CONTENTS

San Francisco

San Francisco holds a secure place in the United States' romantic dream of itself—a cool, elegant, handsome, worldly seaport whose steep streets offer breathtaking views of one of the world's great bays. San Franciscans, according to the dream, are sophisticates whose lives hold full measures of such civilized pleasures as music, art, and good food. Their city is a magic place, almost an island, saved by its location and its history from the overpowering ugliness that, again according to the dream, afflicts so much of the rest of urban California.

For all the truth there may be in this picture, there is, of course, also another San Francisco in which the per capita consumption of alcohol is the highest of any U.S. city, the suicide rate is higher than the national average, and the divorce rate is several times that of New York City. San Francisco is clearly a city in which the tensions between the dream and the reality have been costly.

Furthermore, since World War II, San Francisco has had to come to grips with the common urban problems of pollution of both the air and the water; the ugliness that comes from rampant building, violence, and vandalism; and the decay of the inner city. San Francisco has been shrinking as families, mainly white and middle-class, have moved to its suburbs, leaving the city to a population that, viewed statistically, tends to be older and to have fewer married people and fewer whites than the stereotype has it. Almost one of every two San Franciscans is, in the sterile term of the census taker, "nonwhite"—in this case black, East Asian, Filipino, Samoan, or American Indian. Many others are immigrants from Spanish America. Their dreams increasingly demand a realization that has little to do with the romantic dream of San Francisco.

But both the dreams and the realities are important, for they are interwoven in the fabric of the city that might be called Paradox-by-the-Bay.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. Hilly, roughly square, and about 46 square miles (120 square kilometres) in area, San Francisco occupies the northern tip of a peninsula. To its south are the bedroom suburbs of San Mateo County; to the east and northeast is the bay; to the west and northwest lies the Pacific Ocean.

The hills and dizzying streets

The most prominent of San Francisco's hills are Twin Peaks, Mt. Davidson, and Mt. Sutro, all more than 900 feet (270 metres) in height. The best known are Nob Hill, where the wealthy "nobs" built extravagant mansions in the 1870s, and Telegraph Hill, which once looked down on the Barbary Coast, a neighbourhood alive with gaudy wickedness. Thanks to the pioneer planners' prejudice in favour of a squared-off grid, the downtown streets march intrepidly up precipitous slopes, terrifying newly arrived drivers, making the cable cars more than sentimental anachronisms, and providing splendid views of the bay.

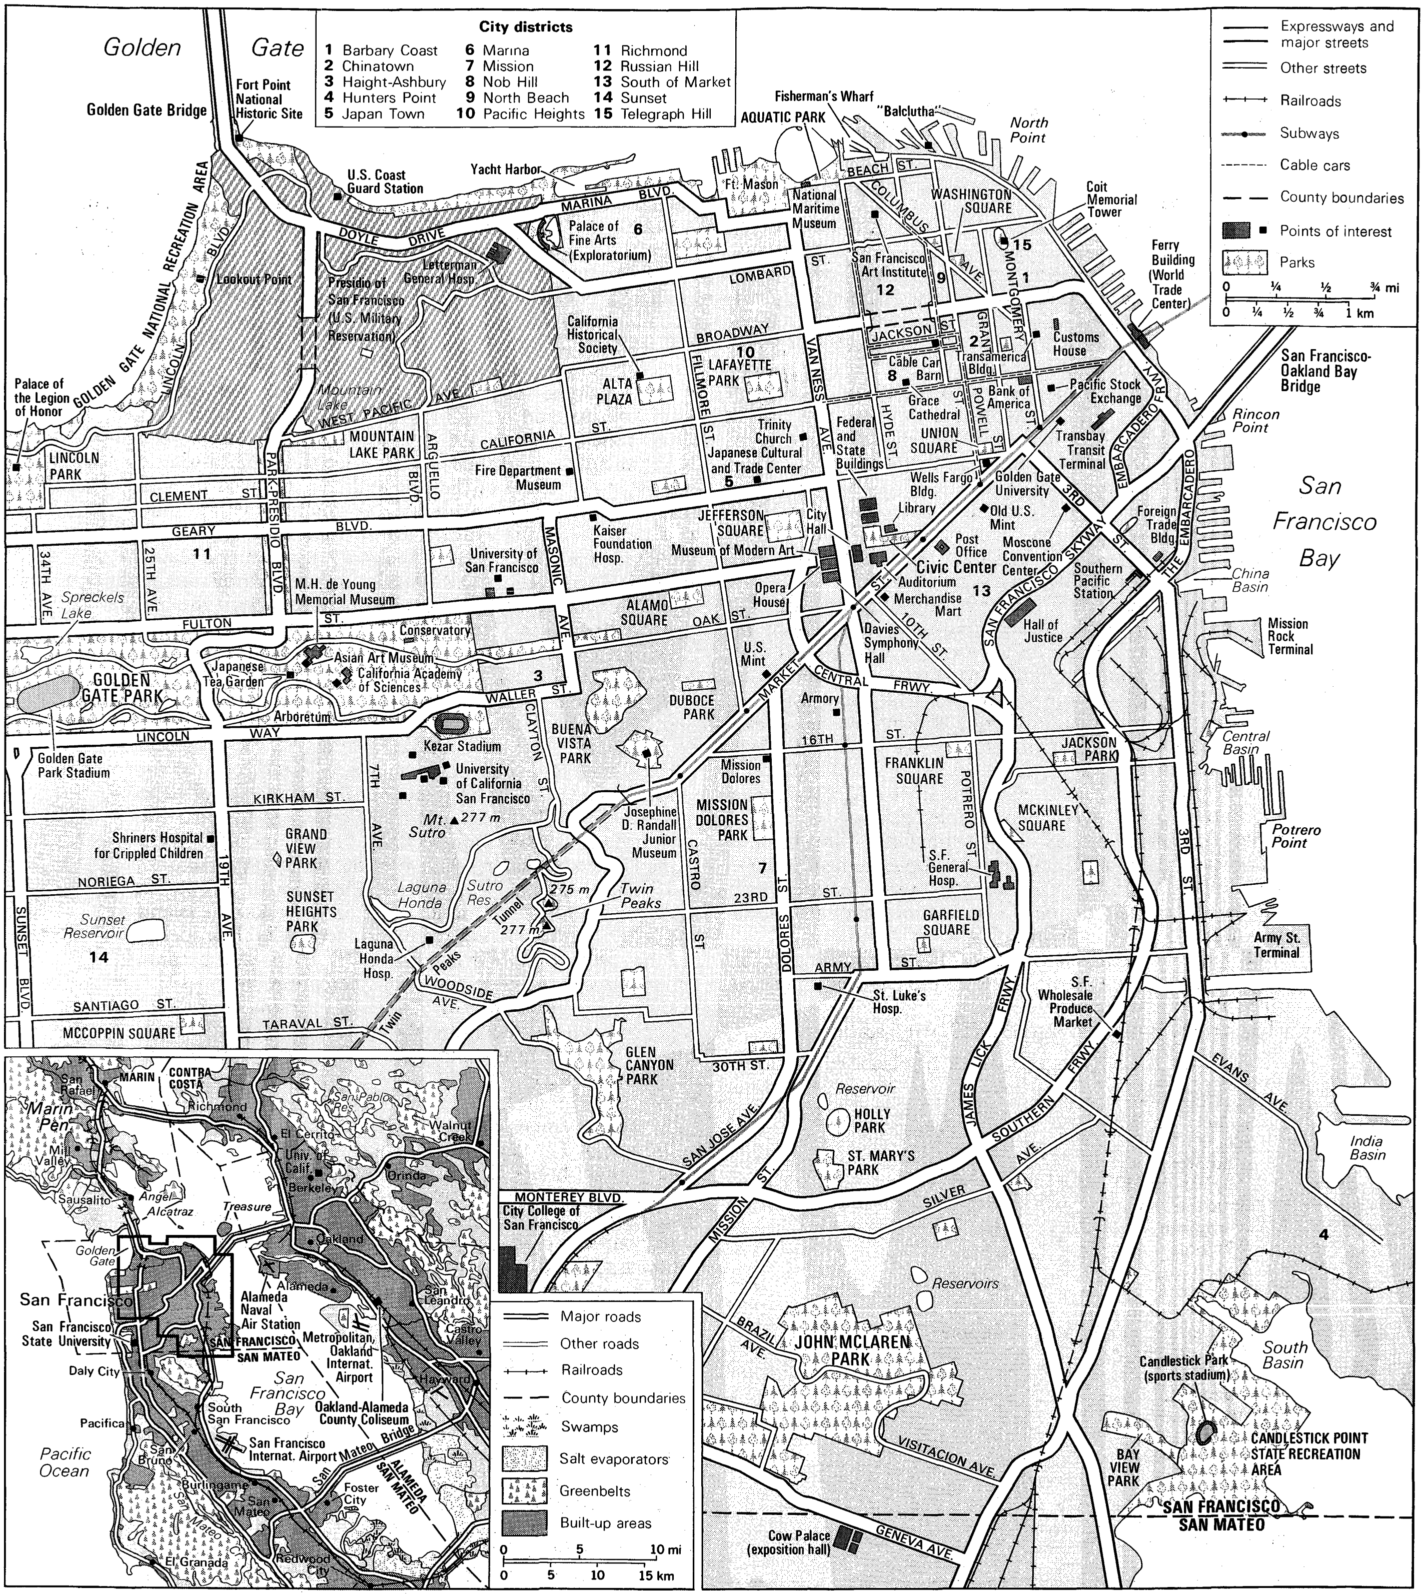
San Francisco Bay is a drowned river valley, submerged during the melting of the last glacial ice sheet. Enthusiastic and profitable filling of the tidelands has reduced its area at mean high tide from about 700 square miles in 1880 to a mere 435 square miles. More than half of the bay is still fillable, but in 1965 the state legislature created the Bay Conservation and Development Commission to control further landfill projects. At its widest point the bay measures 13 miles (21 kilometres) and at its deepest, in the Golden Gate channel, 357 feet. The maximum daily flow of water through the Golden Gate into the Pacific is seven times the flow of the Mississippi River at its mouth.

Within the portion of San Francisco Bay lying inside the city limits are the natural islands of Alcatraz and Yerba Buena and man-made Treasure Island, created for a world's fair in 1939 and later turned into a naval base. Alcatraz (Spanish: "Pelican") was from 1934 to 1963 the most notorious maximum-security, "escape-proof" prison in the United States. In 1969, after the decaying cell blocks had been given up by the Federal Bureau of Prisons, a multi-tribal group of American Indians invaded the island and asserted their rights to abandoned federal property, but they were forcibly evicted in 1971. The island became part of the Golden Gate National Recreation area in 1972.

Climate. Winter in San Francisco is rainy and mild, the spring sunny and mild, the summer foggy and cool, and the autumn sunny and warm. The average minimum temperature is 51° F (11° C), the average maximum, 63° F (17° C). The mean rainfall, almost all of which occurs between November and April, is about 21 inches (533 millimetres). The sun shines during two-thirds of the possible daylight hours. The most characteristic feature of the weather, however, is the summer fog, which lies low over the city until midday, creating consternation among shivering tourists. This fog is a phenomenon of temperature contrasts created when warm, moist ocean air comes in contact with cold water welling up from the ocean bottom along the coast.

The city layout. The central business district, the financial district, North Beach, and Chinatown occupy the site of the Gold Rush city, expanded by progressive fillings along the waterfront. The bones of many a ship deserted in 1849 now lie under business buildings several blocks inland. To the west, at the approach to the Golden Gate Bridge, lies the Presidio, a U.S. military reservation remarkable for its parklike lawns and stands of trees. South of the Presidio is Golden Gate Park, reclaimed from a one-time sandy desert. The rest of San Francisco is largely composed of the residential neighbourhoods, from Pacific Heights, in which the old, moneyed families live, to Hunter's Point, which is predominantly black.

A great change, which has been described as the Manhattanization of San Francisco, became apparent after the late 1960s, and it has been both welcomed and excoriated. In the financial district in particular, one tall building after another has been built in a city in which, for generations, few buildings were higher than 20 stories. Among the modern skyscrapers are the Bank of America Center (52 stories) and the Transamerica Corporation building (48 stories and a 212-foot spire), which rises to a point like an elongated pyramid. (K.La./G.C.Ha.)



Central San Francisco and (inset) its metropolitan area.

The great earthquake and fire of 1906

Concern has also arisen from the experience that San Francisco shares with no other U.S. city—destruction by earthquake. Severe quakes have been felt in 1868, 1898, 1900, 1906, and 1989. But it was the 1906 earthquake that did the most damage and that has become identified with the city. That quake, which occurred on April 18, was followed by a fire that destroyed the centre of town and burned for four days, until the ashes were wetted down by rain. Four square miles, making up 512 blocks in the centre of town, were gone, along with 28,000 buildings and a total property value of about $350,000,000. Approximately 700 people died; 250,000 were left homeless. Survivors camped in Golden Gate Park. An Eastern newspaperman, celebrating the survival of a local distillery, composed the verse, "If, as some say, God spanked the town / For being over frisky, / Why did he burn the Churches down / And save Hotaling's Whisky?"

Since the 1906 earthquake, seismologists and engineers have warned that it could happen again. Several relatively strong earthquakes (measuring more than 5.0 on the Richter scale) have since hit the city and caused little damage, but the 1989 quake (7.1 on the Richter scale) did destroy some structures within the city and even more in the surrounding areas. Modern office towers, however, were largely unaffected, indicating that new building methods may provide some protection for the city.

(K.La./G.C.Ha./Ed.)

THE PEOPLE

The pattern of immigration into San Francisco during the latter half of the 19th century was significantly different from that of anywhere else in the United States. The waves of newcomers included not only native-born Americans moving west but also Europeans arriving directly by ship without previous Americanization along the Eastern Seaboard. The demography of the gold-rush city was summed up concisely by a real-estate firm that advertised that it could "transact business in the English, French, German, Spanish and Italian languages." San Francisco remains one of the two most European of American cities—New Orleans is the other—and surely the most Mediterranean. Italians have remained the dominant European minority, followed by Germans, Irish, and British.

Ethnic minorities

The blacks. Before World War II about 20,000 blacks lived in the entire Bay Area, about 4,000 of them in San Francisco. The 24-fold increase during the next 30 years was set in motion by the war, which brought at least 500,000 war workers to the Bay Area's shipyards and other industries. Among them were tens of thousands from the South, who settled mainly in San Francisco, Oakland, and Richmond. In San Francisco they moved into the old Carpenter Gothic houses in the blocks around Fillmore Street, vacated when the Japanese were driven into wartime internment camps. By the 1980s the character of the district was shifting again as the renovation of these houses and the high cost of property caused rents to rise. Poorer black residents were being forced out of their neighbourhoods and into slum housing in the city's already crowded southeastern sector. An increasing number of black men and women have become prominent in the city's life, however, and blacks have won many elective offices.

The Chinese. Chinatown, which is said to be the largest Chinese community outside of Asia, is also probably the least understood minority community in the city. The colourful shops and restaurants of Grant Avenue mask a slum of crowded tenements and sweatshops that has the highest population density in an already densely populated city. Increasingly, Chinese have moved into North Beach, hitherto predominantly Italian, onto the nearby slopes of Russian Hill, or into the Richmond district north of Golden Gate Park. Many of those who reside in Chinatown are more recent immigrants, from Hong Kong in particular, who prefer their native tongue and way of life.

The Japanese. Never as large as Chinatown, the Japanese community of San Francisco was wiped out at a single stroke by the infamous Executive Order 9066 of 1942, which sent them, foreign-born and native alike, into "relocation centres" that were, in all but name, concentration camps. The present centre of the Japanese community is Japan Town (Nihonmachi), a few blocks east of Fillmore Street. There an ambitious trade and cultural centre has risen, with restaurants, a hotel, shops, and business establishments. Though the rising generation of Japanese-Americans go to Japan Town as visitors, bound for celebrations or to buy imported goods, their own roots are elsewhere.

The Spanish-speaking. Few visitors see the Mission district, which is a great irony because the historic origins of the city extend to Spain and Mexico and the Spanish-speaking population rivals the Chinese as the second greatest ethnic minority.

Before World War II the Mission district, named for the Mission Dolores, was principally blue-collar and Irish. The Irish have largely been replaced by Spanish-speaking immigrants, mainly from Central America and Mexico. Living among them are pockets of American Indians and Samoans.

The Filipinos. The Filipino community in San Francisco has grown remarkably since World War II and spread to all areas of the city, especially the South of Market area. Filipinos have become an active ethnic group, particularly in the fields of politics, education, and business. They are known for their high literacy rate and their love of the arts and music.

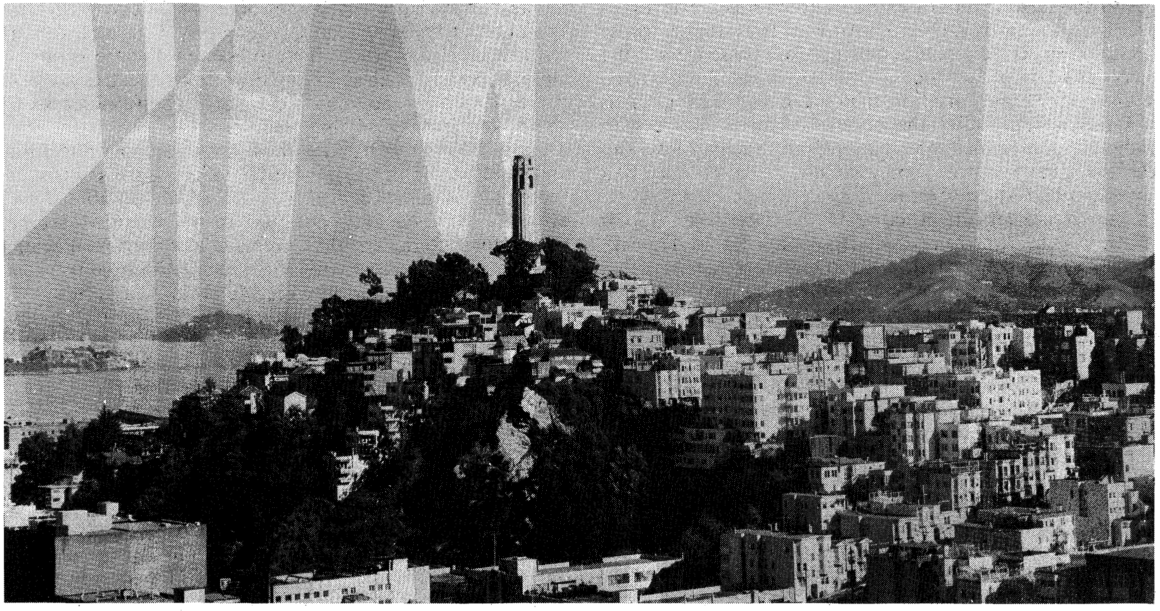
THE ECONOMY

The gold rush to California (1848–49) and other western territories and states in the mid-1800s established San Francisco as the premier city of the West, known from the Oregon border to the pueblo of Los Angeles simply as the City. It is still a great port, the financial and administrative capital of the West, and a substantial centre for commerce and manufacturing.

Components of the economy

A large portion of the city's employed work in the area of finance. Other leading areas of employment include business services (personnel supply, building maintenance, security, computers and data processing, advertising), retail trade, the tourist and convention industry, and professional service. Many companies have chosen to locate their national headquarters in San Francisco.

Colour Library International



The Coit Memorial Tower on Telegraph Hill, San Francisco; at left is Alcatraz Island in San Francisco Bay.

The port. From its beginnings as a port of call in the hide-and-tallow trade and, later, as the home port of the Pacific whale fishery, San Francisco has always been acutely conscious of the importance of shipping. In the 19th century ships sailed around Cape Horn or from the Isthmus of Panama, and "steamer day" was a civic institution; after 1914 cargo and passenger vessels arrived from the East by way of the Panama Canal. In 1867 the Pacific Mail Steamship Company opened the first transpacific service, sailing from San Francisco to Yokohama and Hong Kong.

Imports and exports passing through the San Francisco Customs District make the combined ports of San Francisco Bay—San Francisco, Oakland, Alameda, Sacramento, and Stockton—one of the most active international ports in the country.

Industry. Manufacturing is the main source of income in the Bay Area. In San Francisco, in which manufacturing is a lesser source of income, the principal industries are apparel and other textile products, food processing, and shipbuilding, while the aerospace and electronics industries are strong in the cities of the peninsula.

Finance. A financial centre since the first pinch of gold dust was exchanged for hard cash, San Francisco is the seat of the Pacific Stock Exchange as well as the headquarters of many banks, among them the Bank of America and the Wells Fargo Bank. In banking activity San Francisco ranks second only to New York City.

Transportation. Los Angeles long ago surrendered unconditionally to the automobile; San Francisco has on occasion rebelled and found it possible to oppose "progress." A monument to this revolt is the elevated Embarcadero Freeway, which stops dead as if sliced off by a guillotine. Again, angry citizens in 1964 defeated the state highway commission when it threatened to run a freeway through the "panhandle" of Golden Gate Park.

Among the serious problems that remain is periodic smog, produced mainly by the cars in the area. (An air-pollution-control district was formed in 1955.) Another problem is that access to San Francisco from its commuter towns is largely by a network of freeways that are highly congested at rush hours. Travel from the East Bay cities of Oakland and Berkeley and from Marin County to the north is over two great but overburdened bridges. The 4½-mile-long San Francisco–Oakland Bay Bridge, completed in 1936, consists of two back-to-back suspension bridges, a connecting tunnel on Yerba Buena Island, five truss spans, and a cantilever span. The orange-red Golden Gate Bridge, leading north to Marin County, was completed in 1937. It is a pure suspension bridge with a 4,200-foot centre span.

The once-busy ferries

Until the ferries were doomed by the bridges, San Francisco was served by a great network of ferry routes whose splendid vessels were said to deliver more passengers to the Ferry Building at the foot of Market Street than arrived at any other transportation depot except Charing Cross in London. Only after the bridges began to choke with traffic did San Franciscans realize what they had lost, and the ferries have returned, on a smaller scale, between San Francisco and Marin County.

A much greater undertaking is the interurban rapid-transit system known as BART (Bay Area Rapid Transit), which began operating in 1972. Operating between San Francisco and the East Bay communities through an underwater tube more than 3½ miles long, BART was the first system of its sort, part subway and part elevated, to be built in half a century, but it does not resemble the older systems in all respects. Comfortable, computerized automatic trains running at speeds averaging 80 miles an hour are a major feature.

San Francisco is situated at the head of a peninsula, and it has always been a dead end for rail traffic, with the transcontinental trains (the first westbound train arrived over the tracks of the Central Pacific on September 6, 1869) discharging their passengers in Oakland, whence they were carried to San Francisco by ferry and by bus. As in the rest of the country, the railroad's importance has declined since World War II. For carrying goods, trucking has largely taken over.

San Francisco International Airport is located seven miles south of the city–county limits, on a filled site on the southwestern shore of the bay. It is owned and operated by the municipal government.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Unlike any other California city, San Francisco (incorporated 1850) has a consolidated city–county government. The 1932 freeholders' charter, under which the city–county still operates, provides the mayor with strong executive powers but delegates substantial authority to a chief administrative officer (appointed by the mayor) and a controller. The legislative authority is lodged with an elected board of supervisors. The other key officials are the superintendent of schools and the manager of utilities, both appointed.

Public utilities. Since 1934 San Francisco's principal source of water has been the Hetch Hetchy Reservoir, 167 miles away, in the High Sierra. Other sources are the Calaveras Reservoir in Alameda County and reservoirs in San Mateo County to the south. The Hetch Hetchy project required the damming of a valley in Yosemite National Park almost as splendid as the Yosemite Valley itself and the construction of tunnels, one 25 miles long, through the Coast Range. In 1902 the first high-voltage line transmitting hydroelectric power was completed between a powerhouse on the Mokelumne River and San Francisco, some 180 miles away. Since then, the Bay Area has developed a network of hydroelectric plants on the rivers of the interior, as well as a steam-powered plant on Monterey Bay.

Education. Although strictly speaking they cannot be counted as San Francisco institutions, the greatest universities in the Bay Area are the University of California, located across the bay in Berkeley, and Stanford University, down the peninsula in Palo Alto. Within San Francisco itself noted institutions of higher education are the University of San Francisco (Jesuit) and San Francisco State University (formerly San Francisco State College), which was founded as a normal school in 1899 but has achieved national prominence for its academic excellence. Other institutions include Golden Gate University, the City College of San Francisco (a two-year public college), and the San Francisco Art Institute.

CULTURAL LIFE

San Francisco is the home of two major musical organizations. The San Francisco Symphony performs in the Louise H. Davies Symphony Hall and gives pop concerts in the summer. The San Francisco Opera enjoys an early season so that its leading singers may fulfill their commitments at New York City's Metropolitan Opera. With the exception of the American Conservatory Theatre (ACT), a resident repertory group, the professional theatre is virtually nonexistent. The surviving downtown theatres are occupied largely by the touring casts of Broadway successes.

San Franciscans feel that their city is a haven for the artist. While this is true for those who value architecture and public sculpture, the painting collections do not rival those of Los Angeles and the East Coast. Memorable, however, are the jades and porcelains in the Asian Museum, the Rodin sculptures at the California Palace of the Legion of Honor, and the many treasures in small museums such as the Fire Department Pioneer Memorial Museum.

The Beat poets

One of the greatest writers to make San Francisco his home, although only for a short period in the mid-1860s, was Mark Twain. Other notables of the past century have included Frank Norris, Ambrose Bierce, Bret Harte, Jack London, and Robert Louis Stevenson, who lived in great poverty in a boarding house. During the mid-1950s San Francisco was one of the major gathering places for the Beat poets, including Lawrence Ferlinghetti (publisher and cofounder of the City Lights bookstore, which became a shrine of the movement), Gregory Corso, Allen Ginsberg, Jack Kerouac, and Gary Snyder. The current population of writers includes many reputable practitioners, a number of whom are affiliated with the creative writing program on the campus of San Francisco State University.

A most vital part of San Francisco culture from the beginning has been found in its restaurants, hotels, and drinking places. To this must be added the popular culture of the ethnic enclaves—Chinatown, the Italian community of North Beach, the black culture of the Fillmore district, Japan Town, the Russian colony along Clement Street, and the Spanish-speaking Mission district.

San Francisco's greatest contribution to the nation's life, however, has had nothing to do either with its ethnic cultures or with its officially anointed institutions—or, indeed, as has been suggested, with the emergence of the "topless" dancer in a North Beach nightclub in 1964. Instead, it was the unheralded appearance in 1967 of the "flower children," a generation of young people, long of hair and usually grubby in appearance, who declared themselves in headlong flight from the Great Society and preached the saving graces of peace and love. Unfortunately, by the 1970s the main street of their capital, the Haight-Ashbury district, had turned into an ugly and dangerous marketplace for drugs.

San Francisco also emerged, for a period in the late 1960s, as a capital of rock music, which achieved national prominence for the San Francisco sound of such groups as the Jefferson Airplane, the Grateful Dead, and the Quicksilver Messenger Service, as well as such individual performers as Janis Joplin. The city has become a centre for advocates of rights for homosexuals and has one of the largest homosexual communities in the country.

History

EXPLORATION AND EARLY SETTLEMENT

It is extraordinary that the site of San Francisco should have been explored first by land instead of from the sea, for San Francisco Bay is one of the most splendid natural harbours of the world, and great captains and explorers sailed unheeding past the entrance—Juan Rodríguez Cabrillo (1542–43), Sir Francis Drake (1579), and Sebastián Vizcaíno (1602). In 1769 a scouting party from an expedition led by the Spanish explorer Gaspar de Portolá looked down from a hilltop onto a broad body of water, the first white men known to have seen San Francisco Bay. It was not until August 5, 1775, that the first Spanish ship, the "San Carlos," commanded by Lieut. Juan Manuel de Ayala, turned eastward between the headlands, breasted the ebbing tide, and dropped anchor just inside the harbour mouth. (Though it is possible that Drake may have entered the bay, most evidence is against it.)

Settlers from Monterey, under Lieut. José Joaquin Moraga and the Rev. Francisco Palóu, established themselves at the tip of the San Francisco peninsula the next year. The military post (which remains in service as the Presidio of San Francisco) was founded September 17, 1776, and the Mission San Francisco de Asis (popularly called the Mission Dolores) was opened on October 9.

Almost half a century later, a village sprang up on the shore of Yerba Buena Cove, two miles east of the mission. The pioneer settler was an Englishman, Capt. William Anthony Richardson, who in 1835 cleared a plot of land and erected San Francisco's first dwelling—a tent made of four pieces of redwood and a ship's foresail. In the same year, the United States tried unsuccessfully to buy San Francisco Bay from the Mexican government, having heard reports from whalers and captains in the hide-and-tallow trade that the great harbour held bright commercial possibilities. Richard Henry Dana, whose ship entered the bay in 1835, wrote in *Two Years Before the Mast* (1840) that "If California ever becomes a prosperous country, this bay will be the centre of its prosperity."

The Americans had to wait only another 11 years. After fighting began along the Rio Grande, Capt. John B. Montgomery sailed the sloop of war "Portsmouth" into the bay on June 3, 1846, anchored in Yerba Buena Cove, and later went ashore with a party of sailors and marines to raise the U.S. flag in the plaza. On January 30, 1847, Yerba Buena was renamed San Francisco, which was regarded as a more propitious name for the town's future development.

The permanent white population of Yerba Buena in 1844 did not exceed 50 persons. By 1846 the settlement had a white population of 375 in addition to 83 blacks, American Indians, and Sandwich Islanders (Hawaiians). Two years later, just before the discovery of gold on the American River, the town had grown to about 200 shacks and adobes inhabited by about 800 whites.

THE GROWTH OF THE METROPOLIS

The discovery of gold

The city of the '49ers. With the discovery of gold, San Francisco picked up pace and direction. The modest village was at first almost deserted as its population scrambled inland to the Mother Lode, and then it exploded into one of the most extraordinary cities ever constructed. Some 40,000 gold hunters arrived by sea, another 30,000 plodded across the Great Basin, and still another 9,000 moved north from Mexico. By 1851 more than 800 ships rode at anchor in the cove, deserted by their crews.

Everybody except the miners got rich. Eggs sold for $1 apiece, and downtown real estate claimed prices that would almost hold their own against the appreciated values of the late 20th century. Until the bubble burst in the Panic of 1857, 50,000 San Franciscans became rich and went bankrupt, cheated and swindled one another, and took to the pistol and knife all too readily. As *The Sacramento Union* noted in 1856, there had been "some fourteen hundred murders in San Francisco in six years, and only three of the murderers hung, and one of these was a friendless Mexican." Two vigilance committees (1851 and 1856) responded to the challenge with crude and extralegal justice, hanging four men apiece as an example to the others.

In 1859 silver was discovered in the Nevada Territory. The exploitation in Nevada of the Comstock Lode, which eventually yielded $300,000,000, turned San Francisco from a frontier boomtown into a metropolis whose leading citizens were bankers, speculators, and lawyers who dressed their ladies in Paris gowns and ate and drank in splendid restaurants and great hotels.

San Francisco then was by all accounts an intoxicating city whose many charms moved the historian-moralist B.E. Lloyd to advise parents in 1876

> to look closer to their daughters, for they know not the many dangers to which they are exposed . . . and to mildly counsel their sons, for when upon the streets of this gay city they are wandering among many temptations.

The 1860s and 1870s marked the birth of the modern San Francisco, which has for more than 100 years laid claim with some justice to being the Athens, Paris, and New York City of the West but which never completely lost the mark of its wild beginning. As Rudyard Kipling was to observe after he visited the city in the 1890s, "San Francisco is a mad city, inhabited for the most part by perfectly insane people whose women are of remarkable beauty."

The 20th century. San Francisco's growth in the first half of the 20th century was shaped by two cataclysmic events. The first of these was the great earthquake and fire of 1906, which destroyed the central business district. Between 1906 and 1910, however, the city rebuilt atop its ashes. The other cataclysm was World War II, during which hundreds of thousands of servicemen passed through San Francisco on their way to the war in the Pacific or were stationed in and around the city; in addition, some 500,000 people came to work in the war-related industries in the area and settled temporarily in the cities around the bay. This was the beginning of the great postwar surge in the San Francisco area's permanent population.

BIBLIOGRAPHY. For accounts of the early history of San Francisco, the serious reader should not be discouraged by the voluminousness and variousness of the works of the historians HUBERT HOWE BANCROFT and THEODORE H. HITTELL, the latter of whom is particularly readable. FRANK SOULÉ, JOHN H. GIHON, and JAMES NISBET, *The Annals of San Francisco* (1855), is invaluable; while BENJAMIN E. LLOYD, *Lights and Shades of San Francisco* (1876), is both vivid and divertingly moralistic. HERBERT ASBURY, *The Barbary Coast* (1934, reprinted 1968), is a classic account of the underworld; while JULIA COOLEY ALTROCCHI, *The Spectacular San Franciscans* (1949), is a useful social history. JOHN HASKELL KEMBLE, *San Francisco Bay: A Pictorial Maritime History* (1957), contains a splendid collection of drawings and photographs. Of the many books about the earthquake and fire of 1906, WILLIAM BRONSON, *The Earth Shook, the Sky Burned* (1959), is a first-rate work of historical reconstruction. The growth of San Francisco is treated in GUNTHER BARTH, *Instant Cities: Urbanization and the Rise of San Francisco and Denver* (1975); JOHN B. MCGLOIN, *San Francisco: The Story of a City* (1978), is a popular history; and FREDERICK M. WIRT, *Power in the City: Decision Making in San Francisco* (1974, reissued 1978), is a study of local politics. The WRITERS' PROGRAM, CALIFORNIA, *San Francisco: The Bay and Its Cities,* new rev. ed. (1973), is a popular city guide; *San Francisco Bay* (1957), written by the naturalist-conservationist HAROLD GILLIAM, is both authoritative and evocative; and MELLIER G. SCOTT, *The San Francisco Bay Area: A Metropolis in Perspective* (1959), is a good systematic description of the metropolitan area. See also GLADYS HANSEN, *San Francisco Almanac: Everything You Wanted to Know About the City* (1980); and LAWRENCE FERLINGHETTI and NANCY J. PETERS, *Literary San Francisco: A Pictorial History from the Beginnings to the Present Day* (1980).

(K.La./G.C.Ha.)

São Paulo

The largest city of Brazil and dynamic capital of the state of the same name, São Paulo is the foremost industrial centre in Latin America. With one of the world's fastest growing metropolitan populations, it is also the largest city of the Southern Hemisphere and one of the largest conurbations in the world. Sometimes called the "locomotive that pulls the rest of Brazil," São Paulo has a vibrant and energetic urban core characterized by an ever-growing maze of modern steel, concrete, and glass skyscrapers. The city is located in the hills of the Serra do Mar, which forms part of the Great Escarpment that extends between the Brazilian Highlands and the Atlantic Ocean. It lies about 220 miles (354 kilometres) southwest of Rio de Janeiro and about 30 miles inland from the port of Santos. The city's name derives from its having been founded by Jesuit missionaries on January 25, 1554, the anniversary of the conversion of St. Paul.

The article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. The Brazilian Highlands are composed of ancient crystalline rocks, which in the vicinity of São Paulo form a surface of gently rounded hills mantled with a reddish clay soil. Rivers such as the Tietê, on which São Paulo is located, rise near the edge of the Great Escarpment and flow generally westward to the Rio Paraná. In their course, they cross stratified sandstones and limestones overlaying the crystalline base, as well as sheets of volcanic rock that form the Paraná Plateau. Here, there are rapids and waterfalls, as well as dams and reservoirs that supply great quantities of hydroelectric power.

Located at an elevation of 2,690 feet (820 metres) above sea level, the city is surrounded by open country, valleys, and foothills. The higher terrain constitutes the preferred residential areas; the lower parts are on alluvial land along the banks of three rivers (the Tietê, the Pinheiros, and the Tamanduateí), and these are occupied by working-class residences, manufacturing establishments, and commercial enterprises. The area of the city is 576 square miles (1,493 square kilometres), but including suburban communities, such as Santo André, Diadema, São Bernardo do Campo, São Caetano do Sul, Osasco, Guarulhos, Mairiporã, Barueri, Santana do Parnaíba, Franco da Rocha, and Mogi das Cruzes, metropolitan São Paulo sprawls over an area of 3,070 square miles. Open spaces on the perimeter of the city, where there are clay soils mixed with sandy deposits, are used for intensive market gardening. A forest reserve of about 39 square miles is maintained in the nearby Serra da Cantareira, while the beaches of Santos and Guarujá provide pleasant resort areas.

Climate. The Tropic of Capricorn, at about 23°27′ S, passes through São Paulo and roughly marks the boundary between the tropical and temperate areas of South America. Because of its elevation, however, São Paulo enjoys a distinctly temperate climate. July is the coldest month, with an average temperature of 57.9° F (14.4° C) and occasional frost. Warmest is February, which averages 69.1° F (20.6° C). Rainfall is abundant, particularly during the summer season from October through March, averaging 56 inches (1,422 millimetres) per year. Humidity and air pollution combine to form a mist that often hangs over the city.

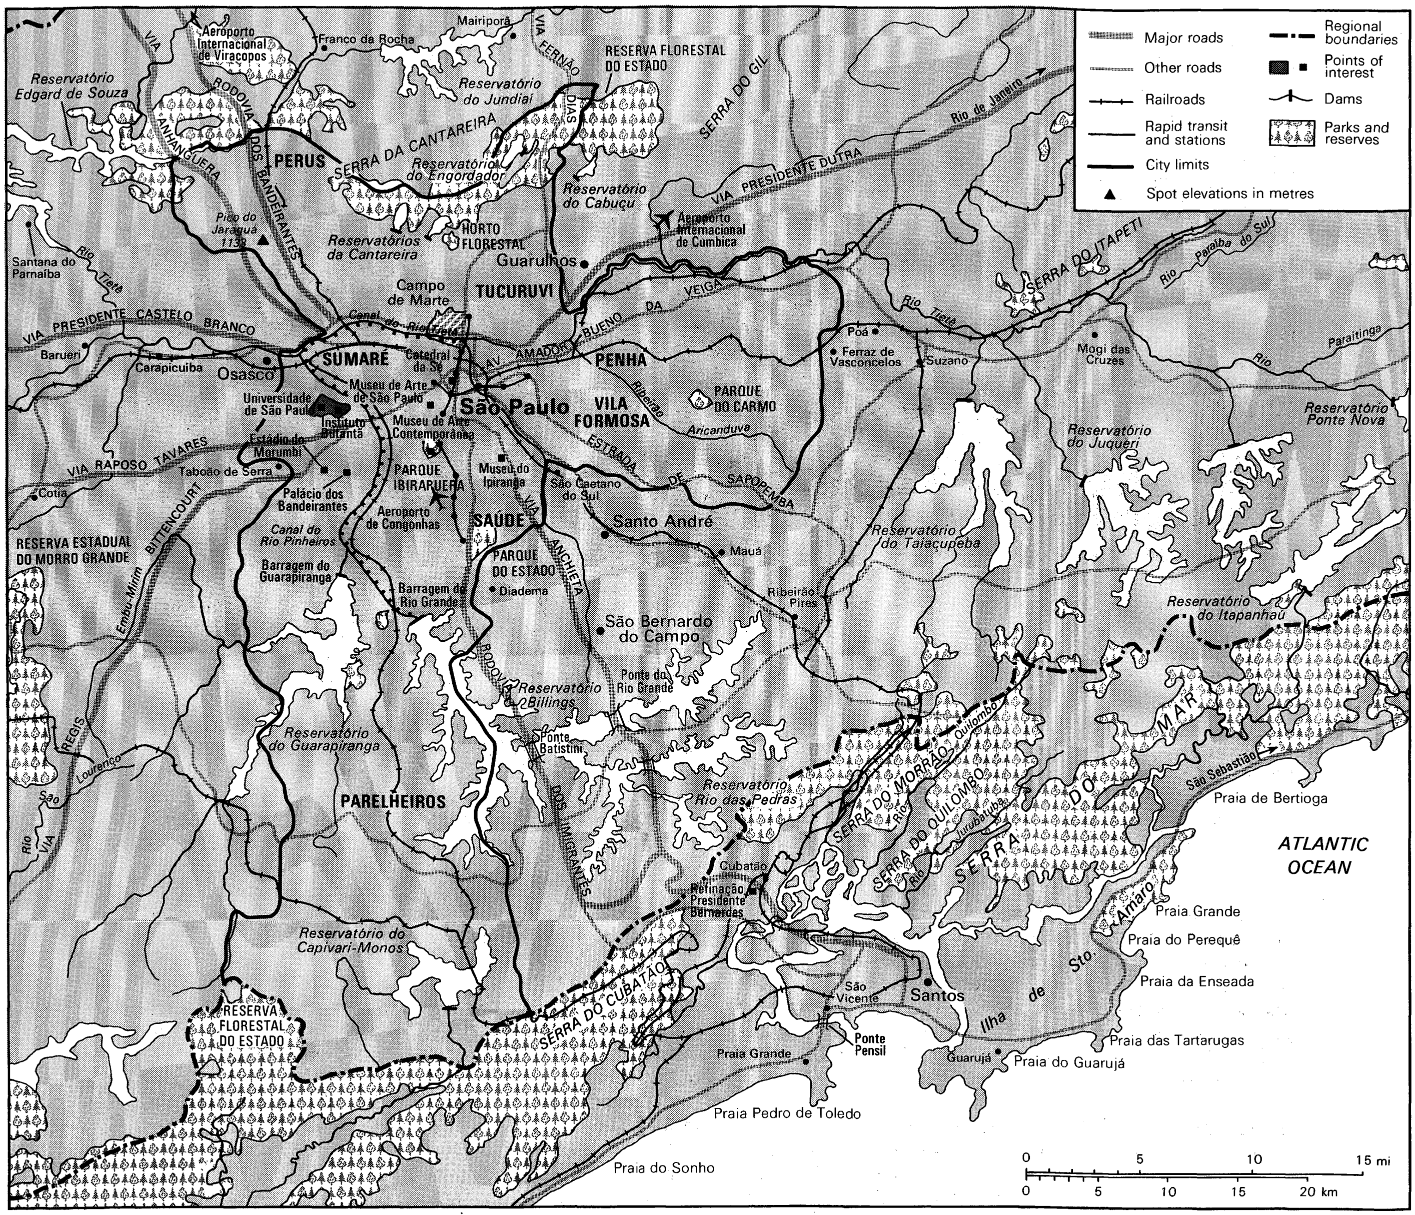
The city plan. The central business district of São Paulo focusses on the famous Triângulo, where the 42-story Edificio Itália, inaugurated in 1975, rises to a height of 558 feet. In 1947 there were only three skyscrapers in all of São Paulo, among which the newly constructed, 36-story Banco do Estado de São Paulo was the tallest. Now, the entire city is studded with modern buildings whose construction reflects a variety of architectural styles and materials.

Surrounding the central business district are extensive areas devoted to manufacturing, wholesale and retail trade, and repair and maintenance services. Most extensive are the residential areas characterized by low, red-roofed houses, interspersed with high-rise apartments or office complexes, singly or in clusters. Suburban shopping centres, like suburban neighbourhoods, have become commonplace.

São Paulo had no city plan until 1889, and no zoning law was passed until 1972. Until well into the 19th century, therefore, this state capital retained a colonial aspect, with narrow, unpaved streets, shabby buildings, and old churches and convents of Jesuit and Franciscan styles. Successive city administrations since then have attempted to stimulate more rational urban growth and to modernize the city's transportation system. Projects have included the straightening and rechannelling of the Tietê and Tamanduateí rivers, the widening and relocation of streets and avenues, the development of new parks and lakes, and the construction of superhighways and of a 40-mile subway network. Still, the city's street pattern shows little overall coherence, and the problems of intraurban traffic congestion and pollution have reached monumental proportions.

THE PEOPLE

The original settlers of São Paulo were relatively poor and largely from southern Portugal. They were, however, a restless people who sought actively to improve their status in life. Among them were the *bandeirantes* ("explorers") who formed expeditions that pushed far into the interior of South America in search of slaves and mineral wealth and, in the process, expanded the frontiers of what has become modern-day Brazil.



São Paulo metropolitan area.

With the great expansion of coffee cultivation in São Paulo state after 1880 came a massive immigration of Europeans. Italians and Portuguese were the most numerous, but there were also many Spaniards, Germans, and eastern Europeans. Other settlers came from Japan and the Middle East. Today, there are more Japanese in São Paulo than in any other community outside Japan, and Japanese farmers supply much of the city's market for fruit and vegetables. Even more numerous are internal migrants, primarily from the Northeast of Brazil. These include many blacks, who are the descendants of African slaves. Overall, the population is more than half European and about one-third black and mulatto, with the remainder made up of small groups of Asians and others. Roman Catholicism is the near-universal religion, and the archdiocese of São Paulo is the world's largest in number of adherents. Various other religions are represented by smaller numbers, and many Paulistas, as the inhabitants of the city are known, also attend the rites of local cults. Portuguese is the predominant language, although other languages are commonly spoken.

THE ECONOMY

Industry and commerce. Industrial development, beginning in the late 19th century, but especially since World War II, has transformed metropolitan São Paulo into the foremost industrial centre in Latin America. This city has often been referred to as the "Chicago of South America," but it actually is a leader of Brazilian commerce and industry to a much greater degree than is Chicago in the United States. The value of its industrial production is by far the country's largest. Its leading industries produce textiles, mechanical and electrical appliances, furniture, foodstuffs, and chemical and pharmaceutical products. There are also heavy metallurgical plants located at nearby Taubaté, oil refineries and chemical plants at Cubatão, and plants manufacturing motor vehicles and farm machinery in São Bernardo do Campo, Santo André, and other suburban communities. The several thousand manufacturing establishments in São Paulo provide employment for some 15 percent of the population. Despite its rapid growth in recent decades, however, the industrial sector has been able to absorb only a small fraction of the growing labour force. Hence, unemployment and underemployment are continuing problems.

Commerce, both wholesale and retail, is well developed and is spread over the city by zones according to specialty. Banks are concentrated in the central Triângulo of the city but maintain branches in almost every district. In addition to important Brazilian banks, there are banking institutions representing interests in North and South America, Europe, Asia, and Africa. No less important, in

Museu Paulista da Universidade de São Paulo (Paulista Museum) in São Paulo.
Colour Library International

terms of employment, are street vending, peddling, and neighbourhood stores.

Transportation. Major arteries of transportation radiate in all directions from São Paulo. Three major airports—Congonhas within the city, Cumbicas 15 miles east, and Viracopos 60 miles northwest—together with several smaller ones, provide São Paulo with both international and domestic service. The Viaçao Aérea São Paulo (VASP), with headquarters in the city, is Brazil's second largest airline and is owned by São Paulo state. Marine transport is provided through the port of Santos. São Paulo is also a hub of railroads, which include a transcontinental line from Santos to Antofagasta, Chile. Modern highways connect with inland cities, Santos, and Rio de Janeiro, and almost all the states of Brazil. Within the city, the first freeway was opened in 1969, and the subway system was inaugurated in 1976. Automobile traffic in the city and suburbs is heavy, and, despite street and highway improvements, congestion is a major and growing problem, which adds to the industrial city's serious conditions of air and noise pollution.

ADMINISTRATION AND SOCIAL CONDITIONS

Government and services. São Paulo is governed by a mayor and city council. It is also the seat of state government, headquartered in the Palácio dos Bandeirantes in the southwestern district (neighbourhood) of Morumbi. In addition to the state offices and departments that have headquarters in the capital, many branches of the federal government are represented there. More than 50 consulates represent countries in the Americas, Europe, Asia, and Africa.

The city has built a chain of reservoirs, tunnels, and canals to supply fresh water to an urban population that it is estimated may top 20,000,000 by the year 2000. The Cantareira water supply project, begun in 1969, increased water supplies greatly, but demand from the burgeoning population continuously outstrips supply. Pollution is an ever-present danger because of the slowdown of dammed streams that carry industrial waste. Electricity has been available in abundance since 1900. First, the waters of the Rio Tietê were dammed and dropped through penstocks from the Great Escarpment to generators below. Subsequently, dams on many rivers to the west, including Itaipú, a joint project with Paraguay, have been built to sustain the city's industries and residential districts.

Public and private health facilities are numerous, including hospitals for civil servants, maternity hospitals, and hospitals specializing in the treatment of cancer, tuberculosis, and other diseases.

Education. São Paulo has a well-developed system of primary and secondary education, both public and private, and a variety of vocational-technical schools. Among the institutions of higher education the largest and most esteemed in all of Brazil is the state-supported Universidade de São Paulo, established in 1934, which incorporated the historic Faculdade de Direito (College of Law) in the old São Francisco Square and preexisting polytechnical schools, as well as schools of pharmacy, dentistry, agriculture, and medicine. Economics, architecture, and engineering were added later. Affiliated institutions include a school of sociology and politics, founded in 1933, and the Instituto Butantã, a world-famous centre for research on snakes and the production of antitoxins and antivenins. The Pontifícia Universidade Católica de São Paulo was established in 1946 and the Universidade Mackenzie in 1952. Also well known is the Escola de Administração de Emprêsas of the Getúlio Vargas Foundation, established after World War II to train administrators.

CULTURAL LIFE

São Paulo early became a prominent cultural and intellectual centre, due largely to the opening in 1827 of the Faculdade de Direito, one of the first two in Brazil, where many of the nation's most eminent leaders were educated. The Instituto Histórico e Geográfico de São Paulo, founded in 1894, is one of the oldest cultural associations in the state. The city is also a leading centre for libraries, publishing houses, and theatres. The municipal library is housed in one of São Paulo's skyscrapers. In 1922 São Paulo's Modern Art Week, celebrated by a group of young writers, artists, and musicians in the Teatro Municipal, introduced modernism in the arts of Brazil. The Museu de Arte de São Paulo, founded in 1947, is perhaps the best in South America, and the Museu de Arte Contemporânea is also outstanding. São Paulo's symphony orchestra is similarly advanced in the field of music.

Publishing and broadcasting have long been established in São Paulo. Several of the nation's largest and most influential newspapers are published in the city, including *O Estado de São Paulo* and the *Diário Popular,* both more than 100 years old. Television was introduced in 1950, and the city is headquarters for some of the most important Latin-American radio stations.

The Paulistas are noted for their enthusiasm in sports. Soccer is the predominant sports attraction, as evidenced by the 150,000-seat Morumbi stadium and the Pacaembu stadium, which seats 70,000. Also popular are swimming, tennis, volleyball, basketball, and auto racing, for which São Paulo has one of the world's largest tracks, at Indianópolis on the city's south side. There are also countless parks, plazas, and playgrounds. The São Paulo zoo, with 3,500 animals, is the largest in Latin America.

