Besides providing remote sensing of the Earth's surface (see above), radar carried by orbiting spacecraft is able to monitor rainfall over the oceans. Large land-based radar systems permit the detection and tracking of satellites and space debris.

Law enforcement. The familiar police radar is a relatively simple, low-power continuous-wave system that measures the speed of vehicles by detecting the Doppler frequency shift introduced in the echo signal by a moving vehicle. The Doppler shift is directly proportional to the radial speed of the vehicle. (A similar kind of CW radar is used to measure the speed of a baseball to determine how fast a pitcher can throw.) Radar also has been used in security systems for intrusion detection; it can "sense" the movement of people attempting to penetrate a protected area.

Instrumentation. Surveyors may make use of special radars to measure distances. CW radars are used to measure speed in certain industrial applications; the sensor does not make contact with the object whose speed is to be determined. Instrumentation radars are employed at missile test ranges for precision tracking of targets.

Radar applications by frequency. Each radar application seems to have a particular frequency band to which it is best suited. The various types of application found at the different radar frequency bands are surveyed below. The frequency letter-band nomenclature used here is that approved by the Institute of Electrical and Electronic Engineers (IEEE Standard 521-1984). These letter bands also are recognized by the U.S. Department of Defense and are listed in its Index of Specifications and Standards.

HF (3 to 30 MHz). Although the first British radar system, Chain Home (see above), operated in the HF band, it is ordinarily not a good frequency region for radar. Antenna beamwidths are very wide, the available bandwidths are narrow, the spectrum is crowded with other users, and the external noise (both natural noise and noise due to other transmitters) is high. There is, nevertheless, an important application for radar in this band—namely, long-range radar, which takes advantage of refraction by the ionosphere to extend ranges by an order of magnitude greater than can be obtained by ground-based microwave aircraft-detection radars. The ionosphere is a region of ionized gases produced by solar radiation at altitudes from about 80 to 400 kilometres or higher. The ions bend radio waves enough to return to Earth at considerable distances (see below *Examples of radar systems: Over-the-horizon radar*).

VHF (30 to 300 MHz). For reasons similar to those cited above, this frequency band is not too popular for radar. However, very long-range radars for either aircraft or satellite detection can be built at the VHF band more economically than at higher frequencies. Radar operations at such frequencies are not bothered by rain clutter or insects, but auroras and meteors produce large echoes that can interfere with target detection.

UHF (300 to 1,000 MHz). Military airborne early warning (AEW) radars operate in the UHF band to detect aircraft in the midst of clutter. This is a good frequency range for detecting extraterrestrial targets (e.g., satellites and missiles), since large antennas and high power are readily obtained for this application.

Police radar

Promoting civilian air safety

Scientific applications of radar

Frequency band for AEW radar

L band (1,000 to 2,000 MHz). This is the preferred frequency band for long-range (200 nautical miles) air surveillance radar, such as the air-traffic control systems used to track aircraft en route between airports. It also is a band of interest for military space surveillance and missile detection because it is not as susceptible to nuclear blackout effects as radar systems that operate at the lower frequencies.

S band (2 to 4 GHz). Medium-range (50 to 60 nautical miles) airport surveillance radars are well suited for this band. It is the preferred frequency band for long-range weather observation radars. Military 3D radars that determine elevation angle as well as range and azimuth angle are often in S band, but they may also be at L band. Frequencies lower than S band are good for long-range surveillance, since large power, large antennas, and good moving-target detection are better there than at high frequencies. Frequencies greater than S band are preferred for extracting target information, as in tracking radars and weapon-control systems. Therefore, when a single frequency must be used for both surveillance and information extraction (as is necessary when only a single-frequency phased-array antenna is employed), S band can be a compromise.

C band (4 to 8 GHz). Single-frequency phased-array radars that must perform both surveillance and weapon control for air defense operate at these frequencies as well as at S band. This frequency region is well suited for long-range, precision-tracking radars.

X band (8 to 12 GHz). This is a band frequently used for shipboard civil marine radar, tracking radar, airborne weather-avoidance radar, systems for detecting mortar and artillery projectiles, and police speed meters. Most synthetic aperture radars operate at X band; the exceptions are some remote-sensing SARs that are designed for lower frequencies.

K band (12 to 40 GHz). Radars at this frequency band are usually of short range, because it is difficult to obtain the large antennas and large power necessary for long-range applications. This band has been used for airborne radar and for short-range airport surface detection (ASDE).

Millimetre waves (40 to 300 GHz). Although there has been much interest in exploring the potential of radars at millimetre wavelengths, it has not been practical for most applications because of high attenuation even in the "clear" atmosphere. It is difficult to use millimetre-wave radar for anything other than short range (a few kilometres) within the atmosphere. For deployment in outer space where there is no atmosphere to attenuate these frequencies, millimetre-wave radar, however, can be considered.

Laser radar. Laser radars, which operate at infrared and optical frequencies, also suffer from attenuation by the atmosphere, especially in bad weather, and therefore are of limited utility. Laser radar systems, however, have been used for precision range-finding in weapon control and for distance measuring in surveying. They also have been considered for use on board spacecraft to probe the nature of the atmosphere.

EXAMPLES OF RADAR SYSTEMS

Airport surveillance radar. This is a medium-range radar system capable of reliably detecting and tracking aircraft at altitudes below 25,000 feet and within 40 to 60 nautical miles of the airport where it is located. Systems of this type have been installed at more than 100 major airports throughout the United States. The ASR-9 is designed to be operable at least 99.9 percent of the time, which means that the system is down less than 10 hours per year. This high availability is attributable to reliable electronic components, a "built-in test" to search for failures, remote monitoring, and redundancy (*i.e.*, the system has two complete channels except for the antenna; when one channel must be shut down for repair, the other continues to operate). The ASR-9 is designed to operate unattended with no maintenance personnel at the radar site. A number of radar units can be monitored and controlled from a single location. When trouble occurs, the fault is identified and a maintenance person dispatched for repair.

Echoes from rain that mask the detection of aircraft are

reduced by the use of Doppler filtering and other techniques devised to separate moving aircraft from undesired clutter. It is important for air-traffic controllers to recognize areas of severe weather so that they can direct aircraft safely around, rather than through, rough or hazardous conditions. The ASR-9 has a separate receiving channel that recognizes weather echoes and provides their location to air traffic controllers. Six different levels of precipitation intensity can be displayed, either with or without the aircraft targets superimposed.

The ASR-9 system operates within S band from 2.7 to 2.9 GHz. Its klystron transmitter has a peak power of 1.3 megawatts, a pulse width of 1 microsecond, and an antenna with a horizontal beamwidth of 1.4 degrees that rotates at 12.5 revolutions per minute (4.8-second rotation period).

The reflector antenna shown in Figure 6 is a section of a paraboloid. It is 16.5 feet wide and 9 feet high. Atop the radar (riding piggyback) is a lightweight planar-array antenna for the air-traffic-control radar-beacon system. Its dimensions are 26 feet by 5.2 feet. ATCRBS is the primary means for detecting and identifying aircraft equipped with a transponder that can reply to the ATCRBS interrogation. The ATCRBS transmitter, which is independent of the radar system and operates at a different frequency, radiates a coded interrogation signal. Aircraft equipped with a suitable transponder can recognize the interrogation and send a coded reply at a frequency different from the interrogation frequency. The interrogator might then ask the aircraft, by means of other coded signals, to automatically identify itself and to report its altitude. ATCRBS only works with cooperative targets (*i.e.*, those with an operational transponder).

Doppler weather radar. For many years radar has been used to provide information about the intensity and extent of rain and other forms of precipitation. This application of radar is well known in the United States from the familiar television weather reports of precipitation observed by the radars of the National Weather Service. A major improvement in the capability of weather radar came about when engineers developed new radars that could measure the Doppler frequency shift in addition to the magnitude of the echo signal reflected from precipitation. The Doppler frequency shift is important because it is related to the radial velocity of the precipitation blown by wind (the component of the wind moving either toward or away from the radar installation). Since tornadoes, mesocyclones (which spawn tornadoes), hurricanes, and

other hazardous weather phenomena tend to rotate, the radial wind speed, as a function of angle (as is measured by Doppler radar), will identify rotating weather patterns. (Rotation is indicated when the measurement of the Doppler frequency shift shows that the wind is coming toward the radar at one angle and away from it at a nearby angle.)

Nexrad

The pulse Doppler weather radars employed by the National Weather Service, known as Nexrad, make quantitative measurements of precipitation, warn of potential flooding or dangerous hail, provide wind speed and direction, indicate the presence of wind shear and gust fronts, track storms, predict thunderstorms, and provide other meteorologic information. In addition to measuring precipitation (from the intensity of the echo signal) and radial velocity (from the Doppler frequency shift), Nexrad can also measure the spread in radial speed (difference between the maximum and the minimum speeds) of the precipitation particles within each radar resolution cell. The spread in radial speed is an indication of wind turbulence.

Another improvement in the weather information provided by Nexrad is the digital processing of radar data, a procedure that renders the information in a form that can be interpreted by an observer who is not necessarily a fully trained meteorologist. The computer automatically identifies severe weather effects and indicates their nature on a CRT display viewed by the observer. High-speed communication lines integrated with the Nexrad system allow timely weather information to be transmitted for display to various users.

The Nexrad radar operates at frequencies from 2.7 to 3.0 GHz (S band) and is equipped with a 25-foot-diameter antenna. It takes five minutes to scan its 1 degree beamwidth through 360 degrees in azimuth and from 0 to 20 degrees in elevation. The Nexrad system can measure rainfall up to a distance of 460 kilometres and determine its radial velocity as far as 230 kilometres.

A serious weather hazard to aircraft in the process of landing or taking off from an airport is the downburst, or microburst. This is the above-mentioned strong downdraft that causes wind shear capable of forcing aircraft to the ground. Terminal Doppler weather radar is the name of the type of system at airports that is specially designed to detect dangerous microbursts. It is similar in principle to Nexrad, but is a shorter-range system since it only has to observe dangerous weather phenomena in the vicinity of an airport. It also operates at a higher frequency (C band) to avoid interference with the Nexrad and ASR systems (which operate at S band).

Airborne combat radar. A modern combat aircraft is generally required not only to intercept hostile aircraft but also to attack surface targets on the ground or on the sea.

The radar that serves such an aircraft must have the capabilities to perform these distinct military missions. This is not easy because each mission has different requirements. The different ranges, accuracies, and rates at which the radar data is required, the effect of the environment (land or sea clutter), and the type of target (land features or moving aircraft) call for different kinds of radar waveforms (different pulse widths and pulse repetition frequencies). In addition, an appropriate form of signal processing is required to extract the particular information needed for each military function. Radar for combat aircraft must therefore be multimode—i.e., operate with different waveforms, signal processing, and antenna scanning. It would not be unusual for an airborne combat radar to have from 8 to 10 air-to-air modes and 6 to 10 air-to-surface modes. Furthermore, the radar system might be required to assist in rendezvous with a companion combat craft or with a refueling aircraft, provide guidance as to air-to-air missiles, and counter hostile electronic jamming. The problem of achieving effectiveness with these many modes is a challenge for the radar designer and is made more difficult by the limited size and weight available on combat aircraft.

Multi-mode systems

The AN/APG-66 radar built for the U.S. F-16 fighter is shown in Figure 7. This is a pulse Doppler radar system that operates in the X-band region of the spectrum. The version of this radar for the British Hawk 200 aircraft occupies a volume of less than three cubic feet, weighs less than 237 pounds, and requires an input power of 2.25 kilowatts. It can search 120 degrees in azimuth and elevation and is supposed to have a range of 35 nautical miles in the "look-up" mode and 27.5 nautical miles in the "look-down" mode. The look-up mode is a more or less conventional radar mode with a low pulse-repetition-frequency that is used when the target is at medium or high altitude and no ground clutter echoes are present to mask target detection. The look-down mode uses a medium-prf pulse Doppler waveform and signal processing that provide target detection in the presence of heavy clutter. (A low prf for an X-band combat radar might be from 250 Hz to 5 kHz, a medium prf from 5 to 20 kHz, and a high prf from 100 to 300 kHz.) Radars for larger combat aircraft can have greater capability but are, accordingly, bigger and heavier than the system just described.

Ballistic missile detection and satellite surveillance radar. The systems for detecting and tracking ballistic missiles and orbiting satellites are much larger than those for aircraft detection because the ranges are longer. Such radars might be required to have maximum ranges of 2,000 to 3,000 nautical miles, as compared with 200 nautical miles for a typical long-range aircraft detection system. The average power of the transmitter might be from several hundred kilowatts to one megawatt or more, which is about 100

By courtesy of Westinghouse Electric Corporation

Figure 7: The AN/APG-66 radar in an F-16 fighter aircraft. The mechanically scanned planar phased-array antenna with radiating horizontal slots is 29 inches wide by 19 inches high.

times greater than the average power of radars designed for aircraft detection. Antennas for this application have dimensions on the order of tens of metres to a hundred metres or more and are electronically scanned phased-array antennas capable of steering the radar beam without moving large mechanical structures. Radar systems so equipped are commonly found at the lower frequencies (typically at frequency bands of 420–450 MHz and 1,215–1,400 MHz).

The Pave Paws radar (or AN/FPS-115) is a UHF (420–450 MHz) phased-array system for detecting submarine-launched ballistic missiles. It is supposed to detect targets with a radar cross section of 10 square metres at a range of 3,000 nautical miles. The array antenna contains 1,792 active elements within a diameter of 72.5 feet. It can be expanded to 102 feet. Each active element is a module with its own solid-state transmitter, receiver, duplexer, and phase shifter. The total average power per antenna is about 145 kilowatts. Two antennas, such as shown in Figure 8, make up a system, with each capable of covering a sector 120 degrees in azimuth. Vertical coverage is from 3 to 85 degrees. An upgraded variant of this type of radar is used in the Ballistic Missile Early Warning System (BMEWS) network, with installations in Alaska, Greenland, and England. BMEWS is designed to provide warning of intercontinental ballistic missiles. Each array antenna measures almost 84 feet across and has 2,560 active elements identical to those of the Pave Paws system. Both the BMEWS and Pave Paws radars detect and track satellites and other space objects in addition to warning of the approach of ballistic missiles.

Ground-probing radar. Radar waves are usually thought of as being reflected from the surface of the ground. At the lower frequencies (below several hundred megahertz) radar energy, however, can propagate into the ground and be reflected from buried objects. The loss in propagating in the ground is very high at these frequencies, but low enough to permit ranges of about 1 to 10 metres or more. This is sufficient for detecting buried utility pipes and cables, probing the subsurface soil, detecting underground tunnels, and monitoring the subsurface conditions of highways and bridge roadways. (The ranges in ice can be much greater because the propagation loss is less in ice than in most soils.) The short ranges require that the radar system be able to resolve closely spaced objects, which means wide-bandwidth signals must be radiated. Normally, wide bandwidth is not available at the lower frequencies (especially when a 30-centimetre range resolution requires a 500 MHz bandwidth). However, since the energy is directed into the ground rather than radiated into

space, the large frequency band needed for high resolution can be obtained without interference to other users of the radio spectrum.

A ground-probing radar might radiate over frequencies ranging from 5 to 500 MHz in order to obtain good penetration (which requires low frequencies) with high resolution (which requires wide bandwidth). The antenna can be placed directly on the ground. The radar unit is small in size and so is portable.

Over-the-horizon radar. Radars at frequencies lower than 100 or 200 MHz are not desirable for radar application except in special cases. The ground-probing radar mentioned above is one such special case; here a radar at the lower frequencies can provide a capability not available with other types of radar or other sensors. Another example where lower frequencies can provide a unique and important capability is in the short wave, or HF, portion of the radio band (from 3 to 30 MHz). The advantage of the HF band is that radio waves of these frequencies are refracted (bent) by the ionosphere so that the waves return to the Earth's surface at long distances beyond the horizon, as shown in Figure 9. This permits target detection at distances from about 500 to 2,000 nautical miles. Thus, an HF OTH radar can detect aircraft at distances up to 10 times that of a ground-based microwave air-surveillance radar whose range is limited by the curvature of the Earth. Besides detection and tracking of aircraft at long ranges, an HF OTH radar can be designed to detect ballistic missiles (particularly the disturbance caused by ballistic missiles as they travel through the ionosphere), ships, and weather effects over the ocean. Winds over the ocean generate waves on the water that can be detected by OTH radar. From the Doppler frequency spectrum produced by echoes from the water waves, one can determine the direction of the waves generated by the wind and, hence, the direction of the wind itself. The strength of the waves (which indicates the state of the sea, or roughness) also can be ascertained. Timely information about the winds that drive waves over a wide expanse of the ocean can be valuable for weather prediction because it is difficult to obtain similar information in other ways.

An HF OTH radar might have an average power of one megawatt or more and have phased-array antennas that sometimes extend several thousands of feet. Radar systems of this variety are especially useful for observing large areas that are not easily covered by microwave radar, as, for example, expanses of oceans.

BIBLIOGRAPHY. Complete basic information on all forms of radar is presented in MERRILL I. SKOLNIK, *Introduction to Radar Systems*, 2nd ed. (1980); and MERRILL I. SKOLNIK (ed.), *Radar Handbook*, 2nd ed. (1990), a comprehensive reference work written for radar engineers, covering the various aspects of radar technology. S.S. SWORDS, *Technical History of the Beginnings of Radar* (1986), surveys the developments prior to World War II, focusing on early European achievements. HENRY E. GUERLAC, *Radar in World War II*, 2 vol. (1987), is an excellent, authoritative history written by a professional historian with a background in science. MERRILL I. SKOLNIK (ed.), *Radar Applications* (1988), is a collection of technical papers describing the various applications of radar, such as air traffic control, military air defense, aircraft and spacecraft surveillance, and remote sensing of the environment. DAVID K. BARTON, *Modern Radar System Analysis* (1988), provides a fine technical presentation of many aspects of radar design.

(M.I.S.)

Radiation

Radiation consists of a flow of atomic and subatomic particles and of waves, such as those that characterize heat rays, light rays, and X rays. All matter is constantly bombarded with radiation of both types from cosmic and terrestrial sources. This article delineates the properties and behaviour of radiation and the matter with which it interacts and describes how energy is transferred from radiation to its surroundings. Considerable attention is devoted to the consequences of such an energy transfer to living matter, including the normal effects on many

life processes (*e.g.*, photosynthesis in plants and vision in animals) and the abnormal or injurious effects that result from the exposure of organisms to unusual types of radiation or to increased amounts of the radiations commonly encountered in nature. The applications of various forms of radiation in medicine and technological fields are touched upon as well.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 111, 112, and 128. The article is divided into the following sections:

General background

TYPES OF RADIATION

Radiation may be thought of as energy in motion either at speeds equal to the speed of light in free space—approximately 3×10^{10} centimetres (186,000 miles) per second—or at speeds less than that of light but appreciably greater than thermal velocities (*e.g.*, the velocities of molecules forming a sample of air). The first type constitutes the spectrum of electromagnetic radiation that includes radio waves, microwaves, infrared rays, visible light, ultraviolet rays, X rays, and gamma rays, as well as the neutrino (see below). These are all characterized by zero mass when (theoretically) at rest. The second type includes such particles as electrons, protons, and neutrons. In a state of rest, these particles have mass and are the constituents of atoms and atomic nuclei. When such forms of particulate matter travel at high velocities, they are regarded as radiation. In short, the two broad classes of radiation are unambiguously differentiated by their speed of propagation and corresponding presence or absence of rest mass. In the discussion that follows, those of the first category are referred to as “electromagnetic rays” (plus the neutrino) and those of the second as “matter rays.”

At one time, electromagnetic rays were thought to be inherently wavelike in character—namely, that they spread out in space and are able to exhibit interference when they come together from two or more sources. (Such behaviour is typified by water waves in the way they propagate and periodically reinforce and cancel one another.) Matter rays, on the other hand, were considered to be inherently particle-like in character—*i.e.*, localized in space and incapable of interference. During the early 1900s, however, major experiments and attendant theories revealed that all forms of radiation, under appropriate conditions, can exhibit both particle-like and wavelike behaviour. This is referred to as the wave-particle duality and provides in large part the foundation for the modern quantum theory of matter and radiation. The wave behaviour of radiation is apparent in its propagation through space, while the particle behaviour is revealed by the nature of interactions with matter. Because of this, care must be exercised to use the terms waves and particles only when appropriate.

Electromagnetic rays and neutrinos. *Visible light and the other components of the electromagnetic spectrum.* According to the theory of relativity, the velocity of light is a fixed quantity independent of the velocity of the emitter, the absorber, or a presumably independent observer, all

Basic
character-
istics

three of which do affect the velocities of common wave-like disturbances such as sound. In an extended definition, the term light embraces the totality of electromagnetic radiation. It includes the following: the long electromagnetic waves predicted by the British physicist James Clerk Maxwell in 1864 and discovered by the German physicist Heinrich Hertz in 1887 (now called radio waves); infrared and ultraviolet rays; the X rays discovered in 1895 by Wilhelm Conrad Röntgen of Germany; the gamma rays that accompany many radioactive-decay processes; and some even more energetic (with higher energy) X rays and gamma rays produced as the normal accompaniment of the operations of ultrahigh-energy machines (*i.e.*, particle accelerators such as the Van de Graaff generator, the cyclotron and its variants, and the linear accelerator).

The behaviour of light seems to have interested ancient philosophers but without stimulating them to experiment, though all of them were impressed by vision. The first meaningful optical experiments on light were performed by the English physicist and mathematician Isaac Newton (beginning in 1666), who showed (1) that white light diffracted by a prism into its various colours can be reconstituted into white light by a prism oppositely arranged and (2) that light of a particular colour selected from the diffracted spectrum of a prism cannot be further diffracted into beams of other colour by an additional prism. Newton hypothesized that light is corpuscular in its nature, each colour represented by a different particle speed, an erroneous assumption. Furthermore, in order to account for the refraction of light, the corpuscular theory required, contrary to the wave theory of the Dutch scientist Christiaan Huygens (developed at about the same time), that light corpuscles travel with greater velocity in the denser medium. Support for the wave theory came in the electromagnetic theory of Maxwell (1864) and the subsequent discoveries of Hertz and of Röntgen of both the very long and the very short waves Maxwell had included in his theory. The German physicist Max Planck proposed a quantum theory of radiation to counter some of the difficulties associated with the wave theory of light, and in 1905 Einstein proposed that light is composed of quanta (later called photons). Thus, experiment and theory had led around from particles (of Newton) that behave like waves (Huygens) to waves (Maxwell) that behave like particles (Einstein), the apparent velocity of which is unaffected by the velocity of the source or the velocity of the receiver. Furthermore it was found, in 1922, that the shorter-wavelength electromagnetic radiations (*e.g.*, X rays) have momentum such as may be expected of particles, part of which can be transferred to electrons with which they collide (*i.e.*, the Compton effect).

Neutrinos and antineutrinos. Neutrinos and their antiparticles are forms of radiation similar to electromagnetic rays in that they travel at the speed of light and have little or no rest mass and zero charge. They too are produced by ultrahigh-energy particle accelerators and certain types of radioactive decay (see below).

Matter rays. Unlike X rays and gamma rays, some high-energy radiations travel at less than the speed of light. Some of these were identified initially by their particulate nature and only later were shown to travel with wavelike character. One example of this kind of radiation is the electron, first established as a negatively charged particle in 1897 by the English physicist Joseph John Thomson and later as the component of beta rays emitted by radioactive elements. The electron was shown by the American physicist Robert Millikan in 1910 to have a fixed charge and by George Paget Thomson, an English physicist, and the American physicists Clinton J. Davisson and Lester H. Germer (1927) to have wavelike as well as particulate character. Electrons classified as radiation have velocities that range from as low as 10^8 centimetres per second to almost the speed of light. The negative electron, still commonly called an electron, is identified more precisely as a negatron. In 1932 the American physicist Carl Anderson demonstrated the existence of a positive electron, generally called a positron and identified as one of the antiparticles of matter. The collision of a positron and an electron results in the intermediate production of a short-

lived atomlike system called positronium, which decays in about 10^{-7} second into two gamma rays. Other entities commonly classified as matter when traveling with high velocity include the positively charged nucleus of the hydrogen atom, or proton; the nucleus of deuterium (*i.e.*, heavy hydrogen, the nucleus of which has double the mass of normal hydrogen's nucleus), or deuteron, also positively charged; and the nucleus of the helium atom, or alpha particle, which has a double positive charge. The more-massive positive nuclei of other atoms show similar wavelike properties when sufficiently accelerated in an electric field. All charged matter rays have a charge exactly equal to that of the negative or positive electron or to some integral multiple of that charge.

The neutron also is a matter ray. It is emitted in certain radioactive-decay processes and in fission, the process in which a nucleus splits into two smaller nuclei. The neutron decays in free space with a 12- to 13-minute half-life—*i.e.*, one-half of any given number of neutrons decay within 12–13 minutes, each into a proton and a negatron plus an antineutrino (see above). The mass of the neutron approximates that of the hydrogen atom, about 1,850 times the mass of the electron.

Another class of the so-called elementary particles is the meson, which comes both positively and negatively charged (*i.e.*, with the same charge as that of an electron), as well as electrically neutral. The masses of mesons are always greater than those of electrons, and most have a mass less than that of the proton; a few have slightly greater mass. Although all mesons are classified as matter rays when traveling at high velocities, they are so few that their chemical effects are not presently studied. Because they are part of the constant bombardment from free space to which all matter is constantly exposed, however, they may have considerable effects, such as contributing to the processes of aging and evolution.

THE STRUCTURE AND PROPERTIES OF MATTER

Matter in bulk comprises particles that, compared to radiation, may be said to be at rest, but the motion of the molecules that compose matter, which is attributable to its temperature, is equivalent to travel at the rate of hundreds of metres per second. Although matter is commonly considered to exist in three forms, solid, liquid, and gas, a review of the effects of radiation on matter must also include mention of the interactions of radiation with glasses, attenuated (low-pressure) gases, plasmas, and matter in states of extraordinarily high density. A glass appears to be solid but is actually a liquid of extraordinarily high viscosity, or a mixture of such a liquid and embedded microcrystalline material, which unlike a true solid remains essentially disorganized at temperatures much below its normal freezing point. Low-pressure gases are represented by the situation that exists in free space, in which the nearest neighbour molecules, atoms, or ions may be literally centimetres apart. Plasmas, by contrast, are regions of high density and temperature in which all atoms are dissociated into their positive nuclei and electrons. (For a detailed description of the various states of matter, see MATTER.)

The capability of analyzing and understanding matter depends on the details that can be observed and to an important extent on the instruments that are used. Bulk, or macroscopic, matter is detectable directly by the senses supplemented by the more common scientific instruments, such as microscopes, telescopes, and balances. It can be characterized by measurement of its mass and, more commonly, its weight, by magnetic effects, and by a variety of more sophisticated techniques, but most commonly by optical phenomena—by the visible or invisible light (*i.e.*, photons) that it absorbs, reflects, or emits or by which its observable character is modified. Energy absorption, which always involves some kind of excitation, and the opposed process of energy emission depend on the existence of ground-state and higher energy levels of molecules and atoms. A simplified system of energy states, or levels, is shown schematically in Figure 1. Such a system is exactly fixed for each atomic and molecular system by the laws of quantum mechanics; the “allowed,”

types

Absorption
and
quantum
laws

Figure 1: Energy states in molecular systems (see text).

or “permitted,” transitions between levels, which may involve energy gain or loss, are also established by those same laws of nature. Excitation to energy levels above those of the energetically stable molecules or atoms may result in dissociation or ionization: molecules can dissociate into product molecules and free radicals, and, if the energy absorption is great enough, atoms as well as molecules can yield ions and electrons (*i.e.*, ionization occurs). Atomic nuclei themselves may exist in various states in which they absorb and emit gamma rays under certain conditions, and, if the nuclei are raised to, or by some process left in, energy states that are sufficiently high, they may themselves emit positrons, negatrons, alpha particles, or neutrons (and neutrinos) or dissociate into the nuclei of two or more lighter atoms. The resulting atoms may be similarly short-lived and unstable, or they may be extremely long-lived and quite stable.