History

São Paulo was the first highland settlement established in Brazil. It began as a small Indian settlement in 1554 under the direction of Portuguese Jesuit missionaries and occupied the lower terraces of the Rio Tietê in the midst of tall grasses and scattered scrub trees. The community grew slowly and had only 300 inhabitants by the end of the 16th century. Yet, São Paulo became a township in 1560 and had a town council that could enact and enforce laws. In 1683 it succeeded São Vicente as seat of the captaincy, or hereditary fief, and the inhabitants already had become known as Paulistanos or Paulistas.

Throughout the 17th century São Paulo was a base for expeditions (*bandeiras*) of armed pioneers (*bandeirantes*) who penetrated the remote hinterlands in search of Indian slaves, gold, silver, and diamonds. In the process they expanded the frontiers of what was to become modern-day Brazil. In 1711 São Paulo attained the status of a city, yet it remained an agrarian town that had yet to experience any significant prosperity.

Brazil's independence was declared on September 7, 1822, by Dom Pedro I, the Portuguese emperor in Brazil, at a site in São Paulo marked by the museum and monument of Ipiranga. Nevertheless, São Paulo continued to retain its colonial character until the latter part of the 19th century. Then, rather suddenly, coffee cultivation spread across the state of São Paulo, providing employment for many of the European and other immigrants who began arriving in great numbers. Included were Italians (who came to outnumber native Brazilians), Portuguese, Spaniards, Germans, eastern Europeans, Syrians, Lebanese, and Japanese. An era that was to transform São Paulo into a modern world-class city had begun.

Between 1885 and 1900 the São Paulo region was transformed from an isolated frontier to a new and independent region that focussed on the city of São Paulo and the port of Santos. With the spread of coffee, the major centre of urban activities was shifted to São Paulo, and the growth of the city was spectacular. New industries by 1905 included textile mills, shoe factories, and others using local raw materials. Cotton textile mills alone employed 39,000 workers.

In the late 19th century São Paulo had only one-tenth the population of Rio de Janeiro; by 1970 it had become the largest city in Brazil and one of the largest in the world. It included almost one-half of the population of São Paulo state, Brazil's most populous political subdivision, and accounted for about one-third of the nation's total industrial employment, and both proportions have continued to grow. Immigrants were pouring into the city at a rate of 300,000 per year, especially from the impoverished Northeast. São Paulo is a dynamic city, and continuous progress and official estimates indicate that by the year 2000 São Paulo will have surpassed Shanghai in population and will be the second largest urban agglomeration in the world, surpassed only by Mexico City.

Scandinavian Literature

Scandinavian literature consists of those writings in the North Germanic group of the Germanic languages, the modern forms of which include Swedish, Norwegian, Icelandic, Danish, and Faeroese. The literary works written in these languages, though manifesting certain differences reflective of distinct national institutions, exhibit strong similarities stemming from deep-seated common linguistic and cultural ties. Some authorities include Finland among the Scandinavian countries on geographical and economic grounds, but the literature of the Finnish-speaking people, like their language, stands apart in a number of respects. (Finnish belongs to the Baltic-Finnic branch of the Finno-Ugric language family and is most closely related to Estonian, Livonian, Votic, and Karelian.) The present article does, however, devote some attention to various notable Finnish authors who wrote in Swedish. (Ed.)

The article is divided into the following sections:

The Middle Ages

The literature of Scandinavia and, in particular, of Iceland has reflected two extraordinary features of the social and cultural history of pagan Europe and of Iceland. The way in which names such as Siegfried, Brunhild, and Attila cropped up again and again in different European literatures has borne witness to the dissemination of legends and traditions common to the early Germanic tribes of Europe, starting from the great movements westward in the 4th, 5th, and 6th centuries. The literature of Iceland provides not only the most detailed descriptions available of the life-style of early Germanic peoples but constitutes the most complete account of their literature and literary traditions. Although the sagas and poems were first written down by Christian scribes, they present a picture of a pre-Christian European culture that reached its heights in the new settlements in Iceland.

A second feature directly concerns the peoples of Scandinavia. A remarkable characteristic of Scandinavian literature was the accuracy with which it described the geography of northern Europe, accuracy that was born of actual knowledge. From the late 8th century until well into the Middle Ages, the history of the Norsemen was one of unceasing movement toward western and central Europe. The Norsemen discovered Iceland, as early Icelandic historians had it, when their ships were blown off course about 860. The next century found the Vikings pushing west by way of Britain, Ireland, and France to Spain and then through the Mediterranean to North Africa and east to Arabia. Across land they reached the Black Sea, by sailing north they came to the White Sea, and finally, turning westward again, they reached America long before Columbus.

NORWEGIAN AND ICELANDIC LITERATURE

The roots of Norwegian literature reach back more than 1,000 years and become inextricably intertwined with early Icelandic literature. Although a large part of this early literature was composed either in Iceland or elsewhere in Scandinavia by Icelanders, the Norwegian element in it is considerable and indisputable, even though this cannot always be isolated and defined. In many instances, it is obvious that some of the literature derives from a time before the Scandinavian settlement of Iceland in the 9th century. In other cases, it appears that the composers of the works had resided for long periods in the mother country of Norway.

The classical period in Iceland. The best known Icelandic literature belongs to the classical period, roughly equivalent to the early and medieval periods in western European literature. Icelandic manuscripts yield much knowledge of European myth and legend, which is in part common to all Germanic peoples. Stories of the Norse gods and myths—of Odin, god of war; Balder the Beautiful; Thor, god of thunder; and Valhalla, hall of the slain—form the nucleus of early Icelandic literature.

Almost all extant early Scandinavian poetry was recorded in Icelandic manuscripts, although some was clearly composed before the Scandinavian peoples reached Iceland in the late 9th century. Much of the oldest poetry was recorded in the Codex Regius manuscript, which contained the *Sæmundar Edda* (*c.* 1270), commonly designated by scholars as the *Poetic Edda*, or *Elder Edda*. The poetry is sometimes called Eddaic and falls into two sections: heroic lays, which, broadly speaking, dealt with the world of men; and mythological lays, which dealt with the world of the gods.

Eddaic poetry

The heroic lays. The heroic lays followed the mythological in the Codex Regius and were probably the earlier of the two. Many of the legends on which they were based originated in Germany or even among the Goths. Oldest of all was perhaps the *Hamdismál* ("Lay of Hamdir"), which forcefully expressed the heroic ideals of Germanic tribal life. The story closely resembled one told by Jordanes, a Gothic historian of the mid-6th century, and his account suggested that his source was an even earlier poem about Hamdir. Another of the older lays in the *Poetic Edda* was the *Atlakvida* ("Lay of Atli"), which referred to events that took place in 5th-century western Germany, Atli (or Attila) being king of the Huns from 434 to 453. Nearly all heroic lays were associated with the story of Sigurd (or Siegfried), the valiant hero, and his ill-fated love for Brunhild, who, too, figured to varying extent in different lays. Many scholars hold that the lays concerned with the spiritual conflict of the heroines Brunhild and Gudrun, which tend to be romantic and sentimental, were later compositions than the austere heroic lays. The *Poetic Edda* contained only a small portion of the poetry known in Iceland in the Middle Ages and now lost. Fragments of ancient lays appeared in 13th- and 14th-century sagas such as the *Hlödskvida* ("Lay of Hlöd") in the *Heidreks saga*, as did mention of Danish and Swedish heroes in some fragments that must also have been known to the author of the Old English epic poem *Beowulf.*

The mythological lays. Mythological lays about the Norse gods made up the first half of the *Poetic Edda.* It is unlikely that any of these originated outside Norway, Iceland, and Norse colonies in the British Isles. The *Völuspá* ("Sibyl's Prophecy") was a striking poem on the history of the world of gods, men, and monsters, from the beginning until the "twilight of the gods." Many passages in the poem are obscure, but most modern scholars agree that it was composed in Iceland about the year 1000, when the people were turning from the old religion to the new. An interesting story of the gods was told in the *Skírnismál* ("Words of Skírnir"): sitting in "Gate Tower," throne of Odin, the god Freyr, lord of the world, gazes into the world of giants and falls in love with a giant maiden; to win her, he sends his messenger Skírnir, who first offers gifts and then threatens the maiden until she agrees to make a tryst with Freyr. Scholars have seen an ancient fertility myth in this story, and it was certainly one of the older mythological poems in the *Poetic Edda* and probably originated in Norway before Iceland was settled by Norwegians.

Didactic element in Eddaic poetry

The mythological poems so far mentioned were all narrative, but many of those in the *Poetic Edda* were didactic. The *Hávamál* ("Words of the High One"; *i.e.,* Odin) consisted of fragments of at least six poems. In the first section, the god speaks of relations between man and man and lays down rules of social conduct; in other sections he discourses on relations between men and women and tells how love of women may be lost or won; the last two sections are about runes and magic power. Most of the poems were probably composed in Norway in the 9th and 10th centuries. Another didactic poem, the *Vafþrúdnir* ("Words of Vafthrúdnir"), related a contest between Odin and a giant.

Some important mythological lays appeared in other manuscripts. *Baldrs draumar* ("Balder's Dreams") described how the god Balder dreamed that his life was threatened and how his father, Odin, rode to the grave of a prophetess to force her to reveal the fate in store for Balder.

The Eddaic verse forms. Three metres are commonly distinguished in Eddaic poetry: the epic measure, the speech measure, and the song measure. Most narrative poems were in the first measure, which consisted of short lines of two beats joined in pairs by alliteration. The number of weakly stressed syllables might vary, but the total number of syllables in the line was rarely fewer than four. In these respects it resembled the measure used by Anglo-Saxon and early Germanic poets. The speech measure used in the *Atlamál* ("Words of Atli") differed little from the epic measure, though its lines usually had a greater number of weakly stressed syllables. The song measure was the most irregular of the Eddaic verse forms. It was chiefly in didactic poems and generally consisted of strophes of six lines divided into half strophes of three lines.

Characteristics of skaldic poetry

Skaldic verse. Norwegians and Icelanders of the 9th to the 13th century also composed skaldic poetry (from the Icelandic word *skáld,* "poet"). It was not composed in the free variable metres of the *Poetic Edda* but was strictly syllabic: every syllable had to be counted and every line had to end in a given form. Like Eddaic lines, the skaldic lines were joined in pairs by alliteration, often using internal rhyme or consonance; but this poetry differed in syntax and choice of expression. Word order is freer than in Eddaic poetry, and a highly specialized poetic vocabulary employed periphrases, or kennings, of such complexity that the poetry resembles riddles. Little is known about skaldic verse forms, but they are thought to have been developed in Norway during the 9th century and could have been influenced by the forms and diction of Irish poets of the period. The earliest known poet was Bragi the Old, who probably wrote in Norway in the latter half of the 9th century. Harald I (died *c.* 940) of Norway was eulogized by several poets, among them Thörbjörn Hornklofi, whose poem the *Haraldskvaedi* ("Lay of Harald") was partly Eddaic and partly skaldic in style.

The distinction between Icelandic and Norwegian literature at this period is difficult to make. Skaldic verse seems to have originated in Norway and to have been developed by Icelandic poets who either, like Egill Skallagrimsson, spent much time in Norway or wrote in praise of Norwegian kings, as did Sigvatr, counsellor and court poet of Olaf II of Norway. Although its complexity means that skaldic poetry is now less appreciated than it deserves, the orally transmitted poems of the 10th and 11th centuries were valuable sources for Icelandic historians in the following centuries.

Influence of Christian missionaries on Iceland

Prose. Iceland's adoption of Christianity in 1000 opened the way for powerful influences from western Europe. Missionaries taught Icelanders the Latin alphabet, and they soon began to study in the great schools of Europe. One of the first was Ísleifr, who after being educated and ordained as a priest was consecrated bishop. His school at Skálholt in southern Iceland was for many centuries the chief bishopric and a main centre of learning. The earliest remembered historian was Saemundr the Wise, but Ari Thorgilsson is regarded as the father of historiography in the vernacular. A short history, *Íslendingabók* (or *Libellus Islandorum, c.* 1125; *The Book of the Icelanders*), and the more detailed *Landnámabók* ("Book of Settlements") are associated with his name. Extant works of the period are few or anonymous. Annals of contemporary events date from the 13th century and the oldest religious manuscripts, consisting of homilies and saints' lives, from *c.* 1150. Larger collections of religious literature appeared in late 12th- and early 13th-century manuscripts. As elsewhere, the most popular books were often lives of the Apostles and saints.

The sagas. The word saga is used in Icelandic for any kind of story or history, whether written or oral. In English it is used to refer to the biographies of a hero or group of heroes written in Iceland between the 12th and 15th centuries. These heroes were most often kings of Norway, early founders of Iceland, or legendary Germanic figures of the 4th to the 8th century. The oldest saga is the fragmentary *Oldest Ólafs saga helga* ("First Saga of St. Olaf"), written about 1180. In form it is a hagiographic narrative, laying emphasis on miracles worked through the agency of the saint. It was probably written in the monastery of Thingeyrar, which played an important part in cultural life in the late 12th and early 13th centuries.

Several sagas about King Olaf Tryggvason, at whose instigation the Icelanders adopted Christianity, were also written at Thingeyrar, where the work of the monks was fanciful rather than realistic. A more critical style of history was established in the south by Saemundr and Ari, and several notable works were written at Skálholt or nearby in the 13th century, such as the *Hungrvaka* ("The Appetizer"), a short history of the bishops of Skálholt from Ísleifr to Kloengr. In the late 12th century several short histories of Norwegian kings were brought from Norway to Iceland, where they influenced Icelandic historians. The *Ágriþ,* a summary of the histories, or sagas, of Norwegian kings, written in the vernacular in Norway, was particularly influential. The *Fagrskinna* ("Fine Skin") covered the same period in more detail, while the *Morkinskinna* ("Rotten Skin"), probably written earlier, covered the period from Magnús the Good (1035–47) to the late 12th century.

The role of Snorri Sturluson

Snorri Sturluson wrote many kinds of works and played an important role in political wrangles in his time. Among works ascribed to him was the *Snorra Edda* (*c.* 1225), a handbook of prosody and poetic diction commonly referred to as the *Prose Edda*, or *Younger Edda*. He twice visited Norway, and a large part of his work consisted of lives of its early kings: he combined his *Ólafs saga* with lives of other Norwegian kings to form the *Heimskringla* (*c.* 1220; "Orb of the World"). The value of these as historical sources has long been debated. Snorri was certainly well read in vernacular history and attempted to write faithful accounts of what he had read in earlier records. He did not aim to write scientific history; his work was creative and therefore portrayed his heroes imaginatively. The stirring *Egils saga* (on the skald Egill Skallagrimsson) is attributed to Snorri.

The Icelanders', or family, sagas. These sagas were about heroes who had supposedly lived in the 10th and 11th centuries. Their origins are unclear, and it is debatable whether they were faithful records of history. One theory is that they were composed in the 11th century and transmitted orally until written down in the 13th century; though researchers now reject this view, it is true that the sagas owed much to oral tales and the tradition of oral verse. Their historicity is difficult to verify, since their content and form were shaped both by the sources used and by the author's intentions.

It is also difficult to determine the date of many of the sagas. The obviously early works were somewhat crudely structured and expressed Norse ideals of loyalty and heroism. The *Gísla saga,* written before the middle of the 13th century, showed a development of artistic skill and contained rich descriptions of nature and verses of considerable beauty and tragic feeling. The *Laxdaela saga* ("Saga of the Men of Laxárdal"), written a few years later, was a delicately worked tragedy in which the author showed an unusual appreciation of visual beauty. One work that was clearly the author's creation was the *Hrafnkels saga Freysgoda* ("Saga of Hrafnkell, Freyr's Priest"): despite realistic detail, the saga contained little historical fact. As the century progressed, a taste for fantastic and romantic elements grew. The *Grettis saga* ("Saga of Grettir the Strong") included several motifs from folklore and portrayed a hero fighting against trolls and ghosts.

The saga of Njáll and Gunnar

The greatest of Icelanders' sagas, the *Njáls saga,* had in fact two heroes, Njáll and Gunnar. Gunnar is young and inexperienced and Njáll is a wise and prudent man endowed with prophetic gifts; he embodies traditional Norse ideals of loyalty and bravery, yet faces his death by burning with the resignation of a Christian martyr.

The heroic sagas. The fantastic element was further developed in the *fornaldar sögur,* literally "the sagas of antiquity," whose heroes were supposed to have lived in Scandinavia and Germany before Iceland was settled. The best known, the *Völsunga saga* (*c.* 1270), retold in prose stories from heroic lays of Sigurd, the Burgundians, and Jörmunrekr, and the *Hrólfs saga kraka* (*c.* 1280–1350) incorporated ancient traditions about Danish and Swedish heroes who also appeared in the Old English poems "Widsith" and *Beowulf.*

Many of the works on contemporary history were combined about 1300 in the *Sturlunga saga,* including the *Íslendinga saga* by Sturla Thórdarson.

Translations from Latin. A quantity of secular literature was translated from Latin between the 12th and 14th centuries. The "Prophecies of Merlin," already translated in verse by a Thingeyrar monk, were combined with a complete translation of Geoffrey of Monmouth's history and titled *Breta sögur* ("Stories of the Britons"). In one 14th-century manuscript this was preceded by the *Trójumanna saga* ("Story of the Trojans"), translated from Dares Phrygius. A Norwegian translation of the Bible was begun in the reign of Haakon V Magnusson (1299–1319).

Romances. Romances were also translated or adapted from continental romances. Interest in romance began in Norway and soon took root in Iceland. The earliest romance was probably the *Tristrams saga* (1226), derived from the Anglo-Norman poet Thomas. This was followed by the *Karlamagnús saga* ("Saga of Charlemagne"), a collection of prose renderings of French chansons de geste, including a Norse version of the *Chanson de Roland.* Romances in Icelandic were numerous, and their effect on the style of later writers is evident in such sagas as the *Laxdaela saga* and *Grettis saga.*

Post-classical literature in Iceland. In the period following the classical age, little was written that attracted attention outside Iceland. Realism and detached objectivity declined, and sentimentality and fantasy gained the upper hand. The decline in literary standards is sometimes attributed to Iceland's loss of independence in 1262 and the changes that followed. Interest in earlier manuscripts continued, and many 14th- and 15th-century manuscript collections of 13th-century material were made. The most beautiful of all Icelandic manuscripts, the *Flateyjarbók* (*c.* 1390), included versions of sagas of Olaf Tryggvason and St. Olaf, together with texts from other sagas or about heroes associated with Iceland.

Decline in literary standards

Prose. Prose literature of the 14th century included several sagas. Among them were the *Finnboga saga ramma* ("Saga of Finnbogi the Strong"), about a 10th-century hero, and another telling the love story of its hero Víglundr. Sagas about bishops, already a theme in the 13th century, became more numerous, as did lives of foreign saints. A large collection of exempla (moral tales) was also made, each short tale illustrating some moral precept.

Ásgrímsson's *Lilja*

Poetry. Much poetry was written up to the time of the Reformation, and many new forms were devised. The best poems were religious pieces, in honour of the Virgin, the Apostles, or other saints. The well-known *Lilja* (*c.* 1350; "The Lily") by Eysteinn Ásgrímsson, a monk from Thykkvabaer, gave an account of the fall of Satan, the creation, the first sin, and the birth, life, and Passion of Christ. The term *rímur*—rhymes—is used of the narrative poetry developed after 1500 that consisted of mainly four-line strophes: the lines had end rhyme. The metrical forms, although apparently derived from Latin hymns, inherited the alliterative system of earlier poetry. Ballads written in Icelandic never attained the popularity of Danish ballads in Denmark nor achieved the high standard of the Norwegian *Draumkvaede* ("Dream Ballad"). Most of those preserved dated from the 14th to the 16th century and were free translations of Danish and Norwegian originals.

SWEDISH LITERATURE

Swedish literature proper began in the late Middle Ages when, after a long period of linguistic change, Old Swedish emerged as a separate language. The foundations of a native literature were established in the 13th century. The oldest extant manuscript in Old Swedish was the *Västgötalagan* ("Law of West Gotland"), part of a legal code compiled in the 1220s. These legal documents often employed concrete images, alliteration, and a solemn prose rhythm suited to their proclamatory nature.

Early Swedish ballads

The poetry of chivalry was first represented in *Eufemiavisorna* ("The Songs of Euphemia"), written in doggerel between 1303 and 1312, which included a translation of Chrétien de Troyes' romance *Yvain.* Anonymous ballads probably dating from the 14th and 15th centuries also reflected a new interest in romance. These ballads, though mostly derived from foreign sources and combining the imported ideals of courtly love with native, pagan themes and historical events, formed the most accessible genre of what can be called Swedish medieval literature.

DANISH LITERATURE

Denmark's first literature appeared in the runic inscriptions scratched on stone or carved in metal, mainly epitaphs of warriors, kings, and priests that occasionally had short, unrhymed alliterative verses in the Viking spirit. Runic inscriptions were used in Denmark from about 250, but most of those preserved date from 800 to 1100. With the introduction of Christianity, Latin became the predominant literary language, and Denmark's first important contribution to world literature, Saxo Grammaticus' *Gesta Danorum* (written between 1185 and 1222; "The Deeds of the Danes"), which contained, for example, the Hamlet story, was written in Latin. The medieval ballads of Denmark are among the most important in Europe; 539 are known in more than 3,000 versions, but nearly all were written down after the end of the Middle Ages, the first printed edition appearing in 1591.

The 16th century

THE IMPACT OF THE REFORMATION ON SWEDISH LETTERS

Two dates mark the beginning of modern Swedish history: 1523—the breach with Denmark and Gustav I Vasa's accession; and 1527—the breach with Rome and the establishment of a national Lutheran Church. The political revolution that eventually brought Sweden to the position of a European power had no considerable effect on literature until a century later, but the Reformation wholly dominated Swedish letters in the 1500s.

The Swedish translation of the Bible

The most important literary event of this period was the translation of the Bible in 1541, which inaugurated modern Swedish and provided an inexhaustible source for poets of subsequent times. Closely involved in the Bible translation were the apostles of the Swedish Reformation, Olaus Petri and his brother Laurentius. Olaus Petri's vigorous approach was revealed in his published sermons and in a Swedish chronicle, the first historical Swedish work based on critical research. Olaus Petri may also have written the biblical *Tobie comedia* (published 1550), the first complete extant Swedish play.

As a consequence of the Reformation, two of Sweden's most distinguished scholars of the period, Johannes Magnus and his brother Olaus, were driven into exile. In his history of all the kings of the Goths and Swedes, Johannes provided Sweden with a number of valiant kings unknown to critical historians. Olaus wrote the first geographical and ethnographical account of Scandinavia, *Historia de gentibus septentrionalibus* (1555; "History of the Northern Peoples").

DEVELOPMENTS IN DANISH LITERATURE

In 1536 the Lutheran Reformation was carried through in Denmark, and the beginning of the 16th century was characterized by many pamphlets for or against the Roman Catholic Church. European humanism and the Renaissance made their influence felt also in Denmark, where Christiern Pedersen was the most prominent humanist who supported the Reformation. He edited *Gesta Danorum* by the 13th-century historian Saxo Grammaticus, translated the New Testament, adapted Martin Luther's pamphlets into Danish, and participated in a translation of the Bible (1550). Poul Helgesen was the most gifted opponent of the Lutheran Reformation and Hans Tausen its most talented spokesman. The *Visitation Book* by the Lutheran bishop Peder Palladius is an important literary document. The two most important historians were Anders Sørensen Vedel and Arild Huitfeldt.

Sixteenth-century Danish poetry was religious or polemical, with fine love poetry and hymns. The earliest plays date from the beginning of the century. The most important playwright of the period was Hieronymus Justesen Ranch, whose farce *Karrig Nidding* ("The Miserly Rascal") was his best play.

ICELANDIC LEARNING AND LITERATURE

The chief political figure and poet of the Reformation was Jón Arason, last Catholic bishop of Hólar, beheaded in 1550. By his life Jon showed that he was a Viking as well as a martyr, although most of his surviving poetry is religious.

The impact of the Reformation

The effect of the Reformation on Icelandic learning and literature was that Catholic poetry was discarded and attempts were made by the first Lutheran bishops to replace it with hymns poorly translated from Danish and German.

Lutheran teachers instructed the people in Protestant dogma, and several translations of sermons and books of instruction by German Lutherans were printed in Icelandic from as early as 1540. Gudbrandur Thorláksson was the most energetic of the Lutheran teachers. In translating the Bible he used earlier Icelandic versions of some books of the Old Testament and Oddur Gottskálksson's Icelandic translation of the New Testament. In his psalmbook he showed appreciation of Icelandic poetic tradition and adhered to Icelandic alliteration and form.

The 17th century

SWEDISH POETRY AND PROSE

Georg Stiernhielm and his followers

In the first half of the 17th century, Swedish literature remained limited in scope and quantity. A unique contribution, however, was made by Lars Wivallius, whose lyrics revealed a feeling for nature new to Swedish poetry. With its intervention in the Thirty Years' War, Sweden established itself as a European power, and this led to a development of national pride and culture, as revealed in literature of this epoch. The outstanding work was the allegorical epic *Hercules* (1658) by Georg Stiernhielm, which reflected many of the social and political problems of the time. Stiernhielm's followers included the two brothers Columbus, one of whom, Samuel, wrote *Odae sueticae* (1674; "Swedish Odes") and the prose *Mål-roo eller roomål,* a charming collection of anecdotes that illumine Stiernhielm's character. A rival to Stiernhielm was the unidentified "Skogekär Bärgbo," whose *Wenerid* (1680) was the first sonnet cycle in Swedish.

Stiernhielm aimed at an integration of Sweden's cultural heritage with the accepted ideals of continental classicism. His *Hercules* is full of old Swedish words that he was eager to revive. Columbus also demanded a more vigorous, flexible language as did "Skogekär Bärgbo" in *Thet swenska språkets klagemål* (1658; "The Lament of the Swedish Language"). National pride and religious feeling are combined in the works of the bishops Haquin Spegel and Jesper Swedberg, father of the Swedish mystic Emanuel Swedenborg. Spegel contributed to Swedberg's new hymnbook of 1695, which became the poetry book of the Swedish people and was of lasting influence. Even Lucidor was represented in it, giving intense expression to the contrasting moods of the period: in his love songs and, above all, in his drinking songs, he was as pagan and reckless as he was devout in his hymns and funeral poems.

At Uppsala, meanwhile, the scholar Petrus Lagerlöf attempted to impose purer classical standards on native literature, and Olof Verelius edited and translated Icelandic sagas. It was Olof Rudbeck, however, who became interested in Verelius' work and developed a theory that Sweden was the lost Atlantis and had been the cradle of Western civilization. He proposed this idea in *Atland eller Manheim* (1679–1702), which, translated into Latin as *Atlantica,* attained European fame.

Baroque and classicist tendencies ran parallel in late 17th-century Swedish literature. Gunno Eurelius (Gunno Dahlstierna) wrote an elaborate epic, *Kungaskald* ("Hymn to the King"), for King Charles XI's funeral in 1697. Simpler in style was Johan Runius, who expressed a Christian stoicism of the kind found among Swedes during the disastrous early decades of the 18th century. Jacob Frese was a gentler and more intimate poet; his lyrics and hymns contained some of the emotional pietism that became a feature of 18th-century thought.

THE LITERARY RENAISSANCE IN DENMARK

The revival of interest in Scandinavian antiquity

The literary Renaissance reached Denmark in the 1600s, giving rise to a strict adherence to classical patterns and blind belief in authority in political, religious, and literary matters. In religious literature Latin dogmatics and pamphlets reflecting the superstitions of the century were dominant. It was, however, a great era of scholarship. Ole Worm is famous for his book on the runic inscriptions, *Monumenta Danica* (1643). Thormod Torfaeus and Árni Magnússon introduced the study of Old Norse literature; Peder Hansen Resen edited and translated some of the poetry of the Old Norse *Edda;* and Erik Pontoppidan and Peder Syv introduced the linguistic study of Danish.

Danish poetry in the 17th century tended to follow the classics slavishly, and the favourite forms were the hexameter, the Alexandrine, and the sonnet. Simplicity is deliberately avoided; the style is precious; allegories, euphemisms, and metaphors abound. Anders Arrebo translated the Psalms and wrote *Hexaëmeron* (1661), a Danish version of the 16th-century French poet Guillaume du Bartas' *La Semaine.* The century was rich in occasional poetry; didactic and pastoral poems were also common. Anders Bording, an interesting exponent of Danish Baroque poetry, was also the founder of the first Danish newspaper, *Den danske Mercurius* (from 1666), in which the news appeared in rhymed Alexandrines. The only truly great poet was Thomas Kingo, a supreme master in almost every kind of poetry. His hymns reflect a violent, passionate character, wörldly and yet deeply religious.

Characteristic poetic forms

Of special interest among Danish works of the 17th century were the memoirs of Leonora Christina, daughter of Christian IV, a fascinating document about her 20 years' imprisonment in the Blue Tower of Copenhagen.

RENEWED LITERARY ACTIVITY IN NORWAY

Political union between Denmark and Norway started in 1380, and the Danish language eventually became the official and the literary medium. Copenhagen, with its university, established itself as the cultural capital of the two countries. Not until after the Reformation were there signs of renewed literary activity in Norway itself; *e.g.,* in the nostalgic apologia for Norway, *Om Norgis rige* ("Concerning the Kingdom of Norway"), written in 1567 by Absalon Pederssøn Beyer. The most original and most conspicuously Norwegian writer of this age was Petter Dass, whose *Nordlands trompet* (*The Trumpet of Nordland*) gives a lively picture in verse of the life of a clergyman; although probably completed before the turn of the century, this work was not printed until 1739.

ICELANDIC LETTERS

In Iceland the foremost poet of the 17th century was Hallgrímur Pétursson, a Lutheran pastor who struggled against poverty and ill health. His *Passíusálmar* (1666; "Hymns on the Passion") is among the most popular books in Iceland. Another interesting poet was Stefán Ólafsson, remembered for both religious and secular works, the latter notable for exuberantly humorous portrayals of contemporaries and satirical observations of manners and customs.

As in other countries, interest in antiquity was stirred during the 17th century, and modern learning may be said to date from that period. Arngrímur Jónsson called the attention of Danish and Swedish scholars to Icelandic traditions and literature in a series of works in Latin, some containing abstracts of sagas now lost. Later in the century Árni Magnússon systematically collected the early Icelandic manuscripts.

The 18th century

SWEDISH CLASSICISM AND ENLIGHTENMENT

After the death of Charles XII (1718) and the collapse of his empire, a utilitarian attitude to life and letters gradually developed in Sweden. Olof von Dalin was the outstanding popularizer of the new ideas of the French and English Enlightenment. Educated at Lund, he later went to Stockholm and began to publish, anonymously, *Then swänska Argus* (1732–34; "The Swedish Argus"), a weekly periodical modelled on that of the Englishman Joseph Addison. One of the first serious journalistic ventures in Sweden, it marked the beginning of a new era, in which orthodoxy gave way to Skepticism and Enlightenment, Baroque to Classicism, and German influence to English and French; at this time the middle class began gradually to take over the function of chief upholder of literature. In *Argus* Dalin ridiculed the foibles of the capital and in *Sagan om hästen* (1740; "The Story of the Horse") he showed himself a master of allegorical satire. He also produced some pseudo-Classicist plays that, like many dramatic ventures of the early and mid-18th century, are academic and lifeless. The one notable exception is *Den Svenska sprätthöken* (1740; "The Swedish Fop"), a comedy by Count Carl Gyllenborg.

English and French influence

With the second phase of the Enlightenment, marked by the influence of Rousseau, are associated Hedvig Charlotta Nordenflycht, the epicurean Gustav Philip Creutz, and his stoic friend Gustaf Fredrik Gyllenborg. In *Den Sörgande turturdufwan* (1743; "The Sorrowing Turtledove"), Fru Nordenflycht laments the death of her husband in highly personal lyrics. Creutz was a more sophisticated personality. He wrote little, but his few writings, of which the pastoral *Atis och Camilla* (1762) is the most important, reveal a mastery of form and versification.

Prose—particularly the novel—developed more slowly. The first genuine novel, *Adalrik och Giöthildas äfventyr* (1742–44; "The Adventures of Adalrik and Giöthilden"), by Jacob Mörk and Anders Törngren, shows the influence of the Icelandic sagas. Only two 18th-century Swedish writers were of European reputation, and both were scientists: Carl von Linné (Linnaeus) and Emanuel Swedenborg.

The first Swedish novel

The Gustavian period takes its name from King Gustav III (1746–92), a brilliant man and a patron of art and letters. He was especially interested in drama and opera and, thanks to his patronage, a proper theatrical tradition developed. Gustav himself sketched out some works, the best of which was a historic opera, *Gustaf Vasa,* which was finished in collaboration between Johan Henrik Kellgren and the composer J.G. Naumann. Kellgren, an academic poet and arbiter of taste, ruled that Swedish literature should be modelled on Classicist French patterns, but, beginning as a Rationalist and satirist after the fashion of Voltaire, he reluctantly accepted pre-Romantic ideas later. In *Stockholmsposten,* the main organ of literary opinion in the capital, Kellgren used his polemical wit against Thomas Thorild, a truculent champion of individual genius. After Kellgren's death the controversy was carried on by Carl Gustaf af Leopold, who imposed pseudo-Classical standards on the academy and applied them in his own rhetorical odes and tragedies. Johan Gabriel Oxenstierna did his most original work while a diplomat in Vienna; his *Skördarne* (1796; "Harvests") reveals pre-Romantic feeling for the beauty of nature. Bengt Lidner was the chief exponent of pre-Romanticism in poetry. His most successful work was the ode *Grefvinnan Spastaras död* (1783; "The Death of Countess Spastara").

Carl Michael Bellman stands apart from the conflicting ideals of the time. A poet and musician, he combined stylized realism with humour and the most uniquely delicate sense of language and rhythm. He was the greatest Swedish lyricist of the 18th century.

The dissertation *Om upplysning* (1793; "On Enlightenment") by Nils von Rosenstein, the first secretary of the Swedish Academy, expressed the ideals of the Gustavian epoch. Memoirs by G.J. Adlerbeth, G.J. Ehrensvärd, and others evoke the witty but artificial atmosphere of Gustav III's court. Gustav IV, who followed, did not encourage literature; nevertheless, Anna Maria Lenngren wrote some of her best verse satires between 1795 and 1800, many aimed at aristocratic foibles. The sentimental idylls of Frans Mikael Franzén are full of pre-Romantic idealism from German and English sources.

LITERARY ACTIVITY IN DENMARK, NORWAY, AND ICELAND

Denmark. The 18th century was a fertile period in Danish literature. The great name in the first half of the century was that of Ludvig Holberg, a Norwegian by birth. His most important contributions, written for the Danish theatre, which opened in 1722, were 32 comedies of character and manner, including some moral allegories in his old age. His aim was to create a modern Danish literature on European lines and to make people laugh at their own follies. Influenced by English and French thinking, he was a Rationalist and a moderate. He also wrote satire, a mock-heroic poem, and *Nicolai Klimii iter Subterraneum* (Latin, 1741; *Journey of Niels Klim to the World Underground*). His *Moralske tanker* (1744; "Moral Thoughts") and his *Epistler* (1748–54; "Letters") are the finest examples of a Danish political essay form.

The comedies of Ludvig Holberg

Among Holberg's contemporaries the finest lyrical poets are H.A. Brorson, a mystic whose pietist hymns often have a background of personal sorrow or agony; and

Ambrosius Stub, whose poems are mainly religious and moralizing verses, witty epigrams, or drinking songs. A satirist, Christian Falster, was a conservative counterpart to Holberg; Friedrich Eilschov and Jens Schelderup Sneedorff, the latter of whom edited *Den patriotiske Tilskuer* ("The Patriotic Spectator"), a Danish *Spectator,* were both Rationalist disciples of Holberg.

Revival of Danish literature

A significant revival of Danish literature took place toward the end of the century. In 1772 the Norwegian Johan Herman Wessel, one of the greatest humorists to use the Danish language, wrote *Kaerlighed uden strømper* ("Love Without Stockings"), a parody of the Danish imitations of Italian operas and French tragedies that had superseded Holberg's comedies.

The works of Johannes Ewald

At the same time a revival of emotional poetry was taking place, influenced by German and English literature. Johannes Ewald, perhaps Denmark's greatest lyrical poet, was the first to discover the poetic wealth of Scandinavian antiquity in the *Gesta Danorum* of Saxo Grammaticus and in the myths, sagas, and ballads. He wrote verse dramas and deeply personal and descriptive poems. *Fiskerne* (1779; "The Fishermen") was the first serious Danish drama in which ordinary people were treated heroically. His memoirs, *Levnet og meninger* (posthumously published in 1804; "Life and Opinions"), were influenced by Laurence Sterne and Jean-Jacques Rousseau. Jens Baggesen at first imitated the satires of Holberg and Wessel but gradually developed as a poet of distinction. In *Labyrinten* (1792–93; "The Labyrinth"), he described his travels in Europe in the manner of Sterne.

Norway. Several of Denmark's leading writers of the 18th century were of Norwegian birth, preeminently Ludvig Holberg and the members of Det Norske Selskab (the Norwegian Society). Established in Copenhagen in 1772 by a group of resident Norwegians, it looked to French rather than to German and English literature for models. Within Norway itself there was little overt literary activity, though the establishment in 1760 of a Royal Norwegian Society of Learning in Trondheim was evidence that Norway was beginning to assert its cultural aspirations.

Iceland. *Húss-Postilla* (1718–20; "Sermons for the Home"), by Jón Vídalín, bishop of Skálholt, is the best example of early 18th-century prose. Among important later writers, Eggert Ólafsson carried out a comprehensive geographical field survey (published in Danish, 1772; partial Eng. trans.) of Iceland's country and its people. In his poetry he expressed 18th-century Rationalism combined with Romantic patriotism. Jón Thorláksson, poet and scholar, translated John Milton's *Paradise Lost* and Alexander Pope's *Essay on Man.*

Finnur Jónsson, bishop of Skálholt, wrote *Historia Ecclesiastica Islandiae* (1772–78), which covers the history of Christianity in Iceland. Jón Espólín published *Íslands árbaekur* (1822–55; "Annals of Iceland"), a history of Iceland from 1262.

The 19th century

SWEDISH LITERATURE

Romanticism. Political changes in Sweden up to 1804 meant that ardent nationalism emerged as a characteristic of Swedish Romanticism. The idealism at the core of this movement was laid by the Kantian teaching of Benjamin Höijer and the impact of Friedrich Schiller, Johann Wolfgang von Goethe, and the German Romantics on Swedish literature. Student societies and their periodicals, such as *Polyfem* (1809–12) and *Phosphorus* (1810–13), led the attack on the traditional school. Most gifted of the Forforister, or Phosphorists, Per Daniel Atterbom, wrote a verse "Prolog" (1810) to *Phosphorus* revealing both talent and commitment to Romanticism.

The return to the literary past

Meanwhile, another society, Götiska Förbundet (Gothic Society), advocated, from its start in 1811, that study of the "Gothic" past could morally improve society. One of its members, Esaias Tegnér, wrote a most popular poem, *Frithiofs saga* (1825), based on an Old Norse theme. Tegnér valued old Northern mythology for the patterns he discerned in it—patterns also found in Greek mythology and Romantic metaphysics, in which religion, philosophy, and poetry appeared to be one and the same. Nevertheless, Tegnér's ideals of clarity of thought and formal perfection led him sometimes to side with traditionalists in their struggle against obscurities and formal innovations.

Several leading Romantics were learned men whose poetry strove to embody a philosophical system or an interpretation of history. The most ambitious attempt of this kind was P.D.A. Atterbom's *Lycksalighetens ö* (1824–27; "The Isle of Bliss"), an allegory dealing with adventures of a legendary king, Astolf, and a history of poetry as an illustration of man's alienation from the divine. The greatest poet was perhaps Erik Johan Stagnelius, who held aloof from schools and coteries. The recurrent theme in his *Liljor i Saron* (1821; "Lilies of Sharon") was the lament of the human soul, imprisoned in a world of darkness and sin.

In prose the most complex personality among the later Romantics was a novelist, Carl Jonas Love Almqvist, who combined an extravagant imagination with realism. A master of prose style, he was at his best in the long short story, in which he foreshadowed Strindberg's method of raising problems for debate. The novel was established by Fredrika Bremer, author of *Grannarna* (1837; "The Neighbours"), whose "sketches from ordinary life" appeared from 1828. Sophie von Knorring wrote chiefly about aristocratic families, and Emilie Flygare-Carlén produced stories dealing with west-coast life, including *Rosen på Tistelön* (1842; *The Rose of Tistelön*).

Scandinavism

Emergence of Realism and Poetic Realism. Realism made only slow headway in spite of the example of the Finno-Swedish poet Johan Ludvig Runeberg (see below). Literature of the 1840s and 1850s was mainly an aftermath of Romanticism. A movement known as Scandinavism produced a good deal of verse: Carl Vilhelm August Strandberg (pseudonym "Talis Qualis"), fieriest poet of this type, later made excellent translations from Byron. Popular reading was provided by August Blanche in *Bilder ur verkligheten* (1863–65; "Pictures of Real Life"), short stories depicting Stockholm life with humour and vivacity, while Frans Hedberg wrote pompous historical plays.

Poetic Realism became an official program of the "pseudonym poets" of the 1860s, including Carl David of Wirsén, Edvard Bäckström, Pontus Wikner, and Carl Snoilsky. Only Snoilsky had the temperament and poetic gift needed to carry out the program. Wirsén, on the other hand, as secretary of the Swedish Academy, launched formidable opposition against innovators; and Viktor Rydberg fell between Idealism and Naturalism. His important early work consisted of an ideological novel, *Den siste athenaren* (1859; *The Last Athenian*), and a treatise, *Bibelns lära om Kristus* (1862; "The Teaching of the Bible About Christ"), which prepared the way for scientific Rationalism.

August Strindberg

Sources of modern Swedish literature. Four influences combined to free Swedish literature from petrifying conventions: the English writings of Charles Darwin, Herbert Spencer, and John Stuart Mill; the French Naturalism of Émile Zola; the drama of the Norwegians Henrik Ibsen and Bjørnstjerne Bjørnson; and the criticism of the Dane Georg Brandes. The modern literature growing out of this was first and best represented in the work of August Strindberg, Sweden's greatest writer. Modern drama has dated from his play *Mäster Olof* (1872), and the modern novel from *Röda rummet* (1879; *The Red Room*). Strindberg overshadowed all the writers of the 1880s, including Gustaf af Geijerstam, author of *Erik Grane* (1885), Anne Charlotte Edgren-Leffler, and the gifted Victoria Benedictsson; the latter two wrote about the adverse position of women in society. Benedictsson's stories, such as *Från Skåne* (1884; "From Skåne"), revealed the regional character of the new prose literature. Regional poetry was written by Albert Bååth and Ola Hansson, both of Skåne.

In 1888 Verner von Heidenstam began the reaction against Utilitarianism and Naturalism with a volume of verse, *Vallfart och vandringsår* ("Pilgrimage and Wander Years"). His later poetry and historical tales won him the Nobel Prize for Literature in 1916. Oscar Levertin, stimulated by Heidenstam's example, wrote poetry full of colour and lore of the past and as a critic was influential in molding contemporary taste. Gustaf Fröding was also influenced by Heidenstam, and his verse constantly mingles the melancholy and gay. Regionalism entered Neoromantic poetry with Fröding, who was from Värmland, and with the work of Erik Axel Karlfeldt the province of Dalarna came into its own. Karlfeldt's mature poetry won him the Nobel Prize in 1931.

Selma Lagerlöf

Meanwhile, Selma Lagerlöf, the first Swede to win a Nobel Prize for Literature (1909), had developed the prose tale; her long series of novels and short stories, beginning with *Gösta Berlings saga* (1891), reached an international public through translation. Per Hallström was a more skillful writer of short stories than of novels. Romantic, too, in his love for the skerries (rocky isles) was Albert Engström, a great humorist.

Finno-Swedish literature. A significant literature in the Swedish language developed in Finland during the 19th century. Its emergence can be traced to the works of Johan Ludvig Runeberg. His epic poems, *Elgskyttarne* (1832; "The Moose Hunters") and *Hanna* (1836), won him a major place in Swedish letters. Notable, too, were the writings of Zacharias Topelius, which contributed much to the development of the Finnish historical novel. Topelius is perhaps best remembered for *Fältskärns berättelser* (1853–67; *The King's Ring and the Surgeon's Stories*), a romanticized account of 17th- and 18th-century Finno-Swedish history.

NORWEGIAN LITERATURE

The Age of Wergeland. After 1814 a new, exciting, and difficult age began for Norway: an opportunity seemed to be offered to develop an independent Norwegian culture and way of life, but there were deep differences of opinion as to how this could best be achieved. A poet and critic, Johan Sebastien Welhaven was chief representative of those who insisted that the existing Danish element in the culture should not be neglected. Henrik Wergeland was a spokesman for those whose nationalistic pride led them, on the other hand, to demand a complete break with Denmark. Welhaven stood for a coolly intellectual approach, for restraint and control, and for conscious artistry, as his own sonnet cycle *Norges daemring* (1834; "The Dawn of Norway") exemplifies. Wergeland was more passionate and revolutionary, and his enormous epic, *Skabelsen, mennesket og messias* (1830; "Creation, Humanity and Messiah"), typified the spirit he admired.

The ideological conflict between Wergeland and Welhaven

Wergeland dominated the age as poet, orator, and social reformer, and the clash between him and Welhaven and between the two factions associated with them—the "patriots" and the "intelligentsia"—began an ideological conflict that has continued to persist in modified forms.

National Romanticism. The literature of the mid-19th century, known as Norway's "national Romanticism," continued to reflect the country's larger aspirations. The compilation and publication, between 1841 and 1844, of *Norske folkeeventyr* ("Norwegian Folk Tales") by Peter Christen Asbjørnsen and Jørgen Engebretsen Moe, and the 1853 collection by Magnus Brostrup Landstad, *Norske folkeviser* ("Norwegian Folk Ballads"), indicated a lively interest in the past, as did Peter Andreas Munch's eight-volume history of the Norwegian people (1857–63). Ivar Aasen was the creative spirit behind the Landsmål movement to establish a literary language based on rural dialects linked with Old Norse. Many publications of these years, including earlier works of Ibsen and Bjørnson, turned consciously to Norway's heroic past and its peasants. To these years belonged also the lyric poetry of Aasmund Olafsson Vinje, founder of the periodical *Dølen,* who adopted Nynorsk (New Norwegian) as his literary language.

The problem dramas of Ibsen and Bjørnson

In 1855 Camilla Collett, Wergeland's sister, published *Amtmandens døttre* ("The Governor's Daughters"), which, by considering the place of women in society, marked a beginning of a trend that, encouraged by the immensely influential Danish critic, Georg Brandes, culminated in the 1870s and the 1880s in the realistic "problem" literature of Ibsen, Bjørnson, and their contemporaries. *Samfundets støtter* (1877; *Pillars of Society*) was the first of a succession of problem dramas by Ibsen to win him worldwide fame. By then he had already written two verse dramas, *Brand* (1866) and *Peer Gynt* (1867), and his long "double drama" *Kejser og Galilaeer* (1873; *The Emperor and the Galilean,* 1876). The first substantial drama of this type by Bjørnson was *En fallit* (1875; *The Bankrupt*). Although never the world figure that Ibsen became, Bjørnson was a leading personality of his age in Norway, as novelist, dramatist, and lyric poet and in public affairs.

The novelists Jonas Lie and Alexander Kielland, together with Ibsen and Bjørnson, were the major figures of modern Norwegian literature and were responsible for a remarkably large body of important work between 1870 and 1884, as the following titles illustrate: Ibsen's works *Et dukkehjem* (*A Doll's House*), *Gengangere* (*Ghosts*), *En folkefiende* (*An Enemy of the People*), and *Vildanden* (*The Wild Duck*); Bjørnson's dramas *Det ny system* (*The New System*), *En handske* (*A Gauntlet*), and *Over aevne* (*Beyond Human Power I*) and his novel *Det flager i byen og på havnen* (*The Heritage of the Kurts*); Lie's novels *Gaa Paa!* ("Go Ahead!"), *Livsslaven* (*One of Life's Slaves*), and *Familjen paa Gilje* (*The Family at Gilje*); and Kielland's *Skipper Worse* (1882), *Gift* (1883; "Poison"), and *Fortuna* (1884; *Professor Lovdahl*). The foremost stylist of his age, Kielland was an elegant, witty novelist with a strong social conscience and an active reforming zeal stemming from an admiration for John Stuart Mill.

The literature of the 1870s emphasized individual development and expression in keeping with the optimistic attitude of the times to social change and improvement. In the following decade, growing skepticism and disillusionment made writers more bitter in their attacks on "established" social institutions. The publication of *Fra Kristiania-Bohêmen* ("From the Christiania Bohemia") in 1885 by Hans Henrik Jaeger created, by its seeming advocacy of sexual license, a public scandal. The most extreme exponent of Naturalism was Amalie Skram, especially in a four-volume novel, *Hellemyrsfolket* (1887–98; "The People of Hellemyr"). Arne Garborg, poet, novelist, dramatist, and critic, was a much superior writer whose work reflected successive movements of Romanticism, Realism, Naturalism, and Neoromanticism. His wider reputation was first established with a novel, *Bondestudentar* (1883; "Peasant Students"), but perhaps his greatest achievement was the poem cycle *Haugtussa* (1895).

DANISH LITERATURE

The works of Adam Oehlenschläger

The Romantic period. The Romantic movement came to Denmark from Germany, inspired partly by the German Jena Romantics and partly by the Neoclassicism of Goethe and Schiller. Friedrich Schelling's philosophy was interpreted in Denmark by the Norwegian Henrik Steffens, but the leading Danish Romantics gave it a form very different from the original. The leader of the Romantic movement in Denmark was Adam Oehlenschläger, whose unparalleled versatility in poetry, drama, and prose showed the influence of certain works of Goethe and Schiller and of German Romanticism. His plays *Sanct Hansaften-Spil* (1802; "Play for Midsummer Eve") and *Aladdin; Hakon Jarl* (1857), one of his many Northern tragedies; and a cycle of dramatic poems, *Helge* (1814), were outstanding. The popular and historical songs and hymns of the poet N.F.S. Grundtvig, as well as his personal poetry, have given him a lasting place in Danish literature. Sharing the Romantic enthusiasm for antiquities of Scandinavia, he translated the 13th-century historians Saxo Grammaticus and Snorri Sturluson (see above) and translated *Beowulf* even before it had appeared in English. Bernhard Severin Ingemann wrote historical novels and a poetic cycle, *Holger Danske* (1837; "Holger the Dane"), around the themes of chivalry and nationalism as well as his unsophisticated *Morgen og aftensange* (1837–39; "Morning and Evening Songs"). Johannes Carsten Hauch wrote tragic and philosophic dramas, novels, and contemplative poetry.

Romantic Realism. New elements of reason and realism appeared after the first quarter of the century in the works of Poul Møller, who wrote the first Danish novel on contemporary life, *En dansk students eventyr* (1824; "The Adventures of a Danish Student"), and dramatic poems and fables, sometimes showing personal disillusionment, and of Steen Steensen Blicher, who, in *Traekfuglene* (1838; "The Birds of Passage"), interpreted human nature with sad resignation. Some of his best poems were in the Jutland dialect. His many *noveller,* or short stories, beginning in 1824 with the masterly "En landsbydegns dagbog" ("The Journal of a Parish Clerk"), struck notes varying from sorrow and resignation to humour and irony.

Minor writers of the same period were Thomasine Gyllembourg-Ehrensvärd, whose novel *En hverdagshistorie* (1828; "A Story of Everyday Life") was much admired; Andreas de Saint-Aubin, who wrote novels under the nom de plume of "Carl Bernhard"; and Carl Bagger, whose novel *Min broders levned* (1835; "My Brother's Life") shocked the literary world by its bold realism.

Basic characteristics

Poetic Realism. About 1830, early Romanticism gave way to a less naive poetic realism, more contemplative and more concerned with form than with content. Johan Ludvig Heiberg, who led this movement, attempted to revivify Danish drama by importing French vaudeville, and in his serious romantic plays *Elverhøj* (1828; "The Elfinhill") and *Syvsoverdag* (1840; "Day of the Seven Sleepers") he juxtaposed poetic and pedestrian reality. His finest achievement was a verse comedy, *En sjael efter døden* (1841; "A Soul After Death"). He was the leading literary critic of his time, profoundly influenced by the philosophy of G.W.F. Hegel. Henrik Hertz also regarded the perfection of poetic form as more important than its content, as was clearly expressed in *Gjenganger-breve* (1830; "Letters of a Ghost"). He also wrote comedies and serious Romantic plays, including *Kong Renés datter* (1845; *King René's Daughter*).

An upsurge of interest in lyrical poetry occurred in the 1830s and 1840s, led by poets concerned with the aesthetic treatment of love and nature. Christian Winther, best known for a long verse novel, *Hjortens flugt* (1885; "The Flight of the Stag"), sang the praises of his native island, Zealand, and of woman. Ludvig Bødtcher wrote delicate and sensitive poetry, some of which was inspired by the Italian scene. Emil Aarestrup treated erotic themes. Frederik Paludan-Müller became an uncompromising moralist; *Adam Homo* (1841–48), a poetic epic, was a bitter contemporary satire. Hans Christian Andersen was most important for his fairy tales, the majority of whose plots were his own invention, though he also wrote novels, plays, travel books, and poems.

Kierkegaard

Søren Kierkegaard holds a position entirely isolated in Danish literature. His highly personal religious philosophy was expressed in such works as *Enten Eller* (1843; *Either/Or: A Fragment of Life*) and *Stadier paa livets vei* (1845; *Stages on Life's Way*). He spent his last years in a violent and passionate attack on "official Christianity."

Meïr Aron Goldschmidt edited a rebellious, anti-royalist weekly, *Corsaren* ("The Corsair"), while many of his novels and short stories were concerned with Jewish life in the Danish community. The 1850s and 1860s produced few new Danish writers of importance: the most original was Hans Egede Schack, whose novel *Phantasterne* (1857; "The Daydreamers") revealed great psychological gifts.

FAEROESE LITERATURE

Emergence of a written literature

Modern Faeroese literature emerged during the second half of the 19th century. Until this time, the literary tradition of the Faeroese was almost exclusively oral. It consisted principally of ballads, epic and fantastic in style and centred on legends such as that of Sigurd. A new, national written literature in Faeroese became possible only after the orthography was normalized by means of rules introduced in 1846 by the linguist and folklorist Venceslaus Ulricus Hammershaimb. Its development was promoted by nationalist agitation, which hastened the restoration of the old Faeroese parliament in 1852 and the end of the Danish royal trade monopoly in 1856.

Much of the writings of these early formative years consisted of patriotic poetry. The most memorable examples of such emotional songs were produced by Fríðrikur Petersen, Rasmus Effersøe, and Jóannes Patursson.

ICELANDIC LITERATURE

The literary and linguistic renaissance in Iceland at the start of the 19th century was fostered by three men in particular: a philologist, Hallgrímur Scheving; a poet and lexicographer, Sveinbjörn Egilsson; and a philosopher and mathematician, Björn Gunnlaugsson. The principal movement in this renaissance was Romanticism. Inspired by the German philosopher Henrik Steffens, Bjarni Thorarensen produced nationalistic poetry that became a model for 19th-century lyrical poetry. Jónas Hallgrímsson, however, surpassed Thorarensen as a metrist. He was one of four involved in the periodical *Fjölnir* ("The Many-Sided"), which aimed to revolutionize literary theory and practice. The Fjölnismenn were anti-traditional and rejected the use of rhymes.

Literary and linguistic renaissance

The group was replaced in the 1840s by another group of poets, of whom the most outstanding were Benedikt Gröndal, Steingrímur Thorsteinsson, and Matthías Jochumsson. Gröndal wrote powerful lyric poetry, two prose fantasies, and an autobiography, *Daegradvöl* (1923; "Day-Spending"). Thorsteinsson wrote nature poetry and satirical epigrams but is best remembered as translator of *King Lear* (1878) and *A Thousand and One Nights* (1857–64). Jochumsson's *Hallgrímur Pétursson* (1874) and hymn *Fadir andanna* (*c.* 1884; "Father of Spirits") established him as the greatest lyric poet of the three. He, too, translated Shakespeare in addition to Ibsen's *Brand.* A poet, Grímur Thomsen, was contemporary with but distinct from this group; his poetry was less lyrical, more austere and rugged, as *Hemings flokkur Áslákssonar* (1885; "The Story of Heming Aslakssonar") exemplifies.

The latter part of the century produced three talented poets: Thorsteinn Erlingsson, author of *Aldaslagur* (1911; "Sound of the Ages"); Einar Benediktsson, a Neoromantic; and Stephan G. Stephansson, an embittered expatriate whose irony passed in Iceland for Realism.

The 19th century also saw a renaissance in imaginative prose. Jón Thoroddsen wrote two novels that have acquired a position not incommensurate with that of the medieval sagas: *Piltur og stúlka* (1850; *Lad and Lass*) and the incomplete *Madur og kona* (1876; "Man and Woman"), distinguished in prose style, narrative skill, wit, and perceptive observation of peasant and small-town life.

The 20th century

NORWEGIAN

In the 1890s established Norwegian writers came under fire from the new generation. The manifesto of new ideas was an essay published in 1890 in the periodical *Samtiden* ("The Present Age") by Knut Hamsun, "Fra det ubevidste Sjaeleliv" ("From the Unconscious Life of the Mind"), which demanded attention to what was individual and idiosyncratic rather than typical. Hamsun was impatient with contemporary emphasis on social problems, and his early novels—*Sult* (1890; *Hunger*), *Mysterier* (1892; *Mysteries*), and *Pan* (1894)—exemplified these ideas; his later novels, such as *Markens grøde* (1917; *Growth of the Soil*), were less extreme but still showed a strong, sometimes savage irony. Hamsun won the Nobel Prize for Literature in 1920.

Knut Hamsun's emphasis on the individual

Lyric poetry at this time flourished with Sigbjørn Obstfelder, who had a close affinity with the Symbolist movement, and Nils Collett Vogt, who produced some of the best lyrics of the 1890s. In drama Gunnar Heiberg, who combined a sharply satirical wit with a lyric deftness, expressed the new spirit in *Kong Midas* (1890), *Gerts have* (1894; "Gert's Garden"), *Balkonen* (1894; "The Balcony"), and *Kjaerlighetens tragedie* (1904; "The Tragedy of Love"). Sharing Hamsun's preoccupation with the irrational side of human conduct was Hans E. Kinck, a writer of considerable power and penetration. In his verse drama *Driftekaren* (1908; "The Drover") and long novel *Sneskavlen brast* (1918–19; "The Avalanche Broke"), Kinck showed himself to be a more reflective and analytical writer than Hamsun.

The real achievements of Norwegian literature in the first half of the 20th century were in the novel and lyric poetry. Drama was not conspicuous, except for the plays of Gunnar Heiberg and Nordahl Grieg. In the early decades of the century, regionalism was a strong element, particularly in the novel; and authors adopted language coloured by dialect, thus becoming identified with their

Central theme of Sigrid Undset's novels

region. Kristofer Uppdal, of the mid-north region of Trøndelag, wrote a remarkable work—a 10-volume novel cycle, *Dansen gjenom skuggeheimen* (1911–24; "The Dance Through the Shadow World"). The novel also treated of conflicts arising from the spread of industrialism, which Norway underwent later than did other European countries. The most proletarian writer was Oskar Braaten, but superior as an artist was Johan Falkberget, who wrote with understanding and historical insight about the miners in Røros in *Christianus Sextus* (1927–35) and in *Nattens brød* (1940; "Bread of Night"). Sigrid Undset, who won the Nobel Prize for Literature in 1928, set her novels in many different ages, and their concern was to examine women's loyalties within the framework of their role in society. A long historical novel, *Kristin Lavransdatter* (1920–22), was a masterpiece of Norwegian literature. Her later novels, *Gymnadenia* (1929; *The Wild Orchid*) and *Den braendende busk* (1930; *The Burning Bush*), were greatly influenced by her conversion to Roman Catholicism. Olav Duun, again of the mid-north region, revealed his insight into life as endless conflict in a six-volume novel cycle about the development of a peasant family through four generations—*Juvikfolke* (1918–23; *The People of Juvik*).

Shortly before World War I, there were several good lyric poets: Herman Wildenvey, Olaf Bull, Tore Ørjasaeter, and Olav Aukrust. Between World Wars I and II, there emerged many socially committed writers: the poet Arnulf Øverland; a novelist and critic, Sigurd Hoel; a dramatist and critic, Helge Krog; and Nordahl Grieg. After World War II, Tarjei Vesaas wrote a remarkable series of novels, including the symbolic *Huset i mørkret* (1945; "The House in the Darkness") and *Bruene* (1966; "The Bridges"). Cora Sandel, who had made a major contribution with her "Alberte" trilogy (1926–39), continued to write, as did Aksel Sandemose, an experimental writer, and Johan Borgen, who won acclaim for his early short stories, the *Lillelord* trilogy (1955–57), and the autobiographical *Barndommens rike* (1965; "Childhood's Realm"). Borgen later became the leading novelist in Norway and maintained this standing until his death in 1979. Since then, Terje Stigen, Knut Faldbakken, and Bjørg Vik have become the dominant figures in prose fiction. Stigen's works are basically realistic narratives that variously treat historical and contemporary subjects. Faldbakken has demonstrated much fantasy and ingenuity, most recently having completed a series of novels that portray the collapse of technological society. An excellent short-story writer, Vik centres her attention on middle-class family life and often portrays it from a mildly feminist viewpoint.

SWEDISH

Mood of decadence and pessimism

The early years of the 20th century were a period of decadence and pessimism in Swedish literature. Representative of this mood were Hjalmar Söderberg and Bo Bergman. Söderberg's forte was the short story (*Historietter* [1898]), in which psychological subtlety and irony were happily combined and in which, as in his novels *Martin Bircks ungdom* (1901; "Martin Birck's Youth") and *Doktor Glas* (1905), he appeared as a master of Swedish prose. Bergman also produced memorable short stories, but his real medium was the lyric; he developed his talent in a series of collections from *Marionetterna* (1903; "The Marionettes") to *Riket* (1944; "The Kingdom").

The modern Swedish novel. The development of the novel was associated with Gustaf Hellström, Ludvig Nordström, Elin Wägner, and Sigfrid Siwertz. Hellström's work as a journalist in Europe, the United States, and England greatly influenced him. Irony and careful detail emerged in his best known novel, *Snörmakare Lekholm får en idé* (1927; *Lacemaker Lekholm Has an Idea*). Siwertz was a more elegant stylist, and a decisive influence upon him was the philosophy of Henri Bergson, reflected in *En flanör* (1914; "An Idler"); but his weightiest work was a family saga, *Selambs* (1920; *Downstream*), a novel of Stockholm during World War I. Nordström, overflowing with vitality and keen but grotesque humour, accomplished some of his best work in *Landsorts-bohème* (1911; "Small-Town Bohemia") and in his short stories—*e.g., Fiskare* (1907; "Fishermen") and *Öbacka-bor* (1921). Elin Wägner was an ardent pacifist and feminist; her most powerful work was a peasant novel, *Åsa-Hanna* (1918). The outstanding novelist of the 1920s was Hjalmar Bergman: with vivid imagination and restless energy, Bergman wrote a long series of stories, many set in "Wadköping" (his native Örebro), others in Italy. In *Loewenhistorier* (1913) he depicted an irrational, impulsive, unsuccessful hero; in *Farmor och vår Herre* (1921; *Thy Rod and Thy Staff*) he portrayed one of the dominating female personalities that fascinated him. The satire *Markurells i Wadköping* (1919; *God's Orchid*) and *Swedenhielms* (performed 1925), one of the few Swedish comedies, were his most widely known works.

The "proletarian" novel

Meanwhile, the "proletarian" novel had been developed by writers concerned with the miseries of the working class, particularly Martin Koch and Ivar Lo-Johansson. There was particularly harsh criticism of working class conditions in stories by Jan Fridegård. Vilhelm Moberg wrote novels of peasant life but achieved his greatest success with the four-part prose epic about a group of Swedish emigrants to North America, *Utvandrarna* (1949–59; *The Emigrants*). The development of the Swedish autobiographical novel was helped by Eyvind Johnson, with the series "Romanen om Olof" (1934–37); Harry Martinson, with *Nässlorna blomma* (1935; *Flowering Nettle*) and *Vägen ut* (1936; "The Way Out"); and Agnes von Krusenstjerna. In her novel cycles, the "Tony" trilogy (1922–26) and the "Fröknarna von Pahlen" series (1930–35), Krusenstjerna described her own aristocratic environment and analyzed a degenerate psychology. Harry Martinson was one of a group of five primitivist writers formed about 1930. He later developed into one of the finest lyricists of the century. Sensuous imagery and a feeling for nature characterized his work. He attempted to revive the verse epic in his *Aniara* (1956), a symbolical story of a voyage of a spaceship.

Pär Lagerkvist's work

The internationally best known Swedish writer of the 20th century was Pär Lagerkvist, who won the Nobel Prize for Literature in 1951. In his youth a bold innovator, he later developed an admirably pure prose style, as in the allegorical novel *Dvärgen* (1944; *The Dwarf*). His collections of poems, *Ångest* (1916; "Anguish"), and early plays—for instance, *Himlens hemlighet* (1919; "The Secret of Heaven")—were Expressionistic in style. The dominant theme throughout Lagerkvist's work was a search for vital, often outspokenly religious values.

Development of lyric poetry. Several of the best Swedish writers were connected with the development of lyric poetry. One of the most notable, Vilhelm Ekelund, was in his youth the chief exponent of Symbolism in Sweden and later, as an author of aphorisms, exerted much influence on the development of literary modernism. Among the most popular poets were Dan Andersson, Birger Sjöberg, and Hjalmar Gullberg. In Gullberg's poetry, religious commitment and classical learning are balanced by irony and wit. A more esoteric style in modernism was introduced by Bertil Malmberg and developed by the group of poets called the generation of the 1940s, which included Erik Lindegren and Karl Vennberg. Stylistically influenced by T.S. Eliot, they often expressed an anguish and disbelief that approached French Existentialism. Lindegren's *Mannen utan väg* (1942; *The Man Without a Way*) was typical of this generation's search for meaning in life. The most distinguished novelist of the 1940s was Lars Ahlin, who was concerned with man's search for grace through love and humiliation in works such as *Min död är min* (1945; "My Death Is Mine").

The greatest lyric poet of the century was Gunnar Ekelöf. His first collection of poems, *Sent på jorden* (1932; "Late on Earth"), was heralded as the first specimen of Surrealism in Swedish literature. Ekelöf's later development passed through successive phases of Romanticism and anti-poetic Skepticism resolved in a trilogy of books blending autobiography and Eastern mysticism.

Emphasis on political and social issues

Contemporary trends. In reaction to the literature of the 1940s and 1950s, which was much concerned with artistic form and the individual approach to life, the 1960s was a period of political and social commitment in poetry and fiction alike. Recurrent topics were the war in Vietnam and bitter onslaughts on the Swedish welfare state. Independent lyric poetry, however, continued to be produced by writers such as Östen Sjöstrand and Thomas Tranströmer, and a tortured experience of life, coloured by Roman Catholicism, was forcefully expressed in the novels of Birgitta Trotzig.

The aforementioned movement toward and subsequently away from profoundly politically committed literature is exemplified by the work of Sara Lidman. During the 1950s she was one of Sweden's most creative novelists but then ceased producing fiction in order to take part in the political debate of the time. Since the late 1970s, however, Lidman has returned to creative literature with a series of novels centred on life in an isolated Swedish community. Sven Lindqvist went through a similar process; after a period of committed writing, he returned in *En älskares dagbok* (1981; "A Lover's Diary") to a more or less autobiographical novel of his own youth. Political writing persists in Sweden, but it has become more imaginative and less tied to immediate events. P.C. Jersild, for example, has painted a chilling picture of civilization after a devastating nuclear war in *Efter floden* (1982; "After the Flood"); he had earlier demonstrated his talent in allegories set in a state veterinary institution and in a hospital. Sven Delblanc also has made use of allegory, and there is sometimes an almost mystical intensity apparent in his work.

Developments in Finno-Swedish literature. The second flourishing of Finno-Swedish literature occurred in the 1920s, with the development of modernism in lyric poetry. This trend was initiated by Edith Södergran, whose visionary, dreamlike poems proved influential throughout much of Scandinavia. After her came such poets as Gunnar Björling, noted for his impressionistic pictures of nature; Rabbe Enckell, a key theoretician of the movement; and Elmer Diktonius, devoted to political concerns.

Among the most talented prose writers of the period was Runar Schildt, whose short stories dealt with such questions as the relation of the intellectual and the artist to life. Several outstanding writers appeared somewhat later in the century, as, for example, Tito Colliander, who treated themes of guilt and atonement from a religious standpoint; Christer Kihlman, whose novels combined social criticism with psychological commentary; and Tove Jansson, internationally famous for her imaginative portrayals of the fairy-tale realm of Moomintrolls.

DANISH

Georg Brandes' radical ideas

The influence of Georg Brandes. About 1870 there arose in Denmark a new movement, led by Georg Brandes, from which a modern (*i.e.,* a Naturalistic or Realistic) literature emerged. His *Hovedstrømninger i det 19de aarhundredes litteratur* (1872–90; *Main Currents in 19th Century Literature*), describing the growth and defeat of reaction, caused a great sensation. As noted earlier, he influenced Ibsen and Strindberg and wrote many scholarly and critical works illustrating radical ideas. His later biographies of Shakespeare, Goethe, Voltaire, Julius Caesar, and Michelangelo revealed how he was influenced by Nietzsche into developing a philosophy of aristocratic radicalism. Among his followers were Jens Peter Jacobsen, whose short story "Mogens" (1872) and novel *Fru Marie Grubbe* (1876) are the supreme examples of Danish Naturalism, while his other novel *Niels Lyhne* (1880) and some of his short stories dealt with dream as against reality; and Holger Drachmann, greatest lyric poet of the period, who later reacted strongly against Brandes and whose poetry and prose were often about the sea.

Henrik Pontoppidan, one of Denmark's greatest novelists, dealt at first with social injustices and contemporary political, moral, and religious problems in his short stories. The Denmark of his day was also the subject of his greatest work, three long novel cycles, *Det forjaettede land* (1891–95; *The Promised Land*), *Lykke-Per* (1898–1904; "Lucky Peter"), and *De dødes rige* (1912–16; "The Realm of the Dead"); and in these he makes penetrating, if unflattering, analyses of Danish national character. Herman Bang was another novelist interested in the outsiders of life and in insignificant people. His skillful, mainly impressionistic technique was displayed in his best novels, *Ved vejen* (1886; "By the Way-Side"), *Tine* (1889), and *Det hvide hus* (1898; "The White House").

Other notable writers at the end of the century were Gustav Wied, whose "satyr plays" and whose novels *Livsens Ondskab* (1899; "Life's Malice") and *Knagsted* (1902) were full of malicious humour; Vilhelm Topsøe, a conservative realist; Peter Nansen, who wrote stories reminiscent of those of Guy de Maupassant; Carl Ewald, whose nature stories were based on Darwinian philosophy; Karl Larsen, who caught the atmosphere of Copenhagen and its inhabitants with fine precision; and several playwrights, including Edvard Brandes, Otto Benzon, Gustav Esmann, Sven Lange, Einar Christiansen, and Henri Nathansen.

Symbolist mode

Neoromantic revival. In the 1890s a Neoromantic poetic revival occurred, reinstating the value of emotion and fantasy. The leader of these Symbolist poets was Johannes Jørgensen, whose finest works show a simplicity of style and intensity of feeling. Other poets of the time included Viggo Stuckenberg, who expressed sad resignation; Sophus Claussen, whose poems, often obscure, show sensuality, pantheistic love of nature, and sophisticated aestheticism; and Helge Rode, a mystic who also wrote plays and criticism attacking intellectualism.

20th-century literary trends. Several women contributed to literature at the turn of the century: Gyrithe Lemche, who wrote a novel cycle, *Edwardsgave* (1900–12); Agnes Henningsen, a brilliant writer who was often concerned with experiences of the emancipated woman; and Karin Michaëlis, a fine psychologist, best known for her novel *Den farlige alder* (1910; *The Dangerous Age*).

Nexø's epics of proletarian life

The two greatest early 20th-century novelists were Martin Andersen Nexø and Johannes Vilhelm Jensen. Nexø's works described the lives of poor people; *Pelle Erobreren* (4 vol., 1906–10; *Pelle the Conqueror*) and *Ditte Menneskebarn* (3 vol., 1917–21; *Ditte: Daughter of Man*) were great epics of proletarian life, and his reminiscences were among the finest in the language. Jensen, who was also a great and original lyric poet and prolific essayist, wrote *Den lange rejse* (6 vol., 1908–22; *The Long Journey*), an ambitious epic of man from the baboon stage to the discovery of America; he was also noted for *Himmerlandshistorier* (1904, revised 1910; "Tales from Himmerland"), based on his childhood memories of North Jutland; *Kongens fald* (1900–01; *The Fall of the King*); and nine volumes of *Myter* (1907–44; "Myths"). Other novelists of this period included Jakob Knudsen, whose interest, taking account of the inequality of man and the need for authority, was with Christian and moral problems; Harald Kidde, an introspective and melancholy writer; and Knud Hjortø, a keen and intelligent writer of psychological novels.

Regional literature of the early 1900s was produced chiefly by Jutland writers. Prominent among them were three poets: Jeppe Aakjaer, Johan Skjoldborg, and Thøger Larsen. Also, Marie Bregendahl and Harry Søiberg drew upon Jutland settings for their novels.

Isak Dinesen

Significant poets of the post-World War I generation were Tom Kristensen, Otto Gelsted, Emil Bønnelycke, Kai Friis Møller, and Per Lange. Among interesting novelists, Jacob Paludan wrote some very good fiction—*Fugle omkring fyret* (1925; *Birds Around the Light*) and *Jørgen Stein* (1932–33)—as also did Hans Kirk, whose *Fiskerne* (1928; "The Fishermen") was social realism at its best. Harald Herdal, a disciple of Nexø, exposed society's hypocrisy in his proletarian novels. Jørgen Nielsen's themes were suppressed hatred, sin, and fear among Jutland peasants. H.C. Branner, an important writer of novels, plays, and short stories, spoke of the loneliness of men and the danger of power. Another writer of these three genres was Knud Sønderby, who had a brilliant style and deep understanding. Nis Petersen, poet and novelist, was famous for *Sandalmagernes gade* (1931; *The Street of the Sandalmakers*) and *Spildt maelk* (1934; *Spilt Milk*). Isak Dinesen (Karen Christence Dinesen, Baroness Blixen-Finecke), an aristocratic writer with subtle irony and unusual sensitivity, wrote both in Danish and in English. Her first notable work, a collection of short stories featuring a strong fairy-tale-like quality, was in fact written in English. Entitled *Seven Gothic Tales*, it was published in 1934 in the United States and subsequently translated by the author into Danish as *Syv fantastiske Fortællinger*. Other major works of Dinesen include her memoir *Den afrikanske Farm* (1937; *Out of Africa*) and two more collections of finely crafted stories, *Vinter-Eventyr* (1942; *Winter's Tales*) and *Sidste Fortællinger* (1957; *Last Tales*).

Two Faeroese novelists also made important contributions to modern Danish prose fiction: Jørgen-Frantz Jacobsen, with his novel *Barbara* (1939), which provides a fascinating portrait of a capricious woman; and William Heinesen, with his masterpiece *De fortabte spillemænd* (1950; *The Lost Musicians*). Here, as in the rest of his varied writings, Heinesen renders Faeroese life as a microcosm illustrative of social, psychological, and cosmic themes. Other distinguished novelists of the time were Hans Scherfig, a great humorist and social satirist; and Martin Alfred Hansen, a psychological novelist, whose best known novel is *Løgneren* (1950; *The Liar*).

The modern Danish theatre

Danish playwrights of the post-World War I period such as Sven Clausen and Svend Borberg were influenced by German Expressionism, Symbolism, Luigi Pirandello, and Sigmund Freud. Kaj Munk, who revived the heroic drama of Shakespeare and Schiller, showed unusual qualities in his best plays—*En idealist* (1928; *Herod the King*) and *Ordet* (1932; *The Word*)—which were concerned with problems of God and man. The work of Kjeld Abell marked a severance from Naturalist drama, and a radical perspective underlay his witty dialogue. His most important plays were *Melodien, der blev vaek* (1935; *The Melody That Got Lost*), *Anna Sophie Hedvig* (1939), *Dage på en sky* (1947; *Days on a Cloud*), and *Skriget* (1961; "The Scream"). C.E. Soya was an important playwright of the period, and also a novelist and fine short-story writer; some of his daring experiments with the theatre have been very successful.

Many postwar poets found an aesthetic manifesto in *Fragmenter af en dagbog* (1948; "Fragments of a Diary"), by Paul la Cour, who was influenced by contemporary French poetry. Jens August Schade, a sophisticated naivist, also had an important influence, as did the prematurely deceased poets Gustaf Munch-Petersen and Morten Nielsen. A revival of poetry followed the liberation (1945), and the Existentialist periodical *Heretica* (1948–53) became the voice of a group of young writers who regarded a Christian philosopher, Vilhelm Grønbech, as their spiritual progenitor. Two outstanding poets apart from the *Heretica* group were Halfdan Rasmussen, who also wrote excellent nonsense verse, and Erik Knudsen, also a brilliant satirical playwright. Both studied contemporary problems and reacted against the anti-rationalism and anti-intellectualism of the *Heretica* movement. Tove Ditlevsen was another important poet, as well as novelist and short-story writer, unattached to any group; his often intensely personal work reflects the loneliness of life in the poorer quarters of Copenhagen. Klaus Rifbjerg has been the dominant novelist in Denmark since the publication of his *Den kroniske uskyld* ("Chronic Innocence") in 1958. He is a writer of great inventiveness and linguistic originality, who has analyzed modern society and its problems, both public and private, in realistic novels. In a more satirical vein, Leif Panduro has examined the place of the individual in society, paying special attention to the problems of middle age and the emptiness of a welfare-state society in novels and television dramas. A more philosophical approach is found in Villy Sørensen, whose Kafkaesque stories place him in the sphere of Absurd literature. There has been, at the same time, a vogue of the documentary novel, the principal exponent of which has been Thorkild Hansen.

The modern poetry that became a hallmark of Danish literature after World War II gave rise to the mature works of Frank Jæger, Thorkild Bjørnvig, and Ivan Malinovski. Further experimentation resulted in Structuralist works such as Inger Christensen's *Det* (1968; "It"). Henrik Nordbrandt has been the leading Danish poet of the 1970s and '80s. A pessimistic sense of isolation pervades his poems, which have been influenced by Oriental writings.

The 1970s saw an upsurge of women authors, some consciously writing for the feminist cause and others content to portray life as experienced by women. Outstanding among them are Dea Mørch, Kirsten Thorup, and Dorit Willumsen.

FAEROESE

Faeroese literature came into its own after the turn of the century. Jens H.O. Djurhuus, who created rhetorical poetry of splendid resonance, was the first to emerge as a writer of international stature. His brother, Hans Andrias Djurhuus, wrote in a more naive manner, producing poems, fairy tales, and plays, which were based on native historical traditions and legends.

Faeroese golden age writers

Five writers dominated the Faeroese literary scene from about the 1930s through mid-century. Of these so-called Faeroese golden age authors two, Jørgen-Frantz Jacobsen and William Heinesen, wrote in Danish (see above), while the other three, Christian Matras, Heðin Brú (Hans Jakob Jacobsen), and Martin Joensen, in Faeroese. The works of Matras reveal a profound lyric poet seeking to interpret the essence of Faeroese culture. A fine stylist, Brú did much to create a Faeroese literary prose in his portrayals of village life in a time of transition (*e.g., Feðgar á ferð* [1940; *The Old Man and His Sons*]). Joensen's novels and short stories are of a similar character, but their emphasis is on psychological realism rather than on style. A prose writer of a distinctly more modern bent is Jens Pauli Heinesen. His works reflect an approach to Faeroese life that is generally more international than that of Brú or Joensen and that is infused with a certain satirical element.

Poetry continues to attract many writers. Karsten Hoydal was the first Faeroese writer to compose verse directly influenced by modern foreign poets; he also translated many of their works, especially those of Edgar Lee Masters of the United States. Regin Dal and Steinbjørn B. Jacobsen have gone much further in their modernism, the latter adopting a style somewhat akin to the Imagism of the U.S. poet Ezra Pound. Other writers whose works exhibit a modernist tendency include Guðrið Helmsdal, the foremost Faeroese woman poet of the contemporary scene.

ICELANDIC

Modern Icelandic prose writing did not really develop until the late 1870s, when a group of young men, influenced by the theories of the Danish critic Georg Brandes, began their literary careers. Unfortunately, they had absorbed Brandes' ideas uncritically, which resulted in introspective, self-pitying works believed by their authors to be realistically written. The early works of Einar Kvaran suffered from this flaw, but Kvaran later developed into a novelist of skill and power.

The works of Halldór Laxness

Notable 20th-century prose writers. Several writers of this time showed a keen eye for character and an understanding of human feelings and of the stark life of rural Iceland: Jón Trausti (Gudmundur Magnússon), who wrote the cycle *Heidarbýlid* (4 vol., 1908–11; "The Mountain Cot"); Gunnar Gunnarsson, whose *Kirken på bjerget* (1923–28; "The Church on the Mountain") was written in Danish; and Gudmundur Hagalín. The outstanding modern prose writer was Halldór Laxness, who was awarded the Nobel Prize for Literature in 1955. His mature works were influenced by his conversion to Roman Catholicism and his identification with the basic ideas of Communism. His major works were *Salka Valka* (1936), *Sjálfstaet fólk* (1935; *Independent People*), *Íslandsklukkan* (1943; "The Bell of Iceland"), and *Gerpla* (1952). He helped restore Icelandic as a sensitive medium for storytelling.

Among more recent prose fiction writers, Guðbergur Bergsson has proved himself one of the most talented and forceful. Reflective of the growing social and political consciousness of the 1960s, some of his novels from that period—*Ástir samlyndra hjóna* (1967; "The Love of a Harmoniously Married Couple") and *Anna* (1969)—subjected contemporary Icelandic society and the military relations of the nation with the United States to biting satirical attacks. His later works, the collection of short stories *Hvað ereldi guðs* (1970; "What Does God Eat") and a series of novels produced in the mid-1970s, were decidedly experimental in character, revealing an attempt by the author to go beyond ordinary reality to expose some of the more disgusting and grotesque aspects of life.

Major poets. At the beginning of the 20th century, poetry had lyricists in Thorsteinn Erlingsson, whose early delicacy later developed into a more powerful note in

"Aldaslagur" (1911; "Sound of the Ages") and in an incomplete epic, "Eidurinn" (1913; "The Oath"); in Einar Benediktsson, who wrote in an ornate style sometimes capable of greatness, as "Í dísarhöll" ("In the Hall of the Muses") shows; and in Stephan G. Stephansson, an expatriate farmer in Canada, who was a more bitter poet, influenced by the "realism" that passed for Georg Brandes' ideas in Icelandic literature—but *Andvökur* (1909–38; "Sleepless Nights") revealed a sensitive spirit.

Prominent poets of the next generation included Davíd Stefánsson, a traditionalist who expressed deep personal feelings in straightforward language and simple verse forms. His approach was shared by Tómas Gudmundsson and Jón Helgason, whose book *Úr landsudri* (1939, revised 1948; "From the South") was outstanding. Steinn Steinarr (Adalsteinn Kristmundsson), who was deeply influenced by Surrealism, experimented with abstract styles and spearheaded modernism in Icelandic poetry with his collection *Ljóð* (1937; "Poems").

Since mid-century several poets have distinguished themselves. The early works of Hannes Pétursson showed great sensitivity and skill in adapting Icelandic to new, European metres. Pétursson's more recent poems (those in the collection *Ur hugskoti* [1976; "Recollections"]), however, reveal a movement away from innovative forms to more traditional verse. Still other contemporary poets of merit include Thorsteinn frá Hamri and Sigurður Pálsson. Hamri's poems *Veðrahjálmur* (1972; "Sun Rings") grapple with questions about lasting values, particularly with the possibility of realizing human fellowship in the modern world. Pálsson's *Ljóð vega salt* (1975; "Poems on the See-Saw") combine autobiographical elements with philosophical questioning about the nature of contemporary life.

The development of the Icelandic drama. Icelandic drama really started to develop through Jóhann Sigurjónsson, whose first success was *Fjalla-Eyvindur* (1911; *Eyvind of the Hills*), followed by *Galdra-Loftur* (1915; "Loftur the Sorcerer"); both plays were based on powerful folktales. Gudmundur Kamban's *Hadda-Padda* (1914) was highly praised by Georg Brandes, and he remained important in Scandinavian drama for the next quarter of a century. After Kamban, there were few plays of lasting value, though Davíd Stefánsson's *Gullna hlidid* (1941; "The Golden Gate"), Jakob Jónsson's *Tyrkja-Gudda* (published 1948), and Agnar Thórdarson's satirical comedy of modern Reykjavík life, *Kjarnorka og kvenhylli* (1957; "Nuclear Force and Female Popularity"), had considerable merit. In *Ganksklukkan* (1962; *The Cuckoo Clock*) the latter produced a powerful play on the dehumanizing effect of modern life.

BIBLIOGRAPHY. ELIAS BREDSDORFF, BRITA MORTENSEN, and RONALD POPPERWELL, *An Introduction to Scandinavian Literature, from the Earliest Time to Our Day* (1951, reprinted 1977), a useful short survey; HARALD BEYER, *A History of Norwegian Literature* (1956, reprinted 1979; originally published in Norwegian, 1952), probably the best survey in English; ALRIK GUSTAFSON, *A History of Swedish Literature* (1961), an excellent critical history, with bibliographical appendix; PHILLIP M. MITCHELL, *A History of Danish Literature,* 2nd ed. (1971); STEFÁN EINARSSON, *A History of Icelandic Literature* (1957).

Classical Scholarship

Classical scholarship comprises the study, in all its aspects, of ancient Greece and Rome. In continental Europe this field is known as "classical philology"; the use, in some circles, of "philology" to denote the study of language and literature—the result of abbreviating the 19th-century "comparative philology"—has lent an unfortunate ambiguity to the term. During the 19th century Germans evolved the concept of *Altertumswissenschaft* ("science of antiquity") to emphasize the unity of the various disciplines of which the study of the ancient world consists. Broadly speaking, the province of classical scholarship in time is the period between the 2nd millennium BC and AD 500 and in space the area covered by the conquests and spheres of influence of Greece and Rome at their widest extent.

This article surveys the history of classical scholarship thus defined from antiquity until the late 20th century. For full treatment of the revival of classical culture and thought during the Renaissance, see HUMANISM; see also GRECO-ROMAN CIVILIZATION, CLASSICAL; and HISTORY, THE STUDY OF.

The article is divided into the following sections:

ANTIQUITY AND THE MIDDLE AGES

Until the Renaissance, Greek scholarship in the East and Latin scholarship in the West tended to follow different courses, and it is therefore convenient to treat them separately during this period.

Exposition of Homeric poetry

Greek scholarship. *Beginnings.* Greek epic poetry was recited in early times by professional performers known as rhapsodists, or rhapsodes, who sometimes offered interpretations of the works as well. In the 6th century BC Theagenes of Rhegium is said to have "searched out Homer's poetry and life and date," to have offered an allegorical interpretation of the battle of the gods in the 20th book of the *Iliad,* and to have been cited for a variant in Homer's text. The Sophists of the 5th century BC—paid writers, lecturers, and teachers such as Protagoras, Prodicus, Gorgias, and Hippias—gave ethical instruction in the form of the exposition of poetry, particularly that of Homer, which from this time formed the staple of Greek education. Some of them were interested in etymology, phonetics, the exact meanings of words, correct diction, and the classification of the parts of speech. Hippias laid the foundations of ancient chronography by making a list of victors in the Olympic Games, and Alcidamas (*c.* 400 BC) wrote a book on Homer. However, the efforts of the Sophists in this direction, considerable as they were, had a more or less casual and arbitrary character.

Plato (*c.* 428/427–348/347 BC) strongly resisted the claim that the poets were reliable interpreters of religion and morality. In his dialogue *Cratylus* he rejected the theory that the study of words can reveal the meaning of things, insisting that things themselves must be studied. Plato's pupil Aristotle (384–322 BC) defended poetry against his master; he valued highly the *Iliad* and the *Odyssey,* which from his time were regarded (together with the mock-epic *Margites*) as the genuine works of an individual Homer. He took a similar view of tragedy, which he believed effected a purification (*katharsis*) of the emotions upon which it played. Aristotle wrote about linguistic, dramatic, and other problems in Homer, refuting such detractors of the poet as Zoilus, compiled lists of Olympic and Pythian victors, collected details about the Athenian tragic and comic festivals, and supplemented his *Politics* with a collection of 158 studies of the constitutions of various Greek states. He also carried further the discussion of the constituent parts of a sentence and discussed the nature of synonyms, compounds, and rare words in early poetry.

The school of Aristotle

The school of Aristotle, known as the Lyceum, or Peripatos, continued to make this kind of learned work an adjunct to its philosophical activities. Aristotle's successor, Theophrastus (*c.* 372–*c.* 287 BC), collected the opinions of earlier philosophers. Dicaearchus (flourished *c.* 320 BC) wrote about the life of Greece, and Aristoxenus (flourished late 4th century BC) about the history and the theory of music. Heracleides Ponticus (*c.* 390–*c.* 322 BC) wrote one book on Archilochus and Homer and another on the dates of Homer and Hesiod. Clearchus collected proverbs, and Demetrius of Phaleron fables. All these philosophers were guided by Aristotle's teleological concept of intellectual activity, according to which philosophy is the culminating element of civilization. A 4th-century commentary on an Orphic poem, discovered in 1963 on a papyrus from a grave in Derveni, Macedonia, deserves mention as the earliest known commentary on a text; it is not a linguistic commentary but offers an allegorical interpretation that is doubtless very different from what the poet had intended.

The Library of Alexandria

During the Hellenistic Age (usually reckoned to extend from the death of Alexander the Great in 323 BC to the 1st century AD) scholarship flourished nowhere more than in the great city of Alexandria, the capital of the Ptolemies, the kings of Egypt. Early in the 3rd century BC Ptolemy I founded the famous Mouseion (Museum) of Alexandria, a community of learned men organized along the lines of a religious cult and headed by a priest of the Muses; part of the Museum was a splendid library that became the most celebrated of the ancient world. In its establishment the king is said to have had the assistance of the eminent Peripatetic scholar and statesman Demetrius of Phaleron, who left Athens about 300 BC; unfortunately, the evidence about the part he played is scanty and unreliable. The Museum community included both poets and scholars, as well as several individuals who combined these pursuits. From the time of the poet-scholar Philetas, or Philitas (*c.* 330–*c.* 270 BC), the tutor of Ptolemy II, the scholars there were much concerned with the collection and interpretation (*glossae*) of rare poetic words. Philetas' pupil Zenodotus of Ephesus (*c.* 325–260 BC) was the first librarian at Alexandria; using the manuscripts collected for the Library but also trusting to his own judgment, sometimes in a manner that seemed to later critics dangerously subjective, he made the first critical edition of Homer, marking passages of doubtful authenticity with critical signs in the margins. Zenodotus also edited Pindar and Anacreon and perhaps other lyric poets; at about the same time the epic and elegiac poet Alexander Aetolus is said to have edited the tragic poets, and the dramatic poet Lycophron the comic poets, but singularly little is known about these editions.

Somewhat later the great poet Callimachus (*c.* 305–*c.* 240 BC) compiled the *Pinakes* ("Tablets"), a vast catalogue raisonné of the chief authors, with biographical and bibliographical information. Callimachus is said to have written a book opposing the chief Peripatetic critic of the time, Praxiphanes, and is widely held to have criticized Peripatetic literary theory; but the scantiness of the evidence for this enjoins great caution.

Rather later the great geographer and mathematician Eratosthenes (*c.* 276–*c.* 194 BC), the third librarian, laid the foundations of a systematic chronography; more of his work would be known had it not been largely superseded in popular use by the 2nd-century chronicles of Apollodorus of Athens, which were a learned compilation but left out the important scientific and mathematical part.

Zenodotus' editions of Homer and Hesiod were improved upon by the fourth librarian, Aristophanes of Byzantium (*c.* 257–180 BC), who also edited the lyric poets, setting out their verses according to a systematic metrical theory; edited Aristophanes, Menander, and perhaps other comic poets; edited Sophocles and at least part of Euripides; and compiled useful summaries of the plots of plays with details of their productions. His *Lexeis* ("Readings") was the most important of the numerous lexicographical works produced at this time, which included lexicons of particular authors and dialects; he also wrote some of the many treatises about literature that were now appearing.

Aristarchus of Samothrace (*c.* 217–145 BC), the sixth librarian, wrote not only monographs about poetry but also important commentaries on Homer, Pindar, and much of tragedy and comedy. Aristarchus was one of the many learned men who left Alexandria in consequence of the disastrous persecution of learning by Ptolemy VIII, from which that city's standing as a great centre of learning never quite recovered. (The great library survived a fire set in Alexandria in 47 BC by Julius Caesar, whose army supported Cleopatra in a civil war. It was finally destroyed in AD 391 by the patriarch Theophilus of Alexandria.)

During the 3rd century BC the Stoics, particularly Chrysippus (*c.* 280–*c.* 206 BC), made important contributions to the study of grammar, linked with the development of Stoic logic. Early in that century the Stoic Crates of Mallus emigrated to the court of King Eumenes II of Pergamum, which the Attalid dynasty had begun to make into a literary centre comparable with, though hardly equal to, Alexandria. Crates probably wrote commentaries on the *Iliad* and the *Odyssey,* characterized by the allegorical interpretation, faith in the accuracy of Homer's geography, and grammatical rigour typical of the Stoic school. Under Stoic influence the Pergamenes tended to stress the element of anomaly in grammar, while the Alexandrians stressed the element of analogy; that is, the Alexandrians insisted on the natural, inherent orderliness of grammar, while the Pergamenes approached the subject as empiricists, being content to organize observations of actual usage into a body of knowledge. But the details of the alleged controversy over this matter are obscure and known largely from suspiciously late sources. If the extant grammar ascribed to Dionysius Thrax, a pupil of Aristarchus active about 120 BC, is genuine, then the Alexandrian school of grammar was by that time already considerably influenced by the Stoics.

During the 1st century BC, by which time Rome was beginning to be the chief centre of Greek scholarship, Philoxenus wrote on Greek dialects, among which he included Latin; he was the first scholar to be aware of the existence of monosyllabic roots. Under Augustus, Tryphon studied the language of prose and made the first study of syntax, the first vocabulary of the written language, and a classification of the so-called figures of speech. About the same time Didymus, known as Chalcenterus ("Brazen-Gutted"), incorporated into huge variorum editions much of the precious material contained in the many commentaries on literature compiled during the Hellenistic Age. This vastly productive scholar was lacking in critical judgment, but it is on his work that the later less extensive commentaries that in part survive depended. Under Tiberius, Theon studied the Hellenistic poets, as well as Pindar.

The Attic
Revival

The 1st century AD saw the beginning of the "Attic Revival," the movement to imitate the language and style of the classical Athenian writers, which lasted far into the Byzantine period with disastrous effects that have not even yet died away. This resulted in the production of many lexica and manuals meant to help people to write correct Attic, such as the works of Phrynichus, Moeris, and Pollux, all probably dating from the 2nd century AD. At that time much learned work was still being done, but it was becoming increasingly mechanical and repetitive. More and more of the chief writers survived only in selections; texts were being produced, often with commentaries, but these derived mainly from the stores of learning accumulated in the past. However, under Hadrian, Apollonius Dyscolus produced a treatment of syntax that acquired great authority, and his son Herodianus produced the standard treatise on accentuation; they were the last known producers of important original work on grammar.

The rise
of Christianity

Christianity proved less hostile to pagan culture than might have been expected. From the 2nd century on, Church Fathers such as Justin, Clement of Alexandria, and Origen used an impressive knowledge of pagan literature to debate with pagan philosophers on equal terms. Prominent on the pagan side was the Neoplatonist Porphyry (*c.* 234–*c.* 305). Besides his published attacks on Christianity, he wrote commentaries on Plato, Aristotle, Theophrastus, and Plotinus. Even after the triumph of Christianity in 313 under Constantine the Great, pagan and Christian scholars often attended one another's lectures. The pagan Libanius of Antioch, the most celebrated rhetor of the time and author of the surviving hypotheses of the orations of Demosthenes, taught Theodore of Mopsuestia, St. John Chrysostom, and probably also St. Basil and Gregory of Nazianzus. Basil (*c.* 329–379) wrote a treatise on the value of pagan literature in which he recommends at least a passing acquaintance with the pagan classics, but he and the other leading Christian authors of his time possessed a good deal more than this. Theodore (*c.* 350–428/429), bishop of Mopsuestia and leader of the school of Antioch, applied what could be called pagan methods of criticism to the Bible by using his knowledge of history and language to illuminate passages of Scripture. Members of the Christian school of Gaza in the 5th and 6th centuries even wrote dialogues modeled on those of Plato. The school's leading member, Procopius, invented the *catena* ("chain"), a commentary on a book of the Bible consisting of a compilation of excerpts from earlier commentaries—something obviously suggested by the variorum editions of classical authors. Notes based on the learned commentaries of the Hellenistic Age now came to be written into the margins of manuscripts; to these scholia is owed most of what is known of ancient scholarship.

The Neoplatonists of the 5th and 6th centuries produced commentaries on Plato, Aristotle, and other philosophers, thus preserving many priceless fragments of earlier philosophical texts now lost. Grammatical work also continued: Proclus wrote a commentary on Hesiod's *Works and Days;* Hesychius of Alexandria compiled a Greek lexicon that preserved vocabulary from the Homeric age up to his own time; and Orus contributed to the work on Greek orthography. Education even received some government support; the 4th-century rhetor Themistius described a plan for the creation of a government scriptorium to ensure the survival of important writers, and some 50 years later, in 425, Emperor Theodosius II is said to have set up a university at Constantinople.

The age of Justinian I (527–565) produced the antiquarian works of Johannes Lydus and the geographical gazetteer of Stephanus of Byzantium. The historians of that era, Procopius and Agathias, wrote in the classical tradition of historiography, publishing chronicles of warfare that weighed the influences on historical events of fate and divine retribution. But in 529 Justinian issued an edict closing the schools of pagan philosophy; some philosophical activity continued after that, but the edict marked an era of Christian intolerance of pagan scholarship. During the 7th century the Arab conquests cut off Syria, Palestine, and Egypt from Greek civilization. The Arab threat forced the Byzantine Empire to submit to the rule of vigorous but not well-educated emperors, some of whom were religious fundamentalists opposed to the use of images, or icons, which was a central feature of worship in the Eastern Church. The resulting Iconoclastic Controversy was a major factor in the creation of a dark age of Byzantine culture that lasted from about the middle of the 7th until the beginning of the 9th century.

The first Byzantine renaissance. The dark age was not completely dark. It saw, for example, the extensive but exceedingly uninspired work of the grammarians Georgius Choeroboscus, active during the second half of the 8th century, and Theognostus, early in the 9th century, as well as the letters of the deacon Ignatius with their surprising wealth of literary allusions. Also, certain developments that occurred at this time were important for the future. In about 800, paper was acquired from the Arabs, who are said to have learned how to make it from Chinese prisoners taken in a battle at Samarkand. It came into general use only very gradually; the Byzantines continued to import it from the Arabs instead of making their own, but since it was less expensive than papyrus, its effect was bound to be important. The Italians acquired it from the Byzantines, and by the 13th century they had developed a flourishing paper industry. From about the same time must date the invention of a new cursive script, the Byzantine minuscule, which was in its early forms the most elegant that the Greeks ever invented. The earliest surviving specimen, the Uspenskij Gospel, dates from 835, but this displays such accomplished writing that the new script probably originated some 50 years earlier. The invention greatly facilitated the rapid production of books. The Stoudion monastery in Constantinople, which flourished under its great abbot St. Theodore (759–826), was once thought to have introduced the new script—and indeed the monastery had a flourishing scriptorium—but this conjecture is by no means certain. During the 9th and 10th centuries the works of many classical authors were transferred from manuscripts in the old uncial writing to the new minuscule, and the surviving books of this period show that script in its most perfect form. Later the elegance of minuscule was spoiled by the admixture of uncial letters and the increasing use of ligatures.

Byzantine minuscule script

The first important scholar of the first Byzantine renaissance was Leo the Philosopher (*c.* 790–*c.* 869), a notable teacher in Constantinople who numbered among his pupils St. Cyril, one of the apostles of the Slavs; Leo had considerable knowledge of Greek culture, particularly of science and mathematics. But the dominant figure in the revival of the 9th century was the patriarch Photius (*c.* 820–891?), who not only compiled a notable Greek lexicon but also produced the *Myriobiblon,* or *Bibliotheca,* a vast collection of summaries and evaluations of various ancient books, mainly historical. Photius also compiled a learned miscellany called the *Amphilochia* and an interesting collection of letters. Arethas (born *c.* 850), archbishop of Caesarea Cappadociae, owned a remarkable private library, from which eight priceless books, commissioned from the finest calligraphers of the time, survive; Euclid, Plato, Aristotle, Lucian, and Aristides are among them. Other valuable classical manuscripts still extant formed part of his collection.