THE EFFECTS OF RADIATION

The interaction of radiation with matter can be considered the most important process in the universe. When the universe began to cool down at an early stage in its evolution, stars, like the Sun, and planets appeared, and elements such as hydrogen (H), oxygen (O), nitrogen (N), and carbon (C) combined into simple molecules such as water (H₂O), ammonia (NH₃), and methane (CH₄). The larger hydrocarbons, alcohols, aldehydes, acids, and amino acids were ultimately built as a result of the action (1) of far-ultraviolet light (wavelength less than 185 nanometres) before oxygen appeared in the atmosphere, (2) of penetrating alpha, beta, and gamma radiations, and (3) of electric discharges from lightning storms when the temperature dropped and water began to condense. These simple compounds interacted and eventually developed into living matter. To what degree—if at all—the radiations from radioactive decay contributed to the synthesis of living matter is not known, but the occurrence of high-energy-irradiation effects on matter at very early times in the history of this world is recorded in certain micas as microscopic, concentric rings, called pleochroic halos, produced as the result of the decay of tiny specks of radioactive material that emitted penetrating products, such as alpha particles. At the termini of their paths, particles of this kind produced chemical changes, which can be seen microscopically as dark rings. From the diameters of the rings and the known penetrating powers of alpha particles from various radioactive elements, the nature of the specks of radioactive matter can be established. In some cases, alpha particles could not have been responsible for the effects observed; in other cases, the elementary specks that occupied the centres of the halos were not those of any presently known elements.

It can be readily surmised that some of the elements that participated in the evolution of the world were not originally present but were produced as the result of external high-energy bombardment, that some disappeared as the result of such processes, and that many compounds

required for the living processes of organisms evolved as a consequence of the high-energy irradiation to which all matter is subjected. Hence, radiation is believed to have played a major role in the evolution of the universe and is ultimately responsible not only for the existence of life but also for the variety of its forms.

Fundamental processes involved in the interaction of radiation with matter

THE PASSAGE OF ELECTROMAGNETIC RAYS

The field concept. A discussion of this subject requires preliminary definition of a few of the more common terms. Around every particle, whether it be at rest or in motion, whether it be charged or uncharged, there are potential fields of various kinds. As one example, a gravitational field exists around the Earth and indeed around every particle of mass that moves with it. At every point in space, the field has direction in respect to the particle. The strength of the gravitational field around a specific particle of mass, m , at any distance, r , is given by the product of g , the universal gravitational constant, and m divided by the square of r , or gm/r^2 . The field extends indefinitely in space, moves with the particle when it moves, and is propagated to any observer with the velocity of light. Newton showed that the mass of a homogeneous spherical object can be assumed to be concentrated at its centre and that all distances can be measured from it. Similarly, electric fields exist around electric charges and move with them. Magnetic fields exist around electric charges in motion and change in intensity with all changes in the accompanying electric field, with the magnetic field at any point being perpendicular to the electric field in free space. Any regular oscillation is time-dependent, as is any change in field strength with time.

Time-dependent electric and magnetic fields occur jointly; together they propagate as what are called electromagnetic waves. In an assumed ideal free space (without intrusion from other fields or forces of any kind, devoid of matter, and, thus, in effect without any intrusions, demarcations, or boundaries), such waves propagate with the speed of light in the so-called transverse electromagnetic mode—one in which the directions of the electric field, the magnetic field, and the propagation of the wave are mutually perpendicular. They constitute a right-handed coordinate system; *i.e.*, with the thumb and first two fingers of the right hand perpendicular to each other, the thumb points in the direction of the electric field, the forefinger in that of the magnetic field, and the middle finger in that of propagation. A boundary may be put on the space by appropriate physical means (bound space), or the medium may be something other than a vacuum (material medium). In either case, other forces and other fields come into the picture, and propagation of the wave is no longer exclusively in the transverse electromagnetic mode. Either the electric field or the magnetic field (a matter of arbitrary choice) may be considered to have a component parallel to the direction of propagation itself. It is this parallel component that is responsible for attenuation of energy of the waves as they propagate.

Frequency range. Electromagnetic waves span an enormous range of frequencies (number of oscillations per second), only a small part of which fall in the visible region. Indeed, it is doubtful that lower or upper limits of frequency exist, except in regard to the applicability of present-day instrumentation. Figure 2 indicates the usual terminology employed for electromagnetic waves of different frequency or wavelength. Customarily, scientists designate electromagnetic waves by fields, waves, and particles in increasing order of the frequency ranges to which they belong. Traditional demarcations into fields, waves, and particles (*e.g.*, gamma-ray photons) are shown in the figure. The distinctions are largely of classical (*i.e.*, nonquantum) origin; in quantum theory there is no need for such distinctions. They are preserved, however, for common usage. The term field is used in a situation in which the wavelength of the electromagnetic waves is larger than the physical size of the experimental setup. For wave designation, the wavelength is comparable to or

The transverse electromagnetic mode

Classification of electromagnetic regions

Figure 2: Electromagnetic spectrum.

Two scales are shown: the frequency scale, expressed in hertz, or cycles per second, and the wavelength scale, expressed in centimetres. Other units of wavelength customarily used to define certain regions of the spectrum are also given; e.g., the nanometre (nm; $1/1,000,000,000$ metre), the unit useful in the visible region, with an approximate range from 760 nm (red) to 380 nm (violet). Demarcations between the various classifications of radiations (e.g., gamma rays and X rays) are not sharp.

smaller than the physical extent of the setup, and at the same time the energy of the photon is low. The particle description is useful when wavelength is small and photon energy is high.

Properties of light. The ordinary properties of light, such as straight-line propagation, reflection and refraction (bending) at a boundary or interface between two mediums, and image formation by mirrors or lenses, can be understood by simply knowing how light propagates, without inquiring into its nature. This area of study essentially is geometrical optics. On the other hand, the extraordinary properties of light do require answers to questions regarding its nature (physical optics). Thus, interference, diffraction, and polarization relate to the wave aspect, while photoelectric effect, Compton scattering, and pair production relate to the particle aspect of light. As noted above, light has dual character. It is the duality in the nature of light, as well as that of matter, that led to quantum theory.

Wave aspects of light. In general, radiation interacts with matter; it does not simply act on nor is it merely acted upon. Understanding of what radiation does to matter requires also an appreciation of what matter does to radiation.

When a ray of light is incident upon a plane surface separating two mediums (e.g., air and glass), it is partly reflected (thrown back into the original medium) and partly refracted (transmitted into the other medium). The laws of reflection and refraction state that all the rays (incident, reflected, and refracted) and the normal (a perpendicular line) to the surface lie in the same plane, called the plane of incidence. Angles of incidence and reflection are equal; for any two mediums the sines of the angles of incidence and refraction have a constant ratio, called the mutual refractive index. All these relations can be derived from the electromagnetic theory of Maxwell, which constitutes the most important wave theory of light. The electromagnetic theory, however, is not necessary to demonstrate these laws.

Double refraction. In double refraction, light enters a crystal the optical properties of which differ along two or more of the crystal axes. What is observed depends on the angle of the beam with respect to the entrant face. Double refraction was first observed in 1669 by Erasmus Bartholin in experiments with Iceland spar crystal and elucidated in 1690 by Huygens.

If a beam of light is made to enter an Iceland spar crystal at right angles to a face, it persists in the crystal as a single

beam perpendicular to the face and emerges as a single beam through an opposite parallel face. If the exit face is at an angle not perpendicular to the beam, however, the emergent beam is split into two beams at different angles, called the ordinary and extraordinary rays, and they are usually of different intensities. Clearly, any beam that enters an Iceland spar crystal perpendicular to its face and emerges perpendicular to another face is of changed character—although superficially it may not appear to be changed. Dependent on the relative intensities and the phase relationship of its electric components (i.e., their phase shift), the beam is described as either elliptically or circularly polarized. There are other ways of producing partially polarized, plane-polarized, and elliptically (as well as circularly) polarized light, but these examples illustrate the phenomena adequately.

Polarization of an electromagnetic wave can be shown mathematically to relate to the space-time relationship of the electromagnetic-field vector (conventionally taken as the electric vector, a quantity representing the magnitude and direction of the electric field) as the wave travels. If the field vector maintains a fixed direction, the wave is said to be plane-polarized, the plane of polarization being the one that contains the propagation direction and the electric vector. In the case of elliptic polarization, the field vector generates an ellipse in a plane perpendicular to the propagation direction as the wave proceeds. Circular polarization is a special case of elliptic polarization in which the so-described ellipse degenerates into a circle.

An easy way to produce circularly polarized light is by passage of the light perpendicularly through a thin crystal, as, for example, mica. The mica sample is so selected that the path difference for the ordinary and the extraordinary rays is one-quarter the wavelength of the single-wavelength, or monochromatic, light used. Such a crystal is called a quarter-wave plate, and the reality of the circular polarization is shown by the fact that, when the quarter-wave plate is suitably suspended and irradiated, a small torque—that is, twisting force—can be shown to be exerted on it. Thus, the action of the crystal on the light wave is to polarize it; the related action of the light on the crystal is to produce a torque about its axis.

The ratio of the intensity of the reflected light to that of the incident light is called the reflection coefficient. This quantitative measure of reflection depends on the angles of incidence and refraction, or the refractive index, and also on the nature of polarization.

It can be shown that the reflection coefficient at any angle of incidence is greater for polarization perpendicular to the plane of incidence than for polarization in the plane of incidence. As a result, if unpolarized light is incident at a plane surface separating two media, reflected light will be partially polarized perpendicular to the plane of incidence, and refracted light will be partially polarized in the plane of incidence. An exceptional case is the Brewster angle, which is such that the sum of the angles of incidence and refraction is 90° . When that happens, the reflection coefficient for polarization in the plane of incidence equals zero. Thus, at the Brewster angle, the reflected light is wholly polarized perpendicular to the plane of incidence. At an air-glass interface, the Brewster angle is approximately 56° , for which the reflection coefficient for perpendicular polarization is 14 percent. Another extremely important angle for refraction is the critical angle of incidence when light passes from a denser medium to a rarer one. It is that angle for which the angle of refraction is 90° (in this case the angle of refraction is greater than the angle of incidence). For angles of incidence greater than the critical angle there is no refracted ray; the light is totally reflected internally. For a glass-to-air interface the critical angle has a value $41^\circ 48'$.

Dispersion. The variation of the refractive index with frequency is called dispersion. It is this property of a prism that effects the colour separation, or dispersion, of white light. An equation that connects the refractive index with frequency is called a dispersion relation. For visible light the index of refraction increases slightly with frequency, a phenomenon termed normal dispersion. The degree of refraction depends on the refractive index. The increased

Kinds of polarization

Brewster angle

Maxwell's theory of radiation

Propaga-
tion
velocity
of electro-
magnetic
energy

bending of violet light over red by a glass prism is therefore the result of normal dispersion. If experiments are done, however, with light having a frequency close to the natural electron frequency, some strange effects appear. When the radiation frequency is slightly greater, for example, the index of refraction becomes less than unity (<1) and decreases with increasing frequency; the latter phenomenon is called anomalous dispersion. A refractive index less than unity refers correctly to the fact that the speed of light in the medium at that frequency is greater than the speed of light in vacuum. The velocity referred to, however, is the phase velocity or the velocity with which the sine-wave peaks are propagated. The propagation velocity of an actual signal or the group velocity is always less than the speed of light in vacuum. Therefore, relativity theory is not violated. An example is shown in Figure 3, in which a light source is initially pointed in the direction A . The source rotates in such a way that the velocity of the light image moves from D to E with a velocity v approximating c . Thus, the phase velocity with which the image moves from A to B is greater than c , but the relativity principle is not violated because the velocity of transmission of matter or energy does not exceed the velocity of light.

Figure 3: Contrast of phase velocity, v , and wave velocity, c . As the light source turns counterclockwise on its axis, the velocity with which the signal moves (e.g., from A to B) can exceed the velocity of light without violation of the relativity principle (see text).

Oscillator
strength

Electromagnetic waves and atomic structure. *Quantum concepts.* Quantum mechanics includes such concepts as "allowed states"—i.e., stationary states of energy content exactly stipulated by its laws. The energy states shown in Figure 1 are of that kind. A transition between such states depends not only on the availability (e.g., as radiation) of the precise amount of energy required but also on the quantum-mechanical probability of such a transition. That probability, the oscillator strength, involves so-called selection rules that, in general terms, state the degree to which a transition between two states (which are described in quantum-mechanical terms) is allowed. As an illustration of allowed transition in Figure 1, the only electronic transitions permitted are those in which the change in vibrational quantum number accompanying a change in electronic excitation is plus or minus one or zero, except that a $0 \leftrightarrow 0$ (zero-to-zero) change is not permitted. All electronic states include vibrational and rotational levels, so that the probability of a specific electronic transition includes the probabilities of transition between all the vibrational and rotational states that can conceivably be involved. Figure 1 is, of course, a simplified picture of a compendium of energy states available to a molecule (polyatomic structure)—and the selection rules are accordingly more involved in such a case. The selection rules are worked out by scientists in a process of discovery; the attempt is to state them systematically so that the applicable rules in an experimentally unstudied case may be stated on the basis of general principle.

Absorption and emission. In transit through matter, the intensity of light decreases exponentially with distance; in effect, the fractional loss is the same for equal distances of penetration. The energy loss from the light appears as energy added to the medium, or what is known as absorption. A medium can be weakly absorbing at one region of the electromagnetic spectrum and strongly absorbing at another. If a medium is weakly absorbing, its dispersion and absorption can be measured directly from the intensity of refracted or transmitted light. If it is strongly absorbing, on the other hand, the light does not survive even a few wavelengths of penetration. The refracted or transmitted light is then so weak that measurements are at best difficult. The absorption and dispersion in such cases, nevertheless, may still be determined by studying the reflected light only. This procedure is possible because the intensity of the reflected light has a refractive index that separates mathematically into contributions from dispersion and absorption. In the far ultraviolet it is the only practical means of studying absorption, a study that has revealed valuable information about electronic energy levels and collective energy losses (see below *Molecular activation*) in condensed material.

Experimental studies of the chemical effects of radiation on matter can be greatly forwarded by the use of beams of high intensity and very short duration. Such studies are made possible by employment of the laser, a light source developed by the American physicists Arthur L. Schawlow and Charles H. Townes (1958) from the application of one of the Einstein equations. Einstein suggested (on the basis of a principle of detailed balancing, or microscopic reversibility) that, just as the amount of light absorbed by a molecular system in a light field must depend on the intensity of the light, the amount of light emitted from excited states of the same system must also exhibit such dependency. In this fundamentally important idea of microscopic reversibility can be seen one of the most dramatic illustrations of the physical effects of radiation.

Principle of
micro-
scopic
reversibility

Under any circumstance, the absorption probability in the ground state is given by the number of molecules (or atoms), N_i , in that state multiplied both by the probability, B_{ij} , for transition from state i to state j and by the light intensity, $I(\nu)$, at frequency symbolized by the Greek letter ν ; i.e., $N_i B_{ij} I(\nu)$. Light emission from an excited state to the ground state depends on the number of molecules (or atoms) in the upper state, N_j , multiplied by the probability of spontaneous emission, A_{ji} , to the ground state plus the additional induced emission term, $N_j B_{ji} I(\nu)$, in which B_{ji} is a term that Einstein showed to be equal to B_{ij} and that relates the probability of such induced emission, so that in the general case in any steady-state situation (in which light absorption and emission are occurring at equal rates):

$$N_i B_{ij} I(\nu) = N_j [A_{ji} + B_{ji} I(\nu)]$$

There is a well-developed theoretical relationship (not here presented) of a quantum-mechanical nature between A_{ji} and B_{ji} . Ordinarily, the light intensity, $I(\nu)$, is so low that the second term on the right can be neglected. At sufficiently high light intensities, however, that term can become important. In fact, if the light intensity is high, as in a laser, the induced-emission probability can easily exceed that of spontaneous emission.

Spontaneous emission of light is random in direction and phase. Induced emission has the same direction of polarization and propagation as that of the incident light. If by some means a greater population is created in the upper level than in the lower one, then, under the stimulus of an incident light of appropriate frequency, the light intensity actually increases with path length provided that there is enough stimulated emission to compensate for absorption and scattering. Such stimulated emission is the basis of laser light. Practical lasers such as the ruby or the helium-neon lasers work, however, on a three-level principle.

Particle aspects of light. The energy required to remove an orbital electron from an atom (or molecule) is called its binding energy in a given state. When light of photon energy greater than the minimum binding energy is incident upon an atom or solid, part or all of its energy

Mechanism
of pair
production

may be transformed through the photoelectric effect, the Compton effect, or pair production—in increasing order of importance with increase of photon energy. In the Compton effect, the photon is scattered from an electron, resulting in a longer wavelength, thus imparting the residual energy to the electron. In the other two cases the photon is completely absorbed or destroyed. In the pair-production phenomenon, an electron-positron pair is created from the photon as it passes close to an atomic nucleus. A minimum energy (1,020,000 electron volts [eV]) is required for this process because the energy of the electron-positron pair at rest—the total mass, $2m$, times the velocity of light squared ($2mc^2$)—must be provided. If the photon energy ($h\nu$) is greater than the rest mass, the difference ($h\nu - 2mc^2$), called the residual energy, is distributed between the kinetic energies of the pair with only a small fraction going to the nuclear recoil.

The photoelectric effect. The photoelectric effect is caused by the absorption of electromagnetic radiation and consists of electron ejection from a solid (or liquid) surface, usually of a metal, though nonmetals have also been studied. In the case of a gas, the term photoionization is more common, though there is basically little difference between these processes. In spite of experimental difficulties connected with surface-adsorbed gas and energy loss of ejected electrons in penetrating a layer of the solid into vacuum, early experimenters established two important features about the photoelectric effect. These are: (1) although the photoelectric current (*i.e.*, the number of photoelectrons) is proportional to the incident-light intensity, the energy of the individual photoelectrons is independent of light intensity; and (2) the maximum energy of the ejected electron is roughly proportional to the frequency of light. These observations cannot be explained in terms of wave theory. Einstein argued that the light is absorbed in quanta of energy equal to Planck's constant (h) times light frequency, $h\nu$, by electrons, one at a time. A minimum energy symbolized by the Greek letter psi, ψ , called the photoelectric work function of the surface, must be supplied before the electron can be ejected. When a quantum of energy is greater than the work function, photoelectric emission is possible with the maximum energy symbolized by the Greek letter epsilon, ϵ , of the photoelectron (ϵ_{\max}) being stated by Einstein's photoelectric equation as equaling the difference between the photon energy and the work function; *i.e.*, $\epsilon_{\max} = h\nu - \psi$. Einstein's interpretation gave strong support for the quantum theory of radiation. Early experiments determined Planck's constant, h , independently through the above equation and also established the fact that an immeasurably small time delay is involved between absorption of a quantum of light and the ejection of an electron. The latter is clearly indicative of particle-like interaction.

Photo-
electric
threshold
frequency

Accurate and reliable values of the work function and ejection energy are now available for most solids; the chief obstacles to the development of such data were the difficulty of preparing clean surfaces and the energy loss of electrons in penetration into vacuum. The photoelectric threshold frequency, symbolized by the Greek letter nu with subscript zero, ν_0 , is that frequency at which the effect is barely possible; it is given by the ratio of the work function symbolized by the Greek letter psi, ψ , to Planck's constant ($\nu_0 = \psi/h$). The photoelectric yield, defined as the ratio of the number of photoelectrons to that of incident photons, serves as a measure of the efficiency of the process. Photoelectric yield starts from a zero value at threshold, reaches a maximum value (about 1/1,000) at about twice the threshold frequency, and falls again when frequency is further increased. Some unusual alloys exhibit yields up to 100 times greater than normal (*i.e.*, about 0.1). Normally the yield depends also on polarization and angle of incidence of the radiation. Parallel polarization (polarization in the plane of incidence) gives higher yield than does perpendicular polarization, in some instances by almost 10 times.

Cross section and Compton scattering. A useful concept in describing the absorption of radiation in matter is called cross section; it is a measure of the probability that photons interact with matter by a particular process.

When the energy of each individual photon ($h\nu$) is much smaller than the rest energy of the electron (its mass times the velocity of light squared [mc^2]), the scattering of photons is described by a cross section derived by J.J. Thomson. This cross section is called the Thomson cross section, symbolized by the Greek letter sigma with subscript zero, σ_0 , and is equal to a numerical factor times the square of the term, electric charge squared divided by electron rest energy, or $\sigma_0 = (8\pi/3) (e^2/mc^2)^2$. When the photon energy is equal to or greater than the electron's rest energy of ($h\nu \geq mc^2$), inelastic (*i.e.*, energy loss) scatterings begin to appear. One such is Compton scattering, in which an X ray or gamma ray (electromagnetic radiation from an atomic nucleus) experiences an increase in wavelength (reduction in energy) after being scattered through an angle. Arthur Holly Compton, an American physicist, correctly interpreted the effect by using the laws of classical relativistic mechanics. He showed that the increase in wavelength symbolized by the Greek letters delta and lambda, $\Delta\lambda$, is independent of the energy of the photon and is given by an expression in which the product of two terms appears. The first is a universal constant symbolized by the Greek letter lambda with subscript zero, λ_0 , generally called the Compton wavelength, and itself equal to Planck's constant, h , divided by the mass of the electron at rest and the velocity of light; *i.e.*, $\lambda_0 = h/mc = 2.4 \times 10^{-10}$ centimetre. The second is a term dependent on the angle symbolized by the Greek letter theta, θ , through which the photon is scattered; it is one minus the cosine of that angle, or $1 - \cos \theta$. The increase in wavelength observed at that angle is simply $\Delta\lambda = \lambda_0(1 - \cos \theta)$. In discussing the Compton effect, the electron is treated as free—that is, not bound to a nucleus—because, in the study of that effect for most materials of low atomic number, the incident photon has energy much greater than the binding energy. For bound electrons, the corrections to the Compton relation are small but complicated. When photons are scattered, the concept of differential cross sections may be used; differential cross section is a measure of the probability that a photon will be scattered within a given small angle.

The differential cross section for the Compton process was derived by the Swedish physicist Oskar Klein and the Japanese physicist Yoshio Nishina. The Klein-Nishina formula shows almost symmetrical scattering for low-energy photons about 90° to the beam direction. As the photon energy increases, the scattering becomes predominantly peaked in the forward direction, and, for photons with energies that are greater than five times the rest energy of the electron, almost the entire scattering is confined within an angle of 30° . When averaged over the angle, the Klein-Nishina cross section shows variation with the incident photon energy. At low energy this cross section increases uniformly and approaches the classical Thomson value as energy is decreased; at high energy the cross section is inversely proportional to the energy. The energy distribution of Compton electrons (recoil or scattered electrons) and outgoing photons may also be derived from the Klein-Nishina theory. The result shows a wide distribution; for atoms of low atomic number and incident photon energies in the region of importance (*i.e.*, 1,000,000 to 100,000,000 eV), the probability of scattering per unit energy interval is fairly constant—except that, for the case of nearly total conversion of the photon energy into electron kinetic energy, a plot of energy versus angle shows a sharp, narrow peak. Thus, as a crude approximation, the average energy of a Compton electron is about half the incident photon energy.

Klein-
Nishina
formula

Compton scattering plays a key role in the interaction of matter with intermediate-energy gamma rays and high-energy X rays. For these radiations, it is almost the exclusive mechanism by which energy is transferred from the radiation and added to the matter. An example may be cited of the penetration of gamma rays from the radioactive substance cobalt-60 into a sample of water or aqueous solution. The electron density is approximately 3×10^{23} per millilitre. Taking the Compton cross section as approximately 3×10^{-25} square centimetre per electron, calculation yields a mean free path for Compton scatter-

Energy
transfer
from
gamma
rays

ing of about 10 centimetres—that is to say, a photon will move about 10 centimetres between successive encounters with electrons. The dominant radiation effect produced by a gamma ray therefore is attributable to the recoil electron and the vast number of progeny (such as secondary and tertiary electrons) that are produced. These higher generation electrons are produced through electron-impact ionization (an electron is removed from an atom by the collision of another electron), a process that continues until barred either by energetic limitation or by low cross section. For cobalt-60 gamma rays the average Compton energy in a material of low atomic number, such as water, is approximately 600,000 eV.

Pair production. Pair production is a process in which a gamma ray of sufficient energy is converted into an electron and a positron. A fundamental law of mechanics, given by Newton, is that in any process total linear (as well as angular) momentum remains unchanged. In the pair-production process a third body is required for momentum conservation. When that body is a heavy nucleus, it takes very little recoil energy, and therefore the threshold is just twice the rest energy of the electron; *i.e.*, twice its mass, m , times the square of the velocity of light, c^2 , or $2mc^2$. Pair production also can occur in the field of an atomic electron, to which considerable recoil energy is thereby imparted. The threshold for such a process is four times the rest energy of an electron, or $4mc^2$. The total pair-production cross section is the sum of the two components, nuclear and electronic. These cross sections depend on the energy of the gamma ray and are usually calculated in an electron theory proposed by the British physicist P.A.M. Dirac through a method of approximation that is a simplification of a method (a “first approximation”) devised by the German physicist Max Born (*i.e.*, a “first Born approximation”). The process is envisaged by Dirac as the transition of an electron from a negative to a positive energy state. Corrections are required for these cross sections at high energy, at high atomic number, and for atomic screening (the intrusion of the field of the electrons in an atom); these are normally made via numerical procedures. The fraction of residual energy, symbolized by the Greek letter alpha, unexpended in conversion of energy to mass, that appears in any one particle (*e.g.*, the electron) is thus given by the kinetic energy of that electron E_e minus its rest energy mc^2 divided by the energy of the gamma ray $h\nu$ (*i.e.*, the product of Planck’s constant and the frequency of the gamma ray) minus twice the rest energy of the electron $2mc^2$, or $\alpha = (E_e - mc^2)/(h\nu - 2mc^2)$. Because the same equation applies to each of the two electrons that are formed, it must be symmetric about the condition that each of the particles has half the residual energy, symbolized by the Greek letter alpha, α (in excess of that conveyed to the “third body”); *i.e.*, that $\alpha = 0.5$. Below an energy of about 10,000,000 eV for the gamma ray, the probability for pair production (*i.e.*, the pair-production cross section) is almost independent of the atomic number of the material, and, up to about 100,000,000 eV of energy, it is also almost independent of the quantity α . Even at extremely high energies the probability that a certain fraction of the total available energy will appear in one particle is almost independent of the fraction as long as energy is comparably distributed between the two particles (excepting in cases in which almost all energy is dumped into one particle alone). Typical pair-production cross sections at 100 MeV (million electron volts) are approximately 10^{-24} to 10^{-22} square centimetre, increasing with atomic number. At high energies, approximately equal to or greater than 100 MeV, pair production is the dominant mechanism of radiation interaction with matter.

Clearly, as the photon energy increases, the dominant interaction mechanism shifts from photoelectric effect to Compton scattering to pair production. Rarely do photoelectric effect and pair production compete at a given energy. Compton scattering, however, at relatively low energy competes with the photoelectric effect and at high energy competes with pair production. Thus, in lead, interaction below 0.1 MeV is almost exclusively photoelectric; between 0.1 MeV and 2.5 MeV both photoelectric and

Compton processes occur; and between 2.5 MeV and 100 MeV Compton scattering and pair production share the interaction. In the pair process the photon is annihilated, and an electron-positron pair is created. On the other hand, an electron or positron with energy approximately equal to or greater than 100 MeV loses its energy almost exclusively by production of high-energy bremsstrahlung (X rays produced by decelerating electric charges) as the result of interaction with the field of a nucleus. The cross section for bremsstrahlung production is nearly independent of energy at high energies, whereas at low energies the dominant energy-loss mechanism is by the creation of ionizations and excitations. A succession of bremsstrahlung and pair-production processes generates a cascade or shower in the absorber substance. This phenomenon can be triggered by an electron, a positron, or a photon, the triggering mechanism being unimportant as long as the starting energy is high. A photon generates a pair through pair production, and the charged particles generate photons through bremsstrahlung, and so on repeatedly as long as the energy is kept sufficiently high. With penetration into the substance, the shower increases in size at first, reaches a maximum, and then gradually decreases. Loss of particles by degradation to lower energies (in which the yield of bremsstrahlung is low), ionization loss, and production and absorption of low-energy photons eventually reduce the size of the cascade. The mathematical theory of cascades has been developed in great detail.

X rays and gamma rays. When light of sufficiently high frequency (or energy equal to $h\nu$), independent of its source, is absorbed in a molecular system, the excited molecular state so produced, or some excited state resultant from it, may either interact with other molecules or decompose to produce intermediate or ultimate products; *i.e.*, chemical reactions ensue. Study of such processes is encompassed in the subject of photochemistry (see also below *Molecular activation*).

Electromagnetic waves of energy greater than those usually described as ultraviolet light (see Figure 2) are included in the classes of X rays or gamma rays. X-ray and gamma-ray photons may be distinguished by definition on the basis of source. They are indistinguishable on the basis of effects when their energy is absorbed in matter.