During the 10th century education was encouraged by the learned emperor Constantine VII Porphyrogenitus (905–959), who apart from producing his own series of historical works preserved several histories by others and planned a vast 53-section encyclopaedia of human activities that was probably never completed. The 10th century also saw the production of a large encyclopaedia cum dictionary, formerly thought to have been the work of one Suidas, but now known to have been called the *Suda,* from a Byzantine Greek word for fortress. Platonism was actively studied by the chief intellectual figure of the 11th century, Michael Psellus (1018–*c.* 1078). His numerous writings show a wide acquaintance with classical culture, though also a very imperfect sympathy with some of its elements. His pupil, John Italus, was anathematized by the ecclesiastical authorities for allowing Platonism to contaminate his Christianity. But Platonic studies continued, and Isaac Sebastocrator, a brother or son of the emperor Alexius I Comnenus, wrote three essays based on Proclus. Early in the 12th century Alexius' daughter, Anna Comnena, was the centre of a circle of Aristotelian scholars, including Michael of Ephesus and Eustratius, who together produced a commentary on the *Ethics.* Gregory of Corinth, active during the same period, wrote works on syntax and style and also one of the few ancient treatments of the Greek dialects that have come down to the present. John Tzetzes wrote some 60 books on Greek literature that are learned but uncritical, and Eustathius of Thessalonica wrote vast commentaries on the *Iliad* and *Odyssey* that incorporate much earlier learning.

Losses during the Fourth Crusade

This epoch of Byzantine learning was rudely put to an end when the knights of the Fourth Crusade, under Venetian leadership, sacked Constantinople in 1204. It may well be argued that this event was an even greater disaster for learning than the Turkish capture of the city in 1453, for which the crusaders paved the way. The sack of the city destroyed a quantity of Greek literature that is difficult to estimate; certainly included among the lost works were the *Aitia* and *Hekale* of Callimachus, which were known to Michael Choniates, archbishop of Athens at the time of the Crusade.

The second Byzantine renaissance. Between 1204, when the imperial capital was moved to Nicaea, and 1261, when Constantinople was recovered by the Palaeologus dynasty, classical studies continued under the difficult conditions outlined in the autobiography of Nicephorus Blemmydes, the leading intellectual of the time. The emperor Theodore II Lascaris (reigned 1254–58) did much to assist cultural life during this time. The period sometimes called the Palaeologan Renaissance saw a revival of classical studies that, under the circumstances, must be called remarkable. Maximus Planudes (1260–*c.* 1310) made many compilations, including a new anthology of epigrams, and even translated into Greek such Latin texts as parts of Ovid, Augustine, and Boethius. He also had some knowledge of Hellenistic poetry and even Arab astronomy and mathematics. From about 1300 the texts of the Greek dramatists were studied critically by Manuel Moschopoulos, Thomas Magister, and finally Demetrius Triclinius. Triclinius had read the metrical handbook of the 2nd-century scholar Hephaestion and understood the simpler metres, and he was also aware of the principle of strophic responsion. He was therefore able to make a number of emendations worthy of serious notice. Theodore Metochites (*c.* 1260–1332), one of the leading intellectuals and public men of his time, commented on Aristotle and wrote a miscellany that contains interesting reflections upon classical authors, especially orators and historians.

Greek in the West. During the 3rd and 4th centuries the knowledge of Greek in the West died out with shocking suddenness; Augustine had only a rudimentary knowledge of the Greek language, and translators such as Jerome (*c.* 347–419/420) and Rufinus (*c.* 345–410/411) were scarce indeed. The few Greek studies were undertaken for the sake of theology or philosophy, and translation of secular authors was rare; Calcidius' (Chalcidius') 4th-century version of the *Timaeus* was for eight centuries the only Latin translation of a Platonic dialogue, Boethius' plan for a series of translations of Plato and Aristotle being interrupted by his execution. Sicily remained Byzantine until the Arab conquest of the 9th century, and Calabria, Lucania, and Apulia (Puglia) until the Norman conquest of the 11th century. The Normans and later the Hohenstaufen rulers favoured Greek studies. In the 12th century Greek, too, benefited from the intellectual revival; Henricus Aristippus, archdeacon of Catania, translated Plato's *Meno* and *Phaedo,* and the admiral Eugenius collaborated in a Latin version of the *Almagest,* an encyclopaedia compiled by the astronomer Ptolemy of Alexandria in the 2nd century AD. Also during the 12th century two Italian scholars, James of Venice and Burgundio of Pisa, traveled to Constantinople in search of theological and philosophical learning; Burgundio brought back literary as well as theo-

Aristotelian revival

logical manuscripts, though he was probably incapable of reading them. The Aristotelian revival of the 13th century led to the production of many translations of Aristotle by William of Moerbeke in Rome, and in England Aristotle was read in the original by Robert Grosseteste and Roger Bacon. During the 14th century contact between Rome and Constantinople was continued; Petrarch (see below *Latin scholarship*) acquired a Byzantine manuscript of Homer, though he never made the effort to enable himself to read it, and later in the century another such manuscript was in the hands of the humanists of Padua. In about 1397 the Byzantine scholar Manuel Chrysoloras went to Italy to teach Greek in Florence. At the Council of Ferrara-Florence in 1438–45 the union of the churches was agreed upon, but it was later repudiated. George Gemistus Plethon (*c.* 1355–1450/52), the famous Neoplatonist of Mistra, was present at that council; with him was his pupil John Bessarion of Trebizond (1403–72), who continued to support church union as an individual, so that when the repudiation took place he converted to the Western church. He stayed behind in Italy, became a cardinal, and made an important gift of books to Venice. Early in the 15th century Italians such as Francesco Filelfo and Giovanni Aurispa were bringing back Greek manuscripts from Constantinople in large quantities, so that well before the capture of Constantinople by the Turks in 1453 many Greek books had found their way to the West.

Latin scholarship. *Republic and early empire.* From the beginning, Roman scholarship imitated Greek: Hellenistic techniques were applied to the treatment of Latin texts, and Latin grammar adopted Greek categories and terminology. Learned Greeks such as Tyrannion, Alexander Polyhistor, and Parthenius were brought to Rome as prisoners in the Mithradatic Wars. Even before that, as early as about 100 BC, the Roman knight Lucius Aelius Stilo Praeconinus had been teaching and writing about Latin grammar. Marcus Terentius Varro (116–27 BC) by his vast learning and prodigious output influenced almost every branch of scholarship; of his 25 books about the Latin language, books V to X survive in nearly complete form. In scholarship as in other matters the early imperial period was one of great achievement. It was the age of commentators such as Gaius Julius Hyginus, who was in charge of the Palatine Library in Rome founded by Augustus; of editors such as Marcus Valerius Probus (*c.* AD 20–105), who made critical editions of Plautus, Terence, Lucretius, Virgil, and Horace; of grammarians such as Verrius Flaccus, the author of a vast work on the meaning of words; of the elder Pliny (AD 23/24–79), whose encyclopaedic *Historia naturalis* (*Natural History*) was a major sourcebook during the Middle Ages; of Gaius Suetonius Tranquillus (*c.* AD 69–after 122), who wrote the lives of poets and grammarians as well as of emperors; and of Aulus Gellius, whose miscellany called *Noctes Atticae* preserved much ancient learning.

Later empire. The barbarian invasions of the 3rd century marked the beginning of a testing time for Latin as well as for Greek scholarship, and the scholars of the 4th and 5th centuries—such as Aelius Donatus, the grammarian and teacher of rhetoric; Servius, the learned commentator on Virgil; Priscian, the Greek author of the most famous Latin grammar of antiquity; and Macrobius, who during the first half of the 5th century wrote the learned miscellany called *Saturnalia*—were epitomizers and compilers living on inherited capital. In the Western Empire the knowledge of Greek was practically extinct, and the earlier literature of Rome itself was threatened with extinction. The classics were still the staple of such education as there was, but the dominance of rhetoric favoured only certain authors; classical poets such as Virgil, Horace, Ovid, and Terence were protected by critics and commentators, but among earlier authors Ennius and Lucilius disappeared and Plautus narrowly escaped. The book, in the form of the vellum or parchment codex, was superseding the papyrus roll, and authors who were not recopied were doomed to oblivion.

The dominance of rhetoric

The early Middle Ages. The period during which the Merovingian dynasty founded by Clovis (*c.* 466–511) was in power was a dark age for learning, but there was no complete breach with the past. Under the influence of the church the barbarian invaders wished to base their civilization on the Latin model, and since it was the language of the church, Latin continued to be the language of literature. Although interest in antiquity for its own sake had little part in the late imperial and early medieval ideal, under the protection of the church learning survived in the medieval schools, and classical texts provided a grounding in grammar, a training in logical thought, and a philosophical premise for theology. Flavius Cassiodorus, a retired statesman who founded a monastery at Vivarium, in southern Italy, sometime after AD 540, encouraged his monks to copy pagan as well as Christian authors, a practice that spread later to other monasteries, particularly those of the Benedictine order. About 563 the Irish missionary Columba (*c.* 521–597) founded a church and monastery on the island of Iona in the Inner Hebrides of Scotland, and soon afterward Irish missionaries converted the whole of Scotland and established monasteries in the north of England. Later Irish missions led by Columban (*c.* 543–615) founded Luxovium (Luxeuil) in the Vosges Mountains of Gaul (590), Bobbio on the Trebbia (*c.* 612–614), and St. Gall in Switzerland; Corbie near Amiens was founded from Luxovium a century later, and these monasteries played a leading role in the preservation of ancient literature. In England, Aldhelm (*c.* 639–709) and Bede (672/673–735) were men of considerable learning. At this time learning was also alive in Visigothic Spain, as is shown by the vast encyclopaedia of Isidore of Seville (*c.* 560–636), which was of great importance for the remainder of the Middle Ages. During the late 7th and 8th centuries the successors of Columban converted first the Frisians and then much of Germany; they founded the important monasteries of Fulda (744), Lorsch, in Hesse (764), and Hersfeld (*c.* 770), while Reichenau, on Lake Constance (724), and nearby Murbach (727) were founded by a refugee from Visigothic Spain.

Christianization of the British Isles

The Carolingian Renaissance. Pepin III the Short (reigned 751–768) began ecclesiastical reforms that Charlemagne continued, and these led to revived interest in classical literature. Charlemagne appointed as head of the cathedral school at Aachen the distinguished scholar and poet Alcuin of York, who had a powerful influence on education in the empire. Many ancient texts were now copied into the new Carolingian minuscule, and the palace library allowed its books to be copied for other libraries, so that learning was rapidly diffused. Latin poetry of some merit was composed at and about the imperial court, and Einhard's life of Charlemagne (probably written *c.* 830–833) is modeled on the biographies of Suetonius. Learned work was resumed, and the historian Paul the Deacon (Paulus Diaconus) abridged the abridgement of the lexicon of Verrius Flaccus that had been made by Festus during the 2nd century AD. The nearest approach in the Middle Ages to a humanistic scholar was Servatus Lupus, abbot of Ferrières (*c.* 805–862), who collected, copied, and excerpted ancient manuscripts on a large scale. Despite the splitting up of the Carolingian Empire in 843 and the troubles resulting from the barbarian attacks on Europe of the 9th and 10th centuries, the educational apparatus created by the so-called Carolingian Renaissance provided enough momentum to keep the classical tradition going until a new impulse arrived to carry it on to fresh developments.

Carolingian minuscule

12th-century renaissance

The later Middle Ages. A renewed period of intellectual activity in the ancient Benedictine foundation of Monte Cassino heralded the renaissance of the 12th century. Dante Alighieri (1265–1321) was familiar not only with Virgil but also with Lucan, Statius, and Ovid, and *The Divine Comedy*'s picture of the cosmos is deeply indebted to Aristotle's *On the Heavens.* William of Malmesbury (died *c.* 1143) and John of Salisbury (1115/20–1180) were considerable Latin scholars. During the 13th century a group of scholars in Padua around Lovato Lovati (1241–1309) and Albertino Mussato (1261–1329) were active humanists. Lovato read Lucretius and Catullus, studied Seneca's tragedies in the famous *Codex Etruscus,* and found and read some of the lost books of Livy. Both men wrote Latin poetry, Mussato composing a Senecan tragedy, the *Ecerinis,* designed to open the eyes of the Paduans to the danger presented by Cangrande della Scala, the tyrant of Verona, by describing the tyrannical conduct of their own former despot, Ezzelino III.

THE REVIVAL OF LEARNING

Renaissance humanism. The humanist movement was consolidated by the generation of Petrarch (Francesco Petrarca; 1304–74). Petrarch actively looked for manuscripts, building up what was for his day a remarkable library, and taught himself to write an elegant classicizing Latin very different from what had been customary during the Middle Ages. Like Politian later, he was a great poet in Italian; but he valued far more than his vernacular poetry his Latin epic *Africa,* a skillful imitation of the Roman poets. Like almost everyone before Politian, Petrarch knew little or no Greek (on the manuscript of Homer that he possessed, see above, *Greek in the West*). Giovanni Boccaccio (1313–75) also looked actively for ancient manuscripts and actively forwarded the aims of humanism.

The age of Petrarch

The revival of classical learning that Petrarch and Boccaccio promoted was only one aspect of the complex phenomenon of the Renaissance. In origin the movement was utilitarian, seeking to exploit classical antiquity in the service of modern man; the early Italian humanists were not scholars so much as *litterati* and educators, and it is a mistake to think that they were pagans. The earlier idea that the invention of printing was an effective agent in the revival is also erroneous; for by 1470, when the first editions of the Latin classics were quickly coming off the presses, the Renaissance was already well past its early stages. Thus, although Greek teachers and Greek manuscripts had long before begun to enter Italy, the advanced study of Greek, apart from the activities of an isolated genius like Politian, made little headway before the 16th century. The early humanists saw that the manuscripts they discovered contained many corruptions and enjoyed trying to emend them, but many of their conjectures were frivolous, and they often omitted to mark them as conjectures, a practice that irritated later scholars.

Petrarch's successor as the leader of the humanist movement was Coluccio Salutati (1331–1406), chancellor of Florence, who acquired many manuscripts and built up a splendid library; it was he who invited Chrysoloras to Florence. A later chancellor, Leonardo Bruni (*c.* 1370–1444), translated into Latin Plutarch, Xenophon, six dialogues of Plato, and Aristotle's *Ethics* and *Politics.* Poggio Bracciolini (1380–1459) was the most active and the most successful hunter of manuscripts, traveling to France, Germany, and even England in pursuit of them. The same period saw the beginning of the study of the ancient monuments of Italy and the collection of coins and inscriptions as well as works of art by scholars such as Flavio Biondo (Flavius Blondus; 1392–1463) and later Pomponius Laetus (1428–97). Cyriacus of Ancona (1391–1452) broke new ground by traveling to the countries of the Turkish Empire, where he drew monuments and copied inscriptions, thus providing the only record of many objects that were later lost.

Beginnings of modern scholarship. What may be called professional standards of scholarship are seen first in the work of Lorenzo Valla (1407–57) and Politian (Angelo Poliziano; 1454–94). Valla in his *Elegantiae* demonstrated the technique of pure and elegant classical Latin, free of medieval awkwardness; when Pope Nicholas V ordered the chief Greek prose writers to be translated into Latin, Valla was responsible for Thucydides. He also translated part of the *Iliad* into Latin prose. In his philosophical works, which include treatises on pleasure and on free will, he was the first modern to throw light on Epicurus. Gifted with the historical sense of the true critic, Valla perceived the spuriousness of several famous documents: a treatise forged in the name of Dionysius the Areopagite, the New Testament convert of St. Paul, by a later writer now called Pseudo-Dionysius; a collection of letters supposedly exchanged by St. Paul and the 1st-century-AD Roman philosopher Seneca; and the so-called Donation of Constantine, by which the emperor Constantine the Great was alleged to have granted to the papacy spiritual and temporal dominion over Rome and the West.

Politian

Politian, like Petrarch a great poet in the vernacular, began studying Greek at the age of 10 and attained a better knowledge of it than any modern to that date; in his collection of notes called *Miscellanea,* the second volume of which was unfortunately lost and was published only in 1972, he threw light on a variety of ancient writers, including even Greek poets of the Hellenistic Age.

By 1500 most of the chief Latin authors were in print. In that year Aldus Manutius (1449–1515) founded in Venice his "Neacademia" (or Aldine Academy), dedicated to, among other things, the issuing of large and relatively cheap editions of ancient authors. Working in conjunction with the learned Cretan Marcus Musurus (1470–1517), he brought out in 21 years 27 editiones principes (first editions) of Greek authors, including five in the year 1502 alone. During the century that followed, the book evolved from what was essentially an expensive facsimile of a medieval manuscript into a working tool for scholars. Other printers, such as the Giunta family in Florence, followed Aldus' example, and Zacharias Callierges in Rome brought out the first printed texts of Pindar, Callimachus, and the Homeric scholia. Aldus' son Paulus Manutius (1512–74) carried on his father's business and did much for the texts of Cicero. Petrus Victorius (1499–1585) was the leading Italian scholar of his time, editing Aeschylus and Euripides and writing commentaries on Aristotle's *Rhetoric, Poetics, Politics,* and *Nichomachean Ethics,* as well as editing other Greek texts and doing important work on Cicero; he concentrated on producing careful editions of the best manuscripts available, in a reaction against the excessive emendation of earlier scholars. Francesco Robortello (1516–67) also did important work on Aeschylus and Aristotle's *Poetics.* Fulvius Ursinus (1529–1600) built up the Farnese library in Rome, edited the Greek lyric poets, and made important contributions to numismatics and iconography. Carolus Sigonius (1523–84) and Pirro Ligorio (*c.* 1510–83) were active in the field of history and antiquities, Ligorio producing much genuine material besides his notorious forgeries. But after the 16th century, the atmosphere of the Counter-Reformation was not favourable to disinterested inquiry, and Italian scholarship declined. The Jesuits in their educational activities made use of the forms of humanism while abolishing its content.

Advancement of the book

The Renaissance outside Italy. In Spain the Renaissance had made a promising beginning; Antonio of Nebrija (1444–1522) anticipated Erasmus in showing that the Greek language had been pronounced by the ancients differently from the modern Greeks, and later Antonio Agostino, archbishop of Tarragona (1517–86), did important work on ancient law and numismatics. But the Spanish Renaissance was frozen by the Counter-Reformation.

During the late 15th and early 16th centuries the new learning began to establish itself north of the Alps. William Grocyn, who had studied in Italy, was probably the first man to teach Greek in an English university; he was friendly with John Colet and Thomas More, both of England, and later with the Dutch humanist Desiderius Erasmus. Thomas Linacre, later an eminent physician, studied Greek in Italy under Politian; on his return to England he gave lectures at which More was present.

The Northern Renaissance

Erasmus (*c.* 1466–1536), the first editor of the New Testament, was more concerned with biblical and patristic studies than with the Greek and Latin classics for their own sake. Yet his *philosophia Christi,* an attempt to mediate between ancient wisdom and Christian faith, was closely linked with classical scholarship, and he found time to produce numerous editions and translations of Greek and Latin authors, besides making such contributions to scholarship as his famous collection of proverbs, the *Adagia.* The *Utopia* of his English friend Thomas More was profoundly influenced by Platonism. Erasmus' pupil Beatus Rhenanus was one of a group of German scholars who brought out important editions of Latin texts. Philipp Melanchthon (1497–1560) actively promoted scholarship in Germany; his associate Joachim Camerarius (1500–74) did much for Plautus, as did Hieronymus Wolf (1516–80) for the Attic orators.

Erasmus formed a close connection with the great printer of Basel, Johannes Froben. Amerbach, Cratander, and Hervagius were other notable printers of that city, active in the production of critical editions of ancient texts.

Obliged as they were to concede primacy in Latin studies to the Italians, the French during the 16th century took the lead in Greek, although Denis Lambin (Lambinus; 1516–72) did valuable work on Cicero, Lucretius, and Horace. Guillaume Budé (Budaeus; 1467–1540) laid the foundations in Greek studies, and Jean Dorat (Auratus; 1508–88) and Adrien de Tournebu (Turnebus; 1512–65), pioneers in the study of Greek poetry, inspired the contemporary poets Ronsard and du Bellay, the leaders of the Pléiade group, with admiration for Greek literature. The great printer Robert Estienne (Stephanus; 1503–59) produced the first critical edition of the Greek New Testament (1551), reprinting Erasmus' text but adding variants from 15 manuscripts. Estienne's son, Henri, published many editiones principes of Greek authors and a Greek *Thesaurus* (1572) not superseded until the early 19th century.

Scaliger and Casaubon

Two French scholars—Joseph Justus Scaliger (1540–1609) and Isaac Casaubon (1559–1614)—deserve particular mention. Like Erasmus, Scaliger saw that classical learning should be a unity. His diversity was that of the explorer, not the dilettante; each edition opened up a new path: that of Festus (1575) to Old Latin, that of Manilius' *Astronomica* (1579) to ancient astronomy, for example. He assisted Janus Gruterus (1560–1627) by compiling the indexes to his famous *Inscriptiones antiquae totius orbis Romani* and encouraged the collection of the fragments of classical literature. But his greatest achievement was to bring order into the chaos of ancient chronology in his *De emendatione temporum* (1583) and *Thesaurus temporum* (1606).

Casaubon, too, perceived that antiquity must be studied as a whole and also (and this too Erasmus understood) that the study must begin from Greek. Through his series of detailed commentaries on difficult and prolific authors (Strabo, Athenaeus, Polybius), he was instrumental in turning scholarship—hitherto an art—into a science.

Henri Estienne, Scaliger, and Casaubon were all Huguenots, and all died in exile—Estienne in Lyon, Scaliger in Leiden, and Casaubon in London. Another eminent Huguenot scholar of the time, Marcus Antonius Muretus (Marc-Antoine de Muret; 1526–85), the most elegant writer of Ciceronian Latin since Cicero, who defended the practice of emendation against the cautious Victorius, left France when accused of homosexuality, became a Catholic, and enjoyed great success in Rome.

Development of paleography

Scholarship in the 17th century. After the conversion of Henri IV to Roman Catholicism French scholarship declined, as Italian scholarship declined during the age of the Counter-Reformation. But the action of the Jesuits in challenging the authenticity on which the privileges of the Benedictines depended caused the latter to turn to the study of paleography in order to defend themselves, thus occasioning the chief contribution of France to classical studies during the 17th century. Jean Mabillon (1632–1707) established Latin paleography as a modern science, and another inmate of the monastery of St. Germain-des-Prés, Bernard de Montfaucon (1655–1741), did the same for Greek paleography. This kind of work was continued by the great antiquarians of the following century, notably L.A. Muratori (1672–1750) and Scipione Maffei (1675–1755).

As scholarship declined in France (where the series of Delphin Classics supervised by Pierre-Daniel Huet from 1670 to 1680 marks the summit of strictly classical achievement), so it rose and flourished in the Netherlands. Christophe Plantin had founded his great press in Antwerp in 1550 and the Elzevirs theirs in Leiden in 1580 and later in Amsterdam. Scaliger ended his days in the newly founded State University of Leiden. Justus Lipsius (1547–1606) produced important editions of Tacitus and Seneca, at the same time promoting a new Christian Stoicism. The great jurist Hugo Grotius (1583–1645), in many ways the true successor of Erasmus, did brilliant work in classical studies as well as in many other fields. Nicolas Heinsius (1620–81) produced editions, based on extensive study of manuscripts, that earned him the title "saviour of the Latin poets." His counterpart in prose, John Gronovius (1611–71), produced editions of Livy, Seneca, Pliny, and others. The letters of Heinsius and Gronovius testify to as ample a conception of classical studies as that of Scaliger and Casaubon.

Impact of the Thirty Years' War

The Thirty Years' War (1618–48) had a disastrous effect on scholarship. Among the classicists in Holland and Germany, stagnation set in; unwieldy, uncritical variorum editions became the fashion, and the collection of "antiquities," divorced from linguistic study and from critical scholarship, degenerated into the mere piling up of information.

The 18th century: the age of Bentley. Since the late 16th century little had been heard of English scholarship; once the study of Greek had been established by Linacre, Grocyn, Sir John Cheke, and their contemporaries, the English preoccupation with education had set in. John Selden is the most notable of few exceptions, and he was a jurist and antiquary, not an academic, though his *De Diis Syris* (1617) laid the foundations of Eastern scholarship. A new era began with the *Epistola ad Joannum Millium* (1691) of Richard Bentley (1662–1742). This collection of brilliant miscellaneous observations, prompted by the editio princeps of the 6th-century Byzantine chronicle of John Malalas, displayed already the comprehensive learning and rare power of divination that were to enable Bentley to lay the foundations of the critical scholarship of the coming age. Although his achievements in textual criticism were singularly brilliant, Bentley must not be thought of as a mere editor of texts but as the creator of a critical method that was to be applied with powerful effect in every department of antiquity. This is in evidence above all in his *Dissertation upon the Epistles of Phalaris* (expanded edition, 1699), the first important work of classical scholarship written in a modern language. His editions of Horace (1711), Terence (1726), and Manilius (1739) were all of masterly quality. He did remarkable work in collecting fragments of Menander and Callimachus, and although he never completed his proposed editions of Homer and the New Testament, the preparatory work he did toward them had a revolutionary effect in both fields of study.

After Bentley's death the only part of his inheritance taken up by his countrymen was his work in textual criticism. The work of his English contemporaries in this field, who include such important scholars as Jeremiah Markland (1693–1776), Thomas Tyrwhitt (1730–86), Benjamin Heath (1704–66), and Samuel Musgrave (1732–80), was carried further by the next generation. Richard Porson (1759–1808), Peter Elmsley (1773–1825), and P.P. Dobree (1782–1825) all concentrated upon Attic drama, Porson showing a particularly fine feeling for Greek.

Edward Gibbon

In 1786 Sir William Jones (1746–94) began the study of Sanskrit that was to lead to the establishment of the new discipline of comparative philology. Edward Gibbon (1737–94), essentially self-educated despite his early residence at Magdalen College, Oxford, made with *The History of the Decline and Fall of the Roman Empire* (1776–88) the greatest single contribution to the study of ancient history in the whole 18th century. The *Essay on the Original Genius of Homer* by Robert Wood (*c.* 1717–71), printed privately in 1767 and published posthumously in 1775, not only marked a new stage in Homeric studies but also assisted the movement toward exploration of ancient sites in Greece. Exploration was powerfully promoted by the publications in London of the Society of Dilettanti, especially the drawings in *The Antiquities of Athens* (four volumes, 1762–1808), by James Stuart and Nicholas Revett.

Meanwhile in the Netherlands, where Bentley's greatness had at once been recognized, a distinguished series of scholars—Tiberius Hemsterhuys (1685–1766), L.K. Valckenaer (1715–85), the German emigrant David Ruhnken (1723–98), and, later, Daniel Wyttenbach (1746–1820)—continued to do valuable work on Greek texts, including the difficult but rewarding remains of ancient lexicography. Bibliographical works and dictionaries were now improved; Johann Albert Fabricius (1668–1736) put the bibliography of Greek and then Latin literature on a new footing, and Egidio Forcellini in Padua superseded the

Latin thesaurus of Robert Estienne. The study of ancient coins was greatly advanced by the work of the Swiss-born scholar Ezechiel Spanheim (1629–1710) and the Austrian scholar J.H. Eckhel (1737–98).

In archaeology the 18th century saw the beginning of the excavation of Herculaneum and Pompeii and of exploration of the remains of the Etruscan civilization. Historical source criticism (*Quellenkritik*) began in the work of the German historian Barthold Niebuhr (1776–1831). But technical progress was not enough. A new spirit was needed to arouse classical studies to take their place in the modern world, and it came from Germany.

MODERN CLASSICAL SCHOLARSHIP

The new German humanism. The "new humanism" that transformed German intellectual life in the late 18th century was a complex phenomenon, acting through scholarship, education, philosophy, and literature. Educationally the University of Göttingen played a leading part: there J.M. Gesner (1691–1761) and C.G. Heyne (1729–1812) introduced a new approach—an attempt to enter into the spirit of the past as displayed in its artistic monuments as well as in its literature. J.J. Winckelmann (1717–68) was the first to mark out the successive periods into which the history of Greek art falls. He was also the first to isolate and describe the essentially Hellenic element in Greek art and to relate the development of art in antiquity to other aspects of culture. He demonstrated that a large number of vases then known as Etruscan because they had been found in Etruscan cemeteries were in fact Greek, although the original error was to be perpetuated by Josiah Wedgwood, who named his pottery works "Etruria" in 1769. Winckelmann's influence ranged over the literary as well as the academic world, powerfully affecting such figures as Lessing, Herder, and Goethe, who named the memorial essay that he published in 1805 *Winckelmann und sein Jahrhundert* ("Winckelmann and His Century"). Goethe (1749–1832) made a systematic effort to know and understand Greek art and literature, particularly Greek sculpture and the poetry of Homer, and to utilize them for his own purposes; it may be doubted whether anyone since ancient times had understood the Greeks so well. He was a friend of Wilhelm von Humboldt (1767–1835), the great statesman and pioneer of the study of language who founded Frederick William University (later the University of Berlin), which rapidly became the leading university of Europe.

The achievement of Goethe

Goethe was also in touch with F.A. Wolf (1759–1824), a Göttingen pupil of Heyne. Wolf defined the "science of antiquity" (*Altertumswissenschaft*) and mapped out its constituent provinces and principles. Influenced by Herder, with his special interest in the early literatures of various peoples and their special characteristics, Wolf in his *Prolegomena ad Homerum* (1795) raised such questions about Homer as to give rise to a debate that has continued ever since. Goethe was at first carried away by Wolf's theory that the *Iliad* and *Odyssey* were composed orally by a number of authors and that the artistic unity of the poems was a later imposition, but he eventually returned to his belief in an individual Homer, as scholars have done increasingly in the 20th century.

Another great classical scholar in close touch with Goethe was Gottfried Hermann (1772–1848), who continued the tradition of 18th-century rationalism, applying to the study of ancient poetry a critical method based on a strict Kantian logic. Hermann did much to advance the study of Homer, Pindar, late epic poetry, and Greek metre. By his editions of Sophocles, Aeschylus, and part of Euripides he effected a great and permanent improvement in the texts of these poets.

Hermann had many distinguished pupils, including C.A. Lobeck (1781–1860), a grammarian of great learning and acuteness, who in his famous book *Aglaophamus* (1829) refuted the seductive but dubious theory of the Heidelberg professor G.F. Creuzer that the mythology of Homer and Hesiod contained symbolic elements of an ancient Oriental revelation from which it was ultimately derived. August Meineke (1790–1870) did important work on Hellenistic poetry and produced an excellent edition of the fragments of Greek comedy. August Immanuel Bekker (1785–1871), a pupil of Wolf, took advantage of the accumulation in Paris of many previously inaccessible manuscripts from various countries following the Napoleonic conquests to make a valuable contribution to the texts of many prose authors. Wilhelm Dindorf (1802–83) edited many texts, including the scholia on Rome and on Demosthenes. With his brother Ludwig and K.B. Hase, he revised the great Greek *Thesaurus* of Henri Estienne. Hermann's son-in-law Moritz Haupt (1808–74) did important work on Latin poetry. H.L. Ahrens (1809–81) wrote on the Greek dialects and on the bucolic poets. August Nauck (1822–92), who taught in St. Petersburg, made a notable contribution to the establishment of the texts of Greek tragedy.

The school of Hermann with its strong emphasis on linguistic study came occasionally into conflict with the representatives of a newer trend in the approach to antiquity. In Berlin August Boeckh (1785–1867) did important work on Greek poetry, particularly Pindar, but also established on a firm footing the study of Greek private and public economy and the systematic collection of Greek inscriptions. K.O. Müller (1797–1840), the author of an important history of Greek literature, which first appeared in English, was a pioneer of the study of Greek, Roman, and Etruscan origins and of the mythology of the different parts of Greece, which he believed could shed much light on early history. He was a strong upholder of the importance of art and archaeology in the study of antiquity, as was F.G. Welcker (1784–1868), who applied deep knowledge of Greek art and religion to the interpretation of literature and did much to shape the wider conception of the study of antiquity that was now coming to maturity.

Comparative linguistics

The comparative study of Indo-European languages that was initiated by Franz Bopp (1791–1867), one of the famous scholars who gave the University of Berlin its enviable reputation, profoundly influenced the study of the ancient as well as other languages. One field in which this was seen was the study of early Latin, which was now placed on a new basis by Friedrich Ritschl (1806–76), who applied knowledge gained from the study of inscriptions to the elucidation of early Latin texts. There followed much important work on early Latin, such as that of Johannes Vahlen (1830–1911) on Ennius and that of Otto Ribbeck (1827–98) on Roman tragedy.

The rise of textual criticism. Knowledge of ancient literature must always rest on the standards of editing and criticism of Greek and Latin texts that have come down in a corrupt and sometimes mutilated state. Early in the 19th century great advances were made in this field of classical studies. Angelo Cardinal Mai (1782–1854) published hitherto unknown Greek and Latin texts, including much of Cicero's *De republica,* from newly discovered palimpsests. A.I. Bekker, as well as editing many unknown Greek texts in the Paris collections (see above), was able, by use of newly discovered earlier and better manuscripts, to produce better editions of the classical authors than those then current. But the formulation of a technique of systematic recension (*i.e.,* analysis and evaluation of a manuscript tradition) was gradual, with its roots in the 18th century. Such New Testament scholars as J.A. Bengel (1687–1752) had established the principle that the witnesses to a text must be classified and their testimony evaluated according to their textual genealogy. For a time, the perceived barrier between "sacred" and "profane" texts limited the influence of such work on the analysis of "pagan" sources. During the first half of the 19th century the combined efforts of several scholars, notably Ritschl, Jakob Bernays (1824–81), and the Danish Latinist J.N. Madvig (1804–86), evolved the critical method usually associated with the name of Karl Lachmann (1793–1851) because it is most strikingly exemplified in his edition of Lucretius (1850).

The respect felt for Lachmann by such men as his friend and pupil Moritz Haupt turned into something like critical orthodoxy, however: the new techniques were rigorously applied by less gifted scholars, so that in this department of scholarship some work came to be distinguished by a blind confidence in the so-called scientific method as needing little intelligence in its handling. Madvig had realized the importance, restressed in the mid-20th century, of allowing for inequalities and anomalies in an author's style; but these warnings were lost on those who, exuberantly confident in their own powers, proceeded to wholesale athetesis, or rejection of works as spurious, based on inconsistencies within a text. It was a similarly rigid insistence on analogical methods of criticism that marred the achievements of even such a great critic as the Dutch C.G. Cobet (1813–89) and so set a bad example to lesser scholars.

Developments in the study of ancient history and philosophy. Corresponding progress was made in the field of ancient history. Berthold Niebuhr, the pioneer in historical source criticism, applied a rational skepticism to ancient legends and traditions; he also promoted the collection of Latin inscriptions. J.G. Droysen (1808–84) wrote notable histories of Alexander the Great and of the Hellenistic Age; in fact, the very concept of a Hellenistic Age was his invention. Theodor Mommsen (1817–1903), starting as a professor of Roman law, made vast contributions to almost every branch of Roman studies, but particularly to the history of law and government and of the administration of the Roman provinces. He took a central part in the systematic collection of Latin inscriptions and was familiar with virtually every text and document relevant to Roman history. Mommsen's method of studying an entire civilization had influence on historical studies in general far beyond the limits of ancient history; perhaps the most distinguished of his pupils was the great sociologist Max Weber (1864–1920). In the second half of the century, Eduard Meyer (1855–1930), equipped with wide knowledge of Oriental as well as Greek and Latin sources, wrote an important history of the ancient world. Notable histories of Greece were brought out by Georg Busolt (1850–1920) and Karl Julius Beloch (1854–1929).

Greek philosophy

At the beginning of the 19th century Friedrich Schleiermacher (1768–1834), another of the scholars who gave the University of Berlin its special lustre, revitalized the study of Plato. Eduard Zeller (1814–1908) wrote a history of ancient philosophy that has been several times revised and is still useful. Later Hermann Diels (1848–1922) collected the fragments of pre-Socratic philosophers and of the so-called doxographers who preserved much of the evidence for our knowledge of ancient philosophy. The texts relevant to Epicureanism were edited by Hermann Usener (1834–1905), who employed the new methodology of comparative religion to throw much light on the religion of Greece, not disdaining the study of popular culture and of folklore as well; his work was continued by a line of pupils, and he had an important influence on the great art historian Aby Warburg (1866–1929). Late in the century Erwin Rohde (1845–98) wrote *Psyche,* an important study of Greek beliefs about the soul.

Nations other than Germany made more modest contributions to scholarship, most of them being more concerned with teaching than with research. (For the Italian contribution to papyrology, see below.) The literary scholarship of the French, though elegant and polished, was superficial in comparison with that of the Germans. It is significant that the leading Hellenist of France was the German-born Henri Weil (1818–1909). Great figures were exceptional; among them were J.A. Letronne (1787–1848), an archaeologist and epigraphist, and Paul-Émile Littré (1801–81), the famous lexicographer and positivist philosopher whose remarkable translation of Hippocrates emanated merely as a side interest of his philosophical vocation.

In England a notable contribution to ancient history and to the study of Plato and Aristotle came from the banker George Grote (1794–1871), who saw antiquity from the viewpoint of modern liberalism and utilitarianism. Later in the century the ancient universities produced a few distinguished scholars: H.A.J. Munro (1819–85) did important work on Catullus and Lucretius; Sir Richard Jebb (1841–1905) wrote a good commentary on the newly discovered Bacchylides and also one on Sophocles, which despite some technical deficiencies is still useful because of the author's rare feeling for Greek; and Ingram Bywater (1840–1914) contributed significantly to the study of Aristotle's *Ethics* and *Poetics* and acquired rare knowledge of the history of scholarship.

In the United States the leading figure was B.L. Gildersleeve (1831–1924), who insisted that American classical scholars should aim at the highest European standards. Germany was rightly taken as a model, and valuable work was done, especially in grammar, syntax, and linguistics, by such scholars as W.W. Goodwin (1831–1912), J.W. White (1849–1917), and H.W. Smyth (1857–1937). But too often it was not the admirable qualities of the best German scholars but the dryness, pedantry, and verbosity of the worst that were reproduced. This led to a reaction that went too far in the opposite direction and so did considerable damage. In archaeology, however, the vast resources of America were applied with ever-increasing effectiveness.

Developments in archaeology and art history. The foundation of the Instituto di Correspondenza Archeologica in Rome in 1829 provided an international centre for archaeological studies in Italy, which now progressed rapidly. Eduard Gerhard (1795–1867) founded the study of Greek vase painting as a scientific discipline; his report on the numerous Greek vases excavated from the Etruscan necropolis of Vulci (1831) was epoch-making. In Bonn, Welcker built up the first large collection of plaster casts of Greek sculpture. Another pioneer of the study of Greek art was his colleague Otto Jahn (1813–69), also an excellent Latinist. After the establishment of the Greek kingdom in 1830 the various European nations set up schools in Athens as they had done in Rome, and excavations on a large scale took place not only in Greece but all over the eastern Mediterranean world.

In archaeology the great impetus came from an amateur, Heinrich Schliemann (1822–90), whom no one can deprive of the credit for having guessed that remarkable finds might be made at Troy, Mycenae, and Tiryns, for having deliberately made a fortune so that he might do so, and for having discovered and promoted the great archaeologist Wilhelm Dörpfeld (1853–1940). In 1900 the ancient city of Knossos on Crete was excavated by the English archaeologist Sir Arthur Evans (1851–1941), which enabled the study of Mycenaean civilization to be supplemented by that of Minoan. The French excavated the two great Apollonian shrines at Delos and Delphi.

Papyri had been found in large numbers in the Epicurean library at Herculaneum discovered during the 18th century, and from 1878, when a roll turned up in Egypt, sporadic finds were made. From about the 1870s systematic excavation led to a steady stream of discoveries, mostly from al-Fayyūm, where the sunshine acts upon the soil in such a way as to preserve papyrus. The Italian Amedeo Peyron (1785–1870) was a pioneer in the new discipline of papyrology, as was Domenico Comparetti (1835–1927), the author of a famous book about the fortune of Virgil's works during the Middle Ages. The eminent Italian legal scholar and paleographer Girolamo Vitelli (1849–1935) became an expert papyrologist and had great personal influence. In Germany important papyri were published under the supervision of Wilhelm Schubart with the help of Wilamowitz-Moellendorff. In 1891 the *Constitution of Athens* by Aristotle and the poems of Herodas were published from a papyrus in the British Museum, and in 1897 they were followed by the poems of Bacchylides from the 5th century BC. In 1898 the Oxford scholars B.P. Grenfell and A.S. Hunt brought out the first volume of the series, still not concluded, that contains the texts of the papyri found by them at Oxyrhynchus. Documentary papyri supply useful evidence for law and government in Roman Egypt, and literary papyri supply a priceless supplement to the knowledge of Greek (and occasionally Latin) literature.

The rise of papyrology

The 19th century saw the beginning of many great enterprises, both individual and collective, that have equipped scholars with invaluable tools: collections of fragments, inscriptions, and works of art; and improved dictionaries, special lexica, handbooks, encyclopaedias, and catalogs of manuscripts. The invention of photography made it possible to produce facsimiles of manuscripts and documents and to distribute better likenesses of monuments and works of art. Many of these projects were sponsored by the various national academies, which were now linked by the Association des Académies, the driving force of which was Mommsen.

The rise of professionalism. Associated with Germany was the movement toward what may be called professionalism during the second half of the 19th century. Though Wolf's example in founding a classical periodical in the vernacular had been followed elsewhere (*e.g.,* the English *Classical Journal,* 1810–29), journals written primarily by professional scholars for professional scholars only began to proliferate after about 1850. Coupled with this proliferation were the increased importance of universities, seminars, and academies (with their published proceedings) and the growing habit of early publication of, for instance, the Ph.D. dissertation, the academic "program," and the technical monograph.

Professional journals

Specialization was accompanied by a rise in technical standards of argument and presentation and a tendency toward the use of learned jargon—a phenomenon particularly noticeable in classical studies because of the contrast with earlier scholarly literature. An allied change was the replacement of Latin by the vernacular as a medium of scholarly intercourse and publication (with traditional exceptions, such as the preface and apparatus of a critical text). Thus, after about 1850 a classical scholar who wished to keep abreast of developments in his subject had to be able to read at the least English, French, German, Italian, and, in some cases, Russian. These changes had more immediate results in continental Europe and the United States; in England their effects were delayed in part by the insularity that characterized English scholarship after Bentley, in part by the concentration of the older universities on teaching, and a consequent distrust by tutors of a strong professoriate and of "pure research."

Late 19th-century developments in German scholarship. Germany made so vast a contribution to 19th-century classical scholarship that it would be impossible to name all of the eminent scholars of the period. But from a time rather earlier than the establishment of the German Empire (1871), signs of decline might be observed; the new methods had begun to harden into orthodoxy, mechanically applied by a mass of inferior practitioners. There was a strong tendency toward excessive emendation and deletion, and the overconscientious accumulation of details led to much dullness. From this situation German scholarship was to make a remarkable, though not complete, recovery, thanks to the generation of Ulrich von Wilamowitz-Moellendorff (1848–1931), who broke down the barriers that had grown up between the divisions of his subject, making important contributions to them all. He was the author of the first commentary on a Greek poem in which the entire apparatus of modern scholarship, encompassing not only literary knowledge but also that of history, art, archaeology, linguistics, and religion, was brought to bear on the elucidation of the work in question; this was his commentary on the *Herakles* of Euripides (1st edition, with a remarkable introduction to Attic tragedy, 1889; 2nd edition, 1895). Wilamowitz-Moellendorff produced many more texts and commentaries, besides important work on Greek history, religion, metre, and the history of scholarship. As a professor in Greifswald, Göttingen, and finally Berlin, he exercised a powerful influence.

Wilamowitz-Moellendorff

At the same time Eduard Schwartz (1851–1940) did much not only for the study of Greek history and literature but also for the history of the Christian Church; Georg Kaibel (1850–1901) advanced the study of Greek drama and of verse inscriptions; and Carl Robert (1850–1922) combined archaeological with literary expertise in remarkable fashion. Friedrich Leo (1851–1914) contributed significantly to Plautine studies and began a history of Latin literature of high quality. Jacob Wackernagel (1853–1938) of Basel and Wilhelm Schulze (1863–1935) used their mastery of comparative linguistics to throw light on Greek and Latin texts. Richard Reitzenstein (1861–1931) was eminent not only in the field of Greek literature and lexicography but also in that of ancient religion. Ludwig Traube (1861–1907) did important work in Latin paleography.

Classical scholarship in the 20th century. World War I dealt a heavy blow to classical studies, as to all humane letters, and the numbers of those studying Greek and Latin were noticeably affected; but scholars showed courage and energy in adapting themselves to new conditions. Wilamowitz-Moellendorff continued to be active, and his last decade saw more abundant and more important publications than any other of his career. His pupils produced much important detailed work: Felix Jacoby (1876–1959) began and carried far a learned edition of the fragments of the Greek historians; Paul Maas (1880–1964) showed rare expertise in Greek metrics, textual criticism, and paleography; Eduard Fraenkel (1888–1970) did valuable work on Plautus' relation to his Greek originals and later devoted to Aeschylus' *Agamemnon* one of the most learned of all commentaries; and Rudolf Pfeiffer (1889–1979) wrote a masterly commentary on Callimachus and an important history of classical scholarship.

Reacting against the classicism of the age of Goethe, scholars of the late 19th century saw the study of antiquity mainly from a historical standpoint: they accumulated masses of detail, which sometimes led to dryness, and tended to think exclusively in terms of concrete fact. Discontent arose with the recognition that an excessive preoccupation with the details of their development can harm the understanding of works of literature and thought. Attempts were made to revive classical scholarship by rescuing it from the domination of historical study. Werner Jaeger (1888–1961), an Aristotelian scholar who succeeded Wilamowitz-Moellendorff in his Berlin chair, attempted, without much success, to achieve this by institutional means. More was accomplished by Karl Reinhardt (1886–1958), who, though a devoted pupil of Wilamowitz-Moellendorff, had been in contact from his youth with the ideas of Nietzsche and of the circle around the poet Stefan George. Combining deep learning with refined sensibility, Reinhardt did important work on pre-Socratic philosophy and on Poseidonius and later on Sophocles, Aeschylus, and Homer.

Even before the start of World War II, National Socialist persecution had gravely damaged scholarship in Germany, the main centre of classical studies. The United States and, to an even greater extent, England benefited from the efflux of scholars from the Continent. Jaeger and two other eminent pupils of Wilamowitz-Moellendorff, Paul Friedländer (1882–1968) and Hermann Fränkel (1888–1977), spent the rest of their lives in the United States. So did the Russian M.I. Rostovtzev (1870–1952), who made a vast contribution to the study of the social and economic history of the ancient world. Thaddeus Zielinski (1859–1944), the Polish scholar who did important work on Ciceronian clausulae (clauses) and other topics, was murdered by the Nazis. Eduard Norden (1868–1941), who studied the formal prose of the ancients and did important work on ancient religion and on Latin literature, died in Switzerland. Jacoby, Maas, Fraenkel, and Pfeiffer, as well as the eminent archaeologist Paul Jacobsthal (1880–1957), settled in England, where Fraenkel in particular taught most effectively, creating links between English and continental scholarship. Pfeiffer, like Kurt von Fritz (1900–85), who spent the war years in America, returned to Germany.

Impact of Nazism

In Italy the school founded by Vitelli continued under the leadership of Giorgio Pasquali (1887–1952), a pupil of Schwartz and Leo, and Gaetano de Sanctis (1870–1957) did important work on ancient history. In Sweden Einar Löfstedt (1880–1955) and his school threw much light on Vulgar Latin and indirectly on Latin in general, and M.P. Nilsson (1874–1967) wrote a learned history of Greek religion.

In France classical studies to some degree slumbered under the conservative establishment, but Antoine Meillet (1866–1936) and others advanced the study of linguistics, and Louis Gernet (1882–1962) founded an important school of scholars who applied the techniques of modern sociology and anthropology to the study of antiquity.

In England A.E. Housman (1859–1936) continued with great distinction the tradition of exclusively textual study, editing Juvenal, Lucan, and most notably Manilius. J.D. Denniston (1887–1949) made a valuable study of the Greek particles. Edgar Lobel (1887–1981) from 1927 edited the literary papyri from Oxyrhynchus with unrivaled expertise. Sir Denys Page (1908–78) edited many Greek poetical texts with great success. Gilbert Murray (1866–1957) was not only a literary scholar but, like Jane Harrison (1850–1928), a pioneer in the use of anthropological and sociological methods in the study of antiquity. F.M. Cornford (1874–1943) shared this interest but went on to contribute significantly to the study of Plato and the pre-Socratics. E.R. Dodds, starting with Neoplatonism, applied psychological as well as anthropological knowledge to the study of early Greek thought, also writing excellent commentaries on Euripides' *Bacchae* and Plato's *Gorgias.* Sir John Beazley (1885–1970), with deep learning and refined sensibility, put the whole study of Greek vase painting on a new basis by applying the method of the 19th-century Italian art critic Giovanni Morelli to the identification of individual painters.

The Homeric Question

The way in which research may (and indeed must) transcend the conventional limits of individual disciplines is exemplified during this period in the history of the Homeric Question: the efforts of scholars in such diverse fields as linguistics, archaeology, Hittite studies, folklore, and comparative oral literature have materially advanced understanding of the poems. The problem was transformed by the proof of an American scholar, Milman Parry (1902–35), that the poems are typical of a poetic tradition that has passed through a long phase of oral transmission.

Linear B script

Excavation continued, despite many political and financial difficulties, and a steady stream of discoveries came from Greece, Italy, and other Mediterranean lands. Perhaps the most exciting new find after World War II was the discovery by the Greek archaeologist Spyridon Marinatos of a Minoan town, with fine and well-preserved frescoes, on the island of Thera. Although large-scale excavations in search of papyri have been discontinued for many years, new papyri have not ceased to be discovered. Since World War II the authors who have benefited most have been Callimachus, Menander, and Stesichorus. In 1952 Michael Ventris showed that the language of the so-called Linear B syllabic script on clay tablets found at Mycenae and other places is Greek, thus throwing light on a far earlier stage of the language than had previously been known.

The history of classical scholarship has continued to be one of activity and progress. The publication of new inscriptions and of new papyri and other manuscripts has yielded important new material, and, considering the limited resources available, the task of presenting the texts of literary works and documents in up-to-date editions has been carried out with considerable success. Lately the Hellenistic and Imperial periods have received greater emphasis and have been given greater credit for their achievements.