The total effect of X-ray or gamma-ray irradiation of matter, in the almost immediate time interval, is the production of high-energy electrons of energy related to that of the incident ray. Such electrons behave like beta rays (electrons emitted from atomic nuclei) or electrons from a machine source of the same energy. They lose energy by excitation and ionization of atoms and molecules of the systems they traverse. The amount of energy such an electron gives to an atom or molecule tends to exceed that deposited in photochemical processes, and the variety of initial physical (and consequent chemical) effects is more numerous and diverse. The situation is further complicated by the fact that the secondary electrons produced in ionization processes in which the input of energy is high may themselves initiate other ionization and excitation processes that can yield further chemistry, the totality of which is embraced in the title of radiation chemistry (see below *Molecular activation and Ionization and chemical change*).

THE PASSAGE OF MATTER RAYS

Heavy charged particles. Charged particles, such as atomic or molecular ions or molecular fragments, that travel in a material medium deposit energy along their paths, or tracks. If the medium is sufficiently thick, the velocity of the charged particle is reduced to near zero so that its energy is all but totally absorbed and is totally utilized in producing physical, chemical, and, in viable (living) matter, biologic changes. If the sample is sufficiently thin, the particle may ultimately emerge, but with reduced energy.

Linear energy transfer and track structure. The stopping power of a medium toward a charged particle refers to the energy loss of the particle per unit path length in the medium. It is specified by the differential $-dE/dx$, in which $-dE$ represents the energy loss and dx represents

energy
transfer

the increment of path length. What is of interest to the radiation scientist is the spatial distribution of energy deposition in the particle track. In approximate terms, it is customary to refer to linear energy transfer (LET), the energy actually deposited per unit distance along the track (*i.e.*, $-dE/dx$). For not-so-fast particles, stopping power and LET are numerically equal; this situation covers all heavy particles studied so far in chemistry and biology but not electrons. In a refined study and redefinition of LET or restricted linear collision stopping power, a quantity symbolized by the letter *L* with subscript Greek letter delta, L_Δ , is defined as equal to the fractional energy lost ($-dE$) per unit distance traversed along the track (dl), or $L_\Delta = -(dE/dl)_\Delta$, in which the subscript delta (Δ) indicates that only collisions with energy transfer less than an amount Δ are included. The quantity L_Δ may be expressed in any convenient unit of energy per unit length. For Δ equal to 100 eV, even the most energetic secondary electrons (*i.e.*, electrons ejected by the penetrating particle) produce on average only about three subsequent ionizations. The latter, however, are closely spaced because of the low energy of the electron, and hence the corresponding energy density is high. It is higher yet for lower-energy secondary electrons. In contrast, for Δ much in excess of 100 eV, more subsequent ionizations are produced, but their spacing is increased significantly and the corresponding density of energy deposition is low. Since only the region of high energy density is of concern for many applications, the quantity L_{100} is often used to characterize LET.

Concept of
infratrack

The bulk of energy deposition resulting from the passage of a fast-moving, charged particle is concentrated in the "infratrack," a very narrow region extending typically on the order of 10 interatomic distances perpendicular to the particle trajectory. The extent of the infratrack is dependent on the velocity of the particle, and it is defined as the distance over which the electric field of the particle is sufficiently strong and varies rapidly enough to produce electronic excitation. Inside the infratrack, electrons of the medium are attracted toward the trajectory of a positively charged particle. Many cross the trajectory, depositing energy on both sides. Consequently, the infratrack is characterized by an exceedingly high density of energy deposition and plays a vital role in determining the effects of ionizing radiation on the medium. (The magnitude of energy deposition in the infratrack is further increased by the preponderance of collective [plasma] excitations in that region.) The concept of the infratrack was developed by the American physicists Werner Brandt and Rufus H. Ritchie and independently by Myron Luntz. The region outside the infratrack is beyond the direct influence of the penetrating particle. Energy deposition in this outer region, or "ultratrack," is due primarily to electronic excitation and ionization by secondary electrons having sufficient energy to escape from the infratrack. In contrast to the infratrack, the ultratrack does not have well-defined physical bounds. Its spatial extent may reasonably be equated with the maximum range of secondary electrons transverse to the particle trajectory.

For practical purposes, LET is associated with the main track, which may be thought of as including the infratrack and a portion of the ultratrack out to which energy density is still relatively high—*i.e.*, the region over which excitation is caused by secondary electrons of initial energy less than some value Δ , say 100 eV. Energy deposited in "blobs" or "short tracks" to the side of the main track, as described in the Mozumder-Magee theory of track effects (named for Asokendu Mozumder, an Indian-born physicist, and John L. Magee, an American chemist) is purposefully excluded. LET, so defined, characterizes energy deposition within a limited volume—*i.e.*, energy locally deposited about the particle trajectory.

Stopping power. By use of classical mechanics, Bohr developed an equation of stopping power, $-dE/dx$, given as the product of a kinematic factor and a stopping number.

The kinematic factor includes such terms as the electronic charge and mass, the number of atoms per cubic centimetre of the medium, and the velocity of the incident charged particle. The stopping number includes the atomic number and the natural logarithm of a term that includes

the velocity of the incident particle as well as its charge, a typical transition energy in the system (see Figure 1; a crude estimate is adequate because the quantity appears within the logarithm), and Planck's constant, h . Bohr's stopping-power formula does not require knowledge of the details of atomic binding. In terms of the stopping number, B , the full expression for stopping power is given by $-dE/dx = (4\pi Z_1^2 e^4 N/mv^2)B$, where Z_1 is the atomic number of the penetrating particle and N is the atomic density of the medium (in atoms/volume).

For a heavy incident charged particle in the nonrelativistic range (*e.g.*, an alpha particle, a helium nucleus with two positive charges), the stopping number B , according to the German-born American physicist Hans Bethe, is given by quantum mechanics as equal to the atomic number (Z) of the absorbing medium times the natural logarithm (\ln) of two times the electronic mass times the velocity squared of the particle, divided by a mean excitation potential (I) of the atom; *i.e.*, $B = Z \ln (2mv^2/I)$.

Bethe's stopping number for a heavy particle may be modified by including corrections for particle speed in the relativistic range ($\beta^2 + \ln [1 - \beta^2]$), in which the Greek letter beta, β , represents the velocity of the particle divided by the velocity of light, and polarization screening (*i.e.*, reduction of interaction force by intervening charges, represented by the symbol $\delta/2$), as well as an atomic-shell correction (represented by the ratio of a constant C to the atomic number of the medium); *i.e.*, $B = Z (\ln 2mv^2 / I - \beta^2 - \ln [1 - \beta^2] - C/Z - \delta/2)$.

The most important nontrivial quantity in the equation for stopping number is the mean excitation potential, I . Experimental values of this parameter, or quantity, are known for most atoms, but no single theory gives it over the whole range of atomic numbers because the calculation would require knowledge of the ground states and all excited states. Statistical models of the atom, however, come close to providing a theory. Calculations by the American physicist Felix Bloch in 1933 showed that the mean excitation potential in electron volts is about 14 times the atomic number of the element through which the charged particle is passing ($I = 14Z$). A later calculation gives the ratio of the potential to atomic number as equal to a constant (a) plus another constant (b) times the atomic number raised to the $-2/3$ power in which $a = 9.2$ and $b = 4.5$ —*i.e.*, $I/Z = a + bZ^{-2/3}$. This formula is widely applicable. Other exact quantum-mechanical calculations for hydrogen give its mean excitation potential as equal to 15 eV.

Even though the basic stopping-power theory has been developed for atoms, it is readily applied to molecules by virtue of Bragg's rule (named for the British physicist William H. Bragg), which states that the stopping number of a molecule is the sum of the stopping numbers of all the atoms composing the molecule. For most molecules Bragg's rule applies impressively within a few percent, though hydrogen (H_2) and nitrous oxide (NO) are notable exceptions. The rule implies: (1) similarity of atomic binding in different molecules having one common atom or more, and (2) that the vacuum ultraviolet transitions, in which most electronic transitions are concentrated under such irradiation, involve energy losses much higher than the strengths of most chemical bonds.

The charge on a heavy positive ion fluctuates during penetration of a medium. In the beginning it captures an electron, which it quickly loses. As it slows down, however, the cross section of electron loss decreases relative to that for capture. Basically, the impinging ion undergoes charge-exchange cycles involving a single capture followed by a single loss. Ultimately, an electron is permanently bound when it becomes energetically impossible for the ion to lose it. A second charge-exchange cycle then occurs. This phenomenon continues repeatedly until the velocity of the heavy ion approximates the orbital velocity of the electron in Bohr's theory of the atom, when the ion spends part of its time as singly charged and another part as a neutral atom. The kinematic factor in the expression for stopping power is proportional to the square of the nuclear charge of the penetrating particle, and it is modified to account for electron capture as the particle slows

Bethe's
stopping
numberBragg's
rule

down. On slowing down further, the electronic energy-loss mechanism becomes ineffective, and energy loss by elastic scattering dominates. The mathematical expressions presented here apply strictly in the high-velocity, electronic excitation domain.

Range. The total path length traversed by a charged particle before it is stopped is called its range. Range is considered to be taken as the sum of the distance traversed over the crooked path (track), whereas the net projection measured along the initial direction of motion is known as the penetration. The difference between range and penetration distances results from scattering encountered by the particle along its path. For heavy charged particles with high initial velocities (those that are appreciable fractions of the speed of light), large-angle scatterings are rare. The corresponding trajectories are straight, and the difference between range and penetration distance is, for most purposes, negligible.

Computation of particle ranges

Particle ranges may be obtained by (numerical) integration of a suitable stopping-power formula. Experimentally, range is more easily measured than is stopping power. For heavy particles a critical incident energy in low-atomic-number mediums is 1,000,000 eV divided by the mass of the particle in atomic mass units (amu)—i.e., 1 MeV/amu. For incident energies higher than this critical value, range is usually well-known, and computation agrees with experiment within about 5 percent. In the case of aluminum, which is the best studied material, the accuracy is within about 0.5 percent. For incident energies less than the critical value, however, range calculations are usually uncertain, and agreement with experiment is poor. The range-energy relation is often given adequately as a power law, that range (R) is proportional to energy (E) raised to some power (n); that is, $R \propto E^n$. Protons in the energy interval of a few hundred MeV conform to this kind of relation quite well with the exponent n equal to 1.75. Similar situations exist for other heavy particles. Measurements of range and stopping power are of great importance in particle identification and measurement of their energies. Many experimental data and computations are available for ranges of heavy particles as well as of electrons. The theory by which Bethe derived a stopping number is generally accepted as providing the framework for understanding the variation of range with energy, though in practice the mean excitation potential, I , must be obtained in many cases by experimental curve fitting.

Both stopping power and range should be understood as mean (or average) values over an ensemble of atoms or molecules, because energy loss is a statistical phenomenon. Fluctuations are to be expected. In general, these fluctuations are called straggling, and there are several kinds. Most important among them is the range straggling, which suggests that, for statistical reasons, particles in the same medium have varying path lengths between the same initial and final energies. Bohr showed that for long path lengths the range distribution is approximately Gaussian (a type of relationship between number of occurrences and some other variable). For short path lengths, such as those encountered in penetration of thin films, the emergent particles show a kind of energy straggling called Landau type (for the Soviet physicist Lev Landau). This energy straggling means that the distribution of energy losses is asymmetric when a plot is drawn, with a long tail on the high-energy-loss side. The intermediate case is given by a distribution according to Sergey Ivanovich Vavilov, a Soviet physicist, that must be evaluated numerically. There is evidence in support of all three distributions in their respective regions of validity.

Bragg peak

The ionization density (number of ions per unit of path length) produced by a fast charged particle along its track increases as the particle slows down. It eventually reaches a maximum called the Bragg peak close to the end of its trajectory. After that, the ionization density dwindles quickly to insignificance. In fact, the ionization density follows closely the LET. With slowing, the LET at first continues to increase because of the strong velocity denominator in the kinematic factor of the stopping-power formula. At low speeds, however, LET goes through a maximum because of: (1) progressive lowering of charge

by electron capture, and (2) the effect of the logarithmic term in the stopping-power formula. In general, the maximum occurs at a few times the Bohr orbital velocity. A curve of ionization density (also called specific ionization or number of ion pairs—negative electron and associated positive ion—formed per unit path length) versus distance in a given medium is called a Bragg curve. The Bragg curve includes straggling within a beam of particles; thus, it differs somewhat from the specific ionization curve for an individual particle in that it has a long tail of low ionization density beyond the mean range. The mean range of radium-C' alpha particles in air at normal temperature and pressure (NTP), for example, is 7.1 centimetres; the Bragg peak occurs at about 6.3 centimetres from the source with a specific ionization of about 60,000 ion pairs per centimetre.

Electrons. In the first Born approximation, inelastic cross section depends only on velocity and the magnitude of the charge on the incident particle. Hence, an electron and a positron at the same velocity should have identical stopping powers, which should be the same as that of a proton at that velocity. In practice, there is some difference in the case of an electron because of the indistinguishability of the incident and atomic electrons. In describing an ionization caused by an incident electron, the more energetic of the two emergent electrons is called, by convention, the primary. Thus, maximum energy loss (ignoring atomic binding) is half the incident energy. Incorporating this effect, the stopping number of an electron is given by a complicated expression that involves a different arrangement of the parameters found in the stopping number of heavy charged particles; i.e.,

Electron stopping number

$$B_e = \frac{Z}{2} \left[\ln mc^2 \beta^2 E / 2I^2 (1 - \beta^2) - (2\sqrt{1 - \beta^2} - 1 + \beta^2) \right. \\ \left. \ln 2 + (1 - \beta^2) + \frac{1}{8} (1 - \sqrt{1 - \beta^2})^2 - 2 \frac{C}{Z} \delta \right].$$

This stopping-power formula has a wide range of validity, from approximately a few hundred electron volts to a few million electron volts in materials of low atomic number. For low velocities, the Born approximation gradually breaks down, and highly excited states begin to be inaccessible to transitions by virtue of small maximum energy transfer. Yet, with some corrections the electron-stopping-power formula may be extended down to about 50 eV. Below that value any stopping-power formula is of doubtful validity, even though it is certain that most of the energy is still being lost to electronic states down to a few eV of energy.

On the high-velocity side, relativistic effects increase electron-stopping power from about 1,000,000 eV upward. Except for the term δ attributable to polarization screening, the relativistic stopping power tends to infinity as the electron velocity approaches the speed of light ($v/c = \beta \rightarrow 1$). One-half of the stopping power, called the restricted stopping power, is numerically equal to the linear energy transfer and changes smoothly to a constant value, called the Fermi plateau, as the ratio β approaches unity. The other half, called the unrestricted stopping power, increases without limit, but its effect at extreme relativistic velocities (those very near the speed of light) becomes small compared with energy loss by nuclear encounters.

At extremely high velocities an electron loses a substantial part of its energy by radiative nuclear encounter. Lost energy is carried by energetic X rays (i.e., bremsstrahlung). The ratio of energy loss by nuclear radiative encounter to collisional energy loss (excitation and ionization) is given approximately by the incident electron energy (E) in units of 1,000,000 eV times atomic number (Z) divided by 800; i.e., $EZ/800$. For a large class of mediums (atomic number equal to or greater than 8; i.e., that for oxygen), the electron stopping is dominated by bremsstrahlung radiation for energies greater than 100 MeV.

Cherenkov radiation. When the speed of a charged particle in a transparent medium (air, water, plastics) is so high that it is greater than the group velocity of light in that medium, then a part of the energy is emitted as Cherenkov radiation, first observed in 1934 by Pavel A. Cherenkov, a Soviet physicist. Such radiation rarely accounts for more

than a few percent of the total energy loss. Even so, it is invaluable for purposes of monitoring and spectroscopy. Cherenkov radiation is spread over the entire visible region and into the near ultraviolet and near infrared. The direction of its propagation is confined within a cone, the axis of which is the direction of electron motion.

Energy-transfer mechanism. At the low-velocity end of its path, an electron continues to excite electronic levels of atoms or molecules until its kinetic energy falls below the lowest (electronically) excited state (see Figure 1). After that it loses energy mainly by exciting vibrations in a molecule. Such a mechanism proceeds through the intermediary of temporary negative ion states, for direct momentum-transfer collisions are very inefficient. In a condensed medium (liquid, solid, or glass) very low-energy (less than 1 eV) electrons continue to lose energy by a process called phonon emission and by interaction with other low-frequency intermolecular motions of the medium.

An electron and a singly charged heavy particle with the same velocity have about equal stopping powers. Because of the small mass of the electron, however, the relative retardation (decrease in velocity per unit path length) is much more for it. This larger retardation for an electron means that, if an electron and a heavy particle start with the same velocity, the electron will have a much smaller range. Electron tracks show much more straggling and scattering compared with that of a heavy particle. The first effect results from the fact that the electron can lose a large fraction of its energy in a single encounter; the second is the result of small mass. A power law may be used to connect range and energy of electrons in a given medium—i.e., the range is proportional to energy raised to a power n ; as in the case of a heavy particle, the index n is slightly less than two at high energies. At low energies the relationship is such that the exponent is one or less. Many formulas and tables are available for stopping powers and for ranges of electrons as well as of heavy particles over a wide range of energies.

Neutrons. A neutron is an uncharged particle with the same spin as an electron and with mass slightly greater than a proton mass. In free space it decays into a proton, an electron, and an antineutrino and has a half-life of about 12–13 minutes, which is so large compared with lifetimes of interactions with nuclei that the particle disappears predominantly by such interactions.

Neutron beams may be produced in a variety of ways. A modern method is to extract a high-intensity beam from a nuclear reactor. A simpler but expensive device is one that employs a mixture of radium and beryllium. The reaction of the alpha (α) particles emitted by the radium with beryllium nuclei produces a copious output of neutrons. The neutron is a major nuclear constituent and is responsible for nuclear binding. A free neutron interacts with nuclei in a variety of ways, depending on its velocity and the nature of the target. Ordinary interactions include scattering (elastic and inelastic), absorption, and capture by nuclei to produce new elements. Unlike the electron, a neutron loses energy significantly through elastic collisions, because its mass is comparable to masses of atoms of low atomic number. (According to the laws of mechanics, in elastic collision, on the average, an object loses half its energy to another object of equal mass.)

The average fraction of energy transferred from a neutron per collision, symbolized by $(\Delta E/E)_{av}$, is twice the atomic mass number (A) of the struck atom divided by the square of the mass number plus one; i.e.,

$$(-\Delta E/E)_{av} = 2A / (A + 1)^2.$$

Thus, only 18, 25, 42, 90, and 114 collisions are required to thermalize (reduce the energy of motion to that of the surrounding atoms) a fast neutron in hydrogen, deuterium, helium, beryllium, and carbon, respectively.

Pure absorption does not result in a new element, even though it is sometimes accompanied by emission of gamma rays. In certain cases of capture, radioactivity follows, often with production of beta (β) particles. In another class of interaction, a heavy charged particle is ejected (such as an α -particle or proton); the resultant nucleus is often but not always radioactive. As an example, the reaction

of neutrons on boron to produce alpha particles provides the basis for alpha-particle welding. The principle of such welding, invented by the Soviet chemist V.I. Goldansky, is to deposit a thin layer of a boron (or lithium) compound in the interface between diverse materials, which is thereafter irradiated with neutrons. The high-energy α -particles produced from the nuclear reaction weld the materials together.

Extraordinary interactions of the neutron are represented by diffraction, nuclear fission, and nuclear fusion. Diffraction, exhibited by low-energy neutrons (approximately equal to or less than 0.05 eV), demonstrates their wave nature and is consistent with de Broglie's hypothesis of the wave character of matter. Neutron diffraction complements X-ray technique in locating the positions of atoms in molecules and crystals, especially atoms of low atomic number such as hydrogen. Fission is the breakup of a heavy nucleus (either spontaneously or under the impact, for example, of a neutron) into two smaller ones with liberation of energy and neutrons. Spontaneous-fission rates and cross sections of fission induced by agencies other than the neutron are so small that in most applications only neutron-induced fission is important. Also, the neutron-induced-fission cross section depends on the particular isotope (species of an element with the same atomic number and similar chemical behaviour but different atomic mass) involved and the neutron energy. The fission process itself generates fast neutrons, which, when suitably slowed down by elastic scattering (a process called moderation), are again ready to induce more fission. The ratio of neutrons produced to neutrons absorbed is called the reproduction factor. When that factor exceeds unity, a chain reaction may be started, which is the basis of nuclear-power reactors and other fission devices. The chain is terminated by a combination of adventitious absorption, leakage, and other reactions that do not regenerate a neutron. At the power level at which a reactor operates, the loss rate always balances the generation rate through fission. The Hungarian-born American physicist Eugene P. Wigner, in the course of consideration of the possible effects of fast neutrons, suggested in 1942 that the process of energy transfer by collision from neutron to atom might result in important physical and chemical changes. The phenomenon, known as the Wigner effect and sometimes as a "knock on" process, was actually discovered in 1943 by the American chemists Milton Burton and T.J. Neuberger and found to have profound influences on graphite and other materials.

Secondary effects of radiation

PURELY PHYSICAL EFFECTS

With respect to radiation effects the terms primary and secondary are used in a relative sense; the usage depends on the situation under study. Thus, ionization and excitation may be considered as primary with respect to some physical and chemical effects. For other chemical effects, production of free radicals (molecular fragments) may be considered as primary even though that process requires a much longer time for its accomplishment. Still longer times are involved in biologic processes, in which the end product of an earlier chemical reaction may be considered as primary.

Generally, an atomic solid (a material consisting of only one atomic species) exhibits little or no permanent chemical change upon irradiation. Important among the atomic solids are such materials as metals and graphite. Production of molecular carbon (C_2) or bigger clusters upon irradiation of carbon and graphite may, in a certain marginal sense, be considered a chemical change. Ionization of a condensed atomic medium followed by recombination regenerates the same atom, but its locale may be affected. For a molecular medium the situation is quite different. Excited electronic states are often dissociative for a molecule and yield chemically reactive radicals. Positive ions, similarly produced, can experience a variety of reactions even before neutralization occurs. Such an ion may fragment all by itself, or it may react with a neutral molecule in what is called an ion-molecule reaction. In

changes
caused
by ir-
radiation

either case new chemical species are created. These transformed ions and radicals, as well as the electrons, parent ions, and excited states, are capable of reacting with themselves and with molecules of the medium, as well as with a solute (a dissolved substance) that may be present in homogeneous distribution. The end products of the reactions can be, on the one hand, new stable compounds or, on the other, regenerated molecules of the original species, as in the case of water irradiation.

A variety of purely physical effects have been observed in different substances under irradiation. They may be broadly classified as: (1) structural change in the crystal, sometimes accompanied by change in the structural dimensions, (2) change in static mechanical properties, such as elasticity and hardness, (3) change in dynamic mechanical properties, such as internal friction and strain, and (4) changes in transport properties, such as heat conductivity and electrical resistivity. Such changes are considered below in *Tertiary effects of radiation on materials*.

MOLECULAR ACTIVATION

A molecule is considered activated when it absorbs energy by interaction with radiation. In this energy-rich state it may undergo a variety of unusual chemical reactions that are normally not available to it in thermal equilibrium. Of special importance is electronic activation—i.e., production of an electronically excited state of the molecule (see Figure 1). This state can be reached (1) by direct excitation by photon absorption, (2) by impact of charged particles, either directly or indirectly through charge neutralization, or by excitation transfer from excited positive ions, and (3) by charge transfer in collision with (relatively) slow incident positive ions. Among the variety of ensuing processes is light emission, or luminescence.

Luminescence. The language of luminescence is clouded by history. Originally, fast luminescence was called fluorescence and slow (i.e., delayed or protracted) luminescence was called phosphorescence. Present scientific practice is to define the terms on the basis of so-called quantum-mechanical selection rules: fluorescence is an allowed transition (e.g., singlet-singlet) and occurs in a typical time of about 10^{-9} second; phosphorescence is a forbidden transition (e.g., triplet-singlet) and may require 10^{-6} second or longer.

In the gas phase (gaseous state), an excited molecule either luminesces, undergoes a process called internal conversion, or undergoes dissociation. Luminescence is the rule for anthracene, whereas for water it is dissociation into hydrogen (H) and hydroxide (OH). As a rule, luminescence processes occur by default—that is to say, only if dissociation is energetically impossible or involves a complicated energy-transfer process or if internal conversion to a nonluminescing state is inefficient.

Fluorescence usually takes place from the lowest electronically excited state (see Figure 1); if higher states are excited they either dissociate or energetically cascade to the lowest excited state by one of several possible internal transition mechanisms before emission occurs. (A notable exception to this rule is afforded by azulene.)

A similar situation exists for triplet excited molecules. The rate of emission, however, is even slower, for in this case it is forbidden by selection rules. If the triplet excitation energy is insufficient for molecular-bond breakage (dissociation), the molecule may remain in a metastable state (one of apparent, not real, stability) for a long time until it either phosphoresces, undergoes internal conversion, or combines with other triplets. Such a combination produces a highly excited state, which has enough energy for dissociation. Some of the latter excited states are formed as singlets capable of light emission. This discussion relates to the more common, general features. There are also special cases, not discussed, that do not follow the general pattern.

Ionization phenomena. Ionization (see Figure 1) is that extreme form of excitation in which an electron is ejected, leaving behind a positive molecular ion. The minimum energy required for this process is called the ionization potential (IP). The actual energetics are described by the Franck-Condon principle, which simply recognizes that,

during the extremely short time of an electronic transition, the nuclear configuration of a molecule experiences no significant change. As a consequence of this principle, in an optical process the ion is almost invariably formed in some kind of excited state by input of energy greater than the IP. Also, because of Franck-Condon restrictions, excitation of an inner electron may result in initial production of nonionized, superexcited molecules (suggested by R.L. Platzman, an American physicist) with energy exceeding the ionization potential. A superexcited molecule is short-lived and usually converts rapidly (in a time as short as 10^{-14} second) either to neutral products or to an ion plus a free electron with marked excess energy. The ion itself may fragment to give other species with excess kinetic or internal vibrational and rotational energy.

Excitation states. All the various kinds of excitation that occur in the gas phase may also take place in the condensed states of matter (liquid, glass, or solid), but their relative contributions may be affected. In addition, special activated states are produced for which there is no analogue in the gaseous state. They owe their existence to the collective behaviour of atoms and molecules in close proximity. The more important of them are the exciton state, the polaron state, the charge-transfer (or charge-separated) state, and the plasmon state.

The exciton state is a cooperative state of molecules in which the excitation energy belongs simultaneously to all.

In a polaron state an electron belongs to the association of molecules; but its motion is relatively slow so that it carries with it its own polarization field, which is described as "a cloud of virtual phonons." A solvated electron (an electron associated with a particular molecule or group of molecules) is an example of this.

The charge-transfer state is an excited state. In a certain sense, electronic excitation involves motion of an electron from a lower orbit to a higher one. Quantum mechanics notes that the electron does not revolve around an atomic nucleus in a precise classical orbit but rather that it occupies an orbital in which it is to be found with maximum probability in the location of the classical orbit. When a molecule in a condensed system is excited, the resulting electronic orbital may overlay one or more adjacent molecules, and, in that sense, the electron belongs to the group because its excitation level does not correspond to the electronic properties of a single, isolated molecule.

The plasmon state is a highly delocalized state formed collectively through Coulombian (electrostatic) interaction of weakly bound electrons. Energy losses, approximating 10–20 eV in most materials, resulting from formation of plasmon states are seen in the impact of electrons of a few tens of kilovolts energy on thin films. Both metals and nonmetals, including plastics, show plasma energy losses. The lost energy may reappear in the form of ultraviolet or visible radiation (Ferrell radiation, 1960); no chemical effect is known to have occurred from such losses.

Energy transfer. *Fluorescence and phosphorescence.* In general, a small, simple molecule luminesces in the ultraviolet, and a more complex one emits near the blue-violet end of the visible spectrum. Dye molecules, on the other hand, may emit throughout the visible region, including the red end. The ground electronic state of most molecules is a singlet state. Usually, therefore, the optically allowed emission, or fluorescence, is from the lowest excited singlet state to the ground state. The lowest triplet state of the molecule lies somewhat below the excited singlet. Light emission from this triplet state is forbidden by the quantum-mechanical selection rules, but it does occur by default when other processes are even less probable. Such emission is called phosphorescence. It is relatively weak, slow, and shifted toward longer wavelength. Triplet states may be produced from higher singlets by processes called internal conversion and intersystem crossing. The states may also be produced in excitation from the ground state by impact of relatively slow charged particles, such as electrons.

Much of the effect of optical radiation in a condensed system is not on the molecule in which the energy is initially absorbed but on a more remote molecule to which the energy is transferred in a variety of possible processes.