But such are the threats presented by social change and utilitarian pressures that heroic efforts will be needed if progress is to continue. In Europe at the beginning of the 20th century many schools gave a good grounding in the ancient languages. This is now no longer the case and, as a result, the years when the memory is at its best for learning new languages are wasted. In the United States, vast reserves not only of money but also of talent and enthusiasm make a large contribution to classical studies, but progress is impeded not only by the failure of the schools to teach the ancient languages but also by the materialism and utilitarianism that are gaining ground both there and in Europe.

BIBLIOGRAPHY. JOHN EDWIN SANDYS, *A History of Classical Scholarship,* 3 vol. (1903–08, reissued 1967), while not a critical study, is useful for factual information. RUDOLF PFEIFFER, *History of Classical Scholarship from the Beginnings to the End of the Hellenistic Age* (1968), is a masterly critical survey, and *History of Classical Scholarship from 1300 to 1850* (1976), contains much valuable material but is uneven and lacks adequate treatment of the important 19th-century period. The best brief survey is U. VON WILAMOWITZ-MOELLENDORFF, *History of Classical Scholarship* (1982; originally published in German, 1921). A history of classical scholarship in antiquity is found in JAMES E.G. ZETZEL, *Latin Textual Criticism in Antiquity* (1981, reprinted 1984). For a discussion of the transmission of Greek and Latin literature, see L.D. REYNOLDS and N.G. WILSON, *Scribes and Scholars,* 2nd rev. ed. (1974); and L.D. REYNOLDS (ed.), *Texts and Transmission: A Survey of the Latin Classics* (1983). N.G. WILSON, *Scholars of Byzantium* (1983), chronicles the history of Byzantine scholarship. ROBERTO WEISS, *Medieval and Humanist Greek* (1977), is a collection of essays detailing the use of the Greek language in the Latin Middle Ages. Weiss also covers a later age in *The Renaissance Discovery of Classical Antiquity* (1969, reissued 1973). ANTHONY GRAFTON, *Joseph Scaliger: A Study in the History of Classical Scholarship,* vol. 1, *Textual Criticism and Exegesis* (1983), presents a biography of the 16th-century French classicist. For English scholarship, see C.O. BRINK, *English Classical Scholarship: Historical Reflections on Bentley, Porson and Housman* (1985); and M.L. CLARKE, *Greek Studies in England, 1700–1830* (1945). On the history of Greek vase painting, see R.M. COOK, *Greek Painted Pottery,* 2nd ed. (1972). On the history of papyrology, see E.G. TURNER, *Greek Papyri: An Introduction* (1968, reissued 1980). E.J. KENNEY, *The Classical Text: Aspects of Editing in the Age of the Printed Book* (1974); and SEBASTIANO TIMPANARO, *La genesi del metodo del Lachmann,* new rev. ed. (1981), treat the development of textual criticism. For a discussion of classical influences in the 19th and 20th centuries, see HUGH LLOYD-JONES, *Blood for the Ghosts* (1983), and *Classical Survivals: The Classics in the Modern World* (1982). In general see the collections of essays by ARNALDO MOMIGLIANO, many in English: vol. 1 appeared as *Contributo alla storia degli studi classici* (1955, reprinted 1979), and the most recent addition appeared as vol. 7, *Settimo contributo alla storia degli studi classici e del mondo antico* (1984).

(H.L.-J.)

The History of Science

On the simplest level, science is knowledge of the world of nature. There are many regularities in nature that mankind has had to recognize for survival since the emergence of *Homo sapiens* as a species. The Sun and the Moon periodically repeat their movements. Some motions, like the daily "motion" of the Sun, are simple to observe; others, like the annual "motion" of the Sun, are far more difficult. Both motions correlate with important terrestrial events. Day and night provide the basic rhythm of human existence; the seasons determine the migration of animals upon which humans depended for millennia for survival. With the invention of agriculture, the seasons became even more crucial, for failure to recognize the proper time for planting could lead to starvation. Science defined simply as knowledge of natural processes is universal among mankind, and it has existed since the dawn of human existence.

The mere recognition of regularities does not exhaust the full meaning of science, however. In the first place, regularities may be simply constructs of the human mind. Humans leap to conclusions; the mind cannot tolerate chaos, so it constructs regularities even when none objectively exists. Thus, for example, one of the astronomical "laws" of the Middle Ages was that the appearance of comets presaged a great upheaval, as the Norman Conquest of Britain followed the comet of 1066. True regularities must be established by detached examination of data. Science, therefore, must employ a certain degree of skepticism to prevent premature generalization.

Regularities, even when expressed mathematically as laws of nature, are not fully satisfactory to everyone. Some insist that genuine understanding demands explanations of the causes of the laws, but it is in the realm of causation that there is the greatest disagreement. Modern quantum mechanics, for example, has given up the quest for causation and today rests only on mathematical description. Modern biology, on the other hand, thrives on causal chains that permit the understanding of physiological and evolutionary processes in terms of the physical activities of entities such as molecules, cells, and organisms. But even if causation and explanation are admitted as necessary, there is little agreement on the kinds of causes that are permissible, or possible, in science. If the history of science is to make any sense whatsoever, it is necessary to deal with the past on its own terms, and the fact is that for most of the history of science natural philosophers appealed to causes that would be summarily rejected by modern scientists. Spiritual and divine forces were accepted as both real and necessary until the end of the 18th century and, in areas such as biology, deep into the 19th century as well.

Certain conventions governed the appeal to God or the gods or to spirits. Gods and spirits, it was held, could not be completely arbitrary in their actions; otherwise the proper response would be propitiation, not rational investigation. But since the deity or deities were themselves rational, or bound by rational principles, it was possible for humans to uncover the rational order of the world. Faith in the ultimate rationality of the creator or governor of the world could actually stimulate original scientific work. Kepler's laws, Newton's absolute space, and Einstein's rejection of the probabilistic nature of quantum mechanics were all based on theological, not scientific, assumptions. For sensitive interpreters of phenomena, the ultimate intelligibility of nature has seemed to demand some rational guiding spirit. A notable expression of this idea is Einstein's statement that the wonder is not that mankind comprehends the world, but that the world is comprehensible.

Science, then, is to be considered in this article as knowledge of natural regularities that is subjected to some degree of skeptical rigour and explained by rational causes. One final caution is necessary. Nature is known only through the senses, of which sight, touch, and hearing are the dominant ones, and the human notion of reality is skewed toward the objects of these senses. The invention of such instruments as the telescope, the microscope, and the Geiger counter has brought an ever-increasing range of phenomena within the scope of the senses. Thus, scientific knowledge of the world is only partial, and the progress of science follows the ability of humans to make phenomena perceivable.

This article provides a broad survey of the development of science as a way of studying and understanding the world, from the primitive stage of noting important regularities in nature to the epochal revolution in our notion of what constitutes reality that has occurred in 20th-century physics. More detailed treatments of the histories of specific sciences, including developments of the later 20th century, may be found in the articles BIOLOGICAL SCIENCES; EARTH SCIENCES; and PHYSICAL SCIENCES. See also the references in the *Propædia,* Part Ten, Division III.

The article is divided into the following sections:

Science as natural philosophy

PRECRITICAL SCIENCE

Science, as it has been defined above, made its appearance before writing. It is necessary, therefore, to infer from archaeological remains what was the content of that science. From cave paintings and from apparently regular scratches on bone and reindeer horn, it is known that prehistoric humans were close observers of nature who carefully tracked the seasons and times of the year. About 2500 BC there was a sudden burst of activity that seems to have had clear scientific importance. Great Britain and northwestern Europe contain large stone structures from that era, the most famous of which is Stonehenge on the Salisbury Plain in England, that are remarkable from a scientific point of view. Not only do they reveal technical and social skills of a high order—it was no mean feat to move such enormous blocks of stone considerable distances and place them in position—but the basic conception of Stonehenge and the other megalithic structures also seems to combine religious and astronomical purposes. Their layouts suggest a degree of mathematical sophistication that was first suspected only in the mid-20th century. Stonehenge is a circle, but some of the other megalithic structures are egg-shaped and, apparently, constructed on mathematical principles that require at least practical knowledge of the Pythagorean theorem that the square of the hypotenuse of a right triangle is equal to the sum of the squares of the other two sides. This theorem, or at least the Pythagorean numbers that can be generated by it, seems to have been known throughout Asia, the Middle East, and Neolithic Europe two millennia before the birth of Pythagoras.

This combination of religion and astronomy was fundamental to the early history of science. It is found in Mesopotamia, Egypt, China (although to a much lesser extent than elsewhere), Central America, and India. The spectacle of the heavens, with the clearly discernible order and regularity of most heavenly bodies highlighted by extraordinary events such as comets and novae and the peculiar motions of the planets, obviously was an irresistible intellectual puzzle to early mankind. In its search for order and regularity, the human mind could do no better than to seize upon the heavens as the paradigm of certain knowledge. Astronomy was to remain the queen of the sciences (welded solidly to theology) for the next 4,000 years.

Science, in its mature form, developed only in the West. But it is instructive to survey the protoscience that appeared in other areas, especially in light of the fact that until quite recently this knowledge was often, as in China, far superior to Western science.

China. As has already been noted, astronomy seems everywhere to have been the first science to emerge. Its intimate relation to religion gave it a ritual dimension that then stimulated the growth of mathematics. Chinese savants, for example, early devised a calendar and methods of plotting the positions of stellar constellations. Since changes in the heavens presaged important changes on the Earth (for the Chinese considered the universe to be a vast organism in which all elements were connected), astronomy and astrology were incorporated into the system of government from the very dawn of the Chinese state in the 2nd millennium BC. As the Chinese bureaucracy developed, an accurate calendar became absolutely necessary to the maintenance of order. The result was a system of astronomical observations and records unparalleled elsewhere, thanks to which there are, today, star catalogs and observations of eclipses and novae that go back for millennia.

The Chinese calendar

In other sciences, too, the overriding emphasis was on practicality, for the Chinese, almost alone among ancient peoples, did not fill the cosmos with gods and demons whose arbitrary wills determined events. Order was inherent and, therefore, expected. It was for man to detect and describe this order and to profit from it. Chemistry (or, rather, alchemy), medicine, geology, geography, and technology were all encouraged by the state and flourished. Practical knowledge of a high order permitted the Chinese to deal with practical problems for centuries on a level not attained in the West until the Renaissance.

India. Far less is known about science in India, largely because few scholars have investigated it. It is known that astronomy was studied for calendrical purposes to set the times for both practical and religious tasks. Primary emphasis was placed on solar and lunar motions, the fixed stars serving only as a background against which these luminaries moved. Indian mathematics, on the other hand, seems to have been quite advanced, with particular sophistication in geometrical and algebraic techniques. This latter branch was undoubtedly stimulated by the flexibility of the Indian system of numeration that later was to come into the West as the Hindu-Arabic numerals. Indian thought, however, was primarily philosophical and otherworldly and was concerned more with escaping this world than with understanding it.

America. Quite independently of China, India, and the other civilizations of Europe and Asia, the Maya of Central America, building upon older cultures, created a complex society in which astronomy and astrology played important roles. Determination of the calendar, again, had both practical and religious significance. Solar and lunar eclipses were important, as was the position of the bright planet Venus. No sophisticated mathematics are known to have been associated with this astronomy, but the Mayan calendar was both ingenious and the result of careful observation.

The Middle East. In the cradles of Western civilization in Egypt and Mesopotamia, there were two rather different situations. In Egypt, as in China, there was an assumption of cosmic order guaranteed by a host of benevolent gods. But unlike China, whose rugged geography often produced disastrous floods, earthquakes, and violent storms that destroyed crops, Egypt was surpassingly placid and delightful. Life was, in fact, so pleasant that the major concern of most Egyptians was over leaving it. Egyptians found it difficult to believe that all ended with death; enormous intellectual and physical labour, therefore, was devoted to preserving life after death. Both Egyptian theology and the pyramids are testaments to this preoccupation. Science did not flourish in this atmosphere. All of the important questions were answered by religion, so the Egyptians did not concern themselves overmuch with speculations about the universe. The stars and the planets had astrological significance in that the major heavenly bodies were assumed to "rule" the land when they were in the ascendant (from the succession of these "rules" came the seven-day week, after the five planets and the Sun and the Moon), but astronomy was largely limited to the calendrical calculations necessary to predict the annual life-giving flood of the Nile. None of this required much mathematics, and there was, consequently, little of any importance.

Mesopotamia was more like China. The life of the land depended upon the two great rivers, the Tigris and the Euphrates, as that of China depended upon the Huang Ho (Yellow River) and the Yangtze. The land was harsh and made habitable only by extensive damming and irrigation works. Storms, insects, floods, and invaders made life insecure. To create a stable society required both great technological skill, for the creation of hydraulic works, and the ability to hold off the forces of disruption. These latter were early identified with powerful and arbitrary gods who dominated Mesopotamian theology. The cities of the plain were centred on temples run by a priestly caste whose functions included the planning of major public works, like canals, dams, and irrigation systems, the allocation of the resources of the city to its members, and the averting of a divine wrath that could wipe everything out.

Public works in Mesopotamia

Mathematics and astronomy thrived under these conditions. The number system, probably drawn from the system of weights and coinage, was based on 60 (it was in ancient Mesopotamia that the system of degrees, minutes, and seconds developed) and was adapted to a practical arithmetic. The heavens were the abode of the gods, and because heavenly phenomena were thought to presage terrestrial disasters, they were carefully observed and recorded. Out of these practices grew, first, a highly developed mathematics that went far beyond the requirements of daily business, and then, some centuries later, a descriptive astronomy that was the most sophisticated of the ancient world until the Greeks took it over and perfected it.

Nothing is known of the motives of these early mathematicians for carrying their studies beyond the calculations of volumes of dirt to be removed from canals and the provisions necessary for work parties. It may have been simply intellectual play—the role of playfulness in the history of science should not be underestimated—that led them onward to abstract algebra. There are texts from about 1700 BC that are remarkable for their mathematical suppleness. Babylonian mathematicians knew the

Pythagorean relationship well and used it constantly. They could solve simple quadratic equations and could even solve problems in compound interest involving exponents. From about a millennium later there are texts that utilize these skills to provide a very elaborate mathematical description of astronomical phenomena.

Although China and Mesopotamia provide examples of exact observation and precise description of nature, what is missing is explanation in the scientific mode. The Chinese assumed a cosmic order that was vaguely founded on the balance of opposite forces (yin–yang) and the harmony of the five elements (water, wood, metal, fire, and earth). Why this harmony obtained was not discussed. Similarly, the Egyptians found the world harmonious because the gods willed it so. For Babylonians and other Mesopotamian cultures, order existed only so long as all-powerful and capricious gods supported it. In all these societies, humans could describe nature and use it, but to understand it was the function of religion and magic, not reason. It was the Greeks who first sought to go beyond description and to arrive at reasonable explanations of natural phenomena that did not involve the arbitrary will of the gods. Gods might still play a role, as indeed they did for centuries to come, but even the gods were subject to rational laws.

GREEK SCIENCE

The birth of natural philosophy. There seems to be no good reason why the Hellenes, clustered in isolated city-states in a relatively poor and backward land, should have struck out into intellectual regions that were only dimly perceived, if at all, by the splendid civilizations of the Yangtze, the Tigris and Euphrates, and the Nile valleys. There were many differences between ancient Greece and the other civilizations, but perhaps the most significant was religion. What is striking about Greek religion, in contrast to the religions of Mesopotamia and Egypt, is its puerility. Both of the great river civilizations evolved complex theologies that served to answer most, if not all, of the large questions about mankind's place and destiny. Greek religion did not. It was, in fact, little more than a collection of folk tales, more appropriate to the campfire than to the temple. Perhaps this was the result of the collapse of an earlier Greek civilization, now called Mycenaean, toward the end of the 2nd millennium BC, when a dark age descended upon Greece that lasted for three centuries. All that was preserved were stories of gods and men, passed along by poets, that dimly reflected Mycenaean values and events. Such were the great poems of Homer, the *Iliad* and the *Odyssey,* in which heroes and gods mingled freely with one another. Indeed, they mingled too freely, for the gods appear in these tales as little more than immortal adolescents whose tricks and feats, when compared with the concerns of a Marduk or Jehovah, are infantile. There really was no Greek theology in the sense that theology provides a coherent and profound explanation of the workings of both the cosmos and the human heart. Hence, there were no easy answers to inquiring Greek minds. The result was that ample room was left for a more penetrating and ultimately more satisfying mode of inquiry. Thus were philosophy and its oldest offspring, science, born.

The absence of theology

The first natural philosopher, according to Hellenic tradition, was Thales of Miletus, who flourished in the 6th century BC. We know of him only through later accounts, for nothing he wrote has survived. He is supposed to have predicted a solar eclipse in 585 BC and to have invented the formal study of geometry in his demonstration of the bisecting of a circle by its diameter. Most importantly, he tried to explain all observed natural phenomena in terms of the changes of a single substance, water, which can be seen to exist in solid, liquid, and gaseous states. What for Thales guaranteed the regularity and rationality of the world was the innate divinity in all things that directed them to their divinely appointed ends. From these ideas there emerged two characteristics of classical Greek science. The first was the view of the universe as an ordered structure (the Greek *kósmos* means "order"). The second was the conviction that this order was not that of a mechanical contrivance but that of an organism; all parts of the universe had purposes in the overall scheme of things, and objects moved naturally toward the ends they were fated to serve. This motion toward ends is called teleology and, with but few exceptions, it permeated Greek as well as much later science.

Thales inadvertently made one other fundamental contribution to the development of natural science. By naming a specific substance as the basic element of all matter, Thales opened himself to criticism, which was not long in coming. His own disciple, Anaximander, was quick to argue that water could not be the basic substance. His argument was simple: water, if it is anything, is essentially wet; nothing can be its own contradiction. Hence, if Thales were correct, the opposite of wet could not exist in a substance, and that would preclude all of the dry things that are observed in the world. Therefore, Thales was wrong. Here was the birth of the critical tradition that is fundamental to the advance of science.

Thales' conjectures set off an intellectual explosion, most of which was devoted to increasingly refined criticisms of his doctrine of fundamental matter. Various single substances were proposed and then rejected, ultimately in favour of a multiplicity of elements that could account for such opposite qualities as wet and dry, hot and cold. Two centuries after Thales, most natural philosophers accepted a doctrine of four elements: earth (cold and dry), fire (hot and dry), water (cold and wet), and air (hot and wet). All bodies were made from these four.

Pythagoras

The presence of the elements only guaranteed the presence of their qualities in various proportions. What was not accounted for was the form these elements took, which served to differentiate natural objects from one another. The problem of form was first attacked systematically by the philosopher and cult leader Pythagoras in the 6th century BC. Legend has it that Pythagoras became convinced of the primacy of number when he realized that the musical notes produced by a monochord were in simple ratio to the length of the string. Qualities (tones) were reduced to quantities (numbers in integral ratios). Thus was born mathematical physics, for this discovery provided the essential bridge between the world of physical experience and that of numerical relationships. Number provided the answer to the question of the origin of forms and qualities.

Aristotle and Archimedes. Hellenic science was built upon the foundations laid by Thales and Pythagoras. It reached its zenith in the works of Aristotle and Archimedes. Aristotle represents the first tradition, that of qualitative forms and teleology. He was, himself, a biologist whose observations of marine organisms were unsurpassed until the 19th century. Biology is essentially teleological—the parts of a living organism are understood in terms of what they do in and for the organism—and Aristotle's biological works provided the framework for the science until the time of Charles Darwin. In physics, teleology is not so obvious, and Aristotle had to impose it on the cosmos. From Plato, his teacher, he inherited the theological proposition that the heavenly bodies (stars and planets) are literally divine and, as such, perfect. They could, therefore, move only in perfect, eternal, unchanging motion, which, by Plato's definition, meant perfect circles. The Earth, being obviously not divine, and inert, was at the centre. From the Earth to the sphere of the Moon, all things constantly changed, generating new forms and then decaying back into formlessness. Above the Moon the cosmos consisted of contiguous and concentric crystalline spheres moving on axes set at angles to one another (this accounted for the peculiar motions of the planets) and deriving their motion either from a fifth element that moved naturally in circles or from heavenly souls resident in the celestial bodies. The ultimate cause of all motion was a prime, or unmoved, mover (God) that stood outside the cosmos.

Aristotle was able to make a great deal of sense of observed nature by asking of any object or process: what is the material involved, what is its form and how did it get that form, and, most important of all, what is its purpose? What should be noted is that, for Aristotle, all activity that occurred spontaneously was natural. Hence, the proper means of investigation was observation. Experiment, that is, altering natural conditions in order to throw light on the hidden properties and activities of objects, was unnatural and could not, therefore, be expected to reveal the essence of things. Experiment was thus not essential to Greek science.

The problem of purpose did not arise in the areas in which Archimedes made his most important contributions. He was, first of all, a brilliant mathematician whose work on conic sections and on the area of the circle prepared the way for the later invention of the calculus. It was in mathematical physics, however, that he made his greatest contributions to science. His mathematical demonstration of the law of the lever was as exact as a Euclidean proof in geometry. Similarly, his work on hydrostatics introduced and developed the method whereby physical characteristics, in this case specific gravity, which Archimedes discovered, are given mathematical shape and then manipulated by mathematical methods to yield mathematical conclusions that can be translated back into physical terms.

In one major area the Aristotelian and the Archimedean approaches were forced into a rather inconvenient marriage. Astronomy was the dominant physical science throughout antiquity, but it had never been successfully reduced to a coherent system. The Platonic-Aristotelian astral religion required that planetary orbits be circles. But, particularly after the conquests of Alexander the Great had made the observations and mathematical methods of the Babylonians available to the Greeks, astronomers found it impossible to reconcile theory and observation. Astronomy then split into two parts: one was physical and accepted Aristotelian theory in accounting for heavenly motion; the other ignored causation and concentrated solely on the creation of a mathematical model that could be used for computing planetary positions. Ptolemy, in the 2nd century AD, carried the latter tradition to its highest point in antiquity in his *Hē mathēmatikē syntaxis* ("The Mathematical Collection," better known under its Greek-Arabic title, *Almagest*).

Medicine. The Greeks not only made substantial progress in understanding the cosmos but also went far beyond their predecessors in their knowledge of the human body. Pre-Greek medicine had been almost entirely confined to religion and ritual. Disease was considered the result of divine disfavour and human sin, to be dealt with by spells, prayers, and other propitiatory measures. In the 5th century BC a revolutionary change came about that is associated with the name of Hippocrates. It was Hippocrates and his school who, influenced by the rise of natural philosophy, first insisted that disease was a natural, not a supernatural, phenomenon. Even maladies as striking as epilepsy, whose seizures appeared to be divinely caused, were held to originate in natural causes within the body.

Hippocrates

The height of medical science in antiquity was reached late in the Hellenistic period. Much work was done at the museum of Alexandria, a research institute set up under Greek influence in Egypt in the 3rd century BC to sponsor learning in general. The heart and the vascular system were investigated, as were the nerves and the brain. The organs of the thoracic cavity were described, and attempts were made to discover their functions. It was on these researches, and on his own dissections of apes and pigs, that the last great physician of antiquity, Galen of Pergamum, based his physiology. It was, essentially, a tripartite system in which so-called spirits—natural, vital, and animal—passed respectively through the veins, the arteries, and the nerves to vitalize the body as a whole. Galen's attempts to correlate therapeutics with his physiology were not successful, and so medical practice remained eclectic and a matter of the physician's choice. Usually the optimal choice was that propounded by the Hippocratics, who relied primarily on simple, clean living and the ability of the body to heal itself.

Science in Rome and Christianity. The apogee of Greek science in the works of Archimedes and Euclid coincided with the rise of Roman power in the Mediterranean. The Romans were deeply impressed by Greek art, literature, philosophy, and science, and after their conquest of Greece many Greek intellectuals served as household slaves tutoring noble Roman children. The Romans were a practical people, however, and, while they contemplated the Greek intellectual achievement with awe, they also could not help but ask what good it had done the Greeks. Roman common sense was what kept Rome great; science and philosophy were either ignored or relegated to rather low status. Even such a Hellenophile as the statesman and orator Cicero used Greek thought more to buttress the old Roman ways than as a source of new ideas and viewpoints.

The spirit of independent research was quite foreign to the Roman mind, so scientific innovation ground to a halt. The scientific legacy of Greece was condensed and corrupted into Roman encyclopaedias whose major function was entertainment rather than enlightenment. Typical of this spirit was the 1st-century-AD aristocrat Pliny the Elder, whose *Natural History* was a multivolume collection of myths, odd tales of wondrous creatures, magic, and some science, all mixed together uncritically for the titillation of other aristocrats. Aristotle would have been embarrassed by it.

At its height Rome incorporated a host of peoples with different customs, languages, and religions within its empire. One religious sect that proved more significant than the rest was Christianity. Jesus and his kingdom were not of this world, but his disciples and their followers were. This world could not be ignored, even though concern with worldly things could be dangerous to the soul. So the early Christians approached the worldly wisdom of their time with ambivalence: on the one hand, the rhetoric and the arguments of ancient philosophy were snares and delusions that might mislead the simple and the unwary; on the other hand, the sophisticated and the educated of the empire could not be converted unless the Christian message was presented in the terms and rhetoric of the philosophical schools. Before they knew it, the early Christians were enmeshed in metaphysical arguments, some of which involved physics. What, for example, was the nature of Jesus, in purely physical terms? How was it possible that anybody could have two different essential natures, as was claimed for Jesus? Such questions revealed how important knowledge of the arguments of Greek thinkers on the nature of substance could be to those engaged in founding a new theology.

Science and theology

Ancient learning, then, did not die with the fall of Rome and the occupation of the Western Empire by tribes of Germanic barbarians. To be sure, the lamp of learning burned very feebly, but it did not go out. Monks in monasteries faithfully copied out classics of ancient thought and early Christianity and preserved them for posterity. Monasteries continued to teach the elements of ancient learning, for little beyond the elementary survived in the Latin West. In the East, the Byzantine Empire remained strong, and there the ancient traditions continued. There was little original work done in the millennium following the fall of Rome, but the ancient texts were preserved along with knowledge of the ancient Greek language. This was to be a precious reservoir of learning for the Latin West in later centuries.

SCIENCE IN ISLĀM

The torch of ancient learning passed first to one of the invading groups that helped bring down the Eastern Empire. In the 7th century the Arabs, inspired by their new religion, burst out of the Arabian peninsula and laid the foundations of an Islāmic empire that eventually rivalled that of ancient Rome. To the Arabs, ancient science was a precious treasure. The Qur'ān, the sacred book of Islām, particularly praised medicine as an art close to God. Astronomy and astrology were believed to be one way of glimpsing what God willed for mankind. Contact with Hindu mathematics and the requirements of astronomy stimulated the study of numbers and of geometry. The writings of the Hellenes were, therefore, eagerly sought and translated, and thus much of the science of antiquity passed into Islāmic culture. Greek medicine, Greek astronomy and astrology, and Greek mathematics, together with the great philosophical works of Plato and, particularly, Aristotle, were assimilated in Islām by the end of the 9th century. Nor did the Arabs stop with assimilation.

They criticized and they innovated. Islāmic astronomy and astrology were aided by the construction of great astronomical observatories that provided accurate observations against which the Ptolemaic predictions could be checked. Numbers fascinated Islāmic thinkers, and this fascination served as the motivation for the creation of algebra (from Arabic *al-jabr*) and the study of algebraic functions.

MEDIEVAL EUROPEAN SCIENCE

Medieval Christendom confronted Islām chiefly in military crusades, in Spain and the Holy Land, and in theology. From this confrontation came the restoration of ancient learning to the West. The Reconquista in Spain gradually pushed the Moors south from the Pyrenees, and among the treasures left behind were Arabic translations of Greek works of science and philosophy. In 1085 the city of Toledo, with one of the finest libraries in Islām, fell to the Christians. Among the occupiers were Christian monks who quickly began the process of translating ancient works into Latin. By the end of the 12th century much of the ancient heritage was again available to the Latin West.

The medieval world was caricatured by thinkers of the 18th-century Enlightenment as a period of darkness, superstition, and hostility to science and learning. On the contrary, it was one of great technological vitality. The advances that were made may appear today as trifling, but that is because they were so fundamental. They included the horseshoe and the horse collar, without which horsepower cannot be efficiently exploited. The invention of the crank, the brace and bit, the wheelbarrow, and the flying buttress made possible the great Gothic cathedrals. Improvements in the gear trains of waterwheels and the development of windmills harnessed these sources of power with great efficiency. Mechanical ingenuity, building on experience with mills and power wheels, culminated in the 14th century in the mechanical clock, which not only set a new standard of chronometrical accuracy but also provided philosophers with a new metaphor for nature itself.

The mechanical clock

An equal amount of energy was devoted to achieving a scientific understanding of nature, but it is essential to understand to what use medieval thinkers put this kind of knowledge. As the fertility of the technology shows, medieval Europeans had no deep prejudices against utilitarian knowledge. But the areas in which scientific knowledge could find useful expression were few. Instead, science was viewed chiefly as a means of understanding God's creation and, thereby, the Godhead itself. The best example of this attitude is found in the medieval study of optics. Light, as Genesis makes clear, was among the first creations of God. The 12th–13th-century cleric-scholar Robert Grosseteste saw in light the first creative impulse. As light spread it created both space and matter, and, in its reflection from the outermost circle of the cosmos, it gradually solidified into the heavenly spheres. To understand the laws of the propagation of light was to understand, in some slight way, the nature of the creation.

In the course of studying light, particular problems were isolated and attacked. What, for example, is the rainbow? It is impossible to get close enough to a rainbow to see clearly what is going on, for as the observer moves, so too does the rainbow. It does seem to depend upon the presence of raindrops, so medieval investigators sought to bring the rainbow down from the skies into their studies. Insight into the nature of the rainbow could be achieved by simulating the conditions under which rainbows occur. For raindrops the investigators substituted hollow glass balls filled with water, so that the rainbow could be studied at leisure. Valid conclusions about rainbows could then be drawn by assuming the validity of the analogy between raindrops and water-filled globes. This involved the implicit assumptions that nature was simple (*i.e.,* governed by a few general laws) and that similar effects had similar causes. Such a nature was what could be expected of a rational, benevolent deity; hence, the assumption could be persuasively adopted.

Medieval philosophers were not content, as the above example shows, to repeat what the ancients had said. They subjected ancient texts to close critical scrutiny. Usually the intensity of the criticism was directly proportional to the theological significance of the problem involved. Such was the case with motion. Medieval philosophers examined all aspects of motion with great care, for the nature of motion had important theological implications. Thomas Aquinas used Aristotle's dictum, that everything that moves is moved by something else, to show that God must exist, for otherwise the existence of any motion would imply an infinite regression of prior causal motions.

It should be clear that there was no conscious conflict between science and religion in the Middle Ages. As Aquinas pointed out, God was the author of both the book of Scripture and the book of nature. The guide to nature was reason, the faculty that was the image of God in which mankind was made. Scripture was direct revelation, although it needed interpretation, for there were passages that were obscure or difficult. The two books, having the same author, could not contradict each other. For the short term, science and revelation marched hand in hand. Aquinas carefully wove knowledge of nature into his theology, as in his proof from motion of the existence of God. But if his scientific concepts of motion should ever be challenged, there would necessarily be a theological challenge as well. By working science into the very fabric of his theology, he virtually guaranteed that someday there would be conflict. Theologians would side with theology and scientists with science, to create a breach that neither particularly desired.

The glory of medieval science was its integration of science, philosophy, and theology into a magnificent and comprehensible whole. It can be best contemplated in the greatest of all medieval poems, Dante's *Divine Comedy.* Here was an essentially Aristotelian cosmos, finite and easily understood, over which God, his Son, and his saints reigned. Humanity and the Earth occupied the centre, as befitted their centrality in God's plan. The nine circles of hell were populated by humans whose exercise of their free will had led to their damnation. Purgatory contained lesser sinners still capable of salvation. The heavenly spheres were populated by the saved and the saintly. The natural hierarchy gave way to the spiritual hierarchy as one ascended toward the throne of God. Such a hierarchy was reflected in the social and political institutions of medieval Europe, and God, the supreme monarch, ruled his creation with justice and love. All fit together in a grand cosmic scheme, one not to be abandoned lightly.

Natural and spiritual hierarchy

The rise of modern science

THE AUTHORITY OF PHENOMENA

Even as Dante was writing his great work, deep forces were threatening the unitary cosmos he celebrated. The pace of technological innovation began to quicken. Particularly in Italy, the political demands of the time gave new importance to technology, and a new profession emerged, that of civil and military engineer. These people faced practical problems that demanded practical solutions. Leonardo da Vinci is certainly the most famous of them, though he was much more as well. A painter of genius, he closely studied human anatomy in order to give verisimilitude to his paintings. As a sculptor he mastered the difficult techniques of casting metal. As a producer-director of the form of Renaissance dramatic production called the masque, he devised complicated machinery to create special effects. But it was as a military engineer that he observed the path of a mortar bomb being lobbed over a city wall and insisted that the projectile did not follow two straight lines—a slanted ascent followed by a vertical drop—as Aristotle had said it must. Leonardo and his colleagues needed to know nature truly; no amount of book learning could substitute for actual experience, nor could books impose their authority upon phenomena. What Aristotle and his commentators asserted as philosophical necessity often did not gibe with what could be seen with one's own eyes. The hold of ancient philosophy was too strong to be broken lightly, but a healthy skepticism began to emerge.

The first really serious blow to the traditional acceptance of ancient authorities was the discovery of the New World at the end of the 15th century. Ptolemy, the great astronomer and geographer, had insisted that only the three continents of Europe, Africa, and Asia could exist, and Christian scholars from St. Augustine on had accepted it, for otherwise men would have to walk upside down at the antipodes. But Ptolemy, St. Augustine, and a host of other authorities were wrong. The dramatic expansion of the known world also served to stimulate the study of mathematics, for wealth and fame awaited those who could turn navigation into a real and trustworthy science.

In large part the Renaissance was a time of feverish intellectual activity devoted to the complete recovery of the ancient heritage. To the Aristotelian texts that had been the foundation of medieval thought were added translations of Plato, with his vision of mathematical harmonies, of Galen, with his experiments in physiology and anatomy, and, perhaps most important of all, of Archimedes, who showed how theoretical physics could be done outside the traditional philosophical framework. The results were subversive.

The search for antiquity turned up a peculiar bundle of manuscripts that added a decisive impulse to the direction in which Renaissance science was moving. These manuscripts were taken to have been written by or to report almost at first hand the activities of the legendary priest, prophet, and sage Hermes Trismegistos. Hermes was supposedly a contemporary of Moses, and the Hermetic writings contained an alternative story of creation that gave man a far more prominent role than the traditional account. God had made man fully in his image: a creator, not just a rational animal. Man could imitate God by creating. To do so, he must learn nature's secrets, and this could be done only by forcing nature to yield them through the tortures of fire, distillation, and other alchemical manipulations. The reward for success would be eternal life and youth, as well as freedom from want and disease. It was a heady vision, and it gave rise to the notion that, through science and technology, man could bend nature to his wishes. This is essentially the modern view of science, and it should be emphasized that it occurs only in Western civilization. It is probably this attitude that permitted the West to surpass the East, after centuries of inferiority, in the exploitation of the physical world.

Hermes Trismegistos

The Hermetic tradition also had more specific effects. Inspired, as is now known, by late Platonist mysticism, the Hermetic writers had rhapsodized on enlightenment and on the source of light, the Sun. Marsilio Ficino, the 15th-century Florentine translator of both Plato and the Hermetic writings, composed a treatise on the Sun that came close to idolatry. A young Polish student visiting Italy at the turn of the 16th century was touched by this current. Back in Poland, he began to work on the problems posed by the Ptolemaic astronomical system. With the blessing of the church, which he served formally as a canon, Nicolaus Copernicus set out to modernize the astronomical apparatus by which the church made such important calculations as the proper dates for Easter and other festivals.

THE SCIENTIFIC REVOLUTION

Copernicus. In 1543, as he lay on his deathbed, Copernicus finished reading the proofs of his great work; he died just as it was published. His *De revolutionibus orbium coelestium* (*On the Revolutions of the Celestial Spheres*) was the opening shot in a revolution whose consequences were greater than those of any other intellectual event in the history of mankind. The scientific revolution radically altered the conditions of thought and of material existence in which the human race lives, and its effects are not yet exhausted.

All this was caused by Copernicus' daring in placing the Sun, not the Earth, at the centre of the cosmos. Copernicus actually cited Hermes Trismegistos to justify this idea, and his language was thoroughly Platonic. But he meant his work as a serious work in astronomy, not philosophy, so he set out to justify it observationally and mathematically. The results were impressive. At one stroke, Copernicus reduced a complexity verging on chaos to elegant simplicity. The apparent back-and-forth movements of the planets, which required prodigious ingenuity to accommodate within the Ptolemaic system, could be accounted for just in terms of the Earth's own orbital motion added to or subtracted from the motions of the planets. Variation in planetary brightness was also explained by this combination of motions. The fact that Mercury and Venus were never found opposite the Sun in the sky Copernicus explained by placing their orbits closer to the Sun than that of the Earth. Indeed, Copernicus was able to place the planets in order of their distances from the Sun by considering their speeds and thus to construct a system of the planets, something that had eluded Ptolemy. This system had a simplicity, coherence, and aesthetic charm that made it irresistible to those who felt that God was the supreme artist. His was not a rigorous argument, but aesthetic considerations are not to be ignored in the history of science.

Copernicus did not solve all of the difficulties of the Ptolemaic system. He had to keep some of the cumbrous apparatus of epicycles and other geometrical adjustments, as well as a few Aristotelian crystalline spheres. The result was neater, but not so striking that it commanded immediate universal assent. Moreover, there were some implications that caused considerable concern: Why should the crystalline orb containing the Earth circle the Sun? And how was it possible for the Earth itself to revolve on its axis once in 24 hours without hurling all objects, including humans, off its surface? No known physics could answer these questions, and the provision of such answers was to be the central concern of the scientific revolution.

More was at stake than physics and astronomy, for one of the implications of the Copernican system struck at the very foundations of contemporary society. If the Earth revolved around the Sun, then the apparent positions of the fixed stars should shift as the Earth moves in its orbit. Copernicus and his contemporaries could detect no such shift (called stellar parallax), and there were only two interpretations possible to explain this failure. Either the Earth was at the centre, in which case no parallax was to be expected, or the stars were so far away that the parallax was too small to be detected. Copernicus chose the latter and thereby had to accept an enormous cosmos consisting mostly of empty space. God, it had been assumed, did nothing in vain, so for what purposes might he have created a universe in which the Earth and mankind were lost in immense space? To accept Copernicus was to give up the Dantean cosmos. The Aristotelian hierarchy of social place, political position, and theological gradation would vanish, to be replaced by the flatness and plainness of Euclidean space. It was a grim prospect and not one that recommended itself to most 16th-century intellectuals, and so Copernicus' grand idea remained on the periphery of astronomical thought. All astronomers were aware of it, some measured their own views against it, but only a small handful eagerly accepted it.

In the century and a half following Copernicus, two easily discernible scientific movements developed. The first was critical, the second, innovative and synthetic. They worked together to bring the old cosmos into disrepute and, ultimately, to replace it with a new one. Although they existed side by side, their effects can more easily be seen if they are treated separately.

Tycho, Kepler, and Galileo. The critical tradition began with Copernicus. It led directly to the work of Tycho Brahe, who measured stellar and planetary positions more accurately than had anyone before him. But measurement alone could not decide between Copernicus and Ptolemy, and Tycho insisted that the Earth was motionless. Copernicus did persuade Tycho to move the centre of revolution of all other planets to the Sun. To do so, he had to abandon the Aristotelian crystalline spheres that otherwise would collide with one another. Tycho also cast doubt upon the Aristotelian doctrine of heavenly perfection, for when, in the 1570s, a comet and a new star appeared, Tycho showed that they were both above the sphere of the Moon. Perhaps the most serious critical blows struck were those delivered by Galileo after the invention of the telescope. In quick succession, he announced that there were mountains on the Moon, satellites circling Jupiter, and spots upon the Sun. Moreover, the Milky Way was

Invention of the telescope

composed of countless stars whose existence no one had suspected until Galileo saw them. Here was criticism that struck at the very roots of Aristotle's system of the world.

At the same time Galileo was searching the heavens with his telescope, in Germany Johannes Kepler was searching them with his mind. Tycho's precise observations permitted Kepler to discover that Mars (and, by analogy, all the other planets) did not revolve in a circle at all, but in an ellipse, with the Sun at one focus. Ellipses tied all the planets together in grand Copernican harmony. The Keplerian cosmos was most un-Aristotelian, but Kepler hid his discoveries by burying them in almost impenetrable Latin prose in a series of works that did not circulate widely.

What Galileo and Kepler could not provide, although they tried, was an alternative to Aristotle that made equal sense. If the Earth revolves on its axis, then why do objects not fly off it? And why do objects dropped from towers not fall to the west as the Earth rotates to the east beneath them? And how is it possible for the Earth, suspended in empty space, to go around the Sun—whether in circles or ellipses—without anything pushing it? The answers were long in coming.

Galileo attacked the problems of the Earth's rotation and its revolution by logical analysis. Bodies do not fly off the Earth because they are not really revolving rapidly, even though their speed is high. In revolutions per minute, any body on the Earth is going very slowly and, therefore, has little tendency to fly off. Bodies fall to the base of towers from which they are dropped because they share with the tower the rotation of the Earth. Hence, bodies already in motion preserve that motion when another motion is added. So, Galileo deduced, a ball dropped from the top of a mast of a moving ship would fall at the base of the mast. If the ball were allowed to move on a frictionless horizontal plane, it would continue to move forever. Hence, Galileo concluded, the planets, once set in circular motion, continue to move in circles forever. Therefore, Copernican orbits exist. Galileo never acknowledged Kepler's ellipses; to do so would have meant abandoning his solution to the Copernican problem.

Kepler realized that there was a real problem with planetary motion. He sought to solve it by appealing to the one force that appeared to be cosmic in nature, namely magnetism. The Earth had been shown to be a giant magnet by William Gilbert in 1600, and Kepler seized upon this fact. A magnetic force, Kepler argued, emanated from the Sun and pushed the planets around in their orbits, but he was never able to quantify this rather vague and unsatisfactory idea.

Descartes

By the end of the first quarter of the 17th century Aristotelianism was rapidly dying, but there was no satisfactory system to take its place. The result was a mood of skepticism and unease, for, as one observer put it, "The new philosophy calls all in doubt." It was this void that accounted largely for the success of a rather crude system proposed by René Descartes. Matter and motion were taken by Descartes to explain everything by means of mechanical models of natural processes, even though he warned that such models were not the way nature probably worked. They provided merely "likely stories," which seemed better than no explanation at all.

Armed with matter and motion, Descartes attacked the basic Copernican problems. Bodies once in motion, Descartes argued, remain in motion in a straight line unless and until they are deflected from this line by the impact of another body. All changes of motion are the result of such impacts. Hence, the ball falls at the foot of the mast because, unless struck by another body, it continues to move with the ship. Planets move around the Sun because they are swept around by whirlpools of a subtle matter filling all space. Similar models could be constructed to account for all phenomena; the Aristotelian system could be replaced by the Cartesian. There was one major problem, however, and it sufficed to bring down Cartesianism. Cartesian matter and motion had no purpose, nor did Descartes's philosophy seem to need the active participation of a deity. The Cartesian cosmos, as Voltaire later put it, was like a watch that had been wound up at the creation and continues ticking to eternity.

Newton. The 17th century was a time of intense religious feeling, and nowhere was that feeling more intense than in Great Britain. There a devout young man, Isaac Newton, was finally to discover the way to a new synthesis in which truth was revealed and God was preserved.

Newton was both an experimental and a mathematical genius, and it was this combination that enabled him to establish both the Copernican system and a new mechanics. His method was simplicity itself: "from the phenomena of motions to investigate the forces of nature, and then from these forces to demonstrate the other phenomena." Newton's genius guided him in the selection of phenomena to be investigated, and his creation of a new and fundamental mathematical tool—the calculus (simultaneously invented by Gottfried Leibniz)—permitted him to submit the forces he inferred to calculation. The result was *Philosophiae Naturalis Principia Mathematica* (*Mathematical Principles of Natural Philosophy,* usually called simply the *Principia*), which appeared in 1687. Here was a new physics that applied equally well to terrestrial and celestial bodies. Copernicus, Kepler, and Galileo were all justified by Newton's analysis of forces. Descartes was utterly routed.

The role of the divine

Newton's three laws of motion and his principle of universal gravitation sufficed to regulate the new cosmos, but only, Newton believed, with the help of God. Gravity, he more than once hinted, was direct divine action, as were all forces for order and vitality. Absolute space, for Newton, was essential, because space was the "sensorium of God," and the divine abode must necessarily be the ultimate coordinate system. Finally, Newton's analysis of the mutual perturbations of the planets caused by their individual gravitational fields predicted the natural collapse of the solar system unless God acted to set things right again.

The diffusion of scientific method. The publication of the *Principia* marks the culmination of the movement begun by Copernicus and, as such, has always stood as the symbol of the scientific revolution. There were, however, similar attempts to criticize, systematize, and organize natural knowledge that did not lead to such dramatic results. In the same year as Copernicus' great volume, there appeared an equally important book on anatomy: Andreas Vesalius' *De humani corporis fabrica* ("On the Fabric of the Human Body," called the *De fabrica*), a critical examination of Galen's anatomy in which Vesalius drew on his own studies to correct many of Galen's errors. Vesalius, like Newton a century later, emphasized the phenomena, *i.e.,* the accurate description of natural facts. Vesalius' work touched off a flurry of anatomical work in Italy and elsewhere that culminated in the discovery of the circulation of the blood by William Harvey, whose *De Motu Cordis et Sanguinis in Animalibus* (*On the Motion of the Heart and Blood in Animals*) was published in 1628. This was the *Principia* of physiology that established anatomy and physiology as sciences in their own right. Harvey showed that organic phenomena could be studied experimentally and that some organic processes could be reduced to mechanical systems. The heart and the vascular system could be considered as a pump and a system of pipes and could be understood without recourse to spirits or other forces immune to analysis.

In other sciences the attempt to systematize and criticize was not so successful. In chemistry, for example, the work of the medieval and early modern alchemists had yielded important new substances and processes, such as the mineral acids and distillation, but had obscured theory in almost impenetrable mystical argot. Robert Boyle in England tried to clear away some of the intellectual underbrush by insisting upon clear descriptions, reproducibility of experiments, and mechanical conceptions of chemical processes. Chemistry, however, was not yet ripe for revolution.

In many areas there was little hope of reducing phenomena to comprehensibility, simply because of the sheer number of facts to be accounted for. New instruments like the microscope and the telescope vastly multiplied the worlds with which man had to reckon. The voyages of discovery brought back a flood of new botanical and zoological specimens that overwhelmed ancient classificatory schemes. The best that could be done was to describe new things accurately and hope that someday they could all be fitted together in a coherent way.

The growing flood of information put heavy strains upon old institutions and practices. It was no longer sufficient to publish scientific results in an expensive book that few could buy; information had to be spread widely and rapidly. Nor could the isolated genius, like Newton, comprehend a world in which new information was being produced faster than any single person could assimilate it. Natural philosophers had to be sure of their data, and to that end they required independent and critical confirmation of their discoveries. New means were created to accomplish these ends. Scientific societies sprang up, beginning in Italy in the early years of the 17th century and culminating in the two great national scientific societies that mark the zenith of the scientific revolution: the Royal Society of London for the Promotion of Natural Knowledge, created by royal charter in 1662, and the Académie des Sciences of Paris, formed in 1666. In these societies and others like them all over the world, natural philosophers could gather to examine, discuss, and criticize new discoveries and old theories. To provide a firm basis for these discussions, societies began to publish scientific papers. The Royal Society's *Philosophical Transactions,* which began as a private venture of its secretary, was the first such professional scientific journal. It was soon copied by the French academy's *Mémoires,* which won equal importance and prestige. The old practice of hiding new discoveries in private jargon, obscure language, or even anagrams gradually gave way to the ideal of universal comprehensibility. New canons of reporting were devised so that experiments and discoveries could be reproduced by others. This required new precision in language and a willingness to share experimental or observational methods. The failure of others to reproduce results cast serious doubts upon the original reports. Thus were created the tools for a massive assault on nature's secrets.

The rise of scientific societies

Even with the scientific revolution accomplished, much remained to be done. Again, it was Newton who showed the way. For the macroscopic world, the *Principia* sufficed. Newton's three laws of motion and the principle of universal gravitation were all that was necessary to analyze the mechanical relations of ordinary bodies, and the calculus provided the essential mathematical tools. For the microscopic world, Newton provided two methods. Where simple laws of action had already been determined from observation, as the relation of volume and pressure of a gas (Boyle's law, $pv = k$), Newton assumed forces between particles that permitted him to derive the law. He then used these forces to predict other phenomena, in this case the speed of sound in air, that could be measured against the prediction. Conformity of observation to prediction was taken as evidence for the essential truth of the theory. Second, Newton's method made possible the discovery of laws of macroscopic action that could be accounted for by microscopic forces. Here the seminal work was not the *Principia* but Newton's masterpiece of experimental physics, the *Opticks,* published in 1704, in which he showed how to examine a subject experimentally and discover the laws concealed therein. Newton showed how judicious use of hypotheses could open the way to further experimental investigation until a coherent theory was achieved. The *Opticks* was to serve as the model in the 18th and early 19th centuries for the investigation of heat, light, electricity, magnetism, and chemical atoms.

THE CLASSIC AGE OF SCIENCE

Mechanics. Just as the *Principia* preceded the *Opticks,* so, too, did mechanics maintain its priority among the sciences in the 18th century, in the process becoming transformed from a branch of physics into a branch of mathematics. Many physical problems were reduced to mathematical ones that proved amenable to solution by increasingly sophisticated analytical methods. The Swiss Leonhard Euler was one of the most fertile and prolific workers in mathematics and mathematical physics. His development of the calculus of variations provided a powerful tool for dealing with highly complex problems. In France, Jean Le Rond d'Alembert and Joseph-Louis Lagrange succeeded in completely mathematizing mechanics, reducing it to an axiomatic system requiring only mathematical manipulation.

The test of Newtonian mechanics was its congruence with physical reality. At the beginning of the 18th century it was put to a rigorous test. Cartesians insisted that the Earth, because it was squeezed at the Equator by the etherial vortex causing gravity, should be somewhat pointed at the poles, a shape rather like that of an American football; Newtonians, arguing that centrifugal force was greatest at the Equator, calculated an oblate sphere that was flattened at the poles and bulged at the Equator. The Newtonians were proved correct after careful measurements of a degree of the meridian were made on expeditions to Lapland and to Peru. The final touch to the Newtonian edifice was provided by Pierre-Simon, marquis de Laplace, whose masterly *Traité de mécanique céleste* (1798–1827; *Celestial Mechanics*) systematized everything that had been done in celestial mechanics under Newton's inspiration. Laplace went beyond Newton by showing that the perturbations of the planetary orbits caused by the interactions of planetary gravitation are in fact periodic and that the solar system is, therefore, stable, requiring no divine intervention.