Franck-
Condon
principle

Production and reactions of ions in solution

They include excitation transfer either directly between adjacent molecules, by a direct quantum-mechanical interaction of an excited molecule with a remote one at a distance of 40 angstroms (4×10^{-7} centimetre) or less, or by the so-called trivial process of fluorescence emission from one molecule and reabsorption by one at any distance. These processes are studied mostly in regard to fluorescence and phosphorescence phenomena.

With high-energy radiation (such as that of electrons, X rays, and gamma rays), an additional mechanism involving ions is also available. In the case of a solute M in a solvent S , for example, a simplified description of some possible effects of radiation is represented by the following expressions, in which the symbol \rightarrow is read, "is acted upon by high-energy radiation to give" and e represents an ejected electron:

or

Any actual process is considerably more complicated and involves a larger number of species.

Photographic process. One of the most important effects of radiation on matter is seen in photographic action. Apart from its various uses in art, commerce, and industry, photography is an invaluable scientific tool. It is used extensively in spectroscopy, in photometry, and in X-ray examinations. Also, photographic emulsion techniques have been widely used in the detection and characterization of high-energy charged particles. It is important to note that all speculation regarding the primary phenomena involves the notion that, in an energy absorption process, either direct or sensitized, a chloride (or other halide) ion in a silver halide lattice loses an electron. That electron is thereafter captured by a silver ion located at such a point in the lattice that under suitable conditions of exposure and development a silver grain grows to a size representative of the duration and intensity of the light exposure.

IONIZATION AND CHEMICAL CHANGE

Earlier in this section, the ionization phenomenon was briefly discussed as a special case of molecular activation. The ionization process, however, does have certain characteristic features. Most notably, the probabilities (or cross sections) for ionization by light (photoionization) and for ionization by charged-particle impact are different in magnitude and in lowest—radiation—energy of occurrence (*i.e.*, threshold behaviour) for the same atom or molecule. The photoionization cross section shows abrupt onset (*i.e.*, a step behaviour) to a high value at threshold, falling thereafter only gradually with increase of photon energy. Electron-impact ionization in simple atoms (such as hydrogen and helium) begins at the ionization potential, increases in direct proportion to the energy near the threshold, and shows a peak at an incident energy of about 100–200 eV. With molecules the behaviour is similar except that the peak is broad and much less pronounced. When the incident energy is high and the ejected electron has kinetic energy (energy of motion) largely in excess of its binding energy, the cross section for the process approaches a limit called the classical Rutherford value, after the British physicist Ernest Rutherford.

In general, the initial processes resulting from the action of high-energy radiation on matter involve the intermediate production and participation of positive ions (both stable and unstable), electrons, negative ions, excited species, and free radicals and atoms, which in turn may enter into the processes of classical reaction kinetics.

Ordinary low-energy (or optical) processes usually involve only excited species and free radicals and atoms—all

formed by processes that do not involve outright transfer of electric charge (*i.e.*, electrons) between different atoms and molecules.

The important feature that characterizes the chemistry both of optical processes (photochemistry) and of high-energy radiation (radiation chemistry) is that they are conveniently employed and their kinetics studied at room temperature and lower.

Photochemistry. There are two "laws" of photochemistry. The first, the Grotthuss–Draper law (named for the chemists Christian J.D.T. von Grotthuss and John W. Draper), is simply: for light to produce an effect upon matter it must be absorbed. The second, or Stark–Einstein law (for the physicists Johannes Stark and Albert Einstein), in its most modern form is: one resultant primary physical or chemical act occurs per photon absorbed. The quantum yield of a particular species of product is the number of moles of that product divided by the number of einsteins of light (units of 6.02×10^{23} photons)—or the number of molecules of product per photon—absorbed. In the ideal case the quantum yield, frequently denoted by the Greek letters gamma, γ , or phi, Φ , is unity. In real cases, Φ may approach zero on the one hand—particularly if a back reaction is involved—or it may be of the order of 1,000,000, in which case the primary product may start a chain reaction, as in a clean, dry mixture of hydrogen (H) and chlorine (Cl). In the following chemical equations each symbol for an element stands for one atom, and the number of atoms bonded into a molecule is given as a subscript following the symbol, while the number of molecules precedes the formula; the arrow indicates the course of the reaction:

etc.,

in which reactions 2 and 3 reoccur repeatedly in a chain

reaction. The symbol $\xrightarrow{h\nu}$ may be read "when a photon of light frequency, symbolized by the Greek letter nu, ν (which is always stipulated), is absorbed, gives." Because h is Planck's constant of action (approximately 6.6×10^{-27} erg second) and ν is expressed in reciprocal seconds (*i.e.*, second⁻¹), the product $h\nu$ indicates the energy absorbed per photon. Some reactions may give two primary products; *e.g.*,

In that case, there are different quantum yields for each of the primary reactions, and the ratio of those yields varies with the frequency, ν , of the light absorbed.

Radiation chemistry. When a target is bombarded by a positive ion such as the hydrogen ion H^+ or the deuterium ion D^+ from a particle accelerator or the alpha particle $^4\text{He}^{2+}$ from nuclear decay, or indeed any high-energy heavy positive ion, the initial effects differ significantly from those of a high-energy electron. This situation results from the fact that, for the same kinetic energy, $\frac{1}{2}mv^2$, a particle of greater mass, m , travels with smaller velocity, v . The smaller the velocity of a particle of a particular charge in the domain of high (but not ultrarelativistic) velocities, the greater its probability of interaction with the medium traversed—that is to say, the greater the linear energy transfer. Thus, positive ions produce their initial effects close together in the ionization track in a condensed medium such as water (perhaps one or two angstroms, 1 or 2×10^{-8} centimetre, apart), whereas equally energetic electrons traveling through the same medium deposit energy in small collections called spurs, which may be 1,000 angstroms (10^{-5} centimetre) or so apart. The appearance of the excitation and ionization track has been likened to a rope (in the case of positive-ion bombardment), on the one hand, as compared with isolated beads on a string (in the

Grotthuss–Draper and Stark–Einstein laws

Electron-impact ionization

Nature of positive-ion tracks

case of electron bombardment), on the other. The dense track, as well as the isolated spurs, contains ions, excited molecules, and electrons; however, the distributions in the two essentially different types of track are so different that the ensuing chemical reactions (*i.e.*, the track effects) may be quite dissimilar. As an example, alpha-particle irradiation of pure water produces substantial yields of hydrogen and hydrogen peroxide (H_2O_2), whereas irradiation with beta particles, X rays, or gammas is essentially without effect. One of the reaction sequences suggested in overall considerations of the radiation chemistry of water is

in which reaction (1) summarizes the early chemical consequences both of ionization and of excitation. It has been suggested that reactions (2) and (3) occur with high probability in dense tracks (*e.g.*, of alpha particles) but that, in isolated spurs (as in fast-particle tracks), such reactions may occur only with low probability. In such a case, according to the American chemist A. Oliver Allen, the hydrogen atoms and OH radicals enter with somewhat greater probability into back-reaction chains with any $\text{H}_2 + \text{H}_2\text{O}_2$ already produced and existent in the body of the liquid:

The H atom produced in reaction (5) thereupon enters into reaction (4), so that whatever small amounts of H_2 and H_2O_2 are actually produced in reactions (2) and (3) are consumed in reactions (5) and (4), respectively, and remain essentially undetectable no matter how long the reaction is run.

Radiation chemical reactions. In more detailed discussions of the mechanism of radiation chemical reactions, the roles of both excitation and ionization are considered. Information regarding the former is available from the extensive data of photochemistry; frequently, the initial excitation process leads to no significant chemical effect. By contrast, ionization may result in a large variety of chemical changes involving the positive ion, the outgoing electron, and the excited states resultant from charge neutralization, as well as (parent) positive-ion fragmentation and ion-molecule reactions. Some such consequences are summarized for a few cases.

Different channels of fragmentation from the same parent ion (*e.g.*, the propane ion C_3H_8^+), such as

compete unless barred by energetic considerations. Because ionization potentials of various possible fragments may differ greatly, charge localization may occur on only one of them. On the other hand, because the initial ionization rarely leads to the ground state of the positive ion, the energy is usually adequate for bond breakage.

Ion-molecule reactions such as that between a water ion and a molecule,

are more important in the condensed phase, and fragmentation is more important in the gas phase. The parent ion in liquid water almost invariably undergoes ion-molecule reaction as indicated above. Many ion-molecule reactions have high cross sections. The same ion may

undergo fragmentation or ion-molecule reaction, depending on circumstances. Thus, methane (CH_4), acted upon by high-energy gamma radiation, producing an electron, symbolized by

may be followed by fragmentation,

as well as an ion-molecule reaction,

The electron ejected in an initial ionization process may further ionize and excite other molecules in its path, thus causing other chemical transformations. In addition, it may produce chemical changes of its own by dissociative attachment, as in carbon tetrachloride (CCl_4) and nitrous oxide (N_2O),

and by formation of negative ions of either permanent or virtual (*i.e.*, very short-lived) nature. Many of the negative ions produced in a dissociation process are chemically reactive (H^- , O^- , etc.) as well. Virtual negative ions are almost invariably in a high vibrational state—*i.e.*, they are vibrationally hot.

The important point to note from this limited discussion of primary physical effects and their consequences in radiation chemistry is that in general each such effect is the progenitor of many ionizations and excitations, the distribution of which in space depends on the energy of the particle involved as well as on the system traversed. There is no single resultant primary process corresponding to the result of absorption of a single optical photon and thus no analogue to the concept of quantum yield in photochemistry.

In radiation chemistry, yields are conventionally reported on the purely empirical basis of the number of molecules of a particular kind produced (or destroyed) per 100 eV input of a particular type of radiation. In the radiolysis (radiation-induced decomposition) of cyclohexane, for example, by cobalt-60 gamma radiation or by electrons of about 2,000,000 eV of energy, the overall yield of hydrogen per 100 eV input is frequently given as approximately 5.6 or $G(\text{H}_2) \approx 5.6$, in which the symbol G is read as "the 100-electron-volt yield of." Sometimes a small g is used to denote the 100-electron-volt yield of a postulated intermediate not directly determinable by measurement. Table 1 summarizes some typical G values.

Symbolism of radiation chemistry. The symbolism of radiation chemistry differs from that of photochemistry. The chemistry is somewhat more complicated, and the establishment of the variety of initial chemical processes is somewhat more of a chore. For the action of high-energy radiation on water, the variety of early products is typically indicated by the relation

in which $\xrightarrow{\gamma}$ is read "acted upon by high-energy radiation, gives" and e_{aq}^- is the symbol for the hydrated electron. Particular note is addressed to the species e_{aq}^- (*i.e.*, an electron solvated by water) indicated in the same reaction. For many years there was an awareness in the radiation chemistry of water of the anomalous behaviour of the hydrogen atom, H, as compared with the same atom produced in established chemical processes. The anomaly was resolved on the one hand by John W. Boag and E.J. Hart, who spectroscopically observed the species e_{aq}^- in the spectral region predicted by Platzman, and on the other hand by Harold A. Schwarz and Gideon Czapski, who showed the existence of the ionic reducing species with charge of minus unity.

Time scales in radiation chemistry. The time scale characteristic of radiation chemistry ranges from the extraordinarily short time required for a fast electron to traverse a molecule (about 10^{-18} second) to the time required for es-

Chemical studies with linac

sential completion of some neutralization processes in very viscous media (about three hours). In between, there can be a variety of reactions involving intermediate formation and disappearance of the collections of the various species already discussed. The time-scale spread is so great that a *pt* scale (in which *pt* is defined as minus the logarithm, to the base 10, of the time [in seconds] *t* [i.e., $-\log_{10} t$]) is conveniently employed. Actual observances in the long time-scale region follow fairly well-established chemical practice. The short-time region, on the other hand, presents interesting challenges. The Van de Graaff generator and the linear accelerator both made possible irradiations by electrons and X rays in the microsecond (10^{-6} second) region, and spectroscopic devices were quickly devised to make observations in that region. Improvements in irradiation technique (with X rays by Herbert Dreeskamp and Milton Burton, and with ultraviolet by Paul K. Ludwig and Juan d'Alessio) and in observation techniques in the study of luminescence extended precision of observation to 5×10^{-10} second in the work of William P. Helman.

Table 2: Approximate Time Scale of Events in a Condensed System

John K. Thomas combined use of a fast linac (linear accelerator) with Cherenkov radiation as a marker to extend chemical studies into the same region. Use of the same radiation as a light source for spectroscopic observation of the chemistry produced by a traveling electron front (from a linac) made possible actual observations in the time range of $(2 \text{ to } 4) \times 10^{-11}$ second. Table 2 summarizes an approximate time scale of events.

Tertiary effects of radiation on materials

The electrons liberated by high-energy irradiation that have sufficient energy cause further ionizations in which additional electrons are produced. Some of these second generation electrons also cause additional ionizations, and this process continues until their remaining energy becomes inadequate. Even though this process goes through several generations of events, it actually takes little time and thus appears as an impact phenomenon as far as radiation-induced chemical changes are concerned. For this purpose, then, they may be considered as primary. Fast chemical changes induced by radiation may take time on the order of nanoseconds (a nanosecond is 10^{-9} second) or less to complete. Slower reactions involving relatively less reactive scavengers (reagents that eliminate residues) in dilute concentrations may require a time span of approximately 10^{-4} second.

This section is concerned with radiation effects measurable on much longer time scales, arbitrarily greater than about one minute. Attention is here addressed to physical changes in the solid state, about which there is a wealth of experimental information. It should again be emphasized that little chemical change is expected in an atomic medium in which the absorption of ionizing radiation also results ultimately in structural changes and induced imperfections. With neutron irradiation, in addition to specific nuclear interactions, one gets "knocked off" atoms or ions (note the discussion of the Wigner effect in *Neutrons* above). These ions quickly capture electrons and the resulting neutral atoms then travel on. Even though a small effect occurring in ionization and electronic excitation attributable to knocked off ions cannot be denied, it is believed that this effect is small compared with that brought about by the neutral knock offs in the form of structural changes.

HEATING EFFECTS

The simplest ultimate effect of absorption of radiation is heating. It can be argued that, for ionizing radiation of low linear energy transfer, the heating effect is negligible. A spur created by such low-LET radiation is a small spherical region in which the energy deposit is localized in isolation. The temperature rise, ΔT , of the spur above the surrounding temperature has a space-time dependence that, by hypothesis, has a statistical distribution, called Gaussian, because of random superposition of events leading to the heating process. The temperature rise at a point located a distance *r* away from the spur centre at time *t* is given by the equation

$$\Delta T(r, t) = \Delta T_{max} (1 + \frac{4\gamma t}{a^2})^{-3/2} \exp(-\frac{r^2}{a^2 + 4\gamma t}),$$

in which *a* is the initial spur-size parameter, the Greek letter gamma, γ , is the thermal diffusivity of the medium (equal to heat conductivity divided by the product of density and specific heat at constant volume), and ΔT_{max} is the initial maximum temperature rise at the centre of the spur. Taking reasonable values for energy deposition (30 eV) and spur size *a* (20 angstroms, or 2×10^{-7} centimetre) and using (for water) density equal to one gram per cubic centimetre and specific heat 4×10^7 ergs per gram-degree, ΔT_{max} may be estimated to be 30°C (54°F). The time required for the central temperature to drop to half its initial value (i.e., $t_{1/2}$) is given by $(1 + 4\gamma t_{1/2}/a^2)^{3/2} = 2$. With the thermal diffusivity, symbolized by the Greek letter gamma, γ , equal to 10^{-3} centimetre squared per second for water, $t_{1/2} = 6 \times 10^{-12}$ second. The conclusion is that for low-LET radiation the local temperature rise is too small and too brief to have any appreciable

Temperature rise in spur

chemical (or physical) effect. It is particularly notable that the actual temperature rise is smaller than that estimated here because part of the deposited energy is invariably utilized in ionization, dissociation, and similar processes. This part of the energy resides in the potential form and is not completely available for heating. With high-LET ionizing radiations (such as fission fragments, stripped nuclei, and α -particles), the situation is somewhat different. In such a case, a large amount of energy is deposited per unit path length, resulting in cylindrical tracks (rather than spherical spurs). The equation for temperature rise in this case is written in a form much like the equation for spur geometry; that is,

$$\Delta T(r, t) = \Delta T_{\max} \left(1 + \frac{\gamma t}{a^2}\right)^{-1} \exp\left(-\frac{r^2}{a^2 + 4\gamma t}\right),$$

Tempera-
ture rise
to
10,000 K

except that in this case a is the initial size parameter for the track cylinder and ΔT_{\max} is the maximum initial temperature rise on its axis. For fission fragments with LET of 500 eV per angstrom (*i.e.*, 10^{-8} centimetre) and a equal to 20 angstroms, ΔT_{\max} for water is 1.6×10^4 K. Admittedly, this figure is an overestimate for reasons similar to those that apply for low-LET radiations, but it is believed that the temperature rise is high and may approach 10,000 K. The time for this temperature to drop to half the initial value is given by $t_{1/2} = a^2/4\gamma$, which in this case is estimated to be about 10^{-11} second. This time is not much larger than the corresponding time for survival of an isolated spur. Because of the high local temperature, however, the reaction time of the radiation-produced intermediates is also very small. In an intermediate + substrate (*i.e.*, solvent) reaction, for example, with an activation energy of approximately eight kilocalories per mole, the rate constant, k , for such a typical pseudo-first-order reaction may be written, according to the simple usage of chemical kinetics, in the form

$$k = 10^{-11} \exp(-8,000/RT) \text{ cubic centimetre per molecule per second,}$$

in which R is the gas constant in units of two calories per degree and T is the absolute temperature. For a substrate concentration of 10^{22} molecules per cubic centimetre and a temperature of 10,000 K, $-d(\ln v)/dt = 6.6 \times 10^{10}$ reciprocal seconds, in which the Greek letter nu, v , here denotes the concentration of intermediates still existent at time t . Therefore, the time required for the intermediate concentration to drop to an "e-folding" value (*i.e.*, to fraction $1/e$) is approximately 1.5×10^{-11} second, a time that compares favourably with the duration of the temperature pulse. The conclusion is that for very high LET radiation there is indeed a high degree of local heating, and, even though the heat pulse survives only a short time, that time still is long enough to bring about the acceleration of reactions between the short-lived intermediates and the ambient substrate.

CRYSTAL-LATTICE EFFECTS

Cause of
structural
damage

In neutron irradiation of a solid, atoms are dislodged from normal lattice positions and set in motion (the Wigner effect). The fractional amount of energy transfer depends, as in any elastic collision, on the mass ratio of the neutron to that of the recoil atom. Thus, in graphite a carbon atom, on first collision with a neutron of 1,000,000-eV (produced, say, in a fission process), receives a kinetic energy of approximately 10^5 eV, which is large compared with its binding energy in the lattice (about 10 eV). It is estimated that the 1,000,000-electron-volt neutron strikes about 60 carbon atoms before it is thermalized or its speed is so much reduced that it cannot knock off other carbon atoms. Much of the structural damage caused by radiation is attributable to these (relatively heavy) carbon atoms rather than to the original neutron. In this sense, radiation damage by fast neutrons may be viewed as an indirect action. Slowing of the fast carbon (or other dislodged) atoms is basically governed by interaction time. This fact means that the stopping is light in the beginning of the journey of a dislodged atom and results only in occasional displacement of atoms. Toward the end of its career a large number of atoms are displaced in quick

succession along a row, and finally a large amount of residual energy is dumped locally into a relatively small group of atoms. This process generates the displacement (or thermal) spike; the local temperature rise is estimated to be about 1,000 K. Even though the temperature rise lasts only about 10^{-11} second before the track is cooled down, this duration is enough for permanent structural damage. At least a part of the swelling of graphite under reactor-neutron irradiation is the result of this local heating; another part originates in change in lattice dimension under irradiation.

The high temperature rise in a thermal spike probably results in local melting of the solid. Evidence in that direction has been obtained from a study of beta-brass (an alloy consisting of equal numbers of atoms of copper and zinc) under neutron bombardment at low temperature. Before irradiation, the alloy structure is ordered: each copper atom is surrounded by eight zinc atoms as nearest neighbours and vice versa. After irradiation, a general random rearrangement of the atoms can be detected, presumably the result of melting and refreezing.

Long-term effects of radiation on crystals are numerous, and the magnitudes of these effects depend on the crystal structure and previous history. Only some general features of these effects are recounted here.

1. Radiation damage may be thought to consist of pairs of interstitial atoms ejected from their normal lattice sites and the corresponding vacancies left behind. A vacancy-interstitial pair is called a Frenkel defect.

Frenkel
defect

2. A solid has a tendency to recover spontaneously from radiation damage. If it were not for this property, it would indeed be extremely difficult to operate nuclear reactors that are permitted to heat up periodically to remove the effect in the graphite core. The healing (or so-called annealing) is presumably attributable to the recombination of interstitial atoms and vacancies, thereby removing Frenkel defects. It is not necessary that an interstitial atom always recombine with its corresponding vacancy. Often it may recombine with a vacancy that resembles the one that it left; the result is approximate restoration of the original properties of the crystal. Such annealing is facilitated by the increased mobility of the vacancies and interstitials at higher temperature. At a particular temperature called the annealing temperature, the healing becomes fast and essentially complete. The same substance may have somewhat different annealing temperatures depending on the particular property under study. Many experiments on radiation damage must be carried out at low temperatures to freeze in the defects produced. Pure metals are the most easily annealed substances. Annealing temperatures in such cases are relatively low. Accordingly, the annealing temperature for the increase of electrical resistance in pure copper is only around 40 K. On the other hand, changes in elastic modulus and hardness, such as are required to produce tuning-fork characteristics, persist up to room temperature—namely, 293 K. Quick annealing in pure metals is directly attributable to the high mobility of atoms in perfectly ordered structures. At the other extreme are organic solids, particularly polymers, that are composed of large molecules. In this case, the damage originates in the breaking of bonds that ordinarily do not rejoin in the original manner but instead produce chemically different material.

3. In simple metals irradiation decreases conductivity for both heat and electricity. Conduction of both in metallic crystals is attributable to their ordered structure. The more perfect the structure, the better is the conduction. Frenkel defects, generated by irradiation, therefore decrease both conductivities. In extreme cases conductivity decrease of orders of magnitude has been observed. With moderate irradiation, however, both thermal and electrical conductivities decrease usually by half. The thermal conductivity of graphite falls to roughly half the unirradiated value with an exposure of 3×10^{20} neutrons per square centimetre at room temperature. Like other property changes, this effect also can be annealed at elevated temperatures with concomitant release of stored energy. Energy storage in graphite amounts to about 200 calories per gram per 10^{20} neutrons per square centimetre total flux. Interstitial car-

Change in
conduc-
tivities

bon atoms produced in the irradiation scatter electrons and thus decrease electrical conductivity. The pattern of conductivity decrease and increase depends on the nature of the graphite and the duration of exposure in a reactor. With ceramic materials, loss of thermal conductivity by a factor of about 3 to 5 may be observed under conditions in which the decrease is about one-half in graphite. In mica, on the other hand, the change is somewhat less than in graphite.

4. Hardness and ductility depend on perfection of the crystal structure. It is thus found that irradiation results in a loss of ductility and an increase in hardness. Such effects are attributed to glide-plane obstruction in the crystal. Most structured materials become harder, less ductile, and sometimes more brittle as the result of neutron irradiation. Similarly, most polymers also lose ductility on irradiation. In a certain sense radiation-induced damage to the crystal structure is qualitatively similar to that produced by cold-working (for example, by hammering). Neutron irradiation of pure copper, which is naturally soft at room temperature, makes it so hard that it can be made to sing like a tuning fork. Graphite experiences increase in strength and hardness upon irradiation. Annealing is faster at elevated temperatures; also, damage is less when the irradiation is at a higher temperature. A similar effect is seen for the compressive stress-strain curve. Studies of dynamic properties in ceramics indicate a saturation effect at large doses.

5. As was discussed above, irradiation causes expansion and lattice distortion in most cases. A perfect crystal of graphite consists of planes of carbon atoms layer upon layer. When irradiated by neutrons, graphite expands perpendicular to the base plane and contracts slightly parallel to it. After moderate exposure in a nuclear reactor, the expansion is approximately 1 percent for a flux of 10^{20} neutrons per square centimetre. The actual amount of expansion, of course, depends on the fabrication history and operating temperature of the graphite. Expansion of moderator materials such as graphite is of considerable importance in the design of nuclear reactors. Even a small percentage change in dimension can result in large total change in the reactor structure; if this change is not allowed for in the engineering design of the reactor, it may well create strained operating conditions eventually leading to failure.

(M.Bu./A.Moz./M.Lu.)

SURFACE EFFECTS

A surface is distinct from bulk matter in that it constitutes the physical interface with the environment. Whether or not a metal will corrode in salt water, for example, or how much resistance to wear is inherent in the design of a bearing are concerns that relate primarily to the physical condition of surfaces. The latter, in turn, may be selectively modified by the application of coatings or by the action of radiation, or by both. Three of the most common examples of surface modification by radiation—ultraviolet curing, ion implantation, and sputtering—are considered here.

Ultraviolet curing is a process in which polymers, generally employed as coatings, are irradiated by ultraviolet light. Such action produces electronic excitation and ionization of the long chain molecules that make up the polymer, either directly or through the mediation of imbedded, light-sensitive "activators." This results in intermolecular bonding, a process called cross-linking. The entire polymeric coating, typically on the order of tenths of millimetres thick (depending on the application), becomes so highly cross-linked as to take on the character of a single giant molecule. The major effects of ultraviolet irradiation of polymers include reduction of friction, increased resistance to wear, increased hardness, and increased resistance to attack by acids and other corrosive agents. Ultraviolet curing is employed for diverse purposes ranging from the formation of "no-wax" coatings on floor tiles to application in the photolithographic process integral to the fabrication of solid-state electronic devices.

Ion implantation involves the irradiation of solids by beams of energetic ions emanating from particle accelerators. Typical energies employed are on the order of

100 keV (100,000 electron volts). Typical depths of penetration are on the order of several thousand angstroms, depending on energy, ion type, and target material. In ion implantation, virtually any atomic species can be embedded to predetermined depths and with predetermined concentration profiles in any target material so as to modify the surface characteristics without affecting desirable bulk properties. A typical example is the implantation of titanium in iron alloys to reduce wear of bearings and gears. A particularly promising technique was developed by physicists Michael W. Ferralli and Luntz, in which vacuum deposition of polymeric coatings on metallic substrates and simultaneous ion-beam irradiation act to produce implanted hydrocarbon films. The latter can be made to vary in carbon-to-hydrogen ratio from very high values—with the implanted region having some characteristics of diamond—to values on the order of unity and corresponding polymeric characteristics. This is accomplished by a process called preferential sputtering (see below). The films so produced are highly resistant to corrosion and appear to possess important bio-compatibility properties, making them suitable for applications in, for example, the treatment of the surfaces of surgical implants such as artificial hip joints. Such effects of ion implantation result in part from structural changes induced by radiation damage (*e.g.*, implantation of boron or phosphorus in steel can render the surface amorphous so as to eliminate grain boundaries and other corrosion-sensitive sites), and in part from chemical changes arising from bonding of the implanted species with constituents of the substrate.

Sputtering is a process in which atoms, ions, and molecular species in the surface of a target material are ejected under the action of ion-beam irradiation. Energies typical of ion implantation are employed and, while any ion type may be used, noble (or rare) gases such as argon and neon are most common. The latter avoid unwanted chemical interactions between the ions of the beam and the substrate. Sputtering results from several interaction mechanisms. Conceptually, the simplest is rebound sputtering, in which an incident ion strikes an atom on the surface, causing it to recoil into the target. The recoiling atom promptly collides with a neighbouring atom in the target, rebounds elastically, and is ejected from the surface. A similar but somewhat more complex mechanism is recoil sputtering, in which a struck, recoiling surface atom undergoes a random sequence of elastic scatterings in the target material, ultimately migrating back to, and through, the surface. Yet another mechanism is prompt thermal sputtering, in which energized atoms in thermal spikes created close to the surface escape through the surface before annealing occurs. Certain materials (*e.g.*, crystalline alkali halides) are prone to electronic sputtering, in which energy associated with electronic excitations induced by the incident ion is transformed into atomic recoil kinetic energy, often sufficient to cause the ejection of ions through the surface. By means of any of these various mechanisms, several atoms may be sputtered for each ion incident on the target. The number of atoms sputtered per incident ion is called the sputtering yield.

Surface modifications caused by sputtering are characterized as structural (*e.g.*, phase conversion from crystalline to amorphous and vice versa), topographical (*e.g.*, alteration of the shape of surface protrusions such as grain boundaries, development of facets, and the removal of surface contaminants), electronic (*e.g.*, radiation-induced chemical changes), and compositional (*e.g.*, preferential sputtering of a particular atomic species resulting in changes in the composition of alloys).

Biologic effects of ionizing radiation

The biomedical effects of ionizing radiation have been investigated more thoroughly than those of any other environmental agent. Evidence that harmful effects may result from small amounts of such radiation has prompted growing concern about the hazards that may be associated with low-level irradiation from the fallout of nuclear weapons, medical radiography, nuclear power plants, and other sources.

Assessment of the health impact of ionizing radiation requires an understanding of the interactions of radiation with living cells and the subsequent reactions that lead to injury. These subjects are surveyed in the following sections, with particular reference to the principal sources and levels of radiation in the environment and the different types of biologic effects that may be associated with them.

HISTORICAL BACKGROUND

Within weeks after Röntgen revealed the first X-ray photographs in January 1896, news of the discovery spread throughout the world. Soon afterward, the penetrating properties of the rays began to be exploited for medical purposes, with no inkling that such radiation might have deleterious effects.

Early reports of burns and cancer induced by X rays

The first reports of X-ray injury to human tissue came later in 1896. Elihu Thomson, an American electrical engineer, deliberately exposed one of his fingers to X rays and provided accurate observations on the burns produced. That same year, Thomas Alva Edison was engaged in developing a fluorescent X-ray lamp when he noticed that his assistant, Clarence Dally, was so "poisonously affected" by the new rays that his hair fell out and his scalp became inflamed and ulcerated. By 1904 Dally had developed severe ulcers on both hands and arms, which soon became cancerous and caused his early death.

During the next few decades, many investigators and physicians developed radiation burns and cancer, and more than 100 of them died as a result of their exposure to X rays. These unfortunate early experiences eventually led to an awareness of radiation hazards for professional workers and stimulated the development of a new branch of science—namely, radiobiology.

Radiations from radioactive materials were not immediately recognized as being related to X rays. In 1906 Henri Becquerel, the French physicist who discovered radioactivity, accidentally burned himself by carrying radioactive materials in his pocket. Noting that, Pierre Curie, the co-discoverer of radium, deliberately produced a similar burn on himself. Beginning about 1925, a number of women employed in applying luminescent paint that contained radium to clock and instrument dials became ill with anemia and lesions of the jawbones and mouth; some of them subsequently developed bone cancer.

In 1933 Ernest O. Lawrence and his collaborators completed the first full-scale cyclotron at the University of California at Berkeley. This type of particle accelerator was a copious source of neutrons, which had recently been discovered by Sir James Chadwick in England. Lawrence and his associates exposed laboratory rats to fast neutrons produced with the cyclotron and found that such radiation was about two and a half times more effective in killing power for rats than were X rays.

Considerably more knowledge about the biologic effects of neutrons had been acquired by the time the first nuclear reactor was built in 1942 in Chicago. The nuclear reactor, which has become a prime source of energy for the world, produces an enormous amount of neutrons as well as other forms of radiation. The widespread use of nuclear reactors and the development of high-energy particle accelerators, another prolific source of ionizing radiation, have given rise to health physics. This field of study deals with the hazards of radiation and protection against such hazards. Moreover, since the advent of spaceflight in the late 1950s, certain kinds of radiation from space and their effects on human health have attracted much attention. The protons in the Van Allen radiation belts (two doughnut-shaped zones of high-energy particles trapped in the Earth's magnetic field), the protons and heavier ions ejected in solar flares, and similar particles near the top of the atmosphere are particularly important.

UNITS FOR MEASURING IONIZING RADIATION

Ionizing radiation is measured in various units. The oldest unit, the roentgen (R), denotes the amount of radiation that is required to produce 1 electrostatic unit of charge in 1 cubic centimetre of air under standard conditions of pressure, temperature, and humidity. For expressing the dose of radiation absorbed in living tissue, the principal

units are the gray (Gy; 1 Gy = 1 joule of radiation energy absorbed per kilogram of tissue) and the rad (1 rad = 100 ergs per gram of tissue = 0.01 Gy). The sievert (Sv) and the rem make it possible to normalize doses of different types of radiation in terms of relative biologic effectiveness (RBE), since particulate radiations tend to cause greater injury for a given absorbed dose than do X rays or gamma rays. The dose equivalent of a given type of radiation (in Sv) is the dose of the radiation in Gy multiplied by a quality factor that is based on the RBE of the radiation. Hence, one sievert, defined loosely, is that amount of radiation roughly equivalent in biologic effectiveness to one gray of gamma rays (1 Sv = 100 rem). Because the sievert and the rem are inconveniently large units for certain applications, the milligray (mGy; 1 mGy = 1/1000 Gy) and millisievert (mSv; 1 mSv = 1/1000 Sv) are often substituted.

For expressing the collective dose to a population, the person-Sv and person-rem are the units used. These units represent the product of the average dose per person times the number of people exposed (e.g., 1 Sv to each of 100 persons = 100 person-Sv = 10,000 person-rem).

The units employed for measuring the amount of radioactivity contained in a given sample of matter are the becquerel (Bq) and the curie (Ci). One becquerel is that quantity of a radioactive element in which there is one atomic disintegration per second; one curie is that quantity in which there are 3.7×10^{10} atomic disintegrations per second (1 Bq = 2.7×10^{-11} Ci). The dose that will accumulate over a given period (say, 50 years) from exposure to a given source of radiation is called the committed dose, or dose commitment.

Table 3: Cosmic-Radiation Exposure

location	mean dose in millisievert (mSv)* per year
Sea level, temperate zone	0.20–0.40
1,500 metres	0.40–0.60
3,000 metres	0.80–1.20
12,000 metres	28
36–600 kilometres	70–150
Interplanetary space	180–250
Van Allen radiation belt (protons)	<15,000
Single solar flare (protons and helium)	<10,000

*Millisievert is a radiation dose-equivalent unit: it corresponds to a dose equivalent in biologic effectiveness to 10 ergs energy of gamma radiation transferred to one gram of tissue.

SOURCES AND LEVELS OF RADIATION IN THE ENVIRONMENT

Natural sources. From the beginning, life has evolved in the presence of natural background ionizing radiation. The principal types and sources of such radiation are: (1) cosmic rays, which impinge on the Earth from outer space (Table 3; Figure 4); (2) terrestrial radiations, which

Health physics

Figure 4: Major sources of natural background radiation and their respective contributions to the exposure of the average person.

Table 4: External Dose Due to Natural Radioactivity in Soil or Rock

source	dose in mSv per year
Ordinary regions	0.25–1.6
Active regions	
Granite in France	1.8–3.5
Houses in Switzerland (alum shale)	1.58–2.2
Monazite alluvial deposits in Brazil	mean 5; max 10
Monazite sands, Kerala, India	3.7–28

are released by the disintegration of radium, thorium, uranium, and other radioactive minerals in the Earth's crust (Table 4; Figure 4); and (3) internal radiations, which are emitted by the disintegration of potassium-40, carbon-14, and other radioactive isotopes that are normally present within living cells (Table 5; Figure 4). The average total dose received from all three sources by a person residing at sea level is approximately 0.91 mSv per year (Table 6); however, a dose twice this size may be received by a person residing at a higher elevation such as Denver, Colo., where cosmic rays are more intense (Table 3), or by a person residing in a geographic region where the radium content of the soil is relatively high (Table 4). In the latter type of region, the radioactive gas radon, which is formed in the decay of radium, may enter a dwelling through its floor or basement walls and accumulate in the indoor air unless the dwelling is well ventilated periodically; occupants of such a dwelling may therefore receive a dose as high as 100 mSv per year in their lungs from inhalation of the entrapped radon and its disintegration products (Table 5; Figure 4).

Artificial sources. In addition to natural background radiation, people are exposed to radiation from various man-made sources, the largest of which is the application of X rays in medical diagnosis. Although the doses delivered in different types of X-ray examinations vary from a small fraction of a mGy to tens of mGy (Table 7), the average annual dose per capita from medical and dental irradiation in developed countries of the world now approaches in magnitude the dose received from natural background radiation (Table 6). Less significant artificial sources of radiation include radioactive minerals in crushed rock, building materials, and phosphate fertilizers; radiation-emitting components of television sets, smoke detectors, and various other consumer products; radioactive fallout from nuclear weapons (Table 8); and radiation released in nuclear power production (Table 6).

Average total dose from natural sources

Use of X rays in medical diagnosis

Table 5: Average Dose Due to Natural Radioactivity Deposited Internally

isotope	radioactivity in millibecquerel (mBq)*	radiation	dose in mSv (per year)	critical organ
Carbon-14	2.2×10^{-7} per kilogram	beta rays	0.016	gonads
Potassium-40	3.9×10^{-7} per kilogram	beta rays	0.165	gonads
Potassium-40	5.6×10^{-8} per kilogram	gamma rays	0.023	gonads
Radium and daughters	3.7×10^{-9} in body	alpha, beta, gamma rays	7.6	bones
Radon and daughters	1.2×10^{-2} per l in inhaled air	alpha, beta, gamma rays	20	lungs

*Millibecquerel is a unit of radioactive disintegration rate; it corresponds to that quantity of a radioactive element in which there is one disintegration every 1,000 seconds.

Most of the radioactivity produced in nuclear power reactors is safely contained; however, a small percentage escapes as stack gas or liquid effluent and eventually may contaminate the atmosphere and water supply. (There are similar releases from nuclear-fuel reprocessing plants.) Though nuclear plants are basically clean sources of energy, they thus contribute to the worldwide background radiation level. This problem cannot be entirely avoided by using coal instead of nuclear fuel for power production, since many sources of coal contain natural radioactivity (e.g., radium) that is released in stack gases, along with chemical pollutants.

From Table 6 it is evident that the human population is now exposed to about twice as much radiation from all sources combined as it receives from natural sources

alone. Hence, it is important to understand the possible consequences, if any, that may result from the additional exposure to radiation.

In comparison with the relatively small amounts of radiation described above, the dose typically administered to a patient in the treatment of cancer is thousands of times larger; i.e., a total dose of 50 Sv or more is usually delivered to a tumour in daily exposures over a period of four to six weeks. To protect the normal tissues of the patient against injury from such a large dose, as well as to protect medical personnel against excessive occupational exposure to stray radiation, precautions are taken to restrict exposure to the tumour itself insofar as possible. Comparable safeguards are utilized to minimize the exposure of workers employed in other activities involving radiation or radioactive material. Similarly, elaborate safety measures are required for disposal of radioactive wastes from nuclear reactors, due in part to the slow rate at which certain fission products decay. A given amount of plutonium-239, for example, still retains about one-half of its radioactivity after 25,000 years, so that reactor wastes containing this long-lived radionuclide must be safely isolated for centuries.

Table 6: Estimates of Average Annual Dose Equivalent to the Whole Body from Various Sources of Irradiation Received by Members of the U.S. Population

source of radiation	average dose rates (mSv/year)

Miscellaneous	0.05
Subtotal	1.06
Total	1.97

*Values in parentheses indicate range over which average levels for different states vary with elevation. †Range of variation (shown in parentheses) attributable largely to geographic differences in the content of potassium-40, radium, thorium, and uranium in the Earth's crust.

In the event of an atmospheric nuclear bomb explosion, large quantities of radioactivity are released, the dispersal of which depends on the prevailing weather conditions as well as on the height and nature of the blast. Although the level of contamination resulting from such an explosion or from a nuclear-power plant accident is generally highest in the immediate vicinity of the event itself, both radioactive gas and dust may be transported via air or water for many hundreds of kilometres and eventually contaminate the entire globe.

MECHANISM OF BIOLOGIC ACTION

As ionizing radiation penetrates living matter, it gives up its energy through random interactions with atoms and molecules in its path, leading to the formation of reactive

Table 7: Typical Doses to Exposed Tissue Received in Routine X-Ray Diagnosis

examination	dose per exposure in milligray (mGy)*
X-ray photograph	
Chest	0.4–10
Abdominal	10
Extremities	2.5–10
Fluoroscopy	100–200 per minute

Process of indirect action

ions and free radicals. It is the molecular alterations resulting from these ionizations and, in turn, the resultant biochemical changes that give rise to various types of injury. X rays and gamma rays, for example, impart their energy to "planetary" atomic electrons, which are thereby ejected from their orbits. Such an ejection of a planetary electron results in an ion pair consisting of a free electron and the electrically charged atom from which it was ejected. The ejected electron may give rise to a highly reactive free radical, which in turn may diffuse far enough to attack a biologically important target molecule in its vicinity. This so-called indirect action process, through which radiation causes damage via radiation-induced free radicals, may be envisioned as follows:

While the initial steps in the above process occur almost instantaneously, expression of the biologic effect may take years or decades, depending on the type of injury involved. The indirect action of radiation is more important in the biologic effects of low-LET radiations than in those of high-LET radiations (see above), but the latter have a greater capacity to cause injury through direct interaction with biologic targets.

Target theory

Direct biologic actions, studied in detail between 1927 and 1947, gave rise to a target theory of radiobiology that has provided a quantitative treatment of many of the biologic effects of radiation, particularly in the field of genetics. According to this theory, a tissue or cell undergoing irradiation is likened to a field traversed by machine-gun fire, in which the production of a given effect requires one or more hits by an ionized track on a sensitive target. The probability of obtaining the effect is thus dependent on the probability of obtaining the requisite number of hits on the appropriate target or targets.

The distribution of ionizing atomic interactions along the path of an impinging radiation depends on the energy, mass, and charge of the radiation. The ionizations caused by neutrons, protons, and alpha particles are characteristically clustered more closely together than are those caused by X rays or gamma rays (Figure 5). Thus, because the probability of injury depends on the concentration of molecular damage produced at a critical site, or target, in the cell (e.g., a gene or a chromosome), charged particles generally cause greater injury for a given total dose to the cell than do X rays or gamma rays; i.e., they have a high RBE. At the same time, however, charged particles usually penetrate such a short distance in tissue (Figure 5) that they pose relatively little hazard to tissues within the body unless they are emitted by a radionuclide, or radioactive isotope, that has been deposited internally.

RADIONUCLIDES AND RADIOACTIVE FALLOUT

Radionuclides emit various ionizing radiations (e.g., electrons, positrons, alpha particles, gamma rays, or even characteristic X rays), the precise types of which depend on the radionuclide in question. Exposure to a radionuclide and its emissions may be external, in which case the penetrating power of the radiation is an important factor in determining the probability of injury. Alpha particles, for example, do not penetrate deeply enough into the skin to cause damage, whereas energetic beta particles or X rays can be hazardous to the skin and deeper tissues (Figure 5).

From J. Shapiro, *Radiation Protection: A Guide for Scientists and Physicians*, 2nd ed., Harvard University Press, 1981

Figure 5: Density of distribution and range of ionization events along tracks of radiations of different types in soft tissue. Each ionization event is denoted by a dot.

Accumulation in critical organs. Radionuclides can enter the body by ingestion, inhalation, or injection. Once taken into the body, their radiation effects depend on their anatomic distribution, duration of retention in the body, and rate of radioactive decay (see above), as well as on the energies of their emitted radiations. An internally deposited radioactive element may concentrate in, and thus irradiate, certain organs more than others. Radioiodine, for example, collects in the thyroid gland, whereas radium and strontium accumulate chiefly in the bones. Different radioelements also vary in their rates of removal. Radioiodine, for instance, is normally eliminated from the thyroid rapidly enough so that its concentration is halved within days. Strontium-90, on the other hand, is retained in high concentrations in the skeleton for years.

The term critical organ refers to the part of the body most vulnerable to a given isotope. The critical organ for plutonium, radium, strontium, and many other fission products is bone and the adjacent bone marrow. For iodine, the critical organ is the thyroid gland. Insoluble airborne radioactive dust often settles in the alveoli of the lungs, while small colloidal particles may become deposited in the bone marrow, liver, or spleen. Table 9 gives an abbreviated list of the maximum permissible concentrations (U.S. recommendations) of some radionuclides for humans. (The maximum permissible concentration is the largest amount of a radionuclide that can be accumulated in the body without producing undue risk of injury.)

Maximum permissible concentration (MPC)

Table 9: Values for the Maximum Permissible Concentration (MPC) of Certain Radionuclides

isotope	chemical form	critical organ	mBq in body
Tritium (hydrogen-3)	water		7.4×10^{-3}
Carbon-14	carbon dioxide		1.5×10^{-5}
Strontium-90*	water-soluble salt		1.5×10^{-6}
Iodine-131	water-soluble salt	bone	1.5×10^{-7}
		thyroid	1.8×10^{-6}
Cesium-137	water-soluble salt		2.6×10^{-8}

*MPC in drinking water: 3.7×10^{-9} micro Bq per litre. †MPC in air: 3.7×10^{-11} micro Bq per litre. ‡MPC in drinking water: 3.7×10^{-10} micro Bq per litre.

Since a radionuclide delivers radiation continuously to the surrounding tissue, the effect of such protracted continuous exposure must be distinguished from that of a single exposure or of periodically repeated exposures. From experiments with divided doses of gamma radiation or X radiation, it has been found that up to about 60 percent of the radiation effect from a single brief exposure is repaired within several hours. The body therefore is able to tolerate a larger total dose when the dose is accumulated slowly or when part of it is absorbed at a later time. There is less recovery with neutron and alpha radiation, however. (Neutrons are generally more effective agents of mutation than are X rays: for a single brief exposure, by a factor 1 to 8; for chronic irradiation, by a factor up to 100.)

Fallout is the deposition of airborne radioactive contaminants on Earth. Radioisotopes are produced naturally in the air by cosmic radiation, and they may enter the air in stack gases from nuclear power plants or be released through industrial accidents or nuclear explosions. After 1954, nuclear bomb tests carried out by several nations produced measurable fallout on the surface of the entire Earth, arousing great concern and controversy with respect to the resultant health effects. While much of the hazard from the detonation of a nuclear weapon is due to blast waves and heat, the radiation dose from fission products can be so intense that only persons remaining in underground shelters for some weeks could hope to survive. Usually the most prominent isotopes in fallout are fission products; however, all materials exposed to nuclear blasts may become radioactive.

The hazards of long-lived radioisotopes. Several of the radioisotopes contained in fallout are especially hazardous because they remain radioactive for relatively long periods. Cesium-137, strontium-90, and plutonium-239 may be the most significant among these. Fallout material can cover external surfaces and foliage and later be washed into the soil, from which plants may absorb strontium-90, along with the chemically similar calcium, and cesium-137 with potassium. Humans take in these radioactive materials chiefly from drinking water and from plant and animal foods, including milk. Many fallout isotopes that reach the sea and inland waterways eventually end up in concentrated form in the bodies of waterborne animals and plants, becoming a source of concern when they are part of the human food chain.

The most easily detectable fallout product in humans and other animals is iodine-131, an isotope that emits beta and gamma rays and is enriched about 100 times in the thyroid gland through selective accumulation. Because of its relatively short half-life (eight days), iodine-131 is probably not the most hazardous fallout isotope; yet, excessive amounts of radiation from this isotope can lead to metabolic disturbances and an increased incidence of thyroid cancer, especially in children.

A mixture of radioactive gases is discharged into the atmosphere in small amounts by nuclear power reactors. Reactors are thus generally placed at sites where atmospheric mixing and transport are such that the short-lived gases decay and are diluted before they can be inhaled in appreciable amounts by human populations.

Methods that have been developed for biologic protection against fallout range from measures designed to keep radioisotopes out of the body to biochemical means for rapidly eliminating such isotopes from tissues. At times of nuclear emergencies, airborne radioactive particles may be kept from the lungs by staying indoors or by wearing masks with suitable filtration. Absorption of ingested isotopes via the intestinal tract may be inhibited by certain mucoprotein substances that possess great surface affinity for adsorption of strontium and other substances; sodium alginate prepared from seaweed kelp is such a substance. It is possible with appropriate chemicals to remove virtually all radioactive strontium from cow's milk without affecting its essential nutritive components. Certain chelates—for example, EDTA (ethylenediaminetetraacetic acid)—will react with strontium and “cover” this atom. As a result, the presence of EDTA in the blood reduces the deposition of strontium in bones (elimination of already deposited isotopes also is somewhat accelerated). Unfortun-

nately, however, EDTA and most other chelating agents are not specific for strontium; they also chelate the closely related and important element calcium. Consequently, their use requires expert medical supervision and is limited in effectiveness. On the other hand, the uptake of radioactive iodine by the thyroid gland may be reduced by the ingestion of large amounts of stable iodine, which is relatively nontoxic except to those with special sensitivity.

MAJOR TYPES OF RADIATION INJURY

Any living organism can be killed by radiation if exposed to a large enough dose, but the lethal dose varies greatly from species to species. Mammals can be killed by less than 10 Gy, but fruit flies may survive 1,000 Gy. Many bacteria and viruses may survive even higher doses. In general, humans are among the most radiosensitive of all living organisms, but the effects of a given dose in a person depend on the organ irradiated, the dose, and the conditions of exposure.

The biologic effects of radiation in humans and other mammals are generally subdivided into (1) those that affect the body of the exposed individual—somatic effects—and (2) those that affect the offspring of the exposed individual—genetic, or heritable, effects. Among the somatic effects, there are those that occur within a short period of time (*e.g.*, inhibition of cell division) and those that may not occur until years or decades after irradiation (*e.g.*, radiation-induced cancer). In addition, there are those, called non-stochastic effects, that occur only in response to a considerable dose of radiation (*e.g.*, ulceration of the skin) and those, termed stochastic, for which no threshold dose is known to exist (*e.g.*, radiation-induced cancer).

Every type of biologic effect of radiation, irrespective of its precise nature, results from injury to the cell, the microscopic building block of which all living organisms are composed. It therefore seems useful to open a review of such effects with a discussion of the action of radiation on the cell.

Effects on the cell. The effects of radiation on the cell include interference with cell division, damage to chromosomes, damage to genes (mutations), neoplastic transformation (a change analogous to the induction of cancer), and cell death. The mechanisms through which these changes are produced are not yet fully understood, but each change is thought to be the end result of chemical alterations that are initiated by radiation as it randomly traverses the cell.

Any type of molecule in the cell can be altered by irradiation, but the DNA of the genetic material is thought to be the cell's most critical target, since damage to a single gene may be sufficient to kill or profoundly alter the cell. A dose that can kill the average dividing cell (say, 1–2 Sv) produces dozens of lesions in the cell's DNA molecules. Although most such lesions are normally repairable through the action of intracellular DNA repair processes, those that remain unrepaired or are misrepaired may give rise to permanent changes in the affected genes (*i.e.*, mutations) or in the chromosomes on which the genes are carried, as discussed below.

In general, dividing cells (such as cancer cells) are more radiosensitive than nondividing cells. As noted above, a dose of 1–2 Sv is sufficient to kill the average dividing cell, whereas nondividing cells can usually withstand many times as much radiation without overt signs of injury. It is when cells attempt to divide for the first time after irradiation that they are most apt to die as a result of radiation injury to their genes or chromosomes.

The percentage of human cells retaining the ability to multiply generally decreases exponentially with increasing radiation dose, depending on the type of cell exposed and the conditions of irradiation. With X rays and gamma rays, traversal by two or more radiation tracks in swift succession are usually required to kill the cell. Hence, the survival curve is typically shallower at low doses and low dose rates than at high doses and high dose rates (Figure 6). The reduced killing effectiveness of a given dose when it is delivered in two or more widely spaced fractions is attributed to the repair of sublethal damage between successive exposures. ticulate radiations, on the other hand, the survival curve is characteristically steeper than with X rays or gamma rays, and its slope is relatively unaffected by the dose or the dose rate (Figure 6), implying that the death of the cell usually results from a single densely ionizing particle track and that the injury produced by such a track is of a relatively irreparable type.

Damage to genes (mutations). Gene mutations resulting from radiation-induced damage to DNA have been produced experimentally in many types of organisms. In general, the frequency of a given mutation increases in proportion to the dose of radiation in the low-to-intermediate dose range. At higher doses, however, the frequency of mutations induced by a given dose may be dependent on the rate at which the dose is accumulated, tending to be lower if the dose is accumulated over a long period of time.

In human white blood cells (lymphocytes), as in mouse spermatogonia and oocytes, the frequency of radiation-induced mutations approximates 1 mutation per 100,000 cells per genetic locus per Sv. This rate of increase is not large enough to detect with existing methodology in the children of the atomic-bomb survivors of Hiroshima and Nagasaki, owing to their limited numbers and the comparatively small average dose of radiation received by their parents. Accordingly, it is not surprising that heritable effects of irradiation have not been observable thus far in this population or in any other irradiated human population, in spite of exhaustive efforts to detect them.

The observed proportionality between the frequency of induced mutations and the radiation dose has important health implications for the human population, since it implies that even a small dose of radiation given to a large number of individuals may introduce mutant genes into the population, provided that the individuals are below reproductive age at the time of irradiation. The effect on a population of a rise in its mutation rate depends, however, on the role played by mutation in determining the characteristics of the population. Although deleterious genes enter the population through mutations, they tend to be eliminated because they reduce the fitness of their carriers. Thus, a genetic equilibrium is reached at the point where the entry of deleterious genes into the population through mutation is counterbalanced by their loss through reduction in fitness. At the point of equilibrium, an increase of the mutation rate by a given percentage causes a proportionate increase in the gene-handicapped fraction in the population. The full increase is not manifested immediately, however, but only when genetic equilibrium is again established, which requires several generations.

The capacity of radiation to increase the frequency of mutations is often expressed in terms of the mutation-

rate doubling dose, which is the dose that induces as large an additional rate of mutations as that which occurs spontaneously in each generation. The more sensitive are the genes to radiation, the lower is the doubling dose. The doubling dose for high-intensity exposure in several different organisms has been found experimentally to lie between about 0.3 and 1.5 Gy. For seven specific genes in the mouse, the doubling dose of gamma radiation for spermatogonia is about 0.3 Gy for high-intensity exposure and about 1.0 Gy for low-intensity exposure. Little is known about the doubling dose for human genes, but most geneticists assume that it is about the same as the doubling dose for those of mice. Studies of the children of atomic-bomb survivors are consistent with this view, as noted above.

From the results of experiments with mice and other laboratory animals, the dose required to double the human mutation rate is estimated to lie in the range of 0.2–2.5 Sv, implying that less than 1 percent of all genetically related diseases in the human population is attributable to natural background irradiation (Table 10). Although natural background irradiation therefore appears to make only a relatively small contribution to the overall burden of genetic illness in the world's population, millions of individuals may be thus affected in each generation.

Table 10: Estimated Contribution of Natural Background Irradiation to the Occurrence of Genetic Abnormalities in the Human Population

type of genetic abnormality	incidence per million offspring

*Equivalent to 1 mSv per year, the average dose from background radiation, or 30 mSv per generation.

Notwithstanding the fact that the vast majority of mutations are decidedly harmful, those induced by irradiation in seeds are of interest to horticulturists as a means of producing new and improved varieties of plants. Mutations produced in this manner can affect such properties of the plant as early ripening and resistance to disease, with the result that economically important varieties of a number of species have been produced by irradiation. In their effects on plants, fast neutrons and heavy particles have been found to be up to about 100 times more mutagenic than X rays. Radioactive elements taken up by plants also can be strongly mutagenic. In the choice of a suitable dose for the production of mutations, a compromise has to be made between the mutagenic effects and damaging effects of the radiation. As the number of mutations increases, so also does the extent of damage to the plants. In the irradiation of dry seeds by X rays, a dose of 10 to 20 Gy is usually given.

Damage to chromosomes. By breaking both strands of the DNA molecule, radiation also can break the chromosome fibre and interfere with the normal segregation of duplicate sets of chromosomes to daughter cells at the time of cell division, thereby altering the structure and number of chromosomes in the cell. Chromosomal changes of this kind may cause the affected cell to die when it attempts to divide, or they may alter its properties in various other ways.

Chromosome breaks often heal spontaneously, but a break that fails to heal may cause the loss of an essential part of the gene complement; this loss of genetic material is called gene deletion. A germ cell thus affected may be

Chromosome breaks

The mutation-rate doubling dose

capable of taking part in the fertilization process, but the resulting zygote may be incapable of full development and may therefore die in an embryonic state.

When adjoining chromosome fibres in the same nucleus are broken, the broken ends may join together in such a way that the sequence of genes on the chromosomes is changed. For example, one of the broken ends of chromosome A may join onto a broken end of chromosome B, and vice versa in a process termed translocation. A germ cell carrying such a chromosome structural change may be capable of producing a zygote that can develop into an adult individual, but the germ cells produced by the resulting individual may include many that lack the normal chromosome complement and so yield zygotes that are incapable of full development; an individual affected in this way is termed semisterile. Because the number of his descendants is correspondingly lower than normal, such chromosome structural changes tend to die out in successive generations.