Chemistry. Although Newton was unable to bring to chemistry the kind of clarification he brought to physics, the *Opticks* did provide a method for the study of chemical phenomena. One of the major advances in chemistry in the 18th century was the discovery of the role of air, and of gases generally, in chemical reactions. This role had been dimly glimpsed in the 17th century, but it was not fully seen until the classic experiments of Joseph Black on *magnesia alba* (basic magnesium carbonate) in the 1750s. By extensive and careful use of the chemical balance, Black showed that an air with specific properties could combine with solid substances like quicklime and could be recovered from them. This discovery served to focus attention on the properties of "air," which was soon found to be a generic, not a specific, name. Chemists discovered a host of specific gases and investigated their various properties: some were flammable, others put out flames; some killed animals, others made them lively. Clearly, gases had a great deal to do with chemistry.

Lavoisier

The Newton of chemistry was Antoine-Laurent Lavoisier. In a series of careful balance experiments Lavoisier untangled combustion reactions to show that, in contradiction to established theory, which held that a body gave off the principle of inflammation (called phlogiston) when it burned, combustion actually involves the combination of bodies with a gas that Lavoisier named oxygen. The chemical revolution was as much a revolution in method as in conception. Gravimetric methods made possible precise analysis, and this, Lavoisier insisted, was the central concern of the new chemistry. Only when bodies were analyzed as to their constituent substances was it possible to classify them and their attributes logically and consistently.

The imponderable fluids. The Newtonian method of inferring laws from close observation of phenomena and then deducing forces from these laws was applied with great success to phenomena in which no ponderable matter figured. Light, heat, electricity, and magnetism were all entities that were not capable of being weighed, *i.e.,* imponderable. In the *Opticks,* Newton had assumed that particles of different sizes could account for the different refrangibility of the various colours of light. Clearly, forces of some sort must be associated with these particles if such phenomena as diffraction and refraction are to be accounted for. During the 18th century heat, electricity, and magnetism were similarly conceived as consisting of particles with which were associated forces of attraction or repulsion. In the 1780s, Charles-Augustin de Coulomb was able to measure electrical and magnetic forces, using a delicate torsion balance of his own invention, and to show that these forces follow the general form of Newtonian universal attraction. Only light and heat failed to disclose such general force laws, thereby resisting reduction to Newtonian mechanics.

Science and the Industrial Revolution. It has long been a commonsensical notion that the rise of modern science and the Industrial Revolution were closely connected. It is difficult to show any direct effect of scientific discoveries upon the rise of the textile or even the metallurgical industry in Great Britain, the home of the Industrial Revolution, but there certainly was a similarity in attitude to be found in science and nascent industry. Close observation and careful generalization leading to practical utilization were characteristic of both industrialists and experimentalists alike in the 18th century. One point of direct contact is known, namely James Watt's interest in the efficiency of the Newcomen steam engine, an interest that grew from his work as a scientific-instrument maker and that led to his development of the separate condenser that made the steam engine an effective industrial power source. But in general the Industrial Revolution proceeded without much direct scientific help. Yet the potential influence of science was to prove of fundamental importance.

What science offered in the 18th century was the hope that careful observation and experimentation might improve industrial production significantly. In some areas, it did. The potter Josiah Wedgwood built his successful business on the basis of careful study of clays and glazes and by the invention of instruments like the pyrometer with which to gauge and control the processes he employed. It was not, however, until the second half of the 19th century that science was able to provide truly significant help to industry. It was then that the science of metallurgy permitted the tailoring of alloy steels to industrial specifications, that the science of chemistry permitted the creation of new substances, like the aniline dyes, of fundamental industrial importance, and that electricity and magnetism were harnessed in the electric dynamo and motor. Until that period science probably profited more from industry than the other way around. It was the steam engine that posed the problems that led, by way of a search for a theory of steam power, to the creation of thermodynamics. Most importantly, as industry required ever more complicated and intricate machinery, the machine tool industry developed to provide it and, in the process, made possible the construction of ever more delicate and refined instruments for science. As science turned from the everyday world to the worlds of atoms and molecules, electric currents and magnetic fields, microbes and viruses, and nebulae and galaxies, instruments increasingly provided the sole contact with phenomena. A large refracting telescope driven by intricate clockwork to observe nebulae was as much a product of 19th-century heavy industry as were the steam locomotive and the steamship.

Scientific and technical schools

The Industrial Revolution had one further important effect on the development of modern science. The prospect of applying science to the problems of industry served to stimulate public support for science. The first great scientific school of the modern world, the École Polytechnique in Paris, was founded in 1794 to put the results of science in the service of France. The founding of scores more technical schools in the 19th and 20th centuries encouraged the widespread diffusion of scientific knowledge and provided further opportunity for scientific advance. Governments, in varying degrees and at different rates, began supporting science even more directly, by making financial grants to scientists, by founding research institutes, and by bestowing honours and official posts on great scientists. By the end of the 19th century the natural philosopher following his private interests had given way to the professional scientist with a public role.

The Romantic revolt. Perhaps inevitably, the triumph of Newtonian mechanics elicited a reaction, one that had important implications for the further development of science. Its origins are many and complex, and it is possible here to focus on only one, that associated with the German philosopher Immanuel Kant. Kant challenged the Newtonian confidence that the scientist can deal directly with subsensible entities such as atoms, the corpuscles of light, or electricity. Instead, Kant insisted, all that the human mind can know is forces. This epistemological axiom freed Kantians from having to conceive of forces as embodied in specific and immutable particles. It also placed new emphasis on the space between particles; indeed, if one eliminated the particles entirely, there remained only space containing forces. From these two considerations were to come powerful arguments, first, for the transformations and conservation of forces and, second, for field theory as a representation of reality. What makes this point of view Romantic is that the idea of a network of forces in space tied the cosmos into a unity in which all forces were related to all others, so that the universe took on the aspect of a cosmic organism. The whole was greater than the sum of all its parts, and the way to truth was contemplation of the whole, not analysis.

What Romantics, or nature philosophers, as they called themselves, could see that was hidden from their Newtonian colleagues was demonstrated by Hans Christian Ørsted. He found it impossible to believe that there was no connection between the forces of nature. Chemical affinity, electricity, heat, magnetism, and light must, he argued, simply be different manifestations of the basic forces of attraction and repulsion. In 1820 he showed that electricity and magnetism were related, for the passage of an electrical current through a wire affected a nearby magnetic needle. This fundamental discovery was explored and exploited by Michael Faraday, who spent his whole scientific life converting one force into another. By concentrating on the patterns of forces produced by electric currents and magnets, Faraday laid the foundations for field theory, in which the energy of a system was held to be spread throughout the system and not localized in real or hypothetical particles.

The rudiments of field theory

The transformations of force necessarily raised the question of the conservation of force. Is anything lost when electrical energy is turned into magnetic energy, or into heat or light or chemical affinity or mechanical power? Faraday, again, provided one of the early answers in his two laws of electrolysis, based on experimental observations that quite specific amounts of electrical "force" decomposed quite specific amounts of chemical substances. This work was followed by that of James Prescott Joule, Robert Mayer, and Hermann von Helmholtz, each of whom arrived at a generalization of basic importance to all science, the principle of the conservation of energy.

The nature philosophers were primarily experimentalists who produced their transformations of forces by clever experimental manipulation. The exploration of the nature of elemental forces benefitted as well from the rapid development of mathematics. In the 19th century the study of heat was transformed into the science of thermodynamics, based firmly on mathematical analysis; the Newtonian corpuscular theory of light was replaced by Augustin-Jean Fresnel's mathematically sophisticated undulatory theory; and the phenomena of electricity and magnetism were distilled into succinct mathematical form by William Thomson (Lord Kelvin) and James Clerk Maxwell. By the end of the century, thanks to the principle of the conservation of energy and the second law of thermodynamics, the physical world appeared to be completely comprehensible in terms of complex but precise mathematical forms describing various mechanical transformations in some underlying ether.

The submicroscopic world of material atoms became similarly comprehensible in the 19th century. Beginning with John Dalton's fundamental assumption that atomic species differ from one another solely in their weights, chemists were able to identify an increasing number of elements and to establish the laws describing their interactions. Order was established by arranging elements according to their atomic weights and their reactions. The result was the periodic table, devised by Dmitry Mendeleyev, which implied that some kind of subatomic structure underlay elemental qualities. That structure could give rise to qualities, thus fulfilling the prophecy of the 17th-century mechanical philosophers, was shown in the 1870s by Joseph-Achille Le Bel and Jacobus van't Hoff, whose studies of organic chemicals showed the correlation between the arrangement of atoms or groups of atoms in space and specific chemical and physical properties.

The founding of modern biology. The study of living matter lagged far behind physics and chemistry, largely because organisms are so much more complex than inanimate bodies or forces. Harvey had shown that living matter could be studied experimentally, but his achievement stood alone for two centuries. For the time being, most students of living nature had to be content to classify living forms as best they could and to attempt to isolate and study aspects of living systems.

As has been seen, an avalanche of new specimens in both botany and zoology put severe pressure on taxonomy. A giant step forward was taken in the 18th century by the Swedish naturalist Carl von Linné, known by his Latinized name, Linnaeus, who introduced a rational, if somewhat artificial, system of binomial nomenclature. The very artificiality of Linnaeus' system, focussing as it did on only a few key structures, encouraged criticism and attempts at more natural systems. The attention thus called to the organism as a whole reinforced a growing intuition that species are linked in some kind of genetic relationship, an idea first made scientifically explicit by Jean-Baptiste, chevalier de Lamarck.

Darwin

Problems encountered in cataloging the vast collection of invertebrates at the Museum of Natural History in Paris led Lamarck to suggest that species change through time. This idea was not so revolutionary as it is usually painted, for although it did upset some Christians who read the book of Genesis literally, naturalists who noted the shading of natural forms one into another had been toying with the notion for some time. Lamarck's system failed to gain general assent largely because it relied upon an antiquated chemistry for its causal agents and appeared to imply a conscious drive to perfection on the part of organisms. It was also opposed by one of the most powerful paleontologists and comparative anatomists of the day, Georges Cuvier, who happened to take Genesis quite literally. In spite of Cuvier's opposition, however, the idea remained alive and was finally elevated to scientific status by the labours of Charles Darwin. Darwin not only amassed a wealth of data supporting the notion of transformation of species, but he also was able to suggest a mechanism by which such evolution could occur without recourse to other than purely natural causes. The mechanism was natural selection, according to which minute variations in offspring were either favoured or eliminated in the competition for survival, and it permitted the idea of evolution to be perceived with great clarity. Nature shuffled and sorted its own productions, through processes governed purely by chance, so that those organisms that survived were better adapted to a constantly changing environment.

Darwin's *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life,* published in 1859, brought order to the world of organisms. A similar unification at the microscopic level had been brought about by the cell theory announced by Theodor Schwann and Matthias Schleiden in 1838, whereby cells were held to be the basic units of all living tissues. Improvements in the microscope during the 19th century made it possible gradually to lay bare the basic structures of cells, and rapid progress in biochemistry permitted the intimate probing of cellular physiology. By the end of the century the general feeling was that physics and chemistry sufficed to describe all vital functions and that living matter, subject to the same laws as inanimate matter, would soon yield up its secrets. This reductionist view was triumphantly illustrated in the work of Jacques Loeb, who showed that so-called instincts in lower animals are nothing more than physicochemical reactions, which he labelled tropisms.

The most dramatic revolution in 19th-century biology was the one created by the germ theory of disease, championed by Louis Pasteur in France and Robert Koch in Germany. Through their investigations, bacteria were shown to be the specific causes of many diseases. By means of immunological methods first devised by Pasteur, some of mankind's chief maladies were brought under control.

THE 20TH-CENTURY REVOLUTION

By the end of the 19th century, the dream of the mastery of nature for the benefit of mankind, first expressed in all its richness by Sir Francis Bacon, seemed on the verge of realization. Science was moving ahead on all fronts, reducing ignorance and producing new tools for the amelioration of the human condition. A comprehensible, rational view of the world was gradually emerging from laboratories and universities. One savant went so far as to express pity for those who would follow him and his colleagues, for they, he thought, would have nothing more to do than to measure things to the next decimal place.

Einstein

But this sunny confidence did not last long. One annoying problem was that the radiation emitted by atoms proved increasingly difficult to reduce to known mechanical principles. More importantly, physics found itself relying more and more upon the hypothetical properties of a substance, the ether, that stubbornly eluded detection. Within a span of 10 short years, roughly 1895–1905, these and related problems came to a head and wrecked the mechanistic system the 19th century had so laboriously built. The discovery of X rays and radioactivity revealed an unexpected new complexity in the structure of atoms. Max Planck's solution to the problem of thermal radiation introduced a discontinuity into the concept of energy that was inexplicable in terms of classical thermodynamics. Most disturbing of all, the enunciation of the special theory of relativity by Albert Einstein in 1905 not only destroyed the ether and all the physics that depended on it but also redefined physics as the study of relations between observers and events, rather than of the events themselves. What was observed, and therefore what happened, was now said to be a function of the observer's location and motion relative to other events. Absolute space was a fiction. The very foundations of physics threatened to crumble.

This modern revolution in physics has not yet been fully assimilated by historians of science. Suffice it to say that scientists managed to come to terms with all of the upsetting results of early 20th-century physics but in ways that made the new physics utterly different from the old. Mechanical models were no longer acceptable, because there were processes (like light) for which no consistent model could be constructed. No longer could physicists speak with confidence of physical reality, but only of the probability of making certain measurements.

All this being said, there is still no doubt that science in the 20th century has worked wonders. The new physics—relativity, quantum mechanics, particle physics—may outrage common sense, but it enables physicists to probe to the very limits of physical reality. Their instruments and mathematics permit modern scientists to manipulate subatomic particles with relative ease, to reconstruct the first moment of creation, and to glimpse dimly the grand structure and ultimate fate of the universe.

The revolution in physics has spilled over into chemistry and biology and led to hitherto undreamed of capabilities for the manipulation of atoms and molecules and of cells and their genetic structures. Chemists perform molecular tailoring today as a matter of course, cutting and shaping molecules at will. Genetic engineering makes possible active human intervention in the evolutionary process and holds out the possibility of tailoring living organisms, including the human organism, to specific tasks. This second scientific revolution may prove to be, for good or ill, the most important event in the history of mankind.

BIBLIOGRAPHY. For the legacy of the founder of the discipline of the history of science, GEORGE SARTON, see his *History of Science,* 2 vol. (1952–59), or his *Introduction to the History of Science,* 3 vol. in 5 (1927–48, reprinted 1975). A number of modern works cover the whole of the history of science. The most extensive is RENÉ TATON, *A General History of the Sciences,* 4 vol. (1963–66; U.S. title, *History of Science,* 4 vol., 1964–66; originally published in French, 1957–64). COLIN A. RONAN, *The Ages of Science* (1966), *Science: Its History and Development Among the World's Cultures* (1982), and *The Atlas of Scientific Discovery* (1983), are well-written surveys. L. PEARCE WILLIAMS and HENRY JOHN STEFFENS, *The History of Science in Western Civilization,* 3 vol. (1978–79), presents a narrative account of the history of Western science and excerpts from many scientific classics. J.D. BERNAL, *Science in History,* new ed., 4 vol. (1969, reissued 1979), is an orthodox Marxist version of the development of science by a distinguished scientist. The Marxist treatment only becomes seriously distorting when Bernal reaches the 19th century and begins to deal with the social sciences. A.E.E. MCKENZIE, *The Major Achievements of Science,* 2 vol. (1960, reissued 1973), is a brief and interesting account, accompanied by selections from primary sources.

The history of ancient mathematics and astronomy before the Greeks is brilliantly detailed by OTTO NEUGEBAUER, *The Exact Sciences in Antiquity*, 2nd ed. (1957); and by BARTEL L. VAN DER WAERDEN, *Science Awakening*, 4th ed., 2 vol. (1975; originally published in Dutch, 1950–65), who treats also the Greek achievement. A general history of Greek science is MARSHALL CLAGETT, *Greek Science in Antiquity* (1955, reissued 1976). The philosophical dimension of Greek science is masterfully presented by WILLIAM K.C. GUTHRIE, *A History of Greek Philosophy*, 6 vol. (1962–81). SAMUEL SAMBURSKY, *The Physical World of the Greeks*, trans. from the Hebrew (1956, reissued 1962), deals primarily with Stoic physics. EDWARD GRANT, *Physical Science in the Middle Ages* (1971, reprinted 1977), is a good survey, complete with an excellent bibliographical essay. More detailed accounts of medieval physics can be found in MARSHALL CLAGETT, *The Science of Mechanics in the Middle Ages* (1959). The influence of Hermeticism on the origins of modern science is treated by FRANCES A. YATES, *Giordano Bruno and the Hermetic Tradition* (1964, reprinted 1979); and D.P. WALKER, *Spiritual and Demonic Magic from Ficino to Campanella* (1958, reissued 1975).

A. RUPERT HALL, *The Scientific Revolution, 1500–1800: The Formation of the Modern Scientific Attitude*, 2nd ed. (1962, reprinted 1967), remains the best survey of that process. The vast literature is surveyed in RICHARD S. WESTFALL, *The Construction of Modern Science: Mechanisms and Mechanics* (1971, reprinted 1977). The same author's *Never at Rest: A Biography of Isaac Newton* (1980, reprinted 1983), is both brilliant and authoritative and should be read by anyone interested in the origins of modern physics. For a general history of science since the scientific revolution, see CHARLES COULSTON GILLISPIE, *The Edge of Objectivity: An Essay in the History of Scientific Ideas* (1960, reprinted 1973). The most useful reference for the history of science in general is CHARLES COULSTON GILLISPIE (ed.), *Dictionary of Scientific Biography*, 16 vol. (1970–80).

(L.P.W.)

The Art of Sculpture

Sculpture is not a fixed term that applies to a permanently circumscribed category of objects or sets of activities. It is, rather, the name of an art that grows and changes and is continually extending the range of its activities and evolving new kinds of objects. The scope of the term is much wider in the second half of the 20th century than it was only two or three decades ago, and in the present fluid state of the visual arts nobody can predict what its future extensions are likely to be.

Certain features, which in previous centuries were considered essential to the art of sculpture, are not present in a great deal of modern sculpture and can no longer form part of its definition. One of the most important of these is representation. Before the 20th century, sculpture was considered a representational art; but its scope has now been extended to include nonrepresentational forms. It has long been accepted that the forms of such functional three-dimensional objects as furniture, pots, and buildings may be expressive and beautiful without being in any way representational; but it is only in the 20th century that nonfunctional, nonrepresentational, three-dimensional works of art have been produced.

Again, before the 20th century, sculpture was considered primarily an art of solid form, or mass. It is true that the negative elements of sculpture—the voids and hollows within and between its solid forms—have always been to some extent an integral part of its design, but their role has been a secondary one. In a great deal of modern sculpture, however, the focus of attention has shifted, and the spatial aspects have become dominant. Spatial sculpture is now a generally accepted branch of the art of sculpture.

It was also taken for granted in the sculpture of the past that its components were of a constant shape and size and did not move. With the recent development of kinetic sculpture, neither the immobility nor immutability of its form can any longer be considered essential to the art of sculpture.

Finally, 20th-century sculpture is not confined to the two traditional forming processes of carving and modelling or to such traditional natural materials as stone, metal, wood, ivory, bone, and clay. Because present-day sculptors use any materials and methods of manufacture that will serve their purposes, the art of sculpture can no longer be identified with any special materials or techniques.

Through all of these changes there is probably only one thing that has remained constant in the art of sculpture, and it is this that emerges as the central and abiding concern of sculptors: the art of sculpture is the branch of the visual arts that is especially concerned with the creation of expressive form in three dimensions.

Sculpture may be either in the round or in relief. A sculpture in the round is a separate, detached object in its own right, leading the same kind of independent existence in space as a human body or a chair. A relief does not have this kind of independence. It projects from and is attached to or is an integral part of something else that serves either as a background against which it is set or a matrix from which it emerges.

The actual three-dimensionality of sculpture in the round limits its scope in certain respects in comparison with the scope of painting. Sculpture cannot conjure up the illusion of space by purely optical means or invest its forms with atmosphere and light as painting can. It does have a kind of reality, a vivid physical presence that is denied to the pictorial arts. The forms of sculpture are tangible as well as visible, and they can appeal strongly and directly to both tactile and visual sensibilities. Blind people, even those who are congenitally blind, can produce and appreciate certain kinds of sculpture. It has, in fact, been argued by the 20th-century art critic Sir Herbert Read that sculpture should be regarded as primarily an art of touch and that the roots of sculptural sensibility can be traced to the pleasure one experiences in fondling things.

All three-dimensional forms are perceived as having an expressive character as well as purely geometric properties. They strike the observer as delicate, aggressive, flowing, taut, relaxed, dynamic, soft, and so on. By exploiting the expressive qualities of form, a sculptor is able to create images in which subject matter and expressiveness of form are mutually reinforcing. Such images go beyond the mere presentation of fact and communicate a wide range of subtle and powerful feelings.

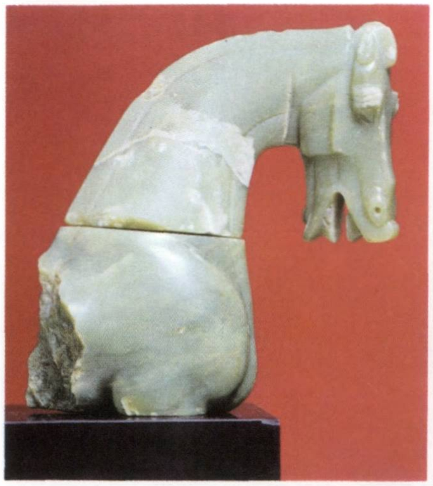
The aesthetic raw material of sculpture is, so to speak, the whole realm of expressive three-dimensional form. A sculpture may draw upon what already exists in the endless variety of natural and man-made form, or it may be an art of pure invention. It has been used to express a vast range of human emotions and feelings from the most tender and delicate to the most violent and ecstatic.

All human beings, intimately involved from birth with the world of three-dimensional form, learn something of its structural and expressive properties and develop emotional responses to them. This combination of understanding and sensitive response, often called a sense of form, can be cultivated and refined. It is to this sense of form that the art of sculpture primarily appeals.

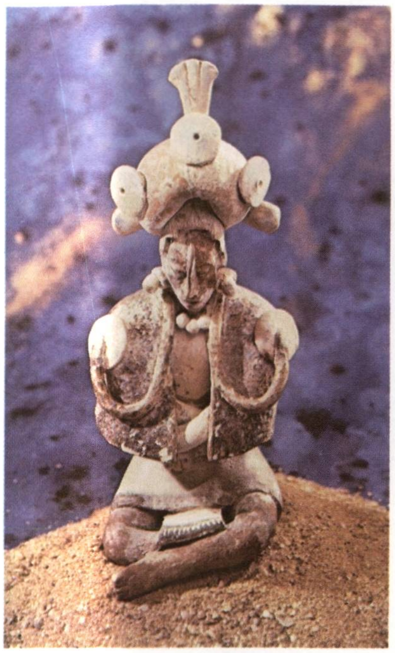
This article deals with the elements and principles of design; the materials, methods, techniques, and forms of sculpture; and its subject matter, imagery, symbolism, and uses. For the history of sculpture in the West, see SCULPTURE, THE HISTORY OF WESTERN. For treatments of sculpture as practiced in non-European cultures, see AFRICAN ARTS; AMERICAN INDIANS: *Visual Arts;* CENTRAL ASIAN ARTS; EAST ASIAN ARTS; EGYPTIAN ARTS AND ARCHITECTURE, ANCIENT; ISLĀMIC ARTS; OCEANIC ARTS; PREHISTORIC PEOPLES AND CULTURES; SOUTH ASIAN ARTS; SOUTHEAST ASIAN ARTS.

The article is divided into the following sections:

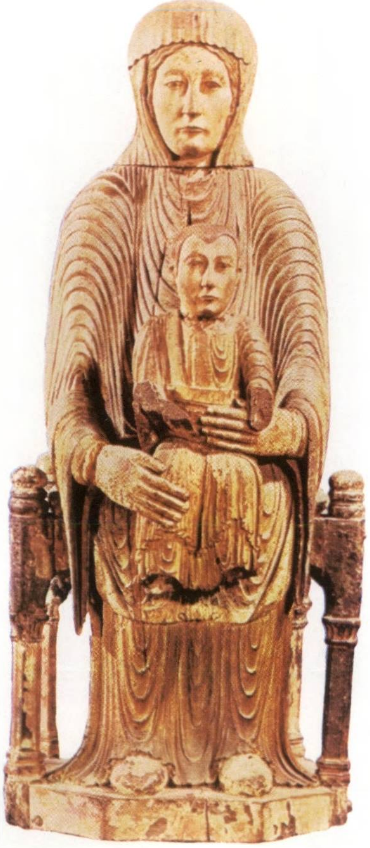
Diverse materials and techniques



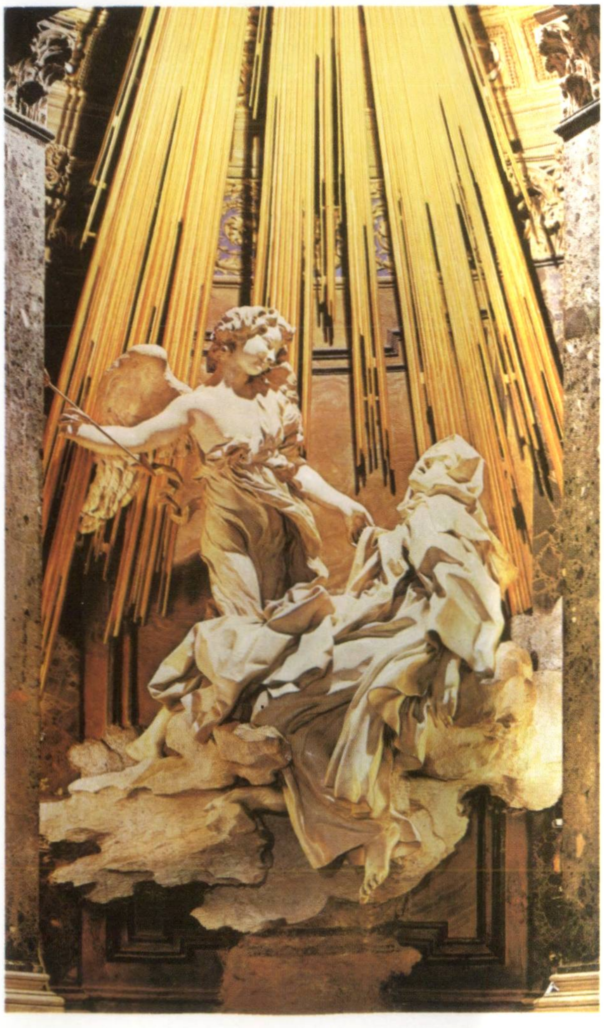
Jade horse head, Chinese, Han dynasty (206 BC–AD 220). In the Victoria and Albert Museum, London. Height 19 cm.

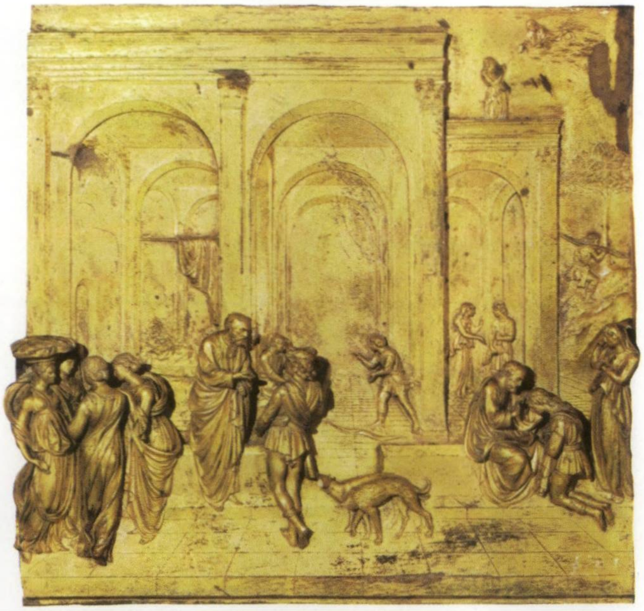


Jaina pottery figurine, late classic Maya style, from the state of Campeche, Mexico. In the collection of Dumbarton Oaks, Washington, D.C. Height 15.5 cm.



"Virgin and Child," polychromed oak statue of the school of Auvergne, France, 12th century. In the Metropolitan Museum of Art, New York. 78.7 × 32.4 cm.



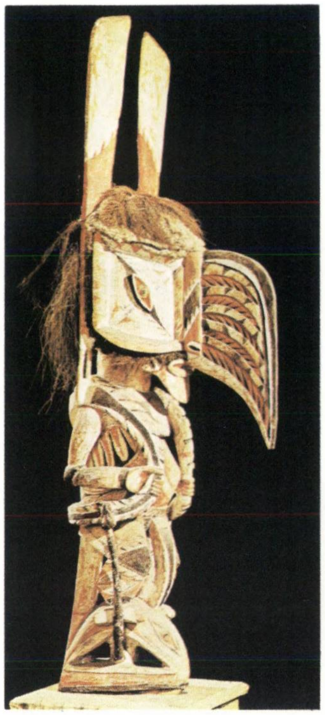


"Isaac, Jacob, and Esau," gilded bronze relief panel from the east doors ("Gates of Paradise") of the baptistery in Florence, by Lorenzo Ghiberti, 1425–52. 79.4 cm square.

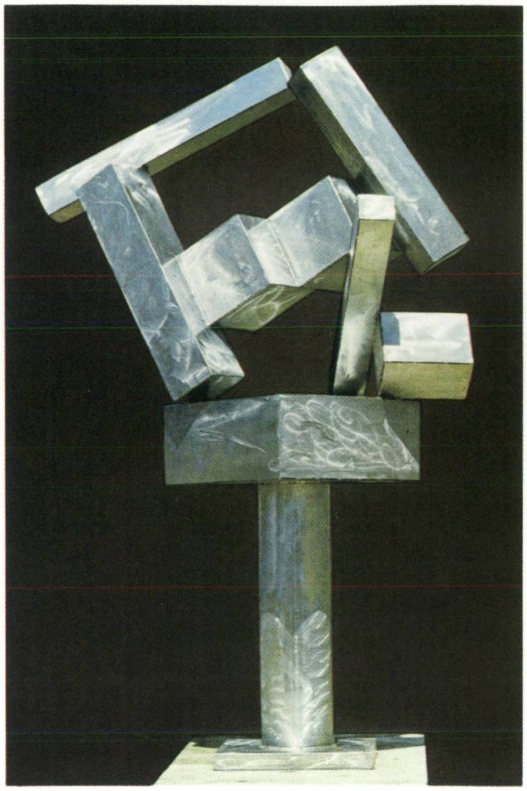
"The Ecstasy of St. Teresa," marble and gilded bronze niche sculpture by Gian Lorenzo Bernini, 1645–52. In the Coronaro Chapel, Sta. Maria della Vittoria, Rome. Lifesize.

Plate 1: By courtesy of (top left) the Victoria and Albert Museum, London, (centre) Dumbarton Oaks, Washington, D.C., (top right) the Metropolitan Museum of Art, New York, gift of J. Pierpont Morgan, 1916; photographs, (bottom left and right) SCALA—Art Resource/EB Inc.

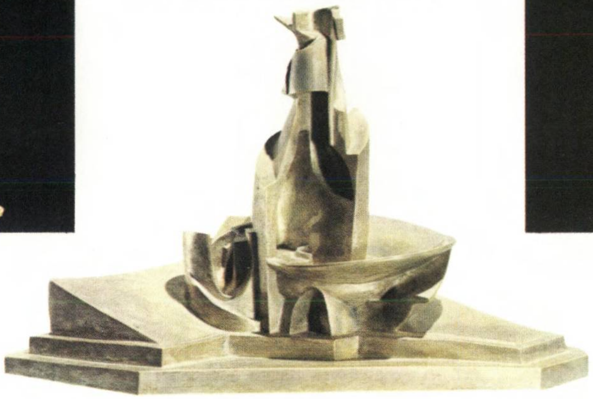
Diverse kinds of representational and nonrepresentational sculpture



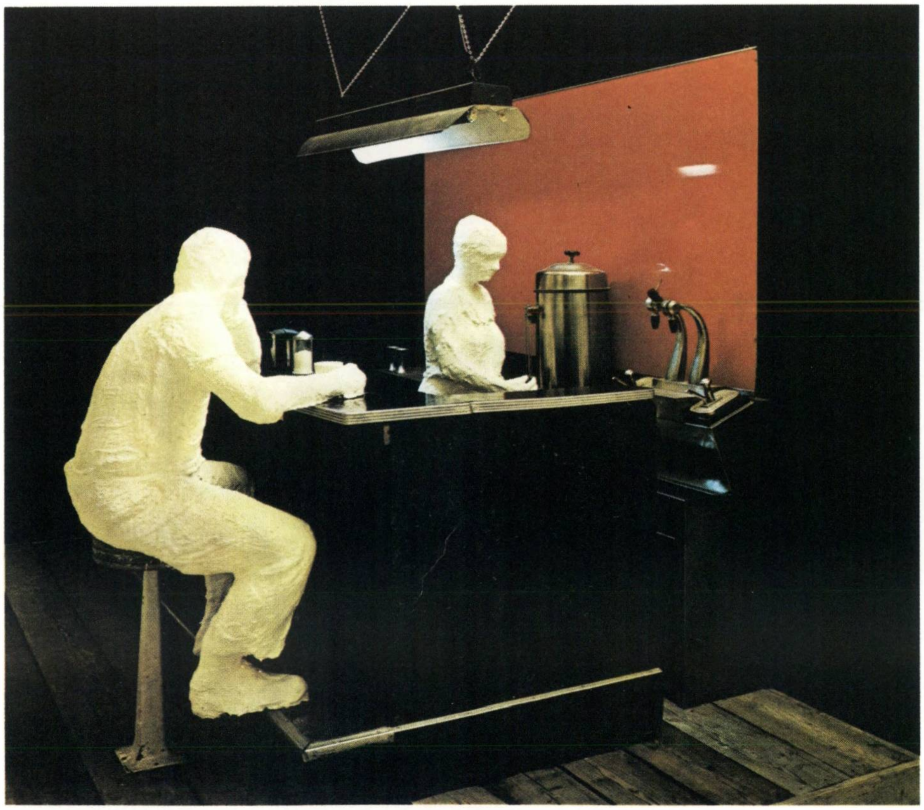
Painted wood male figure standing on a fish, fantastic cult image from Northern New Ireland, Melanesia. In a private collection. Height 1.53 m.



"Cubi XVII," non-objective sculpture by David Smith, stainless steel, 1963. In the Dallas Museum of Fine Arts, Texas. Height 2.74 m.



"Development of a Bottle in Space," nonrepresentational sculpture by Umberto Boccioni, silvered bronze, 1912. In the Museum of Modern Art, New York. 38.1 × 32.7 × 59.7 cm.



"The Diner," representational environmental sculpture by George Segal, mixed media (plaster, wood, chrome, masonite, and formica), 1964–66. In the Walker Art Center, Minneapolis. 2.59 × 2.74 × 2.13 m.

Elements and principles of sculptural design

Ways in which space enters into the design of sculpture

The two most important elements of sculpture—mass and space—are, of course, separable only in thought. All sculpture is made of a material substance that has mass and exists in three-dimensional space. The mass of sculpture is thus the solid, material, space-occupying bulk that is contained within its surfaces. Space enters into the design of sculpture in three main ways: the material components of the sculpture extend into or move through space; they may enclose or enfold space, thus creating hollows and voids within the sculpture; and they may relate one to another across space. Volume, surface, light and shade, and colour are supporting elements of sculpture.

ELEMENTS OF DESIGN

The amount of importance attached to either mass or space in the design of sculpture varies considerably. In Egyptian sculpture and in most of the sculpture of the 20th-century artist Constantin Brancusi, for example, mass is paramount, and most of the sculptor's thought has been devoted to shaping a lump of solid material. In 20th-century works by Antoine Pevsner or Naum Gabo, on the other hand, mass is reduced to a minimum, consisting only of transparent sheets of plastic or thin metal rods. The solid form of the components themselves is of little importance; their main function is to create movement through space and to enclose space. In works by such 20th-century sculptors as Henry Moore and Barbara Hepworth, the elements of space and mass are treated as more or less equal partners.

It is not possible to see the whole of a fully three-dimensional form at once. The observer can only see the whole of it if he turns it around or goes around it himself. For this reason it is sometimes mistakenly assumed that sculpture must be designed primarily to present a series of satisfactory projective views and that this multiplicity of views constitutes the main difference between sculpture and the pictorial arts, which present only one view of their subject. Such an attitude toward sculpture ignores the fact that it is possible to apprehend solid forms as volumes, to conceive an idea of them in the round from any one aspect. A great deal of sculpture is designed to be apprehended primarily as volume.

A single volume is the fundamental unit of three-dimensional solid form that can be conceived in the round. Some sculptures consist of only one volume, others are configurations of a number of volumes. The human figure is often treated by sculptors as a configuration of volumes, each of which corresponds to a major part of the body, such as the head, neck, thorax, and thigh.

Holes and cavities in sculpture, which are as carefully shaped as the solid forms and are of equal importance to the overall design, are sometimes referred to as negative volumes.

The surfaces of sculpture are in fact all that one actually sees. It is from their inflections that one makes inferences about the internal structure of the sculpture. A surface has, so to speak, two aspects: it contains and defines the internal structure of the masses of the sculpture, and it is the part of the sculpture that enters into relations with external space.

The expressive character of different kinds of surfaces is of the utmost importance in sculpture. Double-curved convex surfaces suggest fullness, containment, enclosure, the outward pressure of internal forces. In the aesthetics of Indian sculpture such surfaces have a special metaphysical significance. Representing the encroachment of space into the mass of the sculpture, concave surfaces suggest

the action of external forces and are often indicative of collapse or erosion. Flat surfaces tend to convey a feeling of material hardness and rigidity; they are unbending or unyielding, unaffected by either internal or external pressures. Surfaces that are convex in one curvature and concave in the other can suggest the operation of internal pressures and at the same time a receptivity to the influence of external forces. They are associated with growth, with expansion into space.

The sculptor cannot, like the painter, create his own lighting effects within the work itself. The distribution of light and shade over the forms of his work depends upon the direction and intensity of light from external sources. Nevertheless, to some extent he can determine the kinds of effect this external light will have. If he knows where the work is to be sited, he can adapt it to the kind of light it is likely to receive. The brilliant overhead sunlight of Egypt and India demands a different treatment from the dim interior light of a northern medieval cathedral. Then again, it is possible to create effects of light and shade, or chiaroscuro, by cutting or modelling deep, shadow-catching hollows and prominent, highlighted ridges. Many late Gothic sculptors used light and shade as a powerful expressive feature of their work, aiming at a mysterious obscurity, with forms broken by shadow emerging from a dark background. Greek, Indian, and most Italian Renaissance sculptors shaped the forms of their work to receive light in a way that makes the whole work radiantly clear.

Chiaroscuro effects

The colouring of sculpture may be either natural or applied. In the recent past, sculptors became more aware than ever before of the inherent beauty of sculptural materials. Under the slogan of "truth to materials" many of them worked their materials in ways that exploited their natural properties, including colour and texture. More recently, however, there has been a growing tendency to use bright artificial colouring as an important element in the design of sculpture.

In the ancient world and during the Middle Ages almost all sculpture was artificially coloured, usually in a bold and decorative rather than a naturalistic manner. The sculptured portal of a cathedral, for example, would be coloured and gilded with all the brilliance of a contemporary illuminated manuscript. Combinations of differently coloured materials, such as the ivory and gold of some Greek sculpture, were not unknown before the 17th century; but the early Baroque sculptor Gian Lorenzo Bernini greatly extended the practice by combining variously coloured marbles with white marble and gilt bronze.

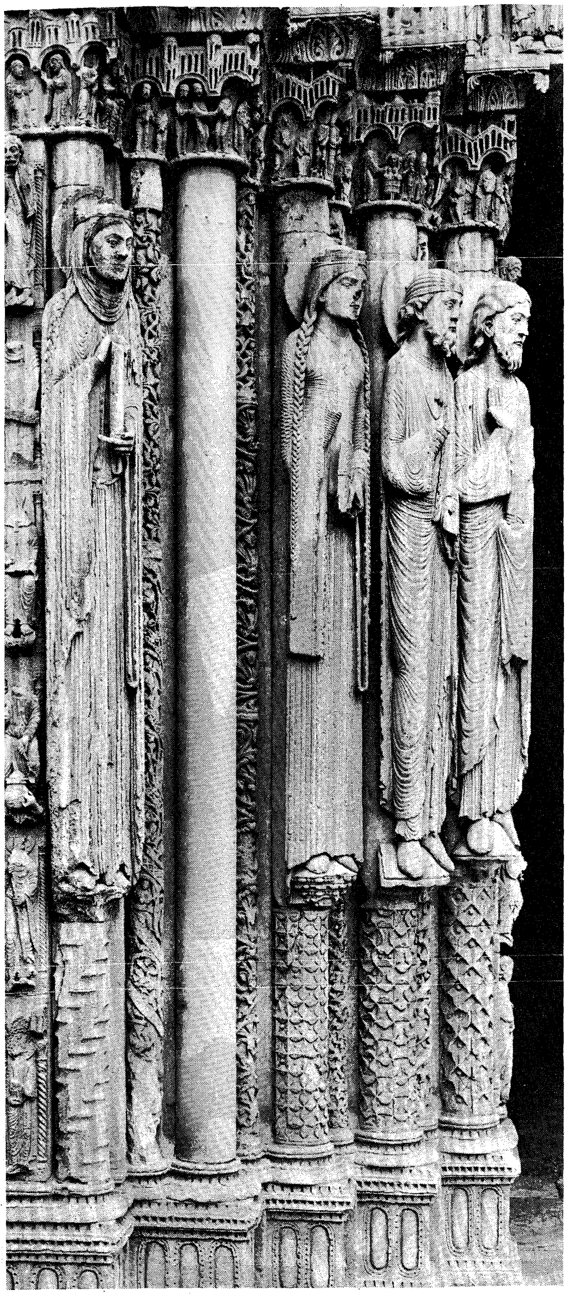
PRINCIPLES OF DESIGN

It is doubtful whether any principles of design are universal in the art of sculpture, for the principles that govern the organization of the elements of sculpture into expressive compositions differ from style to style. In fact, distinctions made among the major styles of sculpture are largely based on a recognition of differences in the principles of design that underlie them. Thus, the art historian Erwin Panofsky was attempting to define a difference of principle in the design of Romanesque and Gothic sculpture when he stated that the forms of Romanesque were conceived as projections from a plane outside themselves, while those of Gothic were conceived as being centred on an axis within themselves. The "principle of axiality" was considered by Panofsky to be "the essential principle of classical statuary," which Gothic had rediscovered.

The principles of sculptural design govern the approaches of sculptors to such fundamental matters as orientation, proportion, scale, articulation, and balance.

For conceiving and describing the orientation of the forms of sculpture in relation to each other, to a spectator, and to their surroundings, some kind of spatial scheme of reference is required. This is provided by a system of axes and planes of reference.

An axis is an imaginary centre line through a symmetrical or near symmetrical volume or group of volumes. Thus, all the main components of the human body have axes of their own, while an upright figure has a single vertical axis running through its entire length. Volumes may rotate or tilt on their axes.



Proportion.

ND photo

Planes of reference are imaginary planes to which the movements, positions, and directions of volumes, axes, and surfaces may be referred. The principal planes of reference are the frontal, the horizontal, and the two profile planes.

The principles that govern the characteristic poses and spatial compositions of upright figures in different styles of sculpture are formulated with reference to axes and the four cardinal planes: for example, the principle of axiality already referred to; the principle of frontality, which governs the design of Archaic sculpture; the characteristic contrapposto (pose in which parts of the body, such as upper and lower, are twisted in opposite directions) of Michelangelo's figures; and in standing Greek sculpture of the Classical period the frequently used balanced "chiastic" pose (stance in which the body weight is taken principally on one leg, thereby creating a contrast of tension and relaxation between the opposite sides of a figure).

Proportional relations exist among linear dimensions,

Use of unnatural proportions

areas, and volumes and masses. All three types of proportion coexist and interact in sculpture, contributing to its expressiveness and beauty. Attitudes toward proportion differ considerably among sculptors. Some sculptors, both abstract and figurative, use mathematical systems of proportion; for example, the refinement and idealization of natural human proportions was a major preoccupation of Greek sculptors. Indian sculptors employed iconometric canons, or systems of carefully related proportions, that determined the proportions of all significant dimensions of the human figure. African and other tribal sculptors base the proportions of their figures on the subjective importance of the parts of the body. Unnatural proportions may be used for expressive purposes or to accommodate a sculpture to its surroundings. The elongation of the figures on the Portail Royal ("Royal Portal") of Chartres cathedral does both: it enhances their otherworldliness and also integrates them with the columnar architecture.

Sometimes it is necessary to adapt the proportions of sculpture to suit its position in relation to a viewer. A figure sited high on a building, for example, is usually made larger in its upper parts in order to counteract the effects of foreshortening. This should be allowed for when a sculpture intended for such a position is exhibited on eye level in a museum.

The scale of sculpture must sometimes be considered in relation to the scale of its surroundings. When it is one element in a larger complex, such as the facade of a building, it must be in scale with the rest. Another important consideration that sculptors must take into account when designing outdoor sculpture is the tendency of sculpture in the open air—particularly when viewed against the sky—to appear less massive than it does in a studio. Because one tends to relate the scale of sculpture to one's own human physical dimensions, the emotional impact of a colossal figure and a small figurine are quite different.

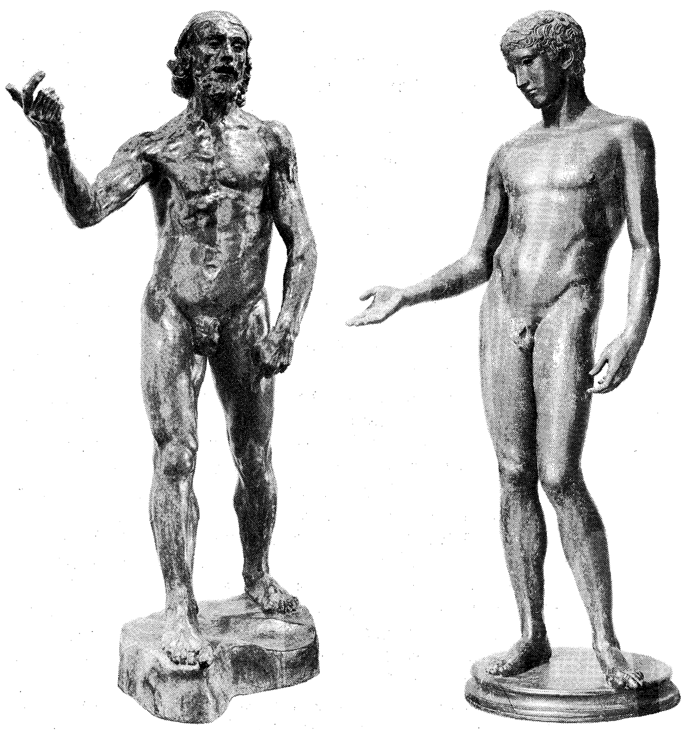
In ancient and medieval sculpture the relative scale of the figures in a composition is often determined by their importance; *e.g.,* slaves are much smaller than kings or nobles. This is sometimes known as hierarchic scale.

The joining of one form to another may be accomplished in a variety of ways. In much of the work of the 19th-century French sculptor Auguste Rodin, there are no clear boundaries, and one form is merged with another in an impressionistic manner to create a continuously flowing surface. In works by the Greek sculptor Praxiteles, the forms are softly and subtly blended by means of smooth, blurred transitions. The volumes of Indian sculpture and the surface anatomy of male figures in the style of the Greek sculptor Polyclitus are sharply defined and clearly articulated. One of the main distinctions between the work of Italian and northern Renaissance sculptors lies in the Italians' preference for compositions made up of clearly articulated, distinct units of form and the tendency of the northern Europeans to subordinate the individual parts to the allover flow of the composition.

The balance, or equilibrium, of freestanding sculpture has three aspects. First, the sculpture must have actual physical stability. This can be achieved by natural balance—that is, by making the sculpture stable enough in itself to stand firmly—which is easy enough to do with a four-legged animal or a reclining figure but not with a standing figure or a tall, thin sculpture, which must be secured to a base. The second aspect of balance is compositional. The interaction of forces and the distribution of weight within a composition may produce a state of either dynamic or static equilibrium. The third aspect of balance applies only to sculpture that represents a living figure. A live human figure balances on two feet by making constant movements and muscular adjustments. Such an effect can be conveyed in sculpture by subtle displacements of form and suggestions of tension and relaxation.

RELATIONSHIPS TO OTHER ARTS

Sculpture has always been closely related to architecture through its role as architectural decoration and also at the level of design. Architecture, like sculpture, is concerned with three-dimensional form; and, although the central problem in the design of buildings is the organization of space rather than mass, there are styles of architecture that are effective largely through the quality and organization of their solid forms. Ancient styles of stone architecture, particularly Egyptian, Greek, and Mexican, tend to treat their components in a sculptural manner. Moreover, most buildings viewed from the outside are compositions of masses. The growth of spatial sculpture is so intimately related to the opening up and lightening of architecture, which the development of modern building technology has made possible, that many 20th-century sculptors can be said to treat their work in an architectural manner.



Articulation.
(Left) Flowing surface exemplified by "St. John the Baptist Preaching," bronze sculpture by Auguste Rodin, 1878. In the Museum of Modern Art, New York City. Height 2 m. (Right) Delineated surface exemplified by "L'Idolino" bronze, Roman copy of a Greek sculpture in the style of Polyclitus, *c.* 440 BC. In the Museo Archeologico, Florence.

Sculpture and the pictorial arts

Some forms of relief sculpture approach very closely the pictorial arts of painting, drawing, engraving, and so on. And sculptures in the round that make use of chiaroscuro and that are conceived primarily as pictorial views rather than as compositions in the round are said to be "painterly"; for example, Bernini's "Ecstasy of St. Teresa" (Sta. Maria della Vittoria, Rome).