As would be expected from target theory considerations, X rays and gamma rays given at high doses and high dose rates induce more two-break chromosome aberrations per unit dose than are produced at low doses and low dose rates (Figure 7). With densely ionizing radiation, by comparison, the yield of two-break aberrations for a given dose is higher than with sparsely ionizing radiation and is proportional to the dose irrespective of the dose rate (Figure 7). From these comparative dose-response relationships, it is inferred that a single X-ray track rarely deposits enough energy at any one point to break two adjoining chromosomes simultaneously, whereas the two-break aberrations that are induced by high-LET irradiation result preponderantly from single particle tracks.

Figure 7: Frequency of dicentric chromosome aberrations in human lymphocytes irradiated in vitro, as a function of the dose and dose rate of neutrons, X rays, and gamma rays.

In irradiated human lymphocytes, the frequency of chromosome aberrations varies so predictably with the dose of radiation (Figure 7) that it is used as a crude biologic dosimeter of exposure in radiation workers and other exposed persons. What effect, if any, an increase in the frequency of chromosome aberrations may have on the health of an affected individual is uncertain. Only a small percentage of all chromosome aberrations is attributable to natural background radiation; the majority result from other causes, including certain viruses, chemicals, and drugs.

Effects on organs of the body (somatic effects). A wide variety of reactions occur in response to irradiation in the different organs and tissues of the body. Some of the reactions occur quickly, while others occur slowly. The killing of cells in affected tissues, for example, may be detectable within minutes after exposure, whereas degenerative changes such as scarring and tissue breakdown may not appear until months or years afterward.

In general, dividing cells are more radiosensitive than nondividing cells (see above), with the result that radiation injury tends to appear soonest in those organs and tissues in which cells proliferate rapidly. Such tissues include the

skin, the lining of the gastrointestinal tract, and the bone marrow, where progenitor cells multiply continually in order to replace the mature cells that are constantly being lost through normal aging. The early effects of radiation on these organs result largely from the destruction of the progenitor cells and the consequent interference with the replacement of the mature cells, a process essential for the maintenance of normal tissue structure and function (Figure 8). The damaging effects of radiation on an organ are generally limited to that part of the organ directly exposed. Accordingly, irradiation of only a part of an organ generally causes less impairment in the function of the organ than does irradiation of the whole organ.

Figure 8: Characteristic sequence of events in the pathogenesis of early and late non-stochastic effect of radiation.

Skin. Radiation can cause various types of injury to the skin, depending on the dose and conditions of exposure. The earliest outward reaction of the skin is transitory reddening (erythema) of the exposed area, which may appear within hours after a dose of 6 Gy or more. This reaction typically lasts only a few hours and is followed two to four weeks later by one or more waves of deeper and more prolonged reddening in the same area. A larger dose may cause subsequent blistering and ulceration of the skin and loss of hair, followed by abnormal pigmentation months or years later.

Bone marrow. The blood-forming cells of the bone marrow are among the most radiosensitive cells in the body. If a large percentage of such cells are killed, as can happen when intensive irradiation of the whole body occurs, the normal replacement of circulating blood cells is impaired. As a result, the blood cell count may become depressed and, ultimately, infection, hemorrhage, or both may ensue. A dose below 0.5–1 Sv generally causes only a mild, transitory depletion of blood-forming cells; however, a dose above 8 Sv delivered rapidly to the whole body usually causes a fatal depression of blood-cell formation.

Gastrointestinal tract. The response of the gastrointestinal tract is comparable in many respects to that of the skin. Proliferating cells in the mucous membrane that lines the tract are easily killed by irradiation, resulting in the denudation and ulceration of the mucous membrane. If a substantial portion of the small intestine is exposed rapidly to a dose in excess of 10 Gy, as may occur in a radiation accident, a fatal dysentery-like reaction results within a very short period of time.

Reproductive organs. Although mature spermatozoa are relatively resistant to radiation, immature sperm-forming cells (spermatogonia) are among the most radiosensitive cells in the body. Hence, rapid exposure of both testes to a dose as low as 0.15 Sv may interrupt sperm-production temporarily, and a dose in excess of 4 Sv may be sufficient to cause permanent sterility in a certain percentage of men.

In the human ovary, oocytes of intermediate maturity are more radiosensitive than those of greater or lesser maturity. A dose of 1.5–2.0 Sv delivered rapidly to both ovaries may thus cause only temporary sterility, whereas a dose exceeding 2–3 Sv is likely to cause permanent sterility in an appreciable percentage of women.

Lens of the eye. Irradiation can cause opacification of the lens, the severity of which increases with the dose. The effect may not become evident, however, until many months after exposure. During the 1940s, some physicists who worked with the early cyclotrons developed cataracts as a result of occupational neutron irradiation, indicating for the first time the high relative biologic effectiveness of neutrons for causing lens damage. The threshold for a progressive, vision-impairing opacity, or cataract, varies

High radio-sensitivity of blood-forming cells of the bone marrow

Cataract development

from 5 Sv delivered to the lens in a single exposure to as much as 14 Sv delivered in multiple exposures over a period of months.

Brain and sensory organs. Generally speaking, humans do not sense a moderate radiation field; however, small doses of radiation (less than 0.01 Gy) can produce phosphene, a light sensation on the dark-adapted retina. American astronauts on the first spacecraft that landed on the Moon (Apollo 11, July 20, 1969) observed irregular light flashes and streaks during their flight, which probably resulted from single heavy cosmic-ray particles striking the retina. In various food-preference tests, rats, when given the choice, avoid radiation fields of even a few mGy. A dose of 0.03 Gy is sufficient to arouse a slumbering rat, probably through effects on the olfactory system, and a dose of the same order of magnitude can accelerate seizures in genetically susceptible mice. The mature brain and nervous system are relatively resistant to radiation injury, but the developing brain is radiosensitive to damage (see below).

Radiation sickness. The signs and symptoms resulting from intensive irradiation of a large portion of the bone marrow or gastrointestinal tract constitute a clinical picture known as radiation sickness, or the acute radiation syndrome. Early manifestations of this condition typically include loss of appetite, nausea, and vomiting within the first few hours after irradiation, followed by a symptom-free interval that lasts until the main phase of the illness (Table 11).

Symptoms of the acute radiation syndrome

Table 11: Symptoms of Acute Radiation Sickness (Hematopoietic Form)			
time after exposure	supralethal dose range (6–10 Gy)	midlethal dose range (2.5–5 Gy)	sublethal dose range (1–2 Gy)
Several hours	no definite symptoms diarrhea, vomiting, inflammation of throat fever, rapid emaciation leading to death for 100 percent of the population	nausea and vomiting	
First week		no definite symptoms	
Second week			
Third week		loss of hair begins loss of appetite general malaise fever, hemorrhages, pallor leading to rapid emaciation and death for 50 percent of the population	loss of appetite sore throat pallor and diarrhea recovery begins (no deaths in absence of complications)

The main phase of the intestinal form of the illness typically begins two to three days after irradiation, with abdominal pain, fever, and diarrhea, which progress rapidly in severity and lead within several days to dehydration, prostration, and a fatal, shocklike state. The main phase of the hematopoietic form of the illness characteristically begins in the second or third week after irradiation, with fever, weakness, infection, and hemorrhage. If damage to the bone marrow is severe, death from overwhelming infection or hemorrhage may ensue four to six weeks after exposure unless corrected by transplantation of compatible unirradiated bone marrow cells.

The higher the dose received, the sooner and more profound are the radiation effects. Following a single dose of more than 5 Gy to the whole body, survival is improbable (Table 11). A dose of 50 Gy or more to the head may cause immediate and discernible effects on the central nervous system, followed by intermittent stupor and incoherence alternating with hyperexcitability, epileptiform seizures, and death within several days (the cerebral form of the acute radiation syndrome).

When the dose to the whole body is between 6 and 10 Gy, the earliest symptoms are loss of appetite, nausea, and vomiting, followed by prostration, watery and bloody diarrhea, abhorrence of food, and fever (Table 11). The blood-forming tissues are profoundly injured, and the white blood cell count may decrease within 15–30 days from about 8,000 per cubic millimetre to as low as 200. As a result of these effects, the body loses

its defenses against microbial infection, and the mucous membranes lining the gastrointestinal tract may become inflamed. Furthermore, internal or external bleeding may occur because of a reduction in blood platelets. Return of the early symptoms, frequently accompanied by delirium or coma, presage death; however, symptoms may vary significantly from individual to individual. Complete loss of hair within 10 days has been taken as an indication of a lethally severe exposure.

In the dose range of 1.5–5.0 Gy, survival is possible (though in the upper range improbable), and the symptoms appear as described above but in milder form and generally following some delay. Nausea, vomiting, and malaise may begin on the first day and then disappear, and a latent period of relative well-being follows. Anemia and leukopenia set in gradually. After three weeks, internal hemorrhages may occur in almost any part of the body, but particularly in mucous membranes. Susceptibility to infection remains high, and some loss of hair occurs. Lassitude, emaciation, and fever may persist for many weeks before recovery or death occurs.

Moderate doses of radiation can severely depress the immunologic defense mechanisms, resulting in enhanced sensitivity to bacterial toxins, greatly decreased fixation of antigens, and reduced efficiency of antibody formation. Antibiotics, unfortunately, are of limited effectiveness in combating postirradiation infections. Hence, of considerable value are plastic isolators that allow antiseptic isolation of a person from his environment; they provide protection against infection from external sources during the period critical for recovery.

Below a dose of 1.5 Gy, an irradiated person is generally able to survive intensive whole-body irradiation. The symptoms following exposure in this dose range are similar to those already described but milder and delayed. With a dose under 1 Gy, the symptoms may be so mild that the exposed person is able to continue his normal occupation in spite of measurable depression of his bone marrow. Some persons, however, suffer subjective discomfort from doses as low as 0.3 Gy. Although such doses may cause no immediate reactions, they may produce delayed effects that appear years later (see below).

Effects on the growth and development of the embryo. The tissues of the embryo, like others composed of rapidly proliferating cells, are highly radiosensitive. The types and frequencies of radiation effects, however, depend heavily on the stage of development of the embryo or fetus at the time it is exposed. For example, when exposure occurs while an organ is forming, malformation of the organ may result. Exposure earlier in embryonic life is more likely to kill the embryo than cause a congenital malformation, whereas exposure at a later stage is more likely to produce a functional abnormality in the offspring than a lethal effect or a malformation.

A wide variety of radiation-induced malformations have been observed in experimentally irradiated rodents. Many of these are malformations of the nervous system, including microcephaly (reduced size of brain), exencephaly (part of the brain formed outside the skull), hydrocephalus (enlargement of the head due to excessive fluid), and anophthalmia (failure of the eyes to develop). Such effects may follow a dose of 1–2 Gy given at an appropriate stage of development. Functional abnormalities produced in laboratory animals by prenatal irradiation include abnormal reflexes, restlessness, and hyperactivity, impaired learning ability, and susceptibility to externally induced seizures. The abnormalities induced by radiation are similar to those that can be caused by certain virus infections, neurotropic drugs, pesticides, and mutagens.

Abnormalities of the nervous system, which occur in 1–2 percent of human infants, were found with greater frequency among children born to women who were pregnant and residing in Hiroshima or Nagasaki at the time of the atomic explosions. The incidence of reduced head size and mental retardation in such children was increased by about 40 percent per Gy when exposure occurred between the eighth and 15th week of gestation, the age of greatest susceptibility to radiation.

The period of maximal sensitivity for each developing

Radiation-induced malformations

organ is sharply circumscribed in time, with the result that the risk of malformation in a particular organ depends heavily on the precise stage of development at which the embryo is irradiated. The risk that a given dose will produce a particular malformation is thus much smaller if the dose is spread out over many days or weeks than if it is received during the few hours of the critical period itself. It also would appear that the induction of a malformation generally requires injury to many cells in a developing organ, so that there is little likelihood of such an effect resulting from the low doses and dose rates characteristic of natural background radiation.

Effects on the incidence of cancer. Atomic-bomb survivors, certain groups of patients exposed to radiation for medical purposes, and some groups of radiation workers have shown dose-dependent increases in the incidence of certain types of cancer. The induced cancers have not appeared until years after exposure, however, and they have shown no distinguishing features by which they can be identified individually as having resulted from radiation, as opposed to some other cause. With few exceptions, moreover, the incidence of cancer has not been increased detectably by doses of less than 0.01 Sv.

Because the carcinogenic effects of radiation have not been documented over a wide enough range of doses and dose rates to define the shape of the dose-incidence curve precisely, the risk of radiation-induced cancer at low levels of exposure can be estimated only by extrapolation from observations at higher dose levels, based on assumptions about the relation between cancer incidence and dose. For most types of cancer, information about the dose-incidence relationship is rather meagre. The most extensive data available are for leukemia and cancer of the female breast.

The overall incidence of all forms of leukemia other than the chronic lymphatic type has been observed to increase roughly in proportion to dose during the first 25 years after irradiation. Different types of leukemia, however, vary in the magnitude of the radiation-induced increase for a given dose, the age at which irradiation occurs, and the time after exposure. The total excess of all types besides chronic lymphatic leukemia, averaged over all ages, amounts to approximately one to three additional cases of leukemia per year per 10,000 persons at risk per sievert to the bone marrow.

Cancer of the female breast also appears to increase in incidence in proportion to the radiation dose. Furthermore, the magnitude of the increase for a given dose appears to be essentially the same in women whose breasts were irradiated in a single, brief exposure (e.g., atomic-bomb survivors), as in those who were irradiated over a period of years (e.g., patients subjected to multiple fluoroscopic examinations of the chest or workers assigned to coating watch and clock dials with paint containing radium), implying that even small exposures widely separated in time exert carcinogenic effects on the breast that are fully additive and cumulative. Although susceptibility decreases sharply with age at the time of irradiation, the excess of breast cancer averaged over all ages amounts to three to six cases per 10,000 women per sievert each year.

Additional evidence that carcinogenic effects can be produced by a relatively small dose of radiation is provided by the increase in the incidence of thyroid tumours that has been observed to result from a dose of 0.06–2.0 Gy of X rays delivered to the thyroid gland during infancy or childhood, and by the association between prenatal diagnostic X irradiation and childhood leukemia. The latter association implies that exposure to as little as 10–50 mGy of X radiation during intrauterine development may increase the subsequent risk of leukemia in the exposed child by as much as 40–50 percent.

Although some, but not all, other types of cancer have been observed to occur with greater frequency in irradiated populations (Table 12), the data do not suffice to indicate whether the risks extend to low doses. It is apparent, however, that the dose-incidence relationship varies from one type of cancer to another. From the existing evidence, the overall excess of all types of cancer combined may be inferred to approximate 0.6–1.8 cases per 1,000 persons

Table 12: Estimated Lifetime Cancer Risks Attributed to Low-Level Irradiation

site irradiated	cancers per 10,000 person-Sv*
Bone marrow (leukemia)	15–20
Thyroid	25–120
Breast (women only)	40–200
Lung	25–140

Skin	10–20
Total (both sexes)	125–1,000

*The unit person-Sv represents the product of the average dose per person times the number of people exposed (1 sievert to each of 10,000 persons = 10,000 person-Sv); all values provided here are rounded.

Source: National Academy of Sciences Advisory Committee on the Biological Effects of Ionizing Radiation, *The Effects on Populations of Exposure to Low Levels of Ionizing Radiation* (1972, 1980); United Nations Scientific Committee on the Effects of Atomic Radiation, *Sources and Effects of Ionizing Radiation* (1977 report to the General Assembly, with annexes).

per sievert per year when the whole body is exposed to radiation, beginning two to 10 years after irradiation. This increase corresponds to a cumulative lifetime excess of roughly 20–100 additional cases of cancer per 1,000 persons per sievert, or to an 8–40 percent per sievert increase in the natural lifetime risk of cancer.

The above-cited risk estimates imply that no more than 1–3 percent of all cancers in the general population result from natural background ionizing radiation. At the same time, however, the data suggest that up to 20 percent of lung cancers in nonsmokers may be attributable to inhalation of radon and other naturally occurring radionuclides present in air.

Shortening of the life span. Laboratory animals whose entire bodies are exposed to radiation in the first half of life suffer a reduction in longevity that increases in magnitude with increasing dose. This effect was mistakenly interpreted by early investigators as a manifestation of accelerated or premature aging. The shortening of life in irradiated animals, however, has since been observed to be attributable largely, if not entirely, to the induction of benign and malignant growths. In keeping with this observation is the finding that mortality from diseases other than cancer has not been increased detectably by irradiation among atomic-bomb survivors.

PROTECTION AGAINST EXTERNAL RADIATION

A growing number of substances have been found to provide some protection against radiation injury when administered prior to irradiation (Table 13). Many of

Table 13: Some Chemicals That Exert Radioprotective Effects in Laboratory Animals

class	specific chemical	effective dose (in milligrams per kilogram of tissue)
Sulfur compounds	glutathione	1,000
	cysteine	1,000

Radiation as a factor in leukemia and breast cancer

them apparently act by producing anoxia or by competing for oxygen with normal cell constituents and radiation-produced radicals. All of the protective compounds tried thus far, however, are toxic, and anoxia itself is hazardous. As a consequence, their administration to humans is not yet practical.

Diurnal changes in the radiosensitivity of rodents indicate that the factors responsible for daily biologic rhythms may also alter the responses of tissues to radiation. Such factors include the hormone thyroxine, a normal secretion of the thyroid gland. Other sensitizers at the cellular level include nucleic-acid analogues (e.g., 5-fluorouracil) as well as certain compounds that selectively radiosensitize hypoxic cells such as metronidazole.

Radiosensitivity is also under genetic control to some degree, susceptibility varying among different inbred mouse strains and increasing in the presence of inherited deficiencies in capacity for repairing radiation-induced damage to DNA. Germ-free mice, which spend their entire lives in a sterile environment, also exhibit greater resistance to radiation than do animals in a normal microbial environment due to elimination of the risk of infection.

For many years it was thought that radiation disease was irreversible once a lethal dose had been received. It has since been found, however, that bone-marrow cells administered soon after irradiation may enable an individual to survive an otherwise lethal dose of X rays, because these cells migrate to the marrow of the irradiated recipient, where they proliferate and repopulate the blood-forming tissues. Under these conditions bone-marrow transplantation is feasible even between histo-incompatible individuals, because the irradiated recipient has lost the ability to develop antibodies against the injected "foreign" cells. After a period of some months, however, the transplanted tissue may eventually be rejected, or it may develop an immune reaction against the irradiated host, which also can be fatal. The transplantation of bone-marrow cells has been helpful in preventing radiation deaths among the victims of reactor accidents, as, for example, those injured in 1986 at the Chernobyl nuclear power plant in the Soviet Union. It should be noted, however, that cultured or stored marrow cells cannot yet be used for this purpose.

CONTROL OF RADIATION RISKS

In view of the fact that radiation is now assumed to play a role in mutagenic or carcinogenic activity, any procedure involving radiation exposure is considered to entail some degree of risk. At the same time, however, the radiation-induced risks associated with many activities are negligibly small in comparison with other risks commonly encountered in daily life. Nevertheless, such risks are not necessarily acceptable if they can be easily avoided or if no measurable benefit is to be gained from the activities with which they are associated. Consequently, systematic efforts are made to avoid unnecessary exposure to ionizing radiation in medicine, science, and industry. Toward this end, limits have been placed on the amounts of radioactivity (Tables 9 and 12) and on the radiation doses (Table 14) that the different tissues of the body are permitted to accumulate in radiation workers or members of the public at large.

Although most activities involving exposure to radiation for medical purposes are highly beneficial, the benefits cannot be assumed to outweigh the risks in situations where radiation is used to screen large segments of the population for the purpose of detecting an occasional person with an asymptomatic disease. Examples of such applications include the "annual" chest X-ray examination and routine mammography. Each use of radiation in medicine (and dentistry) is now evaluated for its merits on a case-by-case basis.

Other activities involving radiation also are assessed with care in order to assure that unnecessary exposure is avoided and that their presumed benefits outweigh their calculated risks. In operating nuclear power plants, for example, much care is taken to minimize the risk to surrounding populations. Because of such precautions, the total impact on health of generating a given amount of electricity from nuclear power is usually estimated to be

Bone-marrow transplantation as a means of preventing radiation deaths

Table 14: Recommended Exposure Limits*

type of exposure	maximum permissible dose
Occupational exposures (annual)†	
Effective dose-equivalent limit (stochastic effects)	50 mSv
Dose-equivalent limits for tissues and organs (non-stochastic effects)	
Lens of eye	150 mSv
All others (e.g., red bone marrow, breast, lung, gonads, skin, and extremities)	500 mSv

smaller than that resulting from the use of coal for the same purpose, even after allowances for severe reactor accidents such as the one at the Soviets' Chernobyl nuclear power plant in 1986. (C.A.T./A.C.U.)

Biologic effects of non-ionizing radiation

EFFECTS OF HERTZIAN WAVES AND INFRARED RAYS

Hertzian waves. The effects of Hertzian waves (electromagnetic waves in the radar and radio range) and of infrared rays usually are regarded as equivalent to the effect produced by heating. The longer radio waves induce chiefly thermal agitation of molecules and excitation of molecular rotations, while infrared rays excite vibrational modes of large molecules and release fluorescent emission as well as heat. Both of these types of radiation are preferentially absorbed by fats containing unsaturated carbon chains.

The fact that heat production resulted from bombardment of tissue with high-frequency alternating current (wavelengths somewhat longer than the longest radio waves) was discovered in 1891, and the possibility of its utilization for medical purposes was realized in 1909, under the term diathermy. This method of internal heating is beneficial for relieving muscle soreness and sprain (see also below). Diathermy can be harmful, however, if so much internal heat is given that the normal cells of the body suffer irreversible damage. Since humans have heat receptors primarily in their skin, they cannot be forewarned by pain when they receive a deep burn from diathermy. Sensitive regions easily damaged by diathermy are those having reduced blood circulation. Cataracts of the eye lens have been produced in animals by microwave radiation applied in sufficient intensity to cause thermal denaturation of the lens protein.

Microwave ovens have found widespread use in commercial kitchens and private homes. These can heat and cook very rapidly and, if used properly, constitute no hazard to operators. In the radio-television industry and in the radar

Effect of long radio waves

Micro-waves and their application

division of the military, persons are sometimes exposed to high densities of microwave radiation. The hazard is particularly pronounced with exposure to masers, capable of generating very high intensities of microwaves (e.g., carbon dioxide masers). The biologic effects depend on the absorptency of tissues. At frequencies higher than 150 megahertz, significant absorption takes place. The lens of the human eye is most susceptible to frequencies around 3,000 megahertz, which can produce cataracts. At still higher frequencies, microwaves interact with superficial tissues and skin, in much the same manner as infrared rays.

Acute effects of microwaves become significant if a considerable temperature rise occurs. Cells and tissues eventually die at temperatures of about 43° C. Microwave heating is minimized if the heat that results from energy absorption is dissipated by radiation, evaporation, and heat conduction. Normally one-hundredth of a watt (10 milliwatts) can be so dissipated, and this power limit generally has been set as the permissible dose. Studies with animals have indicated that, below the permissible levels, there are negligible effects to various organ systems. Microwaves or heat applied to testes tend strongly to decrease the viability of sperm. This effect, however, is not significant at the "safe" levels.

Some investigators in the Soviet Union have documented a variety of nonthermal effects of microwaves and recommend about 1,000 times lower safe occupational dose levels than are in force in the United States. Most prominent among the nonthermal effects appear to be those on the nervous system. Such effects have resulted in untimely tiring, excitability, and insomnia registered by persons handling high-frequency radio equipment. Nonthermal effects have been observed on the electroencephalogram of rabbits. These effects may be due to changes in the properties of neural membranes or to denaturation of macromolecules.

Infrared rays. A significant part of solar energy reaches the Earth in the form of infrared rays. Absorption and emission by the human body of these rays play an important part in temperature exchange and regulation of the body. The principles of infrared emission and absorption must be considered in the design of air conditioning and clothing.

Overdosage of infrared radiation, usually resulting from direct exposure to a hot object (including heating lamps) or flame, can cause severe burns. While infrared exposure is a hazard near any fire, it is particularly dangerous in the course of nuclear chain reactions. In the course of a nuclear detonation, a brief but very intense emission of infrared occurs, together with visible and ultraviolet light emitted from the fireball (flash burns). Of the total energy of nuclear explosion, as much as one-third may be in the form of thermal radiation, moving with the velocity of light. The rays will arrive almost instantaneously at regions removed from the source by only a few kilometres. Smoke or fog can effectively scatter or absorb the infrared components, and even thin clothing can greatly reduce the severity of burn effects.

EFFECTS OF VISIBLE AND ULTRAVIOLET LIGHT

Life could not exist on Earth without light from the Sun. Plants utilize the energy of the Sun's rays in the process of photosynthesis to produce carbohydrates and proteins, which serve as basic organic sources of food and energy for animals. Light has a powerful regulating influence on many biologic systems. Most of the strong ultraviolet rays of the Sun, which are hazardous, are effectively absorbed by the upper atmosphere. At high altitudes and near the Equator, the ultraviolet intensity is greater than at sea level or at northern latitudes.

Ultraviolet light of very short wavelength, below 2200 angstroms, is highly toxic for cells; in the intermediate range, the greatest killing effectiveness on cells is at about 2600 angstroms. The nucleic acids of the cell, of which genetic material is composed, strongly absorb rays in this region. This wavelength, readily available in mercury vapour, xenon, or hydrogen arc lamps, has great effectiveness for germicidal purification of the air.

Since penetration of visible and ultraviolet light in body tissues is small, only the effects of light on skin and on the visual apparatus are of consequence. When incident light exerts its action on the skin without additional external predisposing factors, scientists speak of intrinsic action. In contrast, a number of chemical or biologic agents may condition the skin for action of light; these latter phenomena are grouped under photodynamic action. Visible light, when administered following lethal doses of ultraviolet, is capable of causing recovery of the cells exposed. This phenomenon, referred to as photorecovery, has led to the discovery of various enzyme systems that are capable of restoring damaged nucleic acids in genes to their normal form. It is probable that photorecovery mechanisms are continually operative in some plants exposed to the direct action of sunlight.

The surface of the Earth is protected from the lethal ultraviolet rays of the Sun by the top layers of the atmosphere, which absorb far ultraviolet, and by ozone molecules in the stratosphere, which absorb most of the near ultraviolet. Even so, it is believed that an enzymatic mechanism operating in the skin cells of individuals continually repairs the damage caused by ultraviolet rays to the nucleic acids of the genes. Many scientists believe that chlorofluorocarbons used in aerosol spray products and in various technical applications are depleting the stratospheric ozone layer, thus exposing persons to more intense ultraviolet radiation at ground level.

There is some evidence to indicate that not only overall light intensity but also special compositions have differential effects on organisms. For example, in pumpkins, red light favours the production of pistillate flowers, and blue light leads to development of staminate flowers. The ratio of females to males in guppies is increased by red light. Red light also appears to accelerate the rate of proliferation of some tumours in special strains of mice. The intensity of incident light has an influence on the development of light-sensing organs; the eyes of primates reared in complete darkness, for instance, are much retarded in development.

Intrinsic action. Light is essential to the human body because of its biosynthetic action. Ultraviolet light induces the conversion of ergosterol and other vitamin precursors present in normal skin to vitamin D, an essential factor for normal calcium deposition in growing bones. While some ultraviolet light appears desirable for the formation of vitamin D, an excess amount is deleterious. Humans have a delicate adaptive mechanism that regulates light exposure of the more sensitive deeper layers of the skin. The transmission of light depends on the thickness of the upper layers of the skin and on the degree of skin pigmentation. All persons, with the exception of albinos, are born with varying amounts of melanin pigment in their skin. Exposure to light further enhances the pigmentation already present and can induce production of new pigment granules. The therapeutic possibilities of sunlight and ultraviolet light became apparent around 1900, with popularization of the idea that exposure of the whole body to sunlight promotes health.

By that time, it was already known that large doses of ultraviolet radiation caused sunburn, the wavelength of about 2800 angstroms being most effective. It induces reddening and swelling of the skin (due to dilation of the blood vessels), usually accompanied by pain. In the course of recovery, epidermal cells are proliferated, melanin is secreted, and the outer corneal layer of dead cells is thickened. In 1928 it was first shown clearly that prolonged or repeated exposure to ultraviolet light leads to the delayed development of skin cancer. The fact that ultraviolet light, like X radiation, is mutagenic may explain its ability to cause skin cancer, but the detailed mechanism of cancer induction is not yet completely understood. There seems very little doubt, however, that skin cancer in humans is in some cases correlated with prolonged exposure to large doses of sunlight. Among blacks who are protected by rich melanin formation and thickened corneal structure of the skin, incidence of cancer of the skin is several times less frequent than it is among whites living at the same latitude.

Quality of light and its effects

Hazards of infrared radiation

Light
sensi-
tization

Photodynamic action. There are a number of diseases in humans and other animals in which light sensitivity is involved; for example, hydroa, which manifests itself in blisters on parts of the body exposed to sunlight. It has been suggested that this disease results from a light-sensitive porphyrin compound found in the blood.

Actually there are many organic substances and various materials of biologic origin that make cells sensitive to light. When eosin is added to a suspension of human red blood corpuscles exposed to light, the red corpuscles will break up in a process called hemolysis. Other typical photodynamic substances are rose bengal, hematoporphyrin, and phylloerythrin—all are dyes capable of fluorescence. Their toxicity manifests itself only in the presence of light and oxygen.

Some diseases in domestic animals result from ingestion of plants having photodynamic pigments. For example, St. Johnswort's disease is caused by the plant *Hypericum*. Fagopyrism results from eating buckwheat. In geeldikopp ("yellow thick head"), the photodynamic agent is produced in the animal's own intestinal tract from chlorophyll derived from plants. In humans the heritable condition of porphyria frequently is associated with light sensitivity, as are a number of somewhat ill-defined dermatologic conditions that result from exposure to sunlight. The recessively inherited rare disease xeroderma pigmentosum also is associated with light exposure; it usually results in death at an early age from tumours of the skin that develop on exposed areas. The cells of such individuals possess a serious genetic defect: they lack the ability to repair nucleic-acid lesions caused by ultraviolet light.

Certain drugs (e.g., sulfanilamide) sensitize some persons to sunlight. Many cases are known in which ingestion of or skin contact with a photodynamic substance was followed by increased light sensitivity.

Effects on development and biologic rhythms. In addition to its photosynthetic effect, light exerts an influence on growth and spatial orientation of plants. This phototropism is associated with yellow pigments and is particularly marked in blue light. The presence of illumination is a profound modifier of the cellular activities in plants as well. For example, while some species of blue-green algae carry out photosynthesis in the presence of light, they do not undergo cell division.

Diffuse sensitivity to light also exists in several phyla of animals. Many protozoans react to light. Chameleons, frogs, and octopuses change colour under the influence of light. Such changes are ascribed to special organs known as chromatophores, which are under the influence of the nervous system or endocrine system. The breeding habits and migration of some birds are set in motion by small consecutive changes in the daily cycle of light.

Light is an important controlling agent of recurrent daily physiological alterations (circadian rhythms) in many animals, including humans in all likelihood (see BEHAVIOUR, ANIMAL: *Periodic biological phenomena*). Lighting cycles have been shown to be important in regulating several types of endocrine function: the daily variation in light intensity keeps the secretion of adrenal steroids in synchrony; the annual breeding cycles in many mammals and birds appear to be regulated by light. Ambient light somehow influences the secretions of a tiny gland, the pineal body, located near the cerebellum. The pineal body, under the action of enzymes, produces melatonin, which in higher concentrations slows down the estrous cycle; low levels of melatonin, caused by exposure of animals to light, accelerates estrus. It is believed that light stimulates the retina, and information is then transmitted by sympathetic nerves to the pineal body.

Effects on the eyes. The wavelength of light that produces sunburn also can cause inflammation of the cornea of the eye. This is what occurs in snow blindness or after exposure to strong ultraviolet light sources. Unusual sensitivities have been reported. Ultraviolet light, like infrared or penetrating radiations, can also cause cataract of the eye lens, a condition characterized by denatured protein in the fibrous cells forming the lens (see above). The retina usually is not reached by ultraviolet light, but large doses of visible and infrared light can irreversibly

bleach the visual pigments, as in sun blindness. Numerous pathological conditions of the eye are accompanied by abnormal light sensitivity and pain, a condition that is known as photophobia. The pain appears to be associated with reflex movements of the iris and reflex dilation of the blood vessels of the conjunctiva. Workers exposed to ultraviolet-light sources or to atomic flashes need to wear protective glasses. (C.A.T.)

Applications of radiation

MEDICAL APPLICATIONS

The uses of radiation in diagnosis and treatment have multiplied so rapidly in recent years that one or another form of radiation is now indispensable in virtually every branch of medicine. The many forms of radiation that are used include electromagnetic waves of widely differing wavelengths (e.g., radio waves, visible light, ultraviolet radiation, X rays, and gamma rays), as well as particulate radiations of various types (e.g., electrons, fast neutrons, protons, alpha particles, and pi-mesons).

Imaging techniques. Advances in techniques for obtaining images of the body's interior have greatly improved medical diagnosis. New imaging methods include various X-ray systems, positron emission tomography, and nuclear magnetic resonance imaging.

X-ray systems. In all such systems, a beam of X radiation is shot through the patient's body, and the rays that pass through are recorded by a detection device. An image is produced by the differential absorption of the X-ray photons by the various structures of the body. For example, the bones absorb more photons than soft tissues; they thus cast the sharpest shadows, with the other body components (organs, muscles, etc.) producing shadows of varying intensity.

The conventional X-ray system produces an image of all structures in the path of the X-ray beam, so that a radiograph of, say, the lungs shows the ribs located in front and as well as in back. Such extraneous details often make it difficult for the physician examining the X-ray image to identify tumours or other abnormalities on the lungs. This problem has been largely eliminated by computerized tomographic (CT) scanning, which provides a cross-sectional image of the body part being scrutinized. Since its introduction in the 1970s, CT scanning, also called computerized axial tomography (CAT), has come to play a key role in the diagnosis and monitoring of many kinds of diseases and abnormalities.

In CT scanning a narrow beam of X rays is rotated around the patient, who is surrounded by several hundred X-ray photon detectors that measure the strength of the penetrating photons from many different angles. The X-ray data are analyzed, integrated, and reconstructed by a computer to produce images of plane sections through the body onto the screen of a television-like monitor. Computerized tomography enables more precise and rapid visualization and location of anatomic structures than has been possible with ordinary X-ray techniques. In many cases, lesions can be detected without resorting to exploratory surgery.

Positron emission tomography (PET). This imaging technique permits physicians to determine patterns of blood flow, blood volume, oxygen perfusion, and various other physiological, metabolic, and immunologic parameters. It is used increasingly in diagnosis and research, especially of brain and heart functions.

PET involves the use of chemical compounds "labeled" with short-lived positron-emitting isotopes such as carbon-11 and nitrogen-13, positron cameras consisting of photomultiplier-scintillator detectors, and computerized tomographic reconstruction techniques. After an appropriately labeled compound has been injected into the body, quantitative measurements of its activity are made throughout the sections of the body being scanned by the detectors. As the radioisotope disintegrates, positrons are annihilated by electrons, giving rise to gamma rays that are detected simultaneously by the photomultiplier-scintillator combinations positioned on opposite sides of the patient.

tion of
magnetic
resonance
imaging

method, also referred to as magnetic resonance imaging (MRI), involves the beaming of high-frequency radio waves into the patient's body while it is subjected to a strong magnetic field. The nuclei of different atoms in the body absorb radio waves at different frequencies under the influence of the magnetic field. The NMR technique makes use of the fact that hydrogen nuclei (protons) respond to an applied radio frequency by reemitting radio waves of the same frequency. A computer analyzes the emissions from the hydrogen nuclei of water molecules in body tissues and constructs images of anatomic structures based on the concentrations of such nuclei. This use of proton density makes it possible to produce images of tissues that are comparable, and in some cases superior, in resolution and contrast to those obtained with CT scanning. Moreover, since macroscopic movement affects NMR signals, the method can be adapted to measure blood flow. The ability to image atoms of fluorine-19, phosphorus-31, and other elements besides hydrogen permit physicians and researchers to use the technique for various tracer studies as well. (For information on tracer studies, see *ATOMS: Radioactivity*.)

Other radiation-based medical procedures. *Radionuclides in diagnosis.* Radionuclides have come to play a key role in certain diagnostic procedures. These procedures may be divided into two general types: (1) radiographic imaging techniques for visualizing the distribution of an injected radionuclide within a given organ as a means of studying the anatomic structure of the organ; and (2) quantitative assay techniques for measuring the absorption and retention of a radionuclide within an organ as a means of studying the metabolism of the organ.

Notable among the radionuclides used for imaging purposes is technetium-99m, a gamma-ray emitter with a six-hour half-life, which diffuses throughout the tissues of the body after its administration. Among the radionuclides suitable for metabolic studies, iodine-131 is one of the most widely used. This gamma-ray emitter has a half-life of eight days and concentrates in the thyroid gland, and so provides a measure of thyroid function.

Treating cancer and other diseases with highly energetic forms of ionizing radiation. In addition to X rays and gamma rays, densely ionizing particles—neutrons, protons, mesons, alpha particles, and heavy ions, for example—have been used increasingly to treat cancer and other lesions. Such high-LET radiations (see above) offer potential advantages over conventional X rays and gamma rays in that they have per given dose greater capacity to damage tumours, particularly deep-seated ones, and can be applied more precisely to the lesion under treatment, causing less injury to surrounding tissue. The results of these radiations in cancer treatment, though preliminary, are promising.

Ultraviolet radiation therapy. Ultraviolet radiation ("Wood's" light) is used diagnostically to detect fluorescent materials that are present in certain disorders—e.g., some fungal diseases of the skin. It is also widely employed in combination with a radiosensitizing agent such as 8-methoxypsoralen to treat psoriasis. In this approach, known as PUVA therapy, the entire surface of the skin is bathed repeatedly with ultraviolet radiation.

Phototherapy. Intense visible light is used in treating newborns' jaundice, a disease characterized by the accumulation of the pigment bilirubin in the bloodstream during the first few days of life. Since wavelengths of 420–480 nanometres absorbed in the skin expedite detoxification and elimination of the pigment, the affected infant is bathed in visible light for 12–24 hours in treating the disorder.

Treatment with lasers. The laser is used increasingly for surgery, as it has proved to be a finely controlled and relatively bloodless means of dissecting and destroying tissue. By "tuning" the laser to different wavelengths, one can vary the extent to which its light is absorbed in particular cells or cellular inclusions. Certain types of lesions, such as birthmarks of the "port-wine stain" variety, can thus be destroyed more or less selectively, with minimal damage to surrounding tissues.

The laser also is well-suited for treating lesions of the

inner eye, since a beam of laser light can pass through the intact cornea and lens without harming them. In addition, lasers are used together with optical fibres to treat lesions inside blood vessels and in other locations that are not readily accessible to standard surgical intervention. In this procedure, a fibre-optic probe is inserted into a vessel or body cavity by means of cannulas.

Diathermy. Microwave radiation has long been used for warming internal parts of the body in treating deep-seated inflammations and various other disorders. This approach, termed diathermy, is also being explored as a means of inducing hyperthermia in tumour tissue as an adjunct to radiation therapy (or chemotherapy) in the treatment of certain types of cancer. (A.C.U.)

APPLICATIONS IN SCIENCE AND INDUSTRY

Photochemistry. The principal applications of photochemistry (including photography) are in the initiation of reactions by light that can pass through glass or quartz windows. Such light has a wavelength of not less than about 185 nanometres. Light of shorter wavelength is also effective, but the windows required (sapphire, lithium fluoride, or extraordinarily thin aluminum) and the associated mechanical difficulties seriously limit application of photochemical methods in the range from 185 nanometres down to a conceivable lower limit of about 85 nanometres. Photochemical techniques are particularly applicable when a specific initial process (the breakage of a particular bond in a molecule of a particular substance, for example) is required. For such purposes, high-intensity ultraviolet lamps are generally employed, the window is either glass or quartz, and the initiation reaction is limited to the relatively thin layers in which the light is absorbed. The processes include the photochlorination of aromatic compounds (such as benzene, toluene, and xylene), sulfhydration of olefins, production of cyclohexanone oxime, photopolymerization (principally in surface-curing processes), sulfoxidation, and vitamin-D synthesis. Tunable lasers provide a potential means of initiating photochemical processes of practical interest, one such example being the separation of isotopes.

High-energy radiation. The large-scale use of such ionizing radiation for modifying and synthesizing materials, known as radiation processing, represents a minor yet significant technology. It involves irradiating materials either with a beam of electrons produced by a high-voltage particle accelerator or with gamma rays emitted by the radioisotope cobalt-16 or, in a few cases, cesium-137. The electrons are generally accelerated to an energy range of 0.15–10 MeV. (By comparison, the electron energy in a typical television set is only 0.025 MeV.) The gamma rays given off by cobalt-16 have an energy of 1.25 MeV, while those emitted by cesium-137 have approximately half that amount.

Exposure to such electrons and gamma rays does not induce radioactivity in the materials irradiated, and so the technique can be used in the manufacture or processing of many kinds of consumer and industrial products. Moreover, radiation processing has several major advantages over conventional technologies. It consumes far less energy than thermally and chemically initiated processes and at the same time causes less environmental pollution. Paints and certain other coatings, for example, can be cured at room temperature with one-tenth of the energy required in heat curing. Radiation preservation of food involves substantially less energy expenditure than that associated with either refrigeration or canning. A radiation source that releases 1 kilowatt of gamma energy (roughly equivalent to the electrical requirements of a toaster) can irradiate 10 tons of potatoes per hour; the exposure to a small dose of ionizing radiation inhibits sprouting and thereby delays spoilage.

Because of such advantages, radiation processing has found increasingly wider application. It has proved particularly valuable in the processing of plastics. Chemical reactions induced by electron-beam irradiation permit the cross-linking of polymers that make up the foamed plastic used for sound and thermal insulation. A large fraction of the wire and cable employed in high-temperature

applications and much of the wiring in telecommunications equipment are covered by insulation cross-linked by electron irradiation. The heat-shrinkable polyethylene packaging for hams and turkeys and various other poultry products is manufactured by the same process. The coating of certain audio and video recording tape is cured by exposure to electron beams, as is the rubber in a large percentage of automobile tires. Sterilization of disposable medical supplies, such as syringes, blood transfusion kits, and hospital gowns, is usually done with gamma rays. Other potential applications of radiation processing include the treatment of a wide assortment of food products so as to reduce the amount of chemical preservatives employed, the treatment of sewage for pathogen reduction, and the precipitation of sulfur dioxide and nitrogen oxide (the primary source materials for acid rain) from the stack gases of electric power plants and smelting facilities that burn fossil fuels.

Radiation source technology has developed to a point where reliable, safe, and inexpensive sources are readily available. When electron accelerators are used, radioactivity is not involved in any aspect of the process and there is no conceivable hazard to the surrounding community. In processing facilities that use gamma radiation, the source is encapsulated in a double layer of stainless steel to prevent the escape of radioactivity to the environment. Other safeguards minimize the possibility of accidental exposure of either the plant personnel or the population at large.

Lasers. As noted above, lasers have become a valuable tool in medicine. They also have important uses in a number of other areas, as, for example, communications. Laser light can carry voice messages and digitally encoded information and can do so in large amounts because of its high frequency. Except in satellite-to-satellite communications, laser beams are transmitted via optical fibres. The speed with which the focal spot of a narrow laser beam can be controlled makes it suitable for a variety of applications in information processing—e.g., use in optical scanners, optical disc storage systems, and certain types of computer printers.

A highly intense laser beam can instantly vaporize the surface of a target. When laser pulses are concentrated on frozen deuterium-tritium pellets, they can initiate nuclear fusion (see *ATOMS: Energy from atoms: Nuclear fusion*). High-powered lasers can be used as space weapons to destroy reconnaissance and communications satellites and

perhaps even ballistic missiles. These same capabilities have led to the use of lasers in research as well as in surgery. The laser microprobe is used for microanalysis of surface composition. Laser beams have been found to have a selective effect on cellular components, or organelles: those components that absorb light of the wavelength of the beam are destroyed, whereas transparent parts of the cells remain unaffected. Organelles such as mitochondria, which are responsible for cell respiration, or chloroplasts, which are involved in plant-cell photosynthesis, can be separately studied in this manner.

An intense beam of laser light can be used for small-scale cutting, scribing, and welding in certain industrial processes. Laser “pens” capable of producing such high-intensity light beams have proved useful in the assembly of various electronic components, such as computer memory and logic units consisting of integrated arrays of microcircuit elements (Figure 9).

The use of special dyes can alter laser action. The availability of high-pulse-intensity laser beams is also revolutionizing microscopy. It is possible to photograph microaction in a small fraction of a second and to use holography for image synthesis. (C.A.T./Jo.Si./Ed.)

BIBLIOGRAPHY

General: Historical works include MAX PLANCK, *Introduction to Theoretical Physics*, vol. 4, *Theory of Light* (1932, reprinted 1957; originally published in German, 1927), the classic work on the subject of light and quanta. Other forms of electromagnetic radiation are covered in OTTO GLASSER, *Wilhelm Conrad Röntgen and the Early History of the Roentgen Rays* (1933; originally published in German, 1931). See also R.W. DITCHBURN, *Light*, 3rd ed., 2 vol. (1976), a well-presented text on physical optics that, though not too mathematical, does require understanding of the use of differential equations.

Interaction of radiation with matter: GERHARD K. ROLLEFSON and MILTON BURTON, *Photochemistry and the Mechanism of Chemical Reactions* (1939, reprinted 1946); WILLIAM ALBERT NOYES and PHILIP ALBERT LEIGHTON, *The Photochemistry of Gases* (1941, reprinted 1966), are both classic works that include material on internal conversion and predissociation. The language of intersystem crossing is discussed in detail in a comprehensive text, JACK G. CALVERT and JAMES N. PITTS, *Photochemistry* (1966). The actual effects of radiation on solids are thoroughly summarized in HANS A. BETHE and JULIUS ASHKIN, “Passage of Radiations Through Matter,” in EMILIO SEGRÈ (ed.), *Experimental Nuclear Physics*, vol. 1 (1953), pp. 166–357; G.J. DIENES and G.H. VINEYARD, *Radiation Effects in Solids* (1957); and DOUGLAS S. BILLINGTON and JAMES H. CRAWFORD, JR., *Radiation Damage in Solids* (1961). For a survey of radiation effects on aqueous solutions and organic compounds, see J.W.T. SPINKS and R.J. WOODS, *An Introduction to Radiation Chemistry*, 2nd ed. (1976); *Actions chimiques et biologiques des radiations* (annual 1955–71), the first survey on a large variety of subjects in radiation chemistry written by scientists largely about their own work—some volumes have been translated into English with the title, *The Chemical and Biological Action of Radiations*; and MAX S. MATHESON and LEON M. DORFMAN, *Pulse Radiolysis* (1969), an excellent book on techniques in radiation chemistry. *Advances in Photochemistry* (irregular) is concerned mainly with surveys of advances in the field. See also J.F. ZIEGLER (ed.), *Ion Implantation: Science and Technology* (1984), a treatment of ion implantation mechanisms, techniques, effects, and practical applications; and ORLANDO AUCIELLO and ROGER KELLY (eds.), *Ion Bombardment Modification of Surfaces: Fundamentals and Applications* (1984), covering surface alteration mechanisms with major emphasis on topographical effects. (Non-ionizing): Microwave radiation is treated in NATIONAL COUNCIL OF RADIATION PROTECTION AND MEASUREMENTS, *Biological Effects of Ultrasound: Mechanisms and Clinical Implications* (1983), and *Biological Effects and Exposure Criteria for Radiofrequency and Electromagnetic Fields* (1986); and R.C. PETERSEN, "Bioeffects of Microwaves: A Review of Current Knowledge," *Journal of Occupational Medicine*, 25(2):103-110 (February 1983). Visible and ultraviolet radiations are the subject of WALTER HARM, *Biological Effects of Ultraviolet Radiation* (1980); A. JARRET (ed.), *The Photobiology of the Skin: Lasers and the Skin* (1984); KENDRIC C. SMITH (ed.), *Topics in Photomedicine* (1984); and RICHARD J. WURTMAN, MICHAEL J. BAUM, and JOHN T. POTTS, JR. (eds.), *The Medical and Biological Effects of Light* (1985).

(Nuclear war): Radiation effects of a nuclear war are discussed in SAMUEL GLASSTONE and PHILIP J. DOLAN (eds.), *The Effects of Nuclear Weapons*, 3rd ed. (1977); JEAN PETERSEN and DON HINRICHSSEN (eds.), *Nuclear War: The Aftermath* (1982); JULIUS LONDON and GILBERT F. WHITE (eds.), *The Environmental Effects of Nuclear War* (1984); and FREDRIC SOLOMON and ROBERT Q. MARSTON (eds.), *The Medical Implications of Nuclear War* (1986).

(Radiation protection and safety): Procedures and recommendations for protection are analyzed in INTERNATIONAL COMMISSION ON RADIOLOGICAL PROTECTION, *Recommendations of the International Commission on Radiological Protection*

(1977, reprinted with supplements, 1987), and *Nonstochastic Effects of Ionizing Radiation* (1984); NATIONAL COUNCIL ON RADIATION PROTECTION AND MEASUREMENTS, *Ionizing Radiation Exposure of the Population of the United States* (1987); and MARILYN E. NOZ and GERALD Q. MAGUIRE, JR., *Radiation Protection in the Radiologic and Health Sciences*, 2nd ed. (1985).

Applications of radiation: (Medical): Radiological imaging techniques are explored in R.P. CLARK and M.P. GOFF (eds.), *Recent Developments in Medical and Physiological Imaging* (1986); W.-D. HEISS and M.F. PHELPS (eds.), *Positron Emission Tomography of the Brain* (1983); ALEXANDER R. MAGULIS and CHARLES A. GOODING (eds.), *Diagnostic Radiology*, 1987 (1987); and ALBERT A. MOSS, ERNEST J. RING, and CHARLES B. HIGGINS (eds.), *NMR, CT, and Interventional Radiology* (1984). Radiation therapy is addressed by GILBERT H. FLETCHER, *Textbook of Radiotherapy*, 3rd ed. (1980); and ERNEST J. RING and GORDON K. MCLEAN, *Interventional Radiology: Principles and Techniques* (1981). Specific uses of phototherapy are outlined in AUDREY K. BROWN and JANE SHOWACRE (eds.), *Phototherapy for Neonatal Hyperbilirubinemia: Long-Term Implications* (1977); WAYNE F. MARCH (ed.), *Ophthalmic Lasers: Current Clinical Uses* (1984); and WARWICK L. MORISON, *Phototherapy and Photochemotherapy of Skin Disease* (1983). (A.C.U.)

(Scientific and industrial): A review of ionizing radiation processing in medicine and industrial manufacturing is found in VITOMIR MARKOVIC, "Modern Tools of the Trade," *International Atomic Energy Agency Bulletin*, 27(1):33-39 (Spring 1985). Industrial uses are explored in JOSEPH SILVERMAN, "Radiation Processing: The Industrial Applications of Radiation Chemistry," *Journal of Chemical Education*, 58(2):168-173 (Feb. 1981). INTERNATIONAL ATOMIC ENERGY AGENCY, *Industrial Application of Radioisotopes and Radiation Technology* (1982), is a collection of conference papers. (Jo.Si.)

Relativity

Relativity is concerned with measurements made by different observers moving relative to one another. In classical physics it was assumed that all observers anywhere in the universe, whether moving or not, obtained identical measurements of space and time intervals. According to relativity theory, this is not so, but their results depend on their relative motions.

There are actually two distinct theories of relativity known in physics, one called the special theory of relativity, the other the general theory of relativity. Albert Einstein proposed the first in 1905, the second in 1916. Whereas the special theory of relativity is concerned primarily with electric and magnetic phenomena and with their propagation in space and time, the general theory of relativity was developed primarily in order to deal with gravitation. Both theories centre on new approaches to space and time, approaches that differ profoundly from those useful in everyday life; but relativistic notions of space and time are inextricably woven into any contemporary interpretation of physical phenomena ranging from the atom to the universe as a whole.

This article will set forth the principal ideas comprising both special and general relativity. It will also deal with some implications and applications of these theories.

The article is divided into the following sections:

The special theory of relativity	501

THE SPECIAL THEORY OF RELATIVITY

Historical background. Classical physics owes its definitive formulation to the British scientist Sir Isaac Newton. According to Newton, when one physical body influences another body, this influence results in a change of that body's state of motion, its velocity; that is to say, the force exerted by one particle on another results in the latter's changing the direction of its motion, the magnitude of its speed, or both. Conversely, in the absence of such external influences, a particle will continue to move in one unchanging direction and at a constant rate of speed. This statement, Newton's first law of motion, is known as the law of inertia.

As motion of a particle can be described only in relation to some agreed frame of reference, Newton's law of inertia may also be stated as the assertion that there exist frames of reference (so-called inertial frames of reference) with respect to which particles not subject to external forces move at constant speed in an unvarying direction. Ordinarily, all laws of classical mechanics are understood to hold with respect to such inertial frames of reference. Each frame of reference may be thought of as realized by a grid of surveyor's rods permitting the spatial fixation of any event, along with a clock describing the time of its occurrence.

According to Newton, any two inertial frames of refer-

ence are related to each other in that the two respective grids of rods move relative to each other only linearly and uniformly (with constant direction and speed) and without rotation, whereas the respective clocks differ from each other at most by a constant amount (as do the clocks adjusted to two different time zones on Earth) but go at the same rate. Except for the arbitrary choice of such a constant time difference, the time appropriate to various inertial frames of reference then is the same: If a certain physical process takes, say, one hour as determined in one inertial frame of reference, it will take precisely one hour with respect to any other inertial frame; and if two events are observed to take place simultaneously by an observer attached to one inertial frame, they will appear simultaneous to all other inertial observers. This universality of time and time determinations is usually referred to as the absolute character of time. The idea that a universal time can be used indiscriminately by all, irrespective of their varying states of motion—that is, by a person at rest at his home, by the driver of an automobile, and by the passenger aboard an airplane—is so deeply ingrained in most people that they do not even conceive of alternatives. It was only at the turn of the 20th century that the absolute character of time was called into question as the result of a number of ingenious experiments described below.

As long as the building blocks of the physical universe were thought to be particles and systems of particles that interacted with each other across empty space in accordance with the principles enunciated by Newton, there was no reason to doubt the validity of the space-time notions just sketched. This view of nature was first placed in doubt in the 19th century by the discoveries of a Danish physicist, Hans Christian Ørsted, the English scientist Michael Faraday, and the theoretical work of the Scottish-born physicist James Clerk Maxwell, all concerned with electric and magnetic phenomena. Electrically charged bodies and magnets do not affect each other directly over large distances, but they do affect one another by way of the so-called electromagnetic field, a state of tension spreading throughout space at a high but finite rate, which amounts to a speed of propagation of approximately 186,000 miles (300,000 kilometres) per second. As this value is the same as the known speed of light in empty space, Maxwell hypothesized that light itself is a species of electromagnetic disturbance; his guess has been confirmed experimentally, first by the production of lightlike waves by entirely electric and magnetic means in the laboratory by a German physicist, Heinrich Hertz, in the late 19th century.

Both Maxwell and Hertz were puzzled and profoundly disturbed by the question of what might be the carrier of the electric and magnetic fields in regions free of any known matter. Up to their time, the only fields and waves known to spread at a finite rate had been elastic waves, which appear to the senses as sound and which occur at low frequencies as the shocks of earthquakes, and surface waves, such as water waves on lakes and seas. Maxwell called the mysterious carrier of electromagnetic waves the ether, thereby reviving notions going back to antiquity. He attempted to endow his ether with properties that would account for the known properties of electromagnetic waves, but he was never entirely successful. The ether hypothesis, however, led two U.S. scientists, Albert Abraham Michelson and Edward Williams Morley, to conceive of an experiment (1887) intended to measure the motion of the ether on the surface of the Earth in their laboratory. On the reasonable hypothesis that the Earth is not the pivot of the whole universe, they argued that the motion of the Earth relative to the ether should result in slight variations in the observed speed of light (relative to the Earth and to the instruments of a laboratory) travelling in different directions. The measurement of the speed

The idea of absolute time

Maxwell's ether hypothesis

of light requires but one clock, if, by use of a mirror, a pencil of light is made to travel back and forth so that its speed is measured by clocking the total time elapsed in a round trip at one site; such an arrangement obviates the need for synchronizing two clocks at the ends of a one-way trip. Finally, if one is concerned with variations in the speed of light, rather than with an absolute determination of that speed itself, then it suffices to compare with each other round-trip travel times along two tracks at right angles to each other, and that is essentially what Michelson and Morley did. To avoid the use of a clock altogether, they compared travel times in terms of the numbers of wavelengths travelled, by making the beams travelling on the two distinct tracks interfere optically with each other. (If the waves meet at a point when both are in the same phase—e.g., both at their peak—the result is visible as the sum of the two in amplitude; if the peak of one coincides with the trough of the other, they cancel each other and no light is visible. Since the wavelengths are known, the relative positions of the peaks give an exact measure of how far one wave has advanced with respect to the other.) This highly precise experiment, repeated many times with ever-improved instrumental techniques, has consistently led to the result that the speed of light relative to the laboratory is the same in all directions, regardless of the time of the day, the time of the year, and the elevation of the laboratory above sea level.