The borderlines between sculpture and pottery and the metalworking arts are not clear-cut, and many pottery and metal artifacts have every claim to be considered as sculpture. Today there is a growing affinity between the work of industrial designers and sculptors. Sculptural modelling techniques, and sometimes sculptors themselves, are often involved, for example, in the initial stages of the design of new automobile bodies.

The close relationships that exist between sculpture and the other visual arts are attested by the number of artists who have readily turned from one art to another; for example, Michelangelo, Bernini, Pisanello, Degas, and Picasso.

Materials

Any material that can be shaped in three dimensions can be used sculpturally. Certain materials, by virtue of their structural and aesthetic properties and their availability, have proved especially suitable. The most important of these are stone, wood, metal, clay, ivory, and plaster. There are also a number of materials of secondary importance and many that have only recently come into use.

PRIMARY

Throughout history, stone has been the principal material of monumental sculpture. There are practical reasons for this: many types of stone are highly resistant to the weather and therefore suitable for external use; stone is available in all parts of the world and can be obtained in large blocks; many stones have a fairly homogeneous texture and a uniform hardness that make them suitable for carving; stone has been the chief material used for the monumental architecture with which so much sculpture has been associated.

Stones belonging to all three main categories of rock formation have been used in sculpture. Igneous rocks, which are formed by the cooling of molten masses of mineral as they approach the Earth's surface, include granite, diorite, basalt, and obsidian. These are some of the hardest stones used for sculpture. Sedimentary rocks, which include sandstones and limestones, are formed from accumulated deposits of mineral and organic substances. Sandstones are agglomerations of particles of eroded stone held together by a cementing substance. Limestones are formed chiefly from the calcareous remains of organisms. Alabaster (gypsum), also a sedimentary rock, is a chemical deposit. Many varieties of sandstone and limestone, which vary greatly in quality and suitability for carving, are used for sculpture. Because of their method of formation, many sedimentary rocks have pronounced strata and are rich in fossils.

Metamorphic rocks result from changes brought about in the structure of sedimentary and igneous rocks by extreme pressure or heat. The most well-known metamorphic rocks used in sculpture are the marbles, which are recrystallized limestones. Italian Carrara marble, the best known, was used by Roman and Renaissance sculptors, especially Michelangelo, and is still widely used. The best known varieties used by Greek sculptors, with whom marble was more popular than any other stone, are Pentelic—from which the Parthenon and its sculpture are made—and Parian.

Because stone is extremely heavy and lacks tensile strength, it is easily fractured if carved too thinly and not properly supported. A massive treatment without vulnerable projections, as in Egyptian and pre-Columbian American Indian sculpture, is therefore usually preferred. Some stones, however, can be treated more freely and openly; marble in particular has been treated by some European sculptors with almost the same freedom as bronze, but such displays of virtuosity are achieved by overcoming rather than submitting to the properties of the material itself.

Colours and textures of stone

The colours and textures of stone are among its most delightful properties. Some stones are fine-grained and can be carved with delicate detail and finished with a high polish; others are coarse-grained and demand a broader treatment. Pure white Carrara marble, which has a translucent quality, seems to glow and responds to light in a delicate, subtle manner. (These properties of marble were brilliantly exploited by 15th-century Italian sculptors such as Donatello and Desiderio da Settignano.) The colouring of granite is not uniform but has a salt-and-pepper quality and may glint with mica and quartz crystals. It may be predominantly black or white or a variety of grays, pinks, and reds. Sandstones vary in texture and are often warmly coloured in a range of buffs, pinks, and reds. Limestones vary greatly in colour, and the presence of fossils may add to the interest of their surfaces. A number of stones are richly variegated in colour by the irregular veining that runs through them.

Hardstones, or semiprecious stones, constitute a special group, which includes some of the most beautiful and decorative of all substances. The working of these stones, along with the working of more precious gemstones, is usually considered as part of the glyptic (gem carving or engraving), or lapidary, arts, but many artifacts produced from them can be considered small-scale sculpture. They are often harder to work than steel. First among the hardstones used for sculpture is jade, which was venerated by the ancient Chinese, who worked it, together with other hardstones, with extreme skill. It was also used sculpturally by Mayan and Mexican artists. Other important hardstones are rock crystal, rose quartz, amethyst, agate, and jasper.

The principal material of tribal sculpture in Africa, Oceania, and North America, wood has also been used by every great civilization; it was used extensively during the Middle Ages, for example, especially in Germany and central Europe. Among modern sculptors who have used wood for important works are Ernst Barlach, Ossip Zadkine, and Henry Moore.

Characteristics of wood

Both hardwoods and softwoods are used for sculpture. Some are close-grained, and they cut like cheese; others are open-grained and stringy. The fibrous structure of wood gives it considerable tensile strength, so that it may be carved thinly and with greater freedom than stone. For large or complex open compositions, a number of pieces of wood may be jointed. Wood is used mainly for indoor sculpture, for it is not as tough or durable as stone; changes of humidity and temperature may cause it to split, and it is subject to attack by insects and fungus. The grain of wood is one of its most attractive features, giving variety of pattern and texture to its surfaces. Its colours, too, are subtle and varied. In general, wood has a warmth that stone does not have, but it lacks the massive dignity and weight of stone.

The principal woods for sculpture are oak, mahogany, limewood, walnut, elm, pine, cedar, boxwood, pear, and ebony; but many others are also used. The sizes of wood available are limited by the sizes of trees; North American Indians, for example, could carve gigantic totem poles in pine, but boxwood is available only in small pieces.

In the 20th century, wood was being used by many sculptors as a medium for construction as well as for carving. Laminated timbers, chipboards, and timber in block and plank form can be glued, jointed, screwed, or bolted together, and given a variety of finishes.

Wherever metal technologies have been developed, metals have been used for sculpture. The amount of metal sculpture that has survived from the ancient world does not properly reflect the extent to which it was used, for vast quantities have been plundered and melted down. Countless Far Eastern and Greek metal sculptures have been lost in this way, as has almost all the goldwork of pre-Columbian American Indians.

Advantages of bronze

The metal most used for sculpture is bronze, which is basically an alloy of copper and tin; but gold, silver, aluminum, copper, brass, lead, and iron have also been widely used. Most metals are extremely strong, hard, and durable, with a tensile strength that permits a much greater freedom of design than is possible in either stone or wood. A life-size bronze figure that is firmly attached to a base needs no support other than its own feet and may even be poised on one foot. Considerable attenuation of form is also possible without risk of fracture.

The colour, brilliant lustre, and reflectivity of metal surfaces have been highly valued and made full use of in sculpture although, since the Renaissance, artificial patinas have generally been preferred as finishes for bronze.

Metals can be worked in a variety of ways in order to produce sculpture. They can be cast—that is, melted and poured into molds; squeezed under pressure into dies, as in coin making; or worked directly—for example, by hammering, bending, cutting, welding, and repoussé (hammered or pressed in relief).

Important traditions of bronze sculpture are Greek, Roman, Indian (especially Cōḻa), African (Bini and Yoruba), Italian Renaissance, and Chinese. Gold was used to great effect for small-scale works in pre-Columbian America and medieval Europe. A fairly recent discovery, aluminum has been used a great deal by modern sculptors. Iron has not been used much as a casting material, but in recent years it has become a popular material for direct working by techniques similar to those of the blacksmith. Sheet metal is one of the principal materials used nowadays for constructional sculpture. Stainless steel in sheet form has been used effectively by the American sculptor David Smith.

Clay is one of the most common and easily obtainable of all materials. Used for modelling animal and human figures long before men discovered how to fire pots, it has been one of the sculptor's chief materials ever since.

Clay has four properties that account for its widespread use: when moist, it is one of the most plastic of all substances, easily modelled and capable of registering the most detailed impressions; when partially dried out to a leather-hard state or completely dried, it can be carved and scraped; when mixed with enough water, it becomes a creamy liquid known as slip, which may be poured into molds and allowed to dry; when fired to temperatures of between 700° and 1,400° C (1,300° and 2,600° F), it undergoes irreversible structural changes that make it permanently hard and extremely durable.

Uses of clay

Sculptors use clay as a material for working out ideas; for preliminary models that are subsequently cast in such materials as plaster, metal, and concrete or carved in stone; and for pottery sculpture.

Depending on the nature of the clay body itself and the temperature at which it is fired, a finished pottery product is said to be earthenware, which is opaque, relatively soft, and porous; stoneware, which is hard, nonporous, and more or less vitrified; or porcelain, which is fine-textured, vitrified, and translucent. All three types of pottery are used for sculpture. Sculpture made in low-fired clays, particularly buff and red clays, is known as terra-cotta (baked earth). This term is used inconsistently, however, and is often extended to cover all forms of pottery sculpture.

Unglazed clay bodies can be smooth or coarse in texture and may be coloured white, gray, buff, brown, pink, or red. Pottery sculpture can be decorated with any of the techniques invented by potters and coated with a variety of beautiful glazes.

Paleolithic sculptors produced relief and in-the-round work in unfired clay. The ancient Chinese, particularly during the T'ang (618–907) and Sung (960–1279) dynasties, made superb pottery sculpture, including large-scale human figures. The best known Greek works are the intimate small-scale figures and groups from Tanagra. Mexican and Mayan sculptor-potters produced vigorous, directly modelled figures. During the Renaissance, pottery was used in Italy for major sculptural projects, including the large-scale glazed and coloured sculptures of Luca Della Robbia and his family, which are among the finest works in the medium. One of the most popular uses of the pottery medium has been for the manufacture of figurines—at Staffordshire, Meissen, and Sèvres, for example.

Sources of ivory

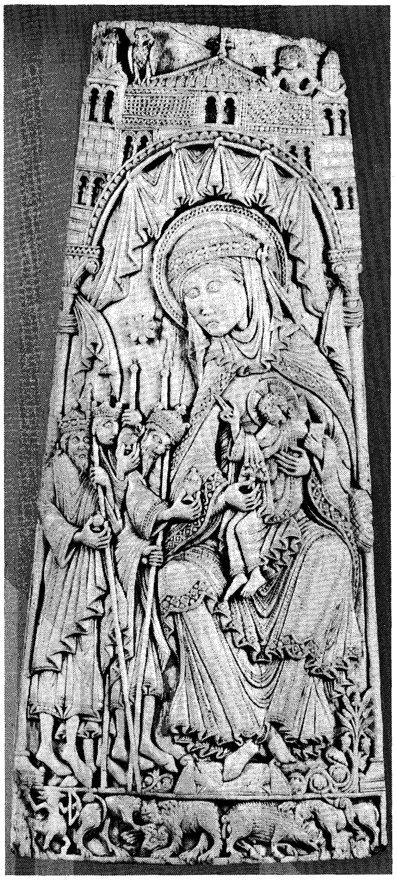
The main source of ivory is elephant tusks; but walrus, hippopotamus, narwhal (an Arctic aquatic animal), and, in Paleolithic times, mammoth tusks also were used for sculpture. Ivory is dense, hard, and difficult to work. Its colour is creamy white, which usually yellows with age; and it will take a high polish. A tusk may be sawed into panels for relief carving or into blocks for carving in the round; or the shape of the tusk itself may be used. The physical properties of the material invite the most delicate, detailed carving, and displays of virtuosity are common.

Ivory was used extensively in antiquity in the Middle and Far East and the Mediterranean. An almost unbroken Christian tradition of ivory carving reaches from Rome and Byzantium to the end of the Middle Ages. Throughout this time, ivory was used mainly in relief, often in conjunction with precious metals, enamels, and precious stones to produce the most splendid effects. Some of its main sculptural uses were for devotional diptychs, portable altars, book covers, retables (raised shelves above altars), caskets, and crucifixes. The Baroque period, too, is rich in ivories, especially in Germany. A fine tradition of ivory carving also existed in Benin, a former kingdom of West Africa.

Related to ivory, horn and bone have been used since Paleolithic times for small-scale sculpture. Reindeer horn and walrus tusks were two of the Eskimo carver's most important materials. One of the finest of all medieval "ivories" is a carving in whalebone, "The Adoration of the Magi" (Victoria and Albert Museum, London).

Plaster of Paris (sulfate of lime) is especially useful for the production of molds, casts, and preliminary models. It was used by Egyptian and Greek sculptors as a casting medium and is today the most versatile material in the sculptor's workshop.

When mixed with water, plaster will in a short time recrystallize, or set—that is, become hard and inert—and its volume will increase slightly. When set, it is relatively fragile and lacking in character and is therefore of limited use for finished work. Plaster can be poured as a liquid, modelled directly when of a suitable consistency, or easily carved after it has set. Other materials can be added to it to retard its setting, to increase its hardness or resistance to heat, to change its colour, or to reinforce it.



Bone carving.

The main sculptural use of plaster in the past was for molding and casting clay models as a stage in the production of cast metal sculpture. Many sculptors today omit the clay-modelling stage and model directly in plaster. As a mold material in the casting of concrete and fibreglass sculpture, plaster is widely used. It has great value as a material for reproducing existing sculpture; many museums, for example, use such casts for study purposes.

SECONDARY

Basically, concrete is a mixture of an aggregate (usually sand and small pieces of stone) bound together by cement. A variety of stones, such as crushed marble, granite chips, and gravel, can be used, each giving a different effect of colour and texture. Commercial cement is gray, white, or black; but it can be coloured by additives. The cement most widely used by sculptors is *ciment fondu,* which is extremely hard and quick setting. A recent invention—at least, in appropriate forms for sculpture—concrete is rapidly replacing stone for certain types of work. Because it is cheap, hard, tough, and durable, it is particularly suitable for large outdoor projects, especially decorative wall surfaces. With proper reinforcement it permits great freedom of design. And by using techniques similar to those of the building industry, sculptors are able to create works in concrete on a gigantic scale.

Advantages of concrete

When synthetic resins, especially polyesters, are reinforced with laminations of glass fibre, the result is a lightweight shell that is extremely strong, hard, and durable. It is usually known simply as fibreglass. After having been successfully used for car bodies, boat hulls, and the like, it has developed recently into an important material for sculpture. Because the material is visually unattractive in itself, it is usually coloured by means of fillers and pigments. It was first used in sculpture in conjunction with powdered metal fillers in order to produce cheap "cold-cast" substitutes for bronze and aluminum, but with the recent tendency to use bright colours in sculpture it is now often coloured either by pigmenting the material itself or by painting.

It is possible to model fibreglass, but more usually it is cast as a laminated shell. Its possibilities for sculpture have not yet been fully exploited.

Various formulas for modelling wax have been used in the past, but these have been generally replaced by synthetic waxes. The main uses of wax in sculpture have been as a preliminary modelling material for metal casting by the lost-wax, or cire perdue, process (see *Methods and techniques,* below) and for making sketches. It is not durable enough for use as a material in its own right, although it has been used for small works, such as wax fruit, that can be kept under a glass dome.

Papier-mâché (pulped paper bonded with glue) has been used for sculpture, especially in the Far East. Mainly used for decorative work, especially masks, it can have considerable strength; the Japanese, for example, made armour from it. Sculpture made of sheet paper is a limited art form used only for ephemeral and usually trivial work.

Numerous other permanent materials—such as shells, amber, and brick—and ephemeral ones—such as feathers, baker's dough, ice and snow, and cake icing—have been used for fashioning three-dimensional images. In view of recent trends in sculpture it is no longer possible to speak of "the materials of sculpture." Modern sculpture has no special materials. Any material, natural or man-made, is likely to be used, including inflated polyethylene, foam rubber, expanded polystyrene, fabrics, and neon tubes; the materials for a mid-20th-century sculpture by Claes Oldenburg, for example, are listed as canvas, cloth, Dacron, metal, foam rubber, and Plexiglas. Real objects, too, may be incorporated in sculpture, as in the mixed-medium compositions of Edward Kienholz; even junk has its devotees, who fashion "junk" sculpture.

Unconventional materials of modern sculpture.

Methods and techniques

Although a sculptor may specialize in, say, stone carving or direct metalwork, the art of sculpture is not identifiable with any particular craft or set of crafts. It presses into its service whatever crafts suit its purposes. Technologies developed for more utilitarian purposes are often easily adapted for sculpture; in fact, useful artifacts and sculptured images have often been produced in the same workshop, sometimes by the same craftsman. The methods and techniques employed in producing a pot, a bronze harness trapping, a decorative stone molding or column, a carved wooden newel post, or even a fibreglass car body are essentially the same as those used in sculpture. For example, the techniques of repoussé, metal casting, blacksmithing, sheet-metal work, and welding, which are used for the production of functional artifacts and decorative metalwork, are also used in metal sculpture; and the preparation, forming, glazing, decoration, and firing of clay are basically the same in both utilitarian pottery and pottery sculpture. The new techniques used by sculptors today are closely related to new techniques applied in building and industrial manufacture.

THE SCULPTOR AS DESIGNER AND AS CRAFTSMAN

The conception of an artifact or a work of art—its form, imaginative content, and expressiveness—is the concern of a designer, and it should be distinguished from the execution of the work in a particular technique and material, which is the task of a craftsman. A sculptor usually functions as both designer and craftsman, but these two aspects of sculpture may be separated.

Expressiveness of direct handling

Certain types of sculpture depend considerably for their aesthetic effect on the way in which their material has been directly manipulated by the artist himself. The direct, expressive handling of clay in a model by Rodin, or the use of the chisel in the stiacciato (very low) reliefs of the 15th-century Florentine sculptor Donatello could no more have been delegated to a craftsman than could the brushwork of Rembrandt. The actual physical process of working materials is for many sculptors an integral part of the art of sculpture, and their response to the working qualities of the material—such as its plasticity, hardness, and texture—is evident in the finished work. Design and craftsmanship are intimately fused in such a work, which is a highly personal expression.

Even when the direct handling of material is not as vital as this to the expressiveness of the work, it still may be impossible to separate the roles of the artist as designer and craftsman. The qualities and interrelationships of forms may be so subtle and complex that they cannot be adequately specified and communicated to a craftsman. Moreover, many aspects of the design may actually be contributed during the process of working. Michelangelo's way of working, for example, enabled him to change his mind about important aspects of composition as the work proceeded.

A complete fusion of design and craftsmanship may not be possible if a project is a large one or if the sculptor is too old or too weak to do all of the work himself. The sheer physical labour of making a large sculpture can be considerable, and sculptors from Phidias in the 5th century BC to Henry Moore in the 20th century have employed pupils and assistants to help with it. Usually the sculptor delegates the time-consuming first stages of the work or some of its less important parts to his assistants and executes the final stages or the most important parts himself.

On occasion, a sculptor may function like an architect or industrial designer. He may do no direct work at all on the finished sculpture, his contribution being to supply exhaustive specifications in the form of drawings and perhaps scale models for a work that is to be entirely fabricated by craftsmen. Obviously, such a procedure excludes the possibility of direct, personal expression through the handling of the materials; thus, works of this kind usually have the same anonymous, impersonal quality as architecture and industrial design. An impersonal approach to sculpture was favoured by many sculptors of the 1960s such as William Tucker, Donald Judd, and William Turnbull. They used the skilled anonymous workmanship of industrial fabrications to make their large-scale, extremely precise, simple sculptural forms that are called "primary structures."

Stages in the production of a major work

General methods. Broadly speaking, the stages in the production of a major work of sculpture conform to the following pattern: the commission; the preparation, submission, and acceptance of the design; the selection and preparation of materials; the forming of materials; surface finishing; installation or presentation.

Almost all of the sculpture of the past and some present-day sculpture originates in a demand made upon the sculptor from outside, usually in the form of a direct commission or through a competition. If the commission is for a portrait or a private sculpture, the client may only require to see examples of the artist's previous work; but if it is a public commission, the sculptor is usually expected to submit drawings and maquettes (small-scale, three-dimensional sketch models) that give an idea of the nature of the finished work and its relation to the site. He may be free to choose his own subject matter or theme, or it may be more or less strictly prescribed. A medieval master sculptor, for example, received the program for a complex scheme of church sculpture from theological advisers, and Renaissance contracts for sculpture were often extremely specified and detailed. Today a great deal of sculpture is not commissioned. It arises out of the sculptor's private concern with form and imagery, and he works primarily to satisfy himself. When the work is finished he may exhibit and attempt to sell it in an art gallery.

Most of the materials used by 20th-century sculptors are readily available in a usable form from builders' or sculptors' suppliers, but certain kinds of sculpture may involve a good deal of preparatory work on the materials. A sculptor may visit a stone quarry in order to select the material for a large project and to have it cut into blocks of the right size and shape. And since stone is costly to transport and best carved when freshly quarried, he may decide to do all of his work at the quarry. Because stone is extremely heavy, the sculptor must have the special equipment required for manoeuvring even small blocks into position for carving. A wood carver requires a supply of well-seasoned timber and may keep a quantity of logs and blocks in store. A modeller needs a good supply of clay of the right kind. For large terra-cottas he may require a specially made-up clay body, or he may work at a brickworks, using the local clay and firing in the brick kilns.

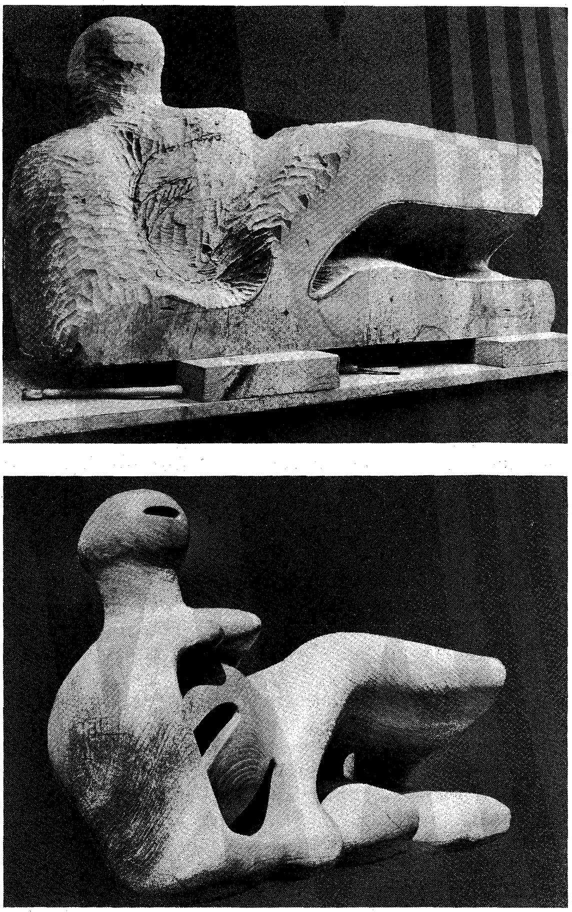
The main part of the sculptor's work, the shaping of the material itself by modelling, carving, or constructional techniques, may be a long and arduous process, perhaps extending over a number of years and requiring assistants. Much of the work, especially architectural decoration, may be carried out at the site, or in situ.

To improve its weathering qualities, to bring out the characteristics of its material to the best advantage, or to make it more decorative or realistic, sculpture is usually given a special surface finish. It may be rubbed down and polished, patinated, metal plated, gilded, painted, inlaid with other materials, and so on.

Installation of sculpture

Finally, the installation of sculpture may be a complex and important part of the work. The positioning and fixing of large architectural sculpture may involve cooperation with builders and engineers; fountains may involve elaborate plumbing; the design and placing of outdoor bases, or plinths, in relation to the site and the spectator may require careful thought. The choice of the materials, shape, and proportions of the base even for a small work requires a considerable amount of care.

Carving. Whatever material is used, the essential features of the direct method of carving are the same; the sculptor starts with a solid mass of material and reduces it systematically to the desired form. After he has blocked out the main masses and planes that define the outer limits of the forms, he works progressively over the whole sculpture, first carving the larger containing forms and planes and then the smaller ones until eventually the surface details are reached. Then he gives the surface whatever finish is required. Even with a preliminary model as a guide, the sculptor's concept constantly evolves and clarifies as the work proceeds; thus, as he adapts his design to the nature of the carving process and the material, his work develops as an organic whole.



Direct carving.
(Top) "Reclining Figure" in progress, elmwood sculpture by Henry Moore, 1945–46. (Bottom) "Reclining Figure." Length 1.90 m.

The process of direct carving imposes a characteristic order on the forms of sculpture. The faces of the original block, slab, or cylinder of material can usually still be sensed, existing around the finished work as a kind of implied spatial envelope limiting the extension of the forms in space and connecting their highest points across space. In a similar way, throughout the whole carving, smaller forms and planes can be seen as contained within implied larger ones. Thus, an ordered sequence of containing forms and planes, from the largest to the smallest, gives unity to the work.

Indirect carving. All of the great sculptural traditions of the past used the direct method of carving, but in Western civilization during the 19th and early 20th centuries it became customary for stone and, to a lesser extent, wood sculpture to be produced by the indirect method. This required the production of a finished clay model that was subsequently cast in plaster and then reproduced in stone or wood in a more or less mechanical way by means of a pointing machine (see *Reproduction and surface-finishing techniques: pointing* below). Usually, the carving was not done by the sculptor himself. At its worst, this procedure results in a carved copy of a design that was conceived in terms of clay modelling. Although indirect carving does not achieve aesthetic qualities that are typical of carved sculpture, it does not necessarily result in bad sculpture. Rodin's marble sculptures, for example, are generally considered great works of art even by those who object to the indirect methods by which they were produced. The indirect method has been steadily losing ground since the revival of direct carving in the early part of the 20th century, and today it is in general disrepute among carvers.

Tools for stone carving

Carving tools and techniques. The tools used for carving differ with the material to be carved. Stone is carved mostly with steel tools that resemble cold chisels. To knock off the corners and angles of a block, a tool called a pitcher is driven into the surface with a heavy iron hammer. The pitcher is a thick, chisel-like tool with a wide bevelled edge that breaks rather than cuts the stone. The heavy point then does the main roughing out, followed by the fine point, which may be used to within a short distance of the final surface. These pointed tools are hammered into the surface at an angle that causes the stone to break off in chips of varying sizes. Claw chisels, which have toothed edges, may then be worked in all directions over the surface, removing the stone in granule form and thus refining the surface forms. Flat chisels are used for finishing the surface carving and for cutting sharp detail. There are many other special tools, including stone gouges, drills, toothed hammers (known as bushhammers or bouchardes), and, often used today, power-driven pneumatic tools, for pounding away the surface of the stone.

Because medieval carvers worked mostly in softer stones and made great use of flat chisels, their work tends to have an edgy, cut quality and to be freely and deeply carved. In contrast is the work done in hard stones by people who lacked metal tools hard enough to cut the stone. Egyptian granite sculpture, for example, was produced mainly by abrasion; that is, by pounding the surface and rubbing it down with abrasive materials. The result is a compact sculpture, not deeply hollowed out, with softened edges and flowing surfaces. It usually has a high degree of tactile appeal.

Although the process of carving is fundamentally the same for wood or stone, the physical structure of wood demands tools of a different type. For the first blocking out of a wood carving a sculptor may use saws and axes, but his principal tools are a wide range of wood-carver's gouges. The sharp, curved edge of a gouge cuts easily through the bundles of fibre and when used properly will not split the wood. Flat chisels are also used, especially for carving sharp details. Wood rasps, or coarse files, and sandpaper can be used to give the surface a smooth finish, or, if preferred, it can be left with a faceted, chiselled appearance. Wood-carving tools have hardwood handles and are struck with round, wooden mallets. African wood sculptors use a variety of adzes rather than gouges and mallets. Ivory is carved with an assortment of saws, knives, rasps, files, chisels, drills, and scrapers.

Modelling. In contrast to the reductive process of carving, modelling is essentially a building-up process in which the sculpture grows organically from the inside. Numerous plastic materials are used for modelling. The main ones are clay, plaster, and wax; but concrete, synthetic resins, plastic wood, stucco, and even molten metal can also be modelled. A design modelled in plastic materials may be intended for reproduction by casting in more permanent and rigid materials, such as metal, plaster, concrete, and fibreglass, or it may itself be made rigid and more permanent through the self-setting properties of its materials (for example, plaster) or by firing.

Clay models

Modelling for casting. The material most widely used for making positive models for casting is clay. A small, compact design or a low relief can be modelled solidly in clay without any internal support; but a large clay model must be formed over a strong armature made of wood and metal. Since the armature may be very elaborate and can only be altered slightly, if at all, once work has started, the modeller must have a fairly clear idea from his drawings and maquettes of the arrangement of the main shapes of the finished model. The underlying main masses of the sculpture are built up firmly over the armature, and then the smaller forms, surface modelling, and details are modelled over them. The modeller's chief tools are his fingers, but for fine work he may use a variety of wooden modelling tools to apply the clay and wire loop tools to cut it away. Reliefs are modelled on a vertical or nearly vertical board. The clay is keyed, or secured, onto the board with galvanized nails or wood laths. The amount of armature required depends on the height of the relief and the weight of clay involved.

To make a cast in metal, a foundry requires from the sculptor a model made of a rigid material, usually plaster. The sculptor can produce this either by modelling in clay and then casting in plaster from the clay model or by modelling directly in plaster. For direct plaster modelling, a strong armature is required because the material is brittle. The main forms may be built up roughly over the armature in expanded wire and then covered in plaster-soaked scrim (a loosely woven sacking). This provides a hollow base for the final modelling, which is done by applying plaster with metal spatulas and by scraping and cutting down with rasps and chisels.

Lost-wax process bronze sculpture.
"Male Portrait Head," bronze from Ife, Nigeria, 12th century. In the Museum of Ife Antiquities. Height 34 cm.
Eliot Elisofon

Fibreglass and concrete sculptures are cast in plaster molds taken from the sculptor's original model. The model is usually clay rather than plaster because if the forms of the sculpture are at all complex it is easier to remove a plaster mold from a soft clay model than from a model in a rigid material, such as plaster.

A great deal of the metal sculpture of the past, including Nigerian, Indian, and many Renaissance bronzes, was produced by the direct lost-wax process, which involves a special modelling technique (see *Reproduction and surface-finishing techniques: casting and molding* below). The design is first modelled in some refractory material to within a fraction of an inch of the final surface, and then the final modelling is done in a layer of wax, using the fingers and also metal tools, which can be heated to make the wax more pliable. Medallions are often produced from wax originals, but because of their small size they do not require a core.

Modelling for pottery sculpture. To withstand the stresses of firing, a large pottery sculpture must be hollow and of an even thickness. There are two main ways of achieving this. In the process of hollow modelling, which is typical of the potter's approach to form, the main forms of the clay model are built up directly as hollow forms with walls of a roughly even thickness. The methods of building are similar to those employed for making hand-built pottery—coiling, pinching, and slabbing. The smaller forms and details are then added, and the finished work is allowed to dry out slowly and thoroughly before firing. The process of solid modelling is more typical of the sculptor's traditional approach to form. The sculpture is modelled in solid clay, sometimes over a carefully considered armature, by the sculptor's usual methods of clay modelling. Then it is cut open and hollowed out, and the armature, if there is one, is removed. The pieces are then rejoined and the work is dried out and fired.

Effects of modelling on the design of sculpture

General characteristics of modelled sculpture. The process of modelling affects the design of sculpture in three important ways. First, the forms of the sculpture tend to be ordered from the inside. There are no external containing forms and planes, as in carved sculpture. The overall design of the work—its main volumes, proportions, and axial arrangement—is determined by the underlying forms; and the smaller forms, surface modelling, and decorative details are all formed around and sustained by this underlying structure. Second, because its extension into space is not limited by the dimensions of a block of material, modelled sculpture tends to be much freer and more expansive in its spatial design than carved sculpture. If the tensile strength of metal is to be exploited in the finished work, there is almost unlimited freedom; designs for brittle materials such as concrete or plaster are more limited. Third, the plasticity of clay and wax encourages a fluent, immediate kind of manipulation, and many sculptors, such as Auguste Rodin, Giacomo Manzù, and Sir Jacob Epstein, like to preserve this record of their direct handling of the medium in their finished work. Their approach contrasts with that of the Benin and Indian bronze sculptors, who refined the surfaces of their work to remove all traces of personal "handwriting."

Constructing and assembling. A constructed or assembled sculpture is made by joining preformed pieces of material. It differs radically in principle from carved and modelled sculpture, both of which are fabricated out of a homogeneous mass of material. Constructed sculpture is made out of such basic preformed components as metal tubes, rods, plates, bars, and sheets; wooden laths, planks, dowels, and blocks; laminated timbers and chipboards; sheets of Perspex, Formica, and glass; fabrics; and wires and threads. These are cut to various sizes and may be either shaped before they are assembled or used as they are. The term assemblage is usually reserved for constructed sculpture that incorporates any of a vast array of ready-made, so-called found objects, such as old boilers, typewriters, engine components, mirrors, chairs, and table legs and other bits of old furniture. Numerous techniques are employed for joining these components, most of them derived from crafts other than traditional sculptural ones; for example, metal welding and brazing, wood joinery, bolting, screwing, rivetting, nailing, and bonding with new powerful adhesives.

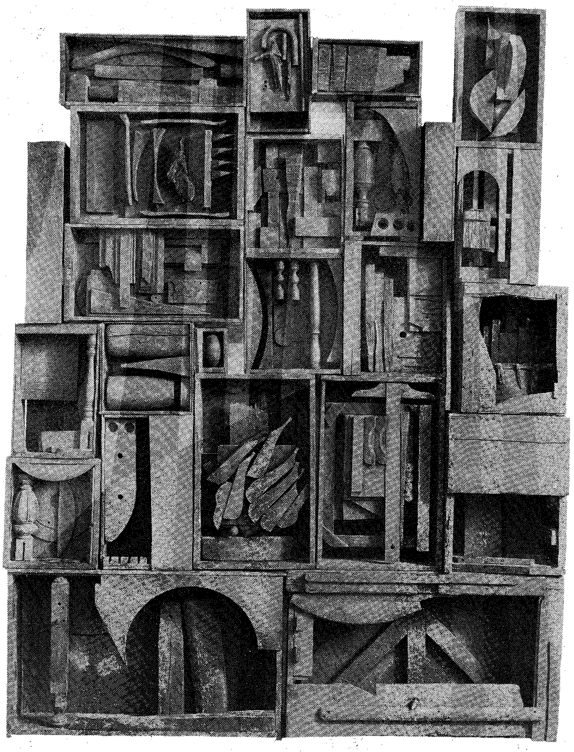
The use of constructional techniques for the production of sculpture is the major technical development of the art of sculpture in recent years. Among the reasons for its popularity are that it lends itself readily to an emphasis on the spatial aspects of sculpture that have preoccupied so many 20th-century artists; it is quicker than carving and modelling; it is considered by many sculptors and critics to be especially appropriate to a technological civilization; it is opening up new fields of imagery and new types of symbolism and form.

For constructed "gallery" sculpture, almost any materials and techniques are likely to be used, and the products are often extremely ephemeral. But architectural sculpture, outdoor sculpture, and indeed any sculpture that is actually used must be constructed in a safe and at least reasonably permanent manner. The materials and techniques employed are therefore somewhat restricted. Metal sculpture constructed by rivetting, bolting, and, above all, welding and brazing is best for outdoor use.

Direct metal sculpture. The introduction of the oxyacetylene welding torch as a sculptor's tool has revolutionized metal sculpture in recent years. A combination of welding and forging techniques was pioneered by the Spanish sculptor Julio González around 1930; and during the 1940s and 1950s it became a major sculptural technique, particularly in Britain and in the United States, where its greatest exponent was David Smith. In the 1960s and early 1970s, more sophisticated electric welding processes were replacing flame welding.

Welding
and
forging

Welding equipment can be used for joining and cutting metal. A welded joint is made by melting and fusing together the surfaces of two pieces of metal, usually with the addition of a small quantity of the same metal as a filler. The metal most widely used for welded sculpture is mild steel, but other metals can be welded. In a brazed joint, the parent metals are not actually fused together but are joined by an alloy that melts at a lower temperature than the parent metals. Brazing is particularly useful for making joints between different kinds of metal, which cannot be done by welding, and for joining nonferrous metals. Forging is the direct shaping of metal by bending, hammering, and cutting.



Assemblage.
"Black Wall," wood sculpture by Louise Nevelson, 1959. In the Tate Gallery, London. 2.84 × 2.16 × 0.65 m.
By courtesy of the trustees of the Tate Gallery, London

Direct metalworking techniques have opened up whole new ranges of form to the sculptor—open skeletal structures, linear and highly extended forms, and complex, curved sheet forms. Constructed metal sculpture may be precise and clean, as that of Minimalist sculptors Donald Judd and Phillip King, or it may exploit the textural effects of molten metal in a free, "romantic" manner.

REPRODUCTION AND SURFACE-FINISHING TECHNIQUES

Casting and molding processes are used in sculpture either for making copies of existing sculpture or as essential stages in the production of a finished work. Numerous materials are used for making molds and casts, and some of the methods are complex and highly skilled. Only a broad outline of the principal methods can be given here.

Casting and molding. These are used for producing a single cast from a soft, plastic original, usually clay. They are especially useful for producing master casts for subsequent reproduction in metal. The basic procedure is as follows. First, the mold is built up in liquid plaster over the original clay model; for casting reliefs, a one-piece mold may be sufficient, but for sculpture in the round a mold in at least two sections is required. Second, when the plaster is set, the mold is divided and removed from the clay model. Third, the mold is cleaned, reassembled, and filled with a self-setting material such as plaster, concrete, or fibreglass-reinforced resin. Fourth, the mold is carefully chipped away from the cast. This involves the destruction of the mold—hence the term "waste" mold. The order of reassembling and filling the mold may be reversed; fibreglass and resin, for example, are "laid up" in the mold pieces before they are reassembled.

Plaster piece molds are used for producing more than one cast from a soft or rigid original and are especially good for reproducing existing sculpture and for slip casting (see below). Before the invention of flexible molds (see below), piece molds were used for producing wax casts for metal casting by the lost-wax process. A piece mold is built up in sections that can be withdrawn from the original model without damaging it. The number of sections depends on the complexity of the form and on the amount of undercutting; tens, or even hundreds, of pieces may be required for really large, complex works. The mold sections are carefully keyed together and supported by a plaster case. When the mold has been filled, it can be removed section by section from the cast and used again. Piece molding is a highly skilled and laborious process.

Made of such materials as gelatin, vinyl, and rubber, flexible molds are used for producing more than one cast; they offer a much simpler alternative to piece molding when the original model is a rigid one with complex forms and undercuts. The material is melted and poured around the original positive in sections, if necessary. Being flexible, the mold easily pulls away from a rigid surface without causing damage. While it is being filled (with wax, plaster, concrete, and fibreglass-reinforced resins), the mold must be surrounded by a plaster case to prevent distortion.

The traditional method of casting metal sculpture

The lost-wax process is the traditional method of casting metal sculpture. It requires a positive, which consists of a core made of a refractory material and an outer layer of wax. The positive can be produced either by direct modelling in wax over a prepared core, in which case the process is known as direct lost-wax casting, or by casting in a piece mold or flexible mold taken from a master cast. The wax positive is invested with a mold made of refractory materials and is then heated to a temperature that will drive off all moisture and melt out all the wax, leaving a narrow cavity between the core and the investment. Molten metal is then poured into this cavity. When the metal has cooled down and solidified, the investment is broken away, and the core is removed from inside the cast. The process is, of course, much more complex than this simple outline suggests. Care has to be taken to suspend the core within the mold by means of metal pins, and a structure of channels must be made in the mold that will enable the metal to reach all parts of the cavity and permit the mold gases to escape. A considerable amount of filing and chasing of the cast is usually required after casting is completed.

While the lost-wax process is used for producing complex, refined metal castings, sand molding is more suitable for simpler types of form and for sculpture in which a certain roughness of surface does not matter. Recent improvements in the quality of sand castings and the invention of the "lost-pattern" process (see below) have resulted in a much wider use of sand casting as a means of producing sculpture. A sand mold, made of special sand held together by a binder, is built up around a rigid positive, usually in a number of sections held together in metal boxes. For a hollow casting, a core is required that will fit inside the negative mold, leaving a narrow cavity as in the lost-wax process. The molten metal is poured into this cavity.

The lost-pattern process is used for the production by sand molding of single casts in metal. After a positive made of expanded polystyrene is firmly embedded in casting sand, molten metal is poured into the mold straight onto the expanded foam original. The heat of the metal causes the foam to pass off into vapour and disappear, leaving a negative mold to be filled by the metal. Channels for the metal to run in and for the gases to escape are made in the mold, as in the lost-wax process. The method is used mainly for producing solid castings in aluminum that can be welded or rivetted together to make the finished sculpture.

Slip casting is primarily a potter's technique that can be used for repetition casting of small pottery sculptures. Liquid clay, or slip, is poured into a plaster piece mold. Some of the water in the slip is absorbed by the plaster and a layer of stiffened clay collects on the surface of the mold. When this layer is thick enough to form a cast, the excess slip is poured off and the mold is removed. The hollow clay cast is then dried and fired.

Simple casts for pottery sculpture—mainly tiles and low reliefs—can be prepared by pressing clay into a rigid mold. More complex forms can be built up from a number of separately press-cast pieces. Simple terra-cotta molds can be made by pressing clay around a rigid positive form. After firing, these press molds can be used for press casting.

Pointing. A sculpture can be reproduced by transposing measurements taken all over its surface to a copy. The process is made accurate and thorough by the use of a pointing machine, which is an arrangement of adjustable metal arms and pointers that are set to the position of any point on the surface of a three-dimensional form and then used to locate the corresponding point on the surface of a copy. If the copy is a stone one, the block is drilled to the depth measured by the pointing machine. When a number of points have been fixed by drilling, the stone is cut away to the required depth. For accurate pointing, a vast number of points have to be taken, and the final surface is approached gradually. The main use of pointing has been for the indirect method of carving.

Enlarged and reduced copies

Enlarged and reduced copies of sculpture can also be produced with the aid of mechanical devices. A sophisticated reducing machine that works on the principle of the pantograph (an instrument for copying on any predetermined scale, consisting of four light, rigid bars jointed in parallelogram form) is used in minting for scaling down the sculptor's original model to coin size.

Surface finishing. Surface finishes for sculpture can be either natural—bringing the material of the sculpture itself to a finish—or applied. Almost all applied surface finishes preserve as well as decorate.

Smoothing and polishing. Many sculptural materials have a natural beauty of colour and texture that can be brought out by smoothing and polishing. Stone carvings are smoothed by rubbing down with a graded series of coarse and fine abrasives, such as carborundum, sandstone, emery, pumice, and whiting, all used while the stone is wet. Some stones, such as marble and granite, will take a high gloss; others are too coarse-grained to be polished and can only be smoothed to a granular finish. Wax is sometimes used to give stone a final polish.

The natural beauty of wood is brought out by sandpapering or scraping and then waxing or oiling. Beeswax and linseed oil are the traditional materials, but a wide range of waxes and oils is currently available.

Ivory is polished with gentle abrasives such as pumice and whiting, applied with a damp cloth.

Concrete can be rubbed down, like stone, with water and abrasives, which both smooth the surface and expose the aggregate. Some concretes can be polished.

Metals are rubbed down manually with steel wool and emery paper and polished with various metal polishes. A high-gloss polish can be given to metals by means of power-driven buffing wheels used in conjunction with abrasives and polishes. Clear lacquers are applied to preserve the polish.

Polychrome sculpture

Painting. Stone, wood, terra-cotta, metal, fibreglass, and plaster can all be painted in a reasonably durable manner provided that the surfaces are properly prepared and suitable primings and paints are used. In the past, stone and wood carvings were often finished with a coating of gesso (plaster of Paris or gypsum prepared with glue) that served both as a final modelling material for delicate surface detail and as a priming for painting. Historically, the painting and gilding of sculpture were usually left to specialists. In Greek relief sculpture, actual details of the composition were often omitted at the carving stage and left for the painter to insert. In the 15th century, the great Flemish painter Rogier van der Weyden undertook the painting of sculpture as part of his work.

Modern paint technology has made an enormous range of materials available. Constructed sculptures are often finished with mechanical grinders and sanders and then sprayed with high-quality cellulose paints.

Gilding. The surfaces of wood, stone, and plaster sculpture can be decorated with gold, silver, and other metals that are applied in leaf or powder form over a suitable priming. Metals, especially bronze, were often fire-gilded; that is, treated with an amalgam of gold and mercury that was heated to drive off the mercury. The panels of the "Gates of Paradise" in Florence, by the 15th-century sculptor Lorenzo Ghiberti, are a well-known example of gilded bronze.

Patinas achieved artificially

Patination. Patinas on metals are caused by the corrosive action of chemicals. Sculpture that is exposed to different kinds of atmosphere or buried in soil or immersed in seawater for some time acquires a patina that can be extremely attractive. Similar effects can be achieved artificially by applying various chemicals to the metal surface.

This is a particularly effective treatment for bronze, which can be given a wide variety of attractive green, brown, blue, and black patinas. Iron is sometimes allowed to rust until it acquires a satisfactory colour, and then the process is arrested by lacquering.

Electroplating. The surfaces of metal sculpture or of specially prepared nonmetal sculpture can be coated with such metals as chrome, silver, gold, copper, and nickel by the familiar industrial process of electroplating. The related technique of anodizing can be used to prevent the corrosion of aluminum sculpture and to dye its surface.

Other finishes. The surfaces of metal sculpture can be decorated by means of numerous metalsmithing techniques—etching, engraving, metal inlaying, enamelling, and so on. Pottery sculpture can be decorated with coloured slips, oxides, and enamels; glazed with a variety of shiny or mat glazes; and brought to a dull polish by burnishing.

Other materials have often been added to the surface of sculpture. The eyes of ancient figure sculpture, for example, were sometimes inlaid with stones. Occasionally—as in Mexican mosaic work—the whole surface of a sculpture is inlaid with mother-of-pearl, turquoise, coral, and many other substances.

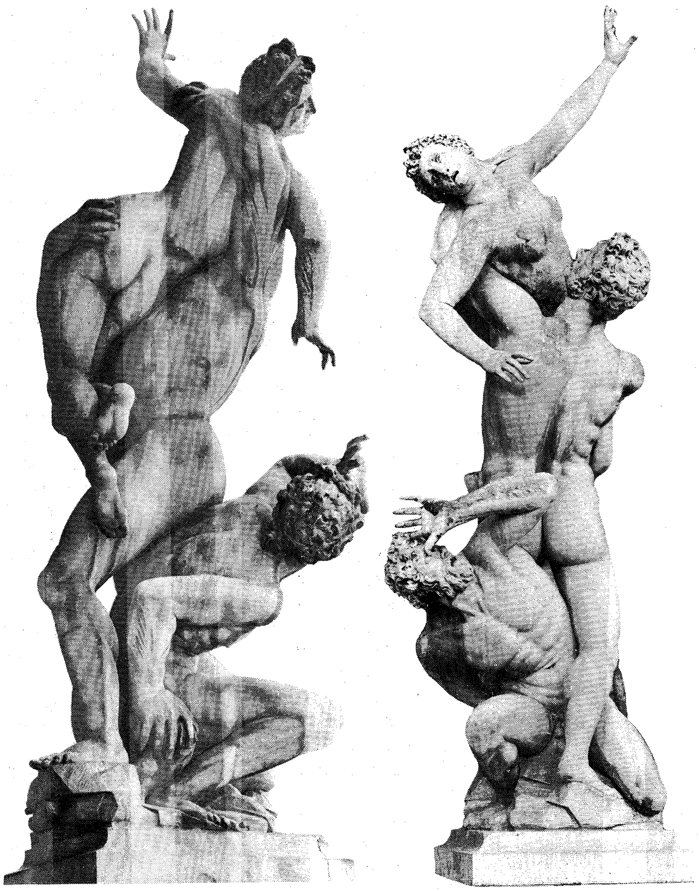
Forms, subject matter, imagery, and symbolism of sculpture

A great deal of sculpture is designed to be placed in public squares, gardens, parks, and similar open places or in interior positions where it is isolated in space and can be viewed from all directions. Other sculpture is carved in relief and is viewed only from the front and sides.

SCULPTURE IN THE ROUND

The opportunities for free spatial design that such freestanding sculpture presents are not always fully exploited. The work may be designed, like many Archaic sculptures, to be viewed from only one or two fixed positions, or it may in effect be little more than a four-sided relief that hardly changes the three-dimensional form of the block at all. Sixteenth-century Mannerist sculptors, on the other hand, made a special point of exploiting the all-around visibility of freestanding sculpture. Giambologna's "Rape of the Sabines," for example, compels the viewer to walk all around it in order to grasp its spatial design. It has no principal views; its forms move around the central axis of the composition, and their serpentine movement unfolds itself gradually as the spectator moves around to follow them. Much of the sculpture of Henry Moore and other 20th-century sculptors is not concerned with movement of this kind, nor is it designed to be viewed from any fixed positions. Rather, it is a freely designed structure of multidirectional forms that is opened up, pierced, and extended in space in such a way that the viewer is made aware of its all-around design largely by seeing through the sculpture. The majority of constructed sculptures are disposed in space with complete freedom and invite viewing from all directions. In many instances the spectator can actually walk under and through them.

The way in which a freestanding sculpture makes contact with the ground or with its base is a matter of considerable importance. A reclining figure, for example, may in effect be a horizontal relief. It may blend with the ground plane and appear to be rooted in the ground like an outcrop of rock. Other sculptures, including some reclining figures, may be designed in such a way that they seem to rest on the ground and to be independent of their base. Others are supported in space above the ground. The most completely freestanding sculptures are those that have no base and may be picked up, turned in the hands, and literally viewed all around like a netsuke (a small toggle of wood, ivory, or metal used to fasten a small pouch or purse to a kimono sash). Of course, a large sculpture cannot actually be picked up in this way, but it can be designed so as to invite the viewer to think of it as a detached, independent object that has no fixed base and is designed all around.



Sculpture in the round.
The changing appearance of freestanding sculpture observed when walking around a statue is suggested by these two views of "Rape of the Sabines," marble sculpture by Giambologna, 1583. In the Loggia dei Lanzi, Florence. Height 411 cm.
Alinari—Art Resource

Sculpture designed to stand against a wall or similar background or in a niche may be in the round and freestanding in the sense that it is not attached to its background like a relief; but it does not have the spatial independence of completely freestanding sculpture, and it is not designed to be viewed all around. It must be designed so that its formal structure and the nature and meaning of its subject matter can be clearly apprehended from a limited range of frontal views. The forms of the sculpture, therefore, are usually spread out mainly in a lateral direction rather than in depth. Greek pedimental sculpture illustrates this approach superbly: the composition is spread out in a plane perpendicular to the viewer's line of sight and is made completely intelligible from the front. Seventeenth-century Baroque sculptors, especially Bernini, adopted a rather different approach. There may be considerable recession and foreshortening in their compositions, but the forms are carefully arranged so that they present a coherent and intelligible whole from one special frontal viewpoint.