The special theory of relativity resulted from the acceptance of this experimental finding. If an Earth-bound observer could not detect the motion of the Earth through the ether, then, it was felt, probably any observer, regardless of his state of motion, would find the speed of light the same in all directions.

Relativity of space and time. An Irish and a Dutch physicist, George Francis FitzGerald and Hendrik Antoon Lorentz, independently showed that the negative outcome of Michelson's and Morley's experiment could be reconciled with the notion that the Earth is travelling through the ether, if one hypothesizes that any body travelling through the ether is foreshortened in the direction of travel (though its dimensions at right angles to the motion remain undisturbed) by a ratio that increases with increasing speed. If v denotes the speed of the body relative to the ether, and c is the speed of light, that ratio equals the quantity $(1 - v^2/c^2)^{1/2}$. At ordinary speeds, c is so much greater than v that the fraction, practically speaking, is zero, and the ratio becomes $\sqrt{1}$, which is 1; i.e., the foreshortening is nil; as v approaches c , however, the fraction becomes significant. The travelling body would be flattened completely if its speed through the ether should ever reach that of light.

Suppose, now, that the variations in the speed of light were to be determined not by interference but by means of an exceedingly accurate clock and assume further that in such a modified experiment (whose actual performance is precluded at present, because even the best atomic clocks available do not possess the requisite accuracy) the motion through the ether were still imperceptible, then, Lorentz showed, one would have to conclude that all clocks moving through the ether are slowed down compared to clocks at rest in the ether, again by the factor $(1 - v^2/c^2)^{1/2}$. Thus, all rods and all clocks would be modified systematically, regardless of materials and construction design, whenever they were moving relative to the ether. Accordingly, for theoretical analysis, one would have to distinguish between "apparent" and "true" space and time measurements, with the further proviso that "true" dimensions and "true" times could never be determined by any experimental procedure.

Conceptually, this was an unsatisfactory situation, which was resolved by Albert Einstein in 1905. Einstein realized that the key concept, on which all comparisons between differently moving observers and frames of reference depended, is the notion of universal, or absolute, simultaneity; that is to say, the proposition that two events that appear simultaneous to any one observer will also be judged to take place at the same time by all other observers. This appears to be a straightforward proposition, provided that knowledge of distant events can be obtained

practically instantaneously. Actually, however, there is no known method of signalling faster than by means of light or radio waves or any other electromagnetic radiation, all of which travel at the same rate, c .

Suppose, now, that someone on Earth observes two events, say two supernovae (suddenly erupting very bright stars) appearing in different parts of the sky. Nothing can be said about whether these two supernovae emerged simultaneously or not from merely noting their appearance in the sky; it is necessary to know also their respective distances from the observer, which typically may amount to several hundred or several thousand light-years (one light-year, the distance light moves in one year, equals approximately 5.88×10^{12} miles, or 9.46×10^{12} kilometres). By the time one sees the eruption of a supernova, it has in actuality faded back into invisibility hundreds of years ago. Applying this simple idea to the observations and measurements made by different observers of the same events, Einstein demonstrated that if each observer applied the same method of analysis to his own data, then events that appeared simultaneous to one would appear to have taken place at different times to observers in different states of motion. Thus, it is necessary to speak of relativity of simultaneity.

Once this theoretical deduction is accepted, the findings of FitzGerald and Lorentz lend themselves to a new interpretation. Whenever two observers are associated with two distinct inertial frames of inference in relative motion to each other, their determinations of time intervals and of distances between events will disagree systematically, without one being "right" and the other "wrong." Nor can it be established that one of them is at rest relative to the ether, the other in motion. In fact, if they compare their respective clocks, each will find that his own clock will be faster than the other; if they compare their respective measuring rods (in the direction of mutual motion), each will find the other's rod foreshortened. The speed of light will be found to equal the same value, $c = 186,000$ miles per second, relative to every inertial frame of reference and in all directions. The status of Maxwell's ether is thereby cast in doubt, as its state of motion cannot be ascertained by any conceivable experiment. Consequently, the whole notion of an ether as the carrier of electromagnetic phenomena has been eliminated in contemporary physics.

The mathematical equations that relate space and time measurements of one observer to those of another, moving observer are known as Lorentz transformations. If the relative motion is measured along the x -axis and if its magnitude is v , these expressions are (see Figure 1):

$$x' = (1 - v^2/c^2)^{-1/2} (x - vt), \quad y' = y, \quad z' = z,$$

$$t' = (1 - v^2/c^2)^{-1/2} (t - vx/c^2).$$

Consequences. The limiting character of the speed of light. As the speed of one inertial frame of reference relative to another is increased, its rods appear increasingly foreshortened and its clocks more and more slowed down. As this relative speed approaches c , both of these effects increase indefinitely. The relative speed of the two frames cannot exceed c if light and other electromagnetic phenomena are to travel at the speed c in all directions when viewed from either frame of reference. Hence the special theory of relativity forecloses relative speeds of frames of reference greater than c . As an inertial frame of reference can be associated with any material object in uniform nonrotational motion, it follows that no material object can travel at a rate of speed exceeding c .

This conclusion is self-consistent only because under the

Figure 1: The Lorentz transformations. (A) Nonrelativistic transformation; (B) relativistic transformation (see text).

"Apparent" time and space

The Lorentz transformations

Lorentz transformations the velocity of a body with respect to one inertial frame of reference is related to its velocity with respect to another frame not by the Newtonian rule that the difference in velocities equals the relative velocity between the two frames but by a more involved formula, which takes into account the changes in scale length, in clock time, and in simultaneity. If all velocities involved have the same direction, then the velocity (see Figure 2) in one frame, u , is related to the velocity in the other frame, u' , by the expression stating that u' equals the sum of u and v divided by 1 plus the product of u and v divided by the square of c :

$$u' = (u + v)/(1 + uv/c^2).$$

As long as neither u nor v exceeds the speed of light, c , u' also will be less than c .

Figure 2: Velocities of the same body in two frames of reference (see text).

Variable mass. The mass of a material body is a measure of its resistance to a change in its state of motion caused by a given force. The larger the mass, the smaller the acceleration. If a material body is already moving at a speed approaching the speed of light, it must offer increasing resistance to any further acceleration so as not to cross the threshold of c . Hence the special theory of relativity leads to the conclusion that the mass of a moving body m is related to the mass that it would have if at rest, m_0 , by a formula in which m equals m_0 divided by the square root of one minus the fraction v^2/c^2 :

$$m = (1 - v^2/c^2)^{-1/2} m_0.$$

Relativistic mass

This changing value of the mass of the moving body, m , is called the relativistic mass. As v approaches c , the figure within the parentheses approaches zero and the mass m becomes infinitely large.

The relativistic mass formula may be interpreted as indicating that the relativistic mass of a body exceeds its rest mass m_0 by an amount that equals its kinetic energy E , divided by c^2 : $m - m_0 = E/c^2$. Hence the hypothesis that generally the energy is c^2 times the mass, or $E = mc^2$, and that energy and mass are, in fact, equivalent physical concepts, differing only by the choice of their units. This hypothesis has been verified experimentally, in that all massive particles have been converted into forms of energy (for instance, gamma radiation) and conversely have been created out of pure energy. It was in part the recognition of this relationship that led to research out of which grew the technology of nuclear fission and fusion.

Invariant intervals. Data on pure time intervals obtained with respect to two relatively moving inertial frames of reference will differ and so will data on spatial distances. It is possible, however, to form from time intervals plus distances a single expression that will have the same value with respect to all inertial frames of reference. If the time interval between two distant events be denoted by T and their distance from each other by L , an expression involving a quantity symbolized by τ can be derived in

which τ squared equals the square of the time interval minus the fraction of distance squared over speed of light squared: $\tau^2 = T^2 - L^2/c^2$. This will have the same value as $\bar{T}^2 - \bar{L}^2/c^2$, with \bar{T} and \bar{L} having been obtained in another inertial frame of reference. If τ^2 is positive, then τ is called the invariant (timelike) interval between the two events. If τ^2 is negative, then the expression λ , derived from the above as $\lambda^2 = L^2 - c^2 T^2$, will be called the invariant (spacelike) interval.

The invariant interval between two instants in the history of one physical system equals the ordinary time lapse T measured by means of a clock at rest relative to that physical system, because, in such a comoving frame of reference, L vanishes. That is why such an invariant (timelike) interval is also referred to as the "proper time" elapsed between the two instants. Any clock will read its own proper time.

The "twin paradox." Given an inertial frame of reference and two similar material systems ("twins")—for instance, two atomic clocks of identical design—suppose that one of these clocks remains permanently at rest in the given frame, whereas the other clock is moved at a high speed first in one direction away from the first clock and subsequently in the opposite direction until the two clocks are again close to each other. According to the Lorentz transformation, the second clock has been slower than the first throughout its journey, and hence it shows a smaller lapse of time than the clock that has remained at rest. By reading the clocks, one can then tell which clock has remained at rest, which one has moved. This difference in behaviour of the two clocks has been called the clock paradox or the twin paradox.

The "paradox" supposedly consists of a violation of the principle of relativity, according to which no asymmetric distinctions exist between different inertial frames of reference. The fallacy of this argument lies in the fact that no inertial frame of reference is associated with the second clock, as it cannot have moved free of acceleration throughout its journey: at least once its velocity (*i.e.*, the direction of its motion) must have been changed drastically, so as to enable it ever to return to its mate. Hence no violation of the principle of relativity; no paradox is involved. Various experiments on moving particles and atoms have indeed confirmed the predictions of the theory.

The clock "paradox"

Four-dimensional space-time. The German mathematical physicist Hermann Minkowski pointed out that the invariant interval between two events has some of the properties of the distance in Euclidean geometry. Based on Euclidean geometry, the Cartesian coordinate system is designed to identify any point (event) in space by its reference to three mutually perpendicular lines or axes meeting at an arbitrary point of origin. The distance s between two events, in accordance with Pythagoras' theorem, in any Cartesian (rectilinear) coordinate system is obtained by taking the square root of the sum of the squares of coordinate distances, $s^2 = x^2 + y^2 + z^2$, and its value is independent of the choice of coordinate system, though the values of x , y , and z are not. The invariant interval, similarly, is the square root of a sum and difference of squares of intervals of both space and time. Accordingly, Minkowski suggested that space and time should be thought of as comprising a single four-dimensional continuum, space-time, often also referred to as the Minkowski universe. Events, localized as regards both space and time, are the natural analogues of points in ordinary three-dimensional geometry; in the history of one particle, its proper time resembles the arc length of a curve in three-space.

In Minkowski's space-time the invariant interval may be either timelike or spacelike. If $L^2 - c^2 T^2$ for two events happens to be zero, the invariant interval is neither, but null, or lightlike, as a light signal emanating from the earlier of the two events may just pass the second as the latter occurs. By contrast, in ordinary geometry the distance between two points, s , vanishes only if the two points coincide. To this extent the analogy between space-time and ordinary space is imperfect.

Minkowski's four-dimensional, geometric approach to relativity appears to add to the original physical concepts of relativity mostly a new terminology but not much

else. Nevertheless, for the further conceptual development of relativity Minkowski's contribution has been of inestimable value.

THE GENERAL THEORY OF RELATIVITY

Physical origins. The general theory of relativity derives its origin from the need to extend the new space and time concepts of the special theory of relativity from the domain of electric and magnetic phenomena to all of physics and, particularly, to the theory of gravitation. As space and time relations underlie all physical phenomena, it is conceptually intolerable to have to use mutually contradictory notions of space and time in dealing with different kinds of interactions, particularly in view of the fact that the same particles may interact with each other in several different ways—electromagnetically, gravitationally, and by way of so-called nuclear forces.

Newton's
theory of
gravity

Newton's explanation of gravitational interactions must be considered one of the most successful physical theories of all time. It accounts for the motions of all the constituents of the solar system with uncanny accuracy, permitting, for instance, the prediction of eclipses hundreds of years ahead. But Newton's theory visualizes the gravitational pull that the Sun exerts on the planets and the pull that the planets in turn exert on their moons and on each other as taking place instantaneously over the vast distances of interplanetary space, whereas according to relativistic notions of space and time any and all interactions cannot spread faster than the speed of light. The difference may be unimportant, for practical reasons, as all of the members of the solar system move at relative speeds far less than $1/1,000$ of the speed of light; nevertheless, relativistic space-time and Newton's instantaneous action at a distance are fundamentally incompatible. Hence Einstein set out to develop a theory of gravitation that would be consistent with relativity.

Proceeding on the basis of the experience gained from Maxwell's theory of the electric field, Einstein postulated the existence of a gravitational field that propagates at the speed of light, c , and that will mediate an attraction as closely as possible equal to the attraction obtained from Newton's theory. From the outset it was clear that mathematically a field theory of gravitation would be more involved than that of electricity and magnetism. Whereas the sources of the electric field, the electric charges of particles, have values independent of the state of motion of the instruments by which these charges are measured, the source of the gravitational field, the mass of a particle, varies with the speed of the particle relative to the frame of reference in which it is determined and hence will have different values in different frames of reference. This complicating factor introduces into the task of constructing a relativistic theory of the gravitational field a measure of ambiguity, which Einstein resolved eventually by invoking the principle of equivalence.

The principle of equivalence. Everyday experience indicates that in a given field of gravity, such as the field caused by the Earth, the greater the mass of a body the greater the force acting on it. That is to say, the more massive a body the more effectively will it tend to fall toward the Earth; in fact, in order to determine the mass of a body one weighs it—that is to say, one really measures the force by which it is attracted to the Earth, whereas the mass is properly defined as the body's resistance to acceleration. Newton noted that the ratio of the attractive force to a body's mass in a given field is the same for all bodies, irrespective of their chemical constitution and other characteristics, and that they all undergo the same acceleration in free fall; this common rate of acceleration on the surface of the Earth amounts to an increase in speed by approximately 32 feet (about 9.8 metres) per second every second.

Weight-
lessness

This common rate of gravitationally caused acceleration is illustrated dramatically in space travel during periods of coasting. The vehicle, the astronauts, and all other objects within the space capsule undergo the same acceleration, hence no acceleration relative to each other. The result is apparent weightlessness: no force holds the astronaut to the floor of his cabin or a liquid in an open container.

To this extent, the behaviour of objects within the freely coasting space capsule is indistinguishable from the condition that would be encountered if the space capsule were outside all gravitational fields in interstellar space and moved in accordance with the law of inertia. Conversely, if a space capsule were to be accelerated upward by its rocket engines in the absence of gravitation, all objects inside would behave exactly as if the capsule were at rest but in a gravitational field. The principle of equivalence states formally the equivalence, in terms of local experiments, of gravitational forces and reactions to an accelerated noninertial frame of reference (*e.g.*, the capsule while the rockets are being fired) and the equivalence between inertial frames of reference and local freely falling frames of reference. Of course, the principle of equivalence refers strictly to local effects: looking out of his window and performing navigational observations, the astronaut can tell how he is moving relative to the planets and moons of the solar system.

Einstein argued, however, that in the presence of gravitational fields there is no unambiguous way to separate gravitational pull from the effects occasioned by the non-inertial character of one's chosen frame of reference; hence one cannot identify an inertial frame of reference with complete precision. Thus the principle of equivalence renders the gravitational field fundamentally different from all other force fields encountered in nature. The new theory of gravitation, the general theory of relativity, adopts this characteristic of the gravitational field as its foundation.

Curved space-time. *The principles.* In terms of Minkowski's space-time, inertial frames of reference are the analogues of rectilinear (straight-line) Cartesian coordinate systems in Euclidean geometry. In a plane these coordinate systems always exist, but they do not exist on the surface of a sphere: any attempt to cover a spherical surface with a grid of squares breaks down when the grid is extended over a significant fraction of the spherical surface. Thus a plane is a flat surface, whereas the surface of a sphere is curved. This distinction, based entirely on internal properties of the surface itself, classifies the surface of a cylinder as flat, as it can be rolled off on a plane and thus is capable of being covered by a grid of squares.

Einstein conjectured that the presence of a gravitational field causes space-time to be curved (whereas in the absence of gravitation it is flat), and that this is the reason that inertial frames cannot be constructed. The curved trajectory of a particle in space and time resulting from the effects of gravitation would then represent not a straight line (which exists only in flat spaces and space-times) but the straightest curve possible in a curved space-time, a geodesic. Geodesics on a sphere (such as the surface of the Earth) are the great circles. (The plane of any great circle goes through the centre of the Earth.) They are the least curved lines one can construct on the surface of a sphere, and they are the shortest curves connecting any two points. The geodesics of space-time connect two events (or two instants in the history of one particle) with the greatest lapse of proper time, as was indicated in the earlier discussion of the twin paradox.

If the presence of a gravitational field amounts to a curvature of space-time, then the description of the gravitational field in turn hinges on a mathematical elucidation of the curvature of four-dimensional space-time. Before Einstein, the German mathematician Bernhard Riemann (1826–66) had developed methods related directly to the failure of any attempt to construct square grids. If one were to construct within any small piece of (two-dimensional) surface a quadrilateral whose sides are geodesics, if the surface were flat, the sum of the angles at the four corners would be 360° . If the surface is not flat, the sum of the angles will not be 360° . The deviation of the actual sum of the angles from 360° will be proportional to the area of the quadrilateral; the amount of deviation per unit of surface will be a measure of the curvature of that surface. If the surface is imbedded in a higher dimensional continuum, then one can consider similarly unavoidable angles between vectors constructed as parallel as possible to each other at the four corners of the quadrilateral, and thus associate several distinct components of curvature

Rieman-
nian space

with one surface. And, of course, there are several independent possible orientations of two-dimensional surfaces, for instance, six in a four-dimensional continuum, such as space-time. Altogether there are 20 distinct and independent components of curvature defined at each point of space-time; in mathematics these are referred to as the 20 components of Riemann's curvature tensor.

The mathematical expression. Einstein discovered that he could relate 10 of these components in a natural way to the sources of the gravitational field, mass (or energy), density, momentum density, and stress, if he were to duplicate approximately Newton's equations of the gravitational field and, at the same time, formulate laws that would take the same form regardless of the choice of frame of reference. The remaining 10 components may be chosen arbitrarily at any one point but are related to each other by partial differential equations at neighbouring points. Einstein derived a field equation that, along with the rule that a freely falling body moves along a geodesic, forms the comprehensive treatment of gravitation known as the general theory of relativity.

Confirmation of the theory. The general theory of relativity is constructed so that its results are approximately the same as those of Newton's theories as long as the velocities of all bodies interacting with each other gravitationally are small compared to the speed of light; *i.e.*, as long as the gravitational fields involved are weak. The latter requirement may be stated roughly in terms of the escape velocity. The escape velocity is defined as the minimal speed with which a projectile must be endowed at any given location to enable it to fly off to infinitely removed regions of the universe without the application of further force. On the surface of the Earth the escape velocity is approximately 7.5 kilometres (4.7 miles) per second. A gravitational field is considered strong if the escape velocity approaches the speed of light, weak if it is much smaller. All gravitational fields encountered in the solar system are weak in this sense.

The success of Newton's theory, incidentally, must be considered a confirmation of the general theory of relativity to the extent that that application of the theory remains confined to situations involving small relative speeds and weak fields. Obviously, any superiority of the new theory over the old one may be inferred only if their predictions disagree and if those of the general theory of relativity are confirmed by experiment and observation.

As the principle of equivalence forms the cornerstone of general relativity, its verification is crucial. Highly precise experiments with this objective were performed between 1888 and 1922 by a Hungarian physicist, Roland, Baron Eötvös, and his collaborators, who confirmed the principle to an accuracy of one part in 10^8 and, in the 1960s, by a U.S. physicist, Robert Dicke, who achieved an accuracy of one part in 10^{11} . Subsequently the Soviet physicist V.L. Braginsky further improved the accuracy to one part in 10^{12} . Through this work the principle of equivalence has become one of the most precisely confirmed general principles of contemporary physics.

Some other new predictions of general relativity are explained below.

Advance of Mercury's perihelion. The major axes of the elliptical trajectories of the various planets about the Sun turn slowly within their planes, because of the interactions of the planets with each other, but it was discovered in the 19th century that interplanetary perturbations could not account fully for the turning rate of Mercury's orbit, leaving unexplained about 43" of arc per century. The general theory of relativity, however, accounts exactly for this discrepancy. In 1967 Dicke—and more recently Henry Allen Hill, also of the United States—suggested that a small part of Mercury's perihelion advance may be caused by the slight flattening of the Sun at its poles, thus opening the way for possible modification of general relativity. On the other hand, support for Einstein's original version of the theory has come from a comprehensive evaluation of solar system data by the U.S. investigator Ronald W. Hellings and from investigations of the binary pulsar system PSR 1913+16 by the U.S. astronomer Joseph H. Taylor.

Gravitational red shift. General relativity predicts that

the wavelength of light emanating from sources within a gravitational field will be increased (shifted toward the red end of the spectrum) by an amount proportional to the gravitational potential at the site of the source. This effect was searched for and found first in astronomical objects, particularly in stars called white dwarfs, on whose surfaces the gravitational potential is large. The best quantitative confirmation of gravitational red shift was obtained in laboratory experiments performed in Great Britain and the United States in the 1960s; an accuracy of one part in 100 was achieved in measuring the minute difference in gravitational potential between two sites differing in altitude by a few metres.

Optical effects of gravitation. General relativity predicts that the curvature of space-time results in the apparent bending of light rays passing through gravitational fields and in an apparent reduction of their speeds of propagation. The bending was first observed, within a couple of years of Einstein's publication of the new theory, during a total eclipse, when stellar images near the occulted disk of the Sun appeared displaced by fractions of 1" of arc from their usual locations in the sky. The associated delay in travel time was observed in the late 1960s, when ultra-intense radar pulses were reflected off Mercury and Venus just as these planets were passing behind the Sun. These experiments are difficult to perform and their accuracy is difficult to evaluate, but it seems conservative to conclude that they confirm the relativistic effect within a few parts in 100. Finally, extended massive objects such as galaxies may act as "gravitational lenses," providing more than one optical path for light emanating from a source far behind the lens and thus producing multiple images. Such multiple images, typically of quasars, had been discovered by the early 1980s.

Gravitational waves. General relativity predicts the occurrence of gravitational waves, whose properties should resemble in some respects those of electromagnetic waves; they should travel at the same speed, *c*, and they should be polarized. Joseph Weber, a U.S. physicist, announced in 1969 that he had detected events that might be caused by incoming gravitational waves, namely, vibrations occurring simultaneously in pairs of large aluminum cylinders, approximately 1,000 kilometres apart and each weighing several tons. Although these detectors had been insulated with great care from all other potential sources of such vibrations, the separation of gravitational signals from ordinary thermal noise (Brownian motion) presents delicate problems of instrumentation and interpretation, which proved difficult to resolve to the satisfaction of other experimenters attempting to repeat Weber's observations.

Weber's approach has been refined by the choice of different materials for the vibrating masses, by cryogenic techniques reducing the level of thermal noise, and by other improvements. A fundamentally different technique, replacing Weber's stationary cylinders by independently moving masses whose distances from each other would be measured by interferometric means, also has been investigated. While these efforts at direct detection of gravitational waves were under way, observations of the binary pulsar PSR 1913+16 indicated that this double star system is losing energy at precisely the rate that corresponds to the emission of gravitational radiation according to the theory of general relativity.

The discovery of gravitational waves would represent an important confirmation of the validity of the theory. Also, such waves might become the basis of an entirely new technology of astronomical observation, as they are believed to be the most penetrating kind of radiation imaginable.

Future astrophysical tests. The properties of certain astronomical objects, such as quasars (see below *Relativistic cosmology*), pulsars (extremely dense stars that emit electromagnetic pulses with great regularity), very bright galaxies at the cores of which extraordinary amounts of energy are being emitted, and jets of matter moving at relativistic speeds, imply that there are processes involving gravitational fields so strong that general relativity is needed to interpret the observations, which in turn will provide new tests of that theory.

Conceptual implications of general relativity. The gen-

eral theory of relativity represents a further modification of classical concepts of space and time that goes far beyond those implicit in the special theory. The special theory does away with the absolute character of time and with the absolute distance between two objects that are at rest relative to each other. The geometric concepts appropriate to the special theory are the four-dimensional space-time continuum, in which events that are fixed in space and in time are represented by points, often referred to as world points (to distinguish them from the points of ordinary three-dimensional space), and the histories of particles moving through space in the course of time by curves (world curves); the representations of particles that are not accelerated by forces are straight lines.

Minkowski-
skian
space-time

Minkowski's space-time is a rigidly flat continuum, as is the three-dimensional space of Euclid's geometry. Distances between world points are measured by the invariant intervals, whose magnitudes do not depend on the particular coordinate system, or frame of reference, used. The Minkowski universe is homogeneous; that is to say, geometric figures constructed at any site may be transferred to another site without distortion. Finally, among all the possible frames of reference there is a special set, the inertial frames of reference, just as in ordinary space the rectilinear coordinate systems are distinguished by their simplicity among all conceivable coordinate systems. Space-time serves as the immutable backdrop of all physical processes, without being affected by them.

In general relativity, space-time also is a four-dimensional continuum, with invariant intervals being defined at least locally between events taking place close to each other. But only small regions of space-time resemble the continuum envisaged by Minkowski, just as small bits of a spherical surface appear nearly planar. In the broad sense, according to general relativity, space-time is curved, and this curvature is equivalent to the presence of a gravitational field. Far from being rigid and homogeneous, the general-relativistic space-time continuum has geometric properties that vary from point to point and that are affected by local physical processes. Space-time ceases to be a stage, or scaffolding, for the dynamics of nature; it becomes an integral part of the dynamic process. General relativity, it has been said, makes physics part of geometry. It may also be claimed that general relativity makes geometry part of physics, that is to say, of a natural science. Not only are the properties of space and time subject to scientific investigation, to a study by means of experiments, but specific properties, such as the amount of curvature in a particular location at a specified time, are to be measured with the help of physical instruments.

Though the general theory of relativity is universally accepted as the most satisfactory basis of the gravitational force now known, it has not been completely fused with quantum mechanics, of which the central concept is that energy and angular momentum exist only in finite and discrete lumps, called quanta. Since the 1920s quantum mechanics has been the sole rationale of the forces that act between subatomic particles; gravitation doubtless is one of these forces, but its effects are unobservably small in comparison to electromagnetic and nuclear forces. Relativistic phenomena in the subatomic realm have been adequately dealt with by merging quantum mechanics with the special, not the general, theory.

Many physicists, foremost among them Einstein himself, tried during the first half of the 20th century to enrich the geometric structure of space-time so as to encompass all known physical interactions. Their goal, a unified field theory, remained elusive but was brought nearer during the late 1960s by the successful unification of the electromagnetic and the so-called weak nuclear force.

Unified
field
theory

Schwarzschild's solution of the field equations. Immediately on publication of Einstein's paper on general relativity, the German astronomer Karl Schwarzschild found a mathematical solution to the new field equations, which corresponds to the gravitational field of a compact massive body, such as a star or planet, and which is now referred to as Schwarzschild's field. If the mass that serves as the source of the field is fairly diffuse, so that the gravitational field on the surface of the astronomical body

is fairly weak, Schwarzschild's field will exhibit physical properties similar to those described by Newton. Gross deviations will be found if the mass is so highly concentrated that the field on the surface is strong. At the time of Schwarzschild's work, in 1916, this appeared to be a theoretical speculation; but with the discovery of pulsars and their interpretation as probable neutron stars composed of matter that has the same density as atomic nuclei (so-called nuclear matter), the possibility exists that strong fields may soon be accessible to astronomical observation.

The most conspicuous feature of the Schwarzschild field is that if the total mass is thought of as concentrated at the very centre, a point called a singularity, then at a finite distance from that centre, the Schwarzschild radius, the geometry of space-time changes drastically from that to which we are accustomed. Particles and even light rays cannot penetrate from inside the Schwarzschild radius to the outside and be detected. Conversely, to an outside observer any objects approaching the Schwarzschild radius appear to take an infinite time to penetrate toward the inside. There cannot be any effective communication between the inside and the outside, and the boundary between them is called an event horizon.