Difference between wall and niche and freestanding sculpture

The frontal composition of wall and niche sculpture does not necessarily imply any lack of three-dimensionality in the forms themselves; it is only the arrangement of the forms that is limited. Classical pedimental sculpture, Indian temple sculpture such as that at Khajurāho, Gothic niche sculpture, and Michelangelo's Medici tomb figures are all designed to be placed against a background, but their forms are conceived with a complete fullness of volume.

RELIEF SCULPTURE

Relief sculpture is a complex art form that combines many features of the two-dimensional pictorial arts and the three-dimensional sculptural arts. On the one hand, a relief, like a picture, is dependent on a supporting surface, and its composition must be extended in a plane in order to be visible. On the other hand, its three-dimensional properties are not merely represented pictorially but are in some degree actual, like those of fully developed sculpture.

Among the various types of relief are some that approach very closely the condition of the pictorial arts. The reliefs of Donatello, Ghiberti, and other early Renaissance artists make full use of perspective, which is a pictorial method of representing three-dimensional spatial relationships realistically on a two-dimensional surface. Egyptian and most pre-Columbian American low reliefs are also extremely pictorial but in a different way. Using a system of graphic conventions, they translate the three-dimensional world into a two-dimensional one. The relief image is essentially one of plane surfaces and could not possibly exist in three dimensions. Its only sculptural aspects are its slight degree of actual projection from a surface and its frequently subtle surface modelling.

Other types of relief—for example, Classical Greek and most Indian—are conceived primarily in sculptural terms. The figures inhabit a space that is defined by the solid forms of the figures themselves and is limited by the background plane. This back plane is treated as a finite, impenetrable barrier in front of which the figures exist. It is not conceived as a receding perspective space or environment within which the figures are placed nor as a flat surface upon which they are placed. The reliefs, so to speak, are more like contracted sculpture than expanded pictures.

The central problem of relief sculpture is to contract or condense three-dimensional solid form and spatial relations into a limited depth space. The extent to which the forms actually project varies considerably, and reliefs are classified on this basis as low reliefs (bas-reliefs) or high reliefs. There are types of reliefs that form a continuous series from the almost completely pictorial to the almost fully in the round.

Representation of forms in depth

One of the relief sculptor's most difficult tasks is to represent the relations between forms in depth within the limited space available to him. He does this mainly by giving careful attention to the planes of the relief. In a carved relief the highest, or front, plane is defined by the surface of the slab of wood or stone in which the relief is carved; and the back plane is the surface from which the forms project. The space between these two planes can be thought of as divided into a series of planes, one behind the other. The relations of forms in depth can then be thought of as relations between forms lying in different planes.

Sunken relief is also known as incised, coelanaglyphic, and intaglio relief. It is almost exclusively an ancient Egyptian art form, but some beautiful small-scale Indian examples in ivory have been found at Bagrām in Afghanistan. In a sunken relief, the outline of the design is first incised all around. The relief is then carved inside the incised outline, leaving the surrounding surface untouched. Thus, the finished relief is sunk below the level of the surrounding surface and is contained within a sharp, vertical-walled contour line. This approach to relief preserves the continuity of the original surface and creates no projection from it. The outline shows up as a powerful line of light and shade around the whole design.

Figurative low relief is generally regarded by sculptors as an extremely difficult art form. To give a convincing impression of three-dimensional structure and surface modelling with only a minimal degree of projection demands a fusion of draftsmanship and carving or modelling skill of a high order. The sculptor has to proceed empirically, constantly changing the direction of his light and testing the optical effect of his work. He cannot follow any fixed rules or represent things in depth by simply scaling down measurements mathematically, so that, say, one inch of relief space represents one foot.

The forms of low relief usually make contact with the background all around their contours. If there is a slight amount of undercutting, its purpose is to give emphasis, by means of cast shadow, to a contour rather than to give any impression that the forms are independent of their background. Low relief includes figures that project up to about half their natural circumference.

Technically, the simplest kind of low relief is the two-plane relief. For this, the sculptor draws an outline on a surface and then cuts away the surrounding surface, leaving the figure raised as a flat silhouette above the background plane. This procedure is often used for the first stages of a full relief carving, in which case the sculptor will proceed to carve into the raised silhouette, rounding the forms and giving an impression of three-dimensional structure. In a two-plane relief, however, the silhouette is left flat and substantially unaltered except for the addition of surface detail. Pre-Columbian sculptors used this method of relief carving to create bold figurative and abstract reliefs.

Stiacciato relief

Stiacciato relief is an extremely subtle type of flat, low relief carving that is especially associated with the 15th-century sculptors Donatello and Desiderio da Settignano. The design is partly drawn with finely engraved chisel lines and partly carved in relief. The stiacciato technique depends largely for its effect on the way in which pale materials, such as white marble, respond to light and show up the most delicate lines and subtle changes of texture or relief.

The forms of high relief project far enough to be in some degree independent of their background. As they approach the fullness of sculpture in the round, they become of necessity considerably undercut. In many high reliefs, where parts of the composition are completely detached from their background and fully in the round, it is often impossible to tell from the front whether or not a figure is actually attached to its background.

Many different degrees of projection are often combined in one relief composition. Figures in the foreground may be completely detached and fully in the round, while those in the middle distance are in about half relief and those in the background in low relief. Such effects are common in late Gothic, Renaissance, and Baroque sculpture.

MODERN FORMS OF SCULPTURE

Since the 1950s, many new combined forms of art have been developed that do not fit readily into any of the traditional categories. Two of the most important of these, environments and kinetics, are closely enough connected with sculpture to be regarded by many artists and critics as branches or offshoots of sculpture. It is likely, however, that the persistence of the terms environmental sculpture and kinetic sculpture is a result of the failure of language to keep pace with events; for the practice is already growing of referring simply to environments and kinetics, as one might refer to painting, sculpture, and engraving, as art forms in their own right.

Traditional sculptures in relief and in the round are static, fixed objects or images. Their immobility and immutability are part of the permanence traditionally associated with the art of sculpture, especially monumental sculpture. What one refers to as movement in, say, a Baroque or Greek sculpture is not actual physical motion but a movement that is either directly represented in the subject matter (galloping horses) or expressed through the dynamic character of its form (spirals, undulating curves). In recent years, however, the use of actual movement, kineticism, has become an important aspect of sculpture. Naum Gabo, Marcel Duchamp, László Moholy-Nagy, and Alexander Calder were pioneers of kinetic sculpture in modern times, but many kinetic artists see a connection between their work and such forms as the moving toys, dolls, and clocks of previous ages.

There are now types of sculpture in which the components are moved by air currents, as in the well-known mobiles of Calder; by water; by magnetism, the speciality of Nicholus Takis; by a variety of electromechanical devices; or by the participation of the spectator himself. The neo-Dada satire quality of the kinetic sculpture created during the 1960s is exemplified by the works of Jean Tinguely. His self-destructing "Homage to New York" perfected the concept of a sculpture being both an object and an event, or "happening."

Kinetic sculpture.
"Homage to New York," a self-constructing and self-destroying work of art by Jean Tinguely, 1960. Small pieces now in the Museum of Modern Art, New York.

The aim of most kinetic sculptors is to make movement itself an integral part of the design of the sculpture and not merely to impart movement to an already complete static object. Calder's mobiles, for example, depend for their aesthetic effect on constantly changing patterns of relationship. When liquids and gases are used as components, the shapes and dimensions of the sculpture may undergo continual transformations. The movement of smoke; the diffusion and flow of coloured water, mercury, oil, and so on; pneumatic inflation and deflation; and the movement of masses of bubbles have all served as media for kinetic sculpture. In the complex, electronically controlled "spatio-dynamic" and "lumino-dynamic" constructions of Nicolas Schöffer, the projection of changing patterns of light into space is a major feature.

The environmental sculptor creates new spatial contexts that differ from anything developed by traditional sculpture. The work no longer confronts the spectator as an object but surrounds him so that he moves within it as he might within a stage set, a garden, or an interior. The most common type of environment is the "room," which may have specially shaped and surfaced walls, special lighting effects, and many different kinds of contents. Kurt Schwitters' *Merzbau* (destroyed in 1943) was the first of these rooms, which now include the nightmare fantasy of Edward Kienholz' tableaux, such as "Roxy's" (1961) or "The Illegal Operation" (1962); George Segal's compositions, in which casts of clothed human figures in frozen, casual attitudes are placed in interiors; and rooms built of mirrors, such as Yayoi Kusama's "Endless Love Room" and Lucas Samaras' "Mirrored Room," in both of which the spectator himself, endlessly reflected, becomes part of the total effect.

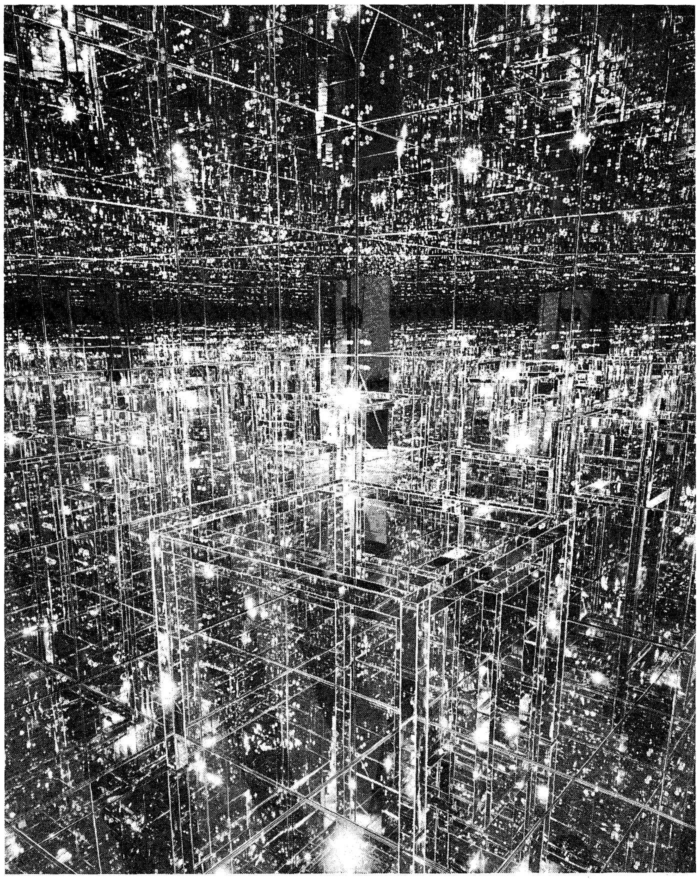
Use of real objects in environmental art

Environmental art, in common with collage and assemblage, has tended toward greater concreteness not by making a more realistic representation, as naturalistic art does, but by including more of reality itself in the work; for example, by using casts taken from the actual human body, real clothes, actual objects and casts of objects, actual lighting effects, and real items of furniture. Plastic elements may be combined with music and sound effects, dance, theatrical spectacles, and film to create so-called happenings, in which real figures are constituents of the "artwork" and operations are performed not on "artistic" materials but are performed on real objects and on the actual environment. Ideas such as these go far beyond anything that has ever before been associated with the term sculpture.

REPRESENTATIONAL SCULPTURE

Sculpture in the round is much more restricted than relief in the range of its subject matter. The representation of, say, a battle scene or a cavalcade in the round would require a space that corresponded in scale in every direction with that occupied by an actual battle or cavalcade. No such problems arise in relief because the treatment of scale and relations in depth is to some extent notional, or theoretical, like that of pictures. Then again, because a relief is attached to a background, problems of weight and physical balance and support do not arise. Figures can be represented as floating in space and can be arranged vertically as well as horizontally. Thus, in general, sculpture in the round is concerned with single figures and limited groups, while reliefs deal with more complex "pictorial" subjects involving crowds, landscape, architectural backgrounds, and so on.

The human figure. The principal subject of sculpture has always been the human figure. Next in importance are animals and fantastic creatures based on human and animal forms. Other subjects—for example, landscape, plants, still life, and architecture—have served primarily as accessories to figure sculpture, not as subjects in their own right. The overwhelming predominance of the human figure is due: first, to its immense emotional importance



Environmental sculpture.

as an object of desire, love, fear, respect, and, in the case of anthropomorphic gods, worship; and, second, to its inexhaustible subtlety and variety of form and expression. The nude or almost nude figure played a prominent role in Egyptian, Indian, Greek, and African sculpture, while in medieval European and ancient Chinese sculpture the figure is almost invariably clothed. The interplay of the linear and modelled forms of free draperies with the solid volumes of the human body was of great interest to Classical sculptors and later became one of the principal themes of Renaissance and post-Renaissance sculpture. The human figure continues to be of central importance in modern sculpture in spite of the growth of nonfigurative art; but the optimistic, idealized, or naturalistic images of man prevalent in previous ages have been largely replaced by images of despair, horror, deformation, and satire.

Devotional images and narrative sculpture. The production of devotional images has been one of the sculptor's main tasks, and many of the world's greatest sculptures are of this kind. They include images of Buddha and the Hindu gods; of Christ, the Virgin, and the Christian saints; of Athena, Aphrodite, Zeus, and other Greek gods; and of all the various gods, spirits, and mythical beings of Rome, the ancient Near East, pre-Columbian America, Black Africa, and the Pacific Islands.

Closely connected with devotional images are all of the narrative sculptures in which legends, heroic deeds, and religious stories are depicted for the delight and instruction of peoples who lived when books and literacy were rare. The Buddhist, Hindu, and Christian traditions are especially rich in narrative sculpture. Stories of the incarnations of Buddha—*Jātaka*—and of the Hindu gods abounded in the temple sculpture of India and Southeast Asia; for example, at Sānchi, Amarāvatī, Borobuḍur, and Angkor. Sculpture illustrating the stories of the Bible is so abundant in medieval churches that the churches have been called "Bibles in stone." Sculpture recounting the heroic deeds of kings and generals are common, especially in Assyria and Rome. The Romans made use of a form known as continuous narrative, the best known example of which is the spiral, or helical, band of relief sculpture that surrounds Trajan's Column (*c.* AD 106–113) and tells the story of the Emperor's Dacian Wars. The episodes in the narrative are not separated into a series of framed compositions but are linked to form a continuous band of unbroken relief.

Portraiture. Portraiture was practiced by the Egyptians but was comparatively rare in the ancient world until the Romans made portrait sculpture one of their major artistic achievements. The features of many famous people are known to modern man only through the work of Roman sculptors on coins and medals, portrait busts, and full-length portraits. Portraiture has been an important aspect of Western sculpture from the Renaissance to the present day. Some of the best known modern portrait sculptors are Rodin, Charles Despiau, Marino Marini, and Jacob Epstein.

Modern portrait sculptors

Scenes of everyday life. Scenes of everyday life have been represented in sculpture mainly on a small scale in minor works. The sculptures that are closest in spirit to the quiet dignity of the great 17th- and 18th-century genre paintings of Jan Vermeer and Jean-Baptiste-Siméon Chardin are perhaps certain Greek tombstones, such as that of the Stele of Hegeso, which represents a quiet, absorbed moment when a seated young woman and her maidservant are looking at a necklace they have just removed from a casket. Intimate scenes of the people and their activities in everyday rural life are often portrayed in medieval and Egyptian reliefs as part of larger compositions.

Animals. Animals have always been important subjects for sculpture. Paleolithic man produced some extraordinarily sensitive animal sculptures both in relief and in the round. Representations of horses and lions are among the finest works of Assyrian sculpture. Egyptian sculptors produced sensitive naturalistic representations of cattle, donkeys, hippopotamuses, apes, and a wide variety of birds and fish. Ancient Chinese sculptors made superb small-scale animal sculptures in bronze and pottery. Animals were the main subject matter for the sculpture of the nomadic tribes of Eurasia and northern Europe, for whom they became the basis for elaborate zoomorphic fantasies. This animal art contributed to the rich tradition of animal sculpture in medieval art. Animals also served as a basis for semi-abstract fantasy in Mexican, Mayan, North American Indian, and Oceanic sculpture. The horse has always occupied an important place in Western sculpture, but other animals have also figured in the work of such sculptors as Giambologna, in the 16th century, and Antoine-Louis Barye, in the 19th, as well as numerous sculptors of garden and fountain pieces. Among modern sculptors who have made extensive use of animals or animal-like forms are Brancusi, Picasso, Gerhard Marcks, Germaine Richier, François Pompon, Pino Pascali, and François-Xavier-Maxime Lalanne.

Fantasy. In their attempts to imagine gods and mythical beings, sculptors have invented fantastic images based on the combination and metamorphosis of animal and human forms. A centaur, the Minotaur, and animal-headed gods of the ancient world are straightforward combinations. More imaginative fantasies were produced by Mexican and Mayan sculptors and by tribal sculptors in many parts of the world. Fantastic creatures abound in the sculpture produced in northern Europe during the early Middle Ages and the Romanesque period. Fantasy of a playful kind is often found in garden sculpture and fountains.

In the period following World War I, fantasy was a dominant element in representational sculpture. Among its many forms are images derived from dreams, the technological fantasy of science fiction, erotic fantasies, and a whole host of monsters and automata. The Surrealists have made a major contribution to this aspect of modern sculpture.

Other subjects. Architectural backgrounds in sculpture range from the simplified baldacchinos (ornamental struc-

GEKS

tures resembling canopies used especially over altars) of early medieval reliefs to the 17th- and 18th-century virtuoso perspective townscapes of Grinling Gibbons. Architectural accessories such as plinths, entablatures, pilasters, columns, and moldings have played a prominent role both in Greek and Roman sarcophagi, in medieval altarpieces and screens, and in Renaissance wall tombs.

Outside the field of ornament, botanical forms have played only a minor role in sculpture. Trees and stylized lotuses are especially common in Indian sculpture because of their great symbolic significance. Trees are also present in many Renaissance reliefs and in some medieval reliefs.

Landscape, which was an important background feature in many Renaissance reliefs (notably those of Ghiberti) and, as sculptured rocks, appeared in a number of Baroque fountains, entered into sculpture in a new way when Henry Moore combined the forms of caves, rocks, hills, and cliffs with the human form in a series of large reclining figures.

There is nothing in sculpture comparable with the tradition of still-life painting. When objects are represented, it is almost always as part of a figure composition. A few modern sculptors, however, notably Giacomo Manzù and Oldenburg, have used still-life subjects.

NONREPRESENTATIONAL SCULPTURE

Kinds of nonrepresentational sculpture

There are two main kinds of nonrepresentational sculpture. One kind uses nature not as subject matter to be represented but as a source of formal ideas. For sculptors who work in this way, the forms that are observed in nature serve as a starting point for a kind of creative play, the end products of which may bear little or no resemblance either to their original source or to any other natural object. Many works by Brancusi, Raymond Duchamp-Villon, Jacques Lipchitz, Henri Laurens, Umberto Boccioni, and other pioneer modern sculptors have this character. The transformation of natural forms to a point where they are no longer recognizable is also common in many styles of primitive and ornamental art.

The other main kind of nonrepresentational sculpture, often known as nonobjective sculpture, is a more completely nonrepresentational form that does not even have a starting point in nature. It arises from a constructive manipulation of the sculptor's generalized, abstract ideas of spatial relations, volume, line, colour, texture, and so on. The approach of the nonobjective sculptor has been likened to that of the composer of music, who manipulates the elements of his art in a similar manner. The inclusion of purely invented, three-dimensional artifacts under the heading of sculpture is a 20th-century innovation.

Some nonobjective sculptors prefer forms that have the complex curvilinearity of surface typical of living organisms; others prefer more regular, simple geometric forms. The whole realm of three-dimensional form is open to nonobjective sculptors, but these sculptors often restrict themselves to a narrow range of preferred types of form. A kind of nonobjective sculpture prominent in the 1950s and '60s, for example, consisted of extremely stark, so-called primary forms. These were highly finished, usually coloured constructions that were often large in scale and made up entirely of plane or single-curved surfaces. Prominent among the first generation of nonobjective sculptors were Jean Arp, Antoine Pevsner, Naum Gabo, Barbara Hepworth, Max Bill, and David Smith. Subsequent artists who worked in this manner include Robert Morris, Donald Judd, and Phillip King.

DECORATIVE SCULPTURE

The devices and motifs of ornamental sculpture fall into three main categories: abstract, zoomorphic, and botanical. Abstract shapes, which can easily be made to fit into any framework, are a widespread form of decoration. Outstanding examples of abstract relief ornament are found on Islāmic, Mexican, and Mayan buildings and on small Celtic metal artifacts. The character of the work varies from the large-scale rectilinear two-plane reliefs of the buildings of Mitla in Mexico, to the small-scale curvilinear plastic decoration of a Celtic shield or body ornament.

Zoomorphic relief decoration, derived from a vast range of animal forms, is common on primitive artifacts and on Romanesque churches, especially the wooden stave churches of Scandinavia.

Botanical forms lend themselves readily to decorative purposes because their growth patterns are variable and

their components—leaf, tendril, bud, flower, and fruit—are infinitely repeatable. The acanthus and anthemion motifs of Classical relief and the lotuses of Indian relief are splendid examples of stylized plant ornament. The naturalistic leaf ornament of Southwell Minster, Reims Cathedral, and other Gothic churches transcends the merely decorative and becomes superbly plastic sculpture in its own right.

SYMBOLISM

Sculptural images may be symbolic on a number of levels. Apart from conventional symbols, such as those of heraldry and other insignia, the simplest and most straightforward kind of sculptural symbol is that in which an abstract idea is represented by means of allegory and personification. A few common examples are figures that personify the cardinal virtues (prudence, justice, temperance, fortitude), the theological virtues (faith, hope, and charity), the arts, the church, victory, the seasons of the year, industry, and agriculture. These figures are often provided with symbolic objects that serve to identify them; for example, the hammer of industry, the sickle of agriculture, the hourglass of time, the scales of justice. Such personifications abound in medieval and Renaissance sculpture and were until recently the stock in trade of public sculpture the world over. Animals are also frequently used in the same way; for example, the owl (as the emblem of Athens and the symbol of wisdom), the British lion, and the American eagle.

Allegory and personification

Beyond this straightforward level of symbolism, the images of sculpture may serve as broader, more abstruse religious, mythical, and civic symbols expressing some of mankind's deepest spiritual insights, beliefs, and feelings. The great tympanums (the space above the lintel of a door that is enclosed by the doorway arch) of Autun, Moissac, and other medieval churches symbolize some of the most profound Christian doctrines concerning the ends of human life and man's relations with the divine. The Hindu image of the dance of Śiva is symbolic in every detail, and the whole image expresses in one concentrated symbol some of the complex cosmological ideas of the Hindu religion. The Buddhist temple of Borobuḍur, in Java, is one of the most complex and integrated of all religious symbols. It is designed as a holy mountain whose structure symbolizes the structure of the spiritual universe. Each of the nine levels of the temple has a different kind of sculptural symbolism, progressing from symbols of hell and the world of desire at the lowest level to austere symbols of the higher spiritual mysteries at its uppermost levels.

In more individualistic societies, works of sculpture may be symbolic on a personal, private level. Michelangelo's "Slaves" have been interpreted as allegories of the human soul struggling to free itself from the bondage of the body, its "earthly prison," or, more directly, as symbols of the struggle of intelligible form against mere matter. But there is no doubt that, in ways difficult to formulate precisely, they are also disturbing symbols of Michelangelo's personal attitudes, emotions, and psychological conflicts. If it is an expression of his unconscious mind, the sculptor himself may be unaware of this aspect of the design of his work.

Many modern sculptors disclaim any attempt at symbolism in their work. When symbolic images do play a part in modern sculpture, they are either derived from obsolete classical, medieval, and other historical sources or they are private. Because there has been little socially recognized symbolism for the modern sculptor to use in his work, symbols consciously invented by individual artists or deriving from the image-producing function of the individual unconscious mind have been paramount. Many of these are entirely personal symbols expressing the artist's private attitudes, beliefs, obsessions, and emotions. They are often more symptomatic than symbolic. Henry Moore is outstanding among modern sculptors for having created a world of personal symbols that also have a universal quality; and Naum Gabo has sought images that would symbolize in a general way modern man's attitudes to the world picture provided by science and technology.

Symbolism of sculptural sites

Examples of sculpture of which the positioning, or siting, as well as the imagery is symbolic are the carved boundary stones of the ancient world; memorials sited on battlegrounds or at places where religious and political martyrs have been killed; the Statue of Liberty and similar civic symbols situated at harbours, town gates, bridges, and so on; and the scenes of the Last Judgment placed over the entrances to cathedrals, where they could serve as an admonition to the congregation.

The choice of symbolism suitable to the function of a sculpture is an important aspect of design. Fonts, pulpits, lecterns, triumphal arches, war memorials, tombstones, and the like all require a symbolism appropriate to their function. In a somewhat different way, the tomb sculptures of Egypt, intended to serve a magical function in the afterlife of the tomb's inhabitants, had to be images suitable for their purpose. These, however, are more in the nature of magical substitutes than symbols.

Uses of sculpture

The vast majority of sculptures are not entirely autonomous but are integrated or linked in some way with other works of art in other mediums. Relief, in particular, has served as a form of decoration for an immense range of domestic, personal, civic, and sacred artifacts, from the spear-throwers of Paleolithic man and the cosmetic palettes of earliest Egyptian civilization to the latest mass-produced plastic reproduction of a Jacobean linenfold panel (a carved or molded panel representing a fold, or scroll, of linen).

The main use of large-scale sculpture has been in conjunction with architecture. It has either formed part of the interior or exterior fabric of the building itself or has been placed against or near the building as an adjunct to it. The role of sculpture in relation to buildings as part of a townscape is also of considerable importance. Traditionally, it has been used to provide a focal point at the meeting of streets, and in marketplaces, town squares, and other open places—a tradition that many town planners today are continuing.

Sculpture has been widely used as part of the total decorative scheme for a garden or park. Garden sculpture is usually intended primarily for enjoyment, helping to create the right kind of environment for meditation, relaxation, and delight. Because the aim is to create a lighthearted arcadian or ideal paradisal atmosphere, disturbing or serious subjects are usually avoided. The sculpture may be set among trees and foliage where it can surprise and delight the viewer or sited in the open to provide a focal point for a vista.

Fountains, too, are intended primarily to give enjoyment to the senses. There is nothing to compare with the interplay of light, movement, sound, and sculptural imagery in great fountains, which combine the movement and sound of sheets, jets, and cataracts of water with richly imaginative sculpture, water plants and foliage, darting fish, reflections, and changing lights. They are the prototypes of all 20th-century "mixed-media" kinetic sculptures.

The durability of sculpture makes it an ideal medium for commemorative purposes, and much of the world's greatest sculpture has been created to perpetuate the memory of persons and events. Commemorative sculpture includes tombs, tombstones, statues, plaques, sarcophagi, memorial columns, and triumphal arches. Portraiture, too, often serves a memorial function.

Sculptural coins and medals

One of the most familiar and widespread uses of sculpture is for coins. Produced for more than 2,500 years, these miniature works of art contain a historically invaluable and often artistically excellent range of portrait heads and symbolic devices. Medals, too, in spite of their small scale, may be vehicles for plastic art of the highest quality. The 15th-century medals of the Italian artist Antonio Pisanello and the coins of ancient Greece are generally considered the supreme achievements in these miniature fields of sculpture.

Also on a small scale are the sculptural products of the glyptic arts—that is, the arts of carving gems and hard stones. Superb and varied work, often done in conjunction with precious metalwork, has been produced in many countries.

Finally, sculpture has been widely used for ceremonial and ritualistic objects such as bishop's croziers, censers, reliquaries, chalices, tabernacles, sacred book covers, ancient Chinese bronzes, burial accessories, the paraphernalia of tribal rituals, the special equipment worn by participants in the sacred ball game of ancient Mexico, processional images, masks and headdresses, and modern trophies and awards.

The History of Western Sculpture

Sculpture may be broadly defined as the art of representing observed or imagined objects in solid materials and in three dimensions. Like Western painting, Western sculpture has tended to be humanistic and naturalistic, concentrating upon the human figure and human action studied from nature. Early in the history of the art there developed two general types: statuary, in which figures are shown in the round, and relief, in which figures project from a ground.

Western sculpture in the ancient world of Greece and Rome and from the late Middle Ages to the end of the 19th century twice underwent a progressive development, from archaic stylization to realism; the term progressive here means that the stylistic sequence was determined by what was previously known about the representation of the human figure, each step depending upon a prior one, and not that there was an aesthetic progression or improvement. Modern criticism has sometimes claimed that much was lost in the change. In any event, the sculptors of the West closely observed the human body in action, at first attempting to find its ideal aspect and proportions and later aiming for dramatic effects, the heroic and the tragic; still later they favoured less significant sentiments, or at least more familiar and mundane subjects.

The pre-Hellenic, early Christian, Byzantine, and early medieval periods contradicted the humanist-naturalist bias of Greece and Rome and the Renaissance; and in the 20th century that contradiction has been even more emphatic. The 20th century has seen the move away from humanistic naturalism to experimentation with new materials and techniques and new and complex imagery. With the advent of abstract art, the concept of the figure has been broadened to encompass a wide range of nonliteral representation; the notion of statuary has been superseded by the more inclusive category of freestanding sculpture; and, further, two new types have risen to prominence: kinetic sculpture, in which actual movement of parts or of the whole sculpture is considered an element of design; and environmental sculpture, in which the artist either alters a given environment as if it were a kind of medium or provides in the sculpture itself an environment for the viewer to enter.

This article is divided into the following sections:

European Metal Age cultures

AEGEAN AND EASTERN MEDITERRANEAN

Aegean civilization is a general term for the prehistoric Bronze Age cultures of the area around the Aegean Sea covering the period from *c.* 3000 BC to *c.* 1100 BC, when iron began to come into general use throughout the area. From the earliest times these cultures fall into three main groups: (1) the Minoan culture (after the legendary king Minos) of Crete, (2) the Cycladic culture of the Cyclades islands, and (3) the Helladic culture of mainland Greece (Hellas). For convenience, the three cultures are each divided into three phases, Early, Middle, and Late, in accordance with the phases of the Bronze Age. The culture of Cyprus in the eastern Mediterranean, although it commenced somewhat later than those of the Aegean, came to parallel them by the Middle Bronze Age. The Late Bronze Age phase of the mainland is usually called Mycenaean after Mycenae, the chief Late Bronze Age site in mainland Greece.

Cultures of the Aegean

The first centre of high civilization in the Aegean area, with great cities and palaces, a highly developed art, extended trade, writing, and use of seal stones, was Crete. Here from the end of the 3rd millennium BC onward a very distinctive civilization, owing much to the older civilizations of Egypt and the Middle East but original in its character, came into being.

The Cretan (Minoan) civilization had begun to spread by the end of the Early Bronze Age across the Aegean to the islands and to the mainland of Greece. During the Late Bronze Age, from the middle of the 16th century onward, a civilization more or less uniform superficially but showing local divergences is found throughout the Aegean area. Eventually people bearing this civilization spread colonies eastward to Cyprus and elsewhere on the southern and western coasts of Asia Minor as far as Syria; also westward to Tarentum in southern Italy and even perhaps to Sicily. In the latter part of this period, after about 1400 BC, the centre of political and economic power, if not of artistic achievement, appears to have shifted from Knossos in Crete to Mycenae on the Greek mainland. (Ed.)

The Early Bronze Age (3000–2000 BC). *Early Minoan.* The early Minoan period saw a thousand years of peaceful development, which eventually gave place to the full flowering of the Minoan spirit, the Middle Minoan period. Pottery was preeminent among the Early Minoan arts.

Early Cycladic. The Early Cycladic culture developed on parallel lines to the Early Minoan. Thanks to obsidian from Melos, marble from many islands, and local sources of gold, silver, and copper, the Cycladic islanders rapidly became prosperous. As in Crete, the Early Bronze Age merged without incident into the Middle Bronze Age.

The Early Cycladic period is celebrated principally for its statuettes and vases carved from the brilliant coarse-crystalled marble of these islands. The statuettes, mostly of goddesses, are among the finest products of the Greek Bronze Age. They owe their charm to the extreme simplification of bodily forms. The typical "Cycladic idol" is a naked female, lying with her head back, her arms crossed over her breasts. These figures vary in size from a few inches to more than six feet in length (Figure 1).

Early Helladic and Early Cypriot. Mainland Greece probably received its Bronze Age settlers from the Cyclades, but the two cultures soon diverged. A prosperous era arose about 2500 BC and lasted until about 2200. Sculpture was overshadowed by pottery, metalwork, and architecture among the Early Helladic arts. In the Early Cypriot, the only surviving sculptures are a series of steatite cruciform figures of a mother goddess (3000–2500 BC) stylized in much the same way as contemporary Cycladic idols, from which they may have been derived.

The Middle Bronze Age (2000–1600 BC). *Middle Minoan.* The Middle Minoan period differs principally from the Early Minoan in the creation of palaces and a palatial life and art. Large-scale sculpture seems not to have found much favour in Crete, although fragments of life-size figures from this period were discovered in the Cyclades in the late 20th century. Miniature sculpture of the highest quality, some of it of fired sand and clay, was produced from at least as early as 1700 BC. Good examples are two female figures (called "Snake Goddesses") from Knossos, dated about 1700 BC (Archaeological Museum, Iráklion, Crete). These women stand with their arms in front of them, holding sacred snakes; they wear a flounced skirt and tight belt, and their breasts are bare.

Minoan "Snake Goddess" figures

Middle Cycladic, Middle Helladic, and Middle Cypriot. During the Middle Cycladic period, the Cyclades suffered a diminution in prosperity and seem to have become politically subordinate to Crete. Two waves of Indo-European peoples seem to have descended on the Greek mainland, one about 2200 BC and the other about 2000 BC. They destroyed much and for long contributed little to Greece's artistic heritage. The pottery of this period, however, is of high quality. The Middle Cypriot period was a development of the Early Cypriot. As on the mainland, no important art apart from pottery has survived.

The Late Bronze Age (1600–1100 BC). *Late Minoan.* Prosperity and artistic achievement remained at a high level until about 1450 BC, when all the great centres of Cretan culture were destroyed by earthquakes (probably connected with a cataclysmic eruption of the volcanic island of Thera). After these disasters, only the palace at Knossos was restored for occupation. About 1375 BC, however, the palace at Knossos was destroyed by fire. Thereafter Crete was a second-class power and became somewhat of a cultural backwater. Miniature sculpture was still popular. No longer in faience, figures were increasingly made of bronze, ivory, and terra-cotta. Some of the bronzes, cast solid by the "lost wax" process (using a wax model), are very fine, the earliest being the best. The subjects include male worshippers wearing boots, tight belt, and kilt; women (perhaps goddesses) dressed like the faience snake goddesses of the Middle Minoan period; and animals, especially bulls.

Carved-stone vases

Carved-stone vases were made between 1600 and 1450 BC. Elegant vessels were carved from such diverse materials as marble, obsidian, and steatite (Figure 2). Others, of soft stone, were made in the shape of bulls' heads, aston-

In the Archaeological Museum, Iráklion. Diameter 14 cm.

Alison Frantz

ishingly true to life, or were carved in relief, with religious or court ritual scenes, and covered with gold leaf.

The art of the seal engraver flourished until 1375 BC. Religious subjects, scenes of the bullring, and depictions of animals in their natural setting were popular. Even the exaggerations of the style reflect careful observation of the movements of the animals and their idiosyncratic anatomy, but they also relate the forms depicted to the shape of the stone—the curve of a bull's back or horns to that of the edge, for instance (Figure 3).

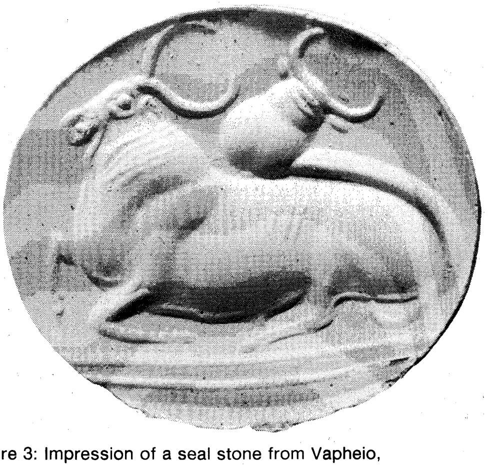

Figure 3: Impression of a seal stone from Vapheio, Greece, dating from *c.* 1500 BC.

Mycenaean. Mainland Greece enjoyed renewed contacts with Crete *c.* 1600 BC, and a rich culture, based on the Late Minoan, rapidly came into being. The Mycenaeans gained control of Crete *c.* 1450 BC, and between 1375 and 1200 BC they became masters of an empire that stretched from Sicily and southern Italy in the west to Asia Minor and the Levant coast in the east. About 1200 BC, however, many of the Mycenaean strongholds were destroyed by fire. There were signs of a renaissance, but the end of Mycenaean civilization came *c.* 1100 BC.

The Lion Gate at Mycenae

The Mycenaeans seem to have had more of a taste for monumental sculpture than had their Minoan mentors. Of the few surviving examples, the best known is a relief over the Lion Gate at Mycenae (*c.* 1250 BC), in which two lions confront each other across an architectural column (Figure 4). Probably heraldic in concept, this design is comparable with those on tiny seals and ivories of Cretan inspiration. Sculpture on a small scale, in ivory, bronze, and terra-cotta, generally Minoan in character, remained popular.

Late Cypriot. Cyprus reached its highest degree of prosperity in the Late Cypriot period, due to increased exploitation of its copper mines. There were close commercial relations not only with the Levant coast, as before, but also with Egypt, Crete, and Mycenaean Greece (the latter being close from 1400 BC). About 1200 BC Mycenaean Greeks, refugees from their homeland, settled in Cyprus. They introduced their skills and produced many luxury articles in a mixed Mycenaean-Cypriot style. Cyprus escaped the invasions that finally destroyed Mycenaean and Minoan culture, but its own culture did not last much longer. By 1050 BC, for reasons that are not clear, it, too, had ceased to exist.

From *Crete and Mycenae* published by Thames & Hudson, London, and Harry N. Abrams, New York; photograph, Hirmer Fotoarchiv, Munchen

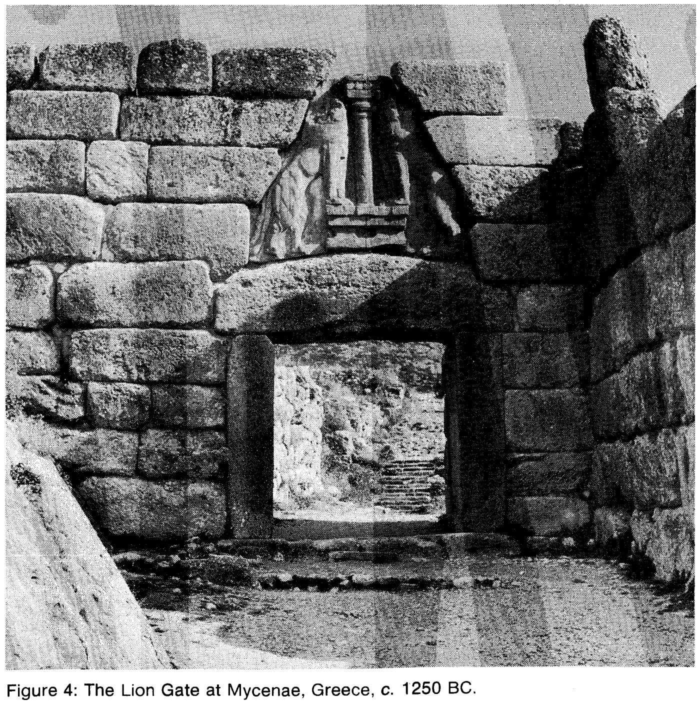

Figure 4: The Lion Gate at Mycenae, Greece, *c.* 1250 BC.

As in Crete, large-scale sculpture was rejected in favour of small-scale work. A bronze figure of a horned god (shortly after 1200 BC) from Enkomi (Cyprus Museum, Nicosia) shows a successful blend of Mycenaean and Cypriot elements. A good example of these characteristics is a carved ivory gaming box (British Museum), also from Enkomi, whose style shows a blend of Mycenaean and Middle Eastern motifs. (R.A.Hi./Ed.)

WESTERN MEDITERRANEAN

Like central and northern Europe, although to a lesser degree, the western Mediterranean was considerably behind the eastern Mediterranean, where civilization, the arts, and writing were born much earlier. The development of the metallurgical industry did not occur simultaneously in the various regions of the western Mediterranean, but it did bring important innovations in the mode of living and, of course, in the arts.

The Chalcolithic (Copper-Stone) era began in Spain at the end of the 3rd millennium BC at Los Millares, near Almería, and in Italy at the beginning of the 2nd millennium with the Remedello civilization. Bronze appeared not long afterward, around 1800 BC, in Italy and Sardinia. The Bronze Age in Italy gave way to the Iron Age at the beginning of the 1st millennium BC, but elsewhere, as in Sardinia or Spain, it lasted longer. The Iron Age flourished on the Illyrian coasts and in Italy from 900 to 800 BC; it also lasted varying lengths of time according to locale. After this, one may speak of the civilizations of Magna Graecia, of Rome, or of Etruria.

During the metal ages, popular migrations, commerce, and wars increased, which resulted in the rise of cities and of fortified works for their protection and defense, such as the talayots (round or quadrangular towers) of the Balearic Isles and the nuraghi (round towers) of Sardinia. With respect to the plastic arts, one particularly remarkable phenomenon was the birth and multiplication of megalithic human representations, which gained in number and importance from the 3rd to the 1st millennium BC. The Neolithic monuments, menhirs (single, vertical megaliths) and dolmens (structures of two vertical stones capped by a horizontal one), which had arisen in the megalithic era, continued to appear in the Copper and Bronze Ages, but then—here and there in Spain, Sardinia, Corsica, Liguria, and in the south of France—stelae-menhirs (carved or inscribed stone slabs used for commemorative purposes), like the stammerings of Western figure sculpture, imitated the human form. They maintained certain stylistic relations with rock engravings of mountainous regions, such as the Val Camonica.

Human representations

Bronze Age cultures. *Sardinia and Corsica.* The nuraghic civilization had an original sculpture expressed in a large production of bronze statuettes, about 500 of which have been found in nuraghi, temples, houses, and tombs (Figure 5). These figurines represent all classes of the proto-Sardinian populations—military chiefs, soldiers, priests, and women, as well as heroes and gods—in what seems to the modern viewer to be an engagingly direct but also sophisticated geometric style. The greatest number of these bronzes are today in the Museo Archeologico Nazionale in Cagliari, Sardinia. Some have been discovered in Etruscan tombs of Vetulonia and Vulci and have been dated to the period extending from the 9th to the 6th century BC.

Corsican menhir, or stela, statuary

Corsican menhir, or stela, statuary constitutes a group of special interest. The stone is imbued with life by a sculptural art that involves roughing-in of the head, animation of the upper portion of the body, and placement of a few elements of ornamentation or weaponry (sculpted in relief or, more rarely, engraved) on the schematically anthropomorphic image. These primitive statues are masculine and, no doubt, represent family or tribal heads made heroic or divine. This megalithic stela statuary art appears not only on Corsica but also in various other countries and regions of the western Mediterranean, including Spain, Sardinia, Liguria, and, in southern France, Provence, Aveyron, Hérault, and Gard, though to a lesser degree. The advance of this type of megalithic sculptural art is difficult to follow, but it is clear that these different groups are related, with close affinities existing between the stelae-menhirs of Corsica and those of the Ligurian coast. Such art is everywhere the expression of a patriarchal society seeking to impose on men's vision, massively and not without grandeur, the image of the departed ancestors.

Italy. From the Bronze Age of far northern Italy there survives an exceptional collection of rock engravings, a remarkable extension of an art that, in fact, had been represented in the prehistoric era and had not yet vanished completely. About 20,000 rock engravings have been found between altitudes of 5,000 and 5,600 feet (1,500 and 1,700 metres) in the Val Camonica, north of the town of Brescia. This art is found again further west, in the Maritime Alps of France on Monte Bego, between altitudes of 6,600 and 8,900 feet, and less remarkably elsewhere. What is exceptional about the carvings of the Val Camonica is that they represent a variety of subjects—rituals, battles, hunting, and daily labour—and that these were treated as compositions.

Rock engravings

Although engraving played a minor role in the case of the menhir statuary mentioned earlier, relations do exist between the sculpted works and the Camunian images of Monte Bego. The same representations of collar torques appear on the menhir statuary of Gard, Aveyron, and Tarn, on the one hand, and on certain monumental engravings of the Val Camonica, on the other. Some kind of relationship thus unites the arts of rock engraving and stela statuary in the Bronze Age.

Iron Age cultures. *Italy.* The Italian peninsula, which in the Bronze Age had been only one among many centres of civilization, took on a special importance in the Iron Age. Widespread and powerful cultural and artistic centres grew up there, first in the Villanovan civilization and later in the Etruscan; their influence was disseminated into the surrounding areas.

At the beginning of the 1st millennium BC there began to develop in the Po plain, in Tuscany, Latium, and some areas of Lucania, a new cremating civilization, which draws its name from that of the Villanova necropolis, discovered near Bologna. It is obviously related to the so-called Urnfield civilization that, at the end of the Bronze Age and beginning of the Iron Age, extended over central and eastern Europe and had developed a metal art with geometric and abstract ornamentation. The ashes of the dead were placed in urns thrust in level with the soil. From the Urnfield civilization arose two others: the Hallstatt civilization, which spread into the Balkans, northern and

Villanovan civilization

central Europe, and France, beyond the Pyrenees; and in Italy the Villanovan civilization and the civilizations that, to the east and west of the Po plain, were related to it, the so-called Golasecca civilization in the great lakes region and the Este civilization in the Venice area.

These Italic civilizations of the Early Iron Age, which appeared at the beginning of the 1st millennium BC and lasted for varying lengths of time, multiplied the number of dwelling sites. Originating as outposts established on naturally strong positions, they began to resemble towns as population increased.

The cinerary urn, which was made first of terra-cotta and later of bronze, assumes, by its form, a symbolic value (Figure 6). Biconical in form and covered with an overturned cup, later with a helmet, it schematically represents the appearance of the human body. Sometimes, as in examples from Latium and Tuscany, the funerary vessel is in the form of a hut or cabin—the house of the dead person whose remains it holds. The ornamentation, painted or engraved on the vases and engraved or in relief on metal objects, is in a geometric, nonfigurative style. Human or animal forms appear only rarely—in the decoration of small utilitarian objects such as vase handles and horse bits. It is a severe art, therefore, which essentially limits itself to linear exercises. Even motifs such as the disk, the solar boat, and the birds that encircle them, inherited from a more distant past and possessing primitively religious value, take on a stylized air and become abstract figures.

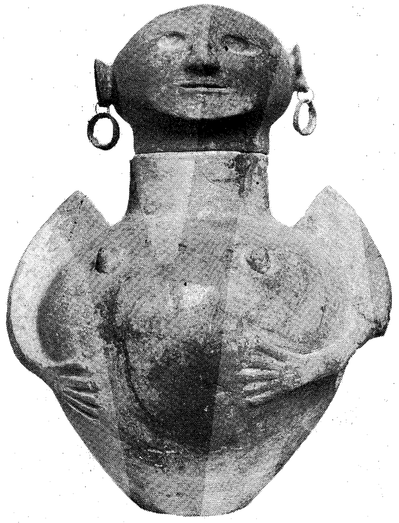

Figure 6: Villanovan canopic vase from Chiusi, Italy, terra-cotta, 6th century BC. In the Museo Archeologico, Florence. Height 44 cm.

A naturalistic note is provided by the imagery that decorates, in zones of superimposed relief, bronze vessels called situlae, a kind of pail found in Eastern countries and in the eastern Alps. These situlae were made in Venetian workshops in particular and were very popular in the neighbouring areas. They rapidly underwent an Etruscan influence, however, that tended to give prominence in the chased ornamentation to human figures at feasts, games, or funerals, as in the masterpiece known from the place of its discovery as the Certosa Situla (Museo Civico Archeologico, Bologna). (R.Bl./Ed.)

Etruria, Latium, and the Faliscan districts fall into three main areas of artistic production: northern, central, and southern, each centred upon cities with a distinctive artistic style. In the southern areas the chief centres were Caere and Veii, in which the Etruscan style most closely approached the Greek. In central Etruria, Vulci was evidently the leading art centre, although Tarquinia was unsurpassed in the beauty of its wall paintings. There were several potteries in Vulci, and the greater part of the central Etruscan bronzes, artistically the best, were produced there. The north was dominated by Clusium, although Perugia seems to have been important along with lesser centres at Volterra and Fiesole.

The very earliest examples of Etruscan statuary are flat, rectilinear figurines from Vetulonia and Capodimonte di Bolsena. These figures occur in later contexts in the Regolini-Galassi and Bernardini tombs, both of which contain pieces in a more advanced style that cannot have developed much later. These are statuettes of women with pigtails and long skirts depicted in a manner that suggests a north Syria influence, although this female type, frequently copied in ivory and amber, is certainly of local origin.

The earliest evidence of Greek influence is the presence of centaurs, perhaps transmitted on Corinthian vases. Their style in Etruria is Orientalizing, with a slim body and elongated legs, perhaps reflecting Cretan influence. These and other mythical creatures found great favour with the Vulci stonemasons. To archaic works of early Etruscan sculpture certain Greek parallels can be found in the late 7th and early 6th centuries, and in general characteristics the works still followed the Greek Archaic Daedalic tradition. The next change in style took place *c.* 550 BC, when art became distinctively Ionian. These new influences can be seen earliest in such pieces of bronze work as the Loeb Tripod from San Valentino near Perugia and the Monteleone chariot platings (in the Metropolitan Museum, New York City), but they soon become apparent also in the relief designs on *bucchero pesante* (heavily embossed black pottery) and in architectural reliefs like those from Tarquinia. By the end of the 6th century BC Veii possessed an excellent school of terra-cotta sculptures in Ionian styles. The statues of Apollo and of a votaress suckling a child are elaborately stylized in features, draperies, and muscles. Clay statuary, still retaining traces of former painting, was made in many Etruscan centres. Examples in the more mature classical style that began in the last quarter of the 5th century are the satyr-and-maiden groups from Satricum (modern Conca) in the Museo Nazionale di Villa Giulia, Rome, which contains a rich collection of architectural terra-cottas from Caere, Falerii, Veii, Satricum, and other sites.

Ionian influences

These pieces of statuary were designed to stand on temple roofs, and the socketed bases by which they were fixed have survived. Terra-cotta sculpture was also used for antefixes for these temples but above all for funerary sculpture. Sarcophagi with the sculptured figures of the husband and his wife reclining on the lids seem to have begun late in the 6th century, the date of the haunting sarcophagus from Caere (Villa Giulia, Rome). Bronze sculptures were also produced from the end of the 6th century, beginning with the famous She-Wolf, the symbol of modern Rome (Musei Capitolini, Rome), and the later Chimera from Arezzo (Museo Archeologico, Florence) or the so-called Mars of Todi (Vatican Museums) of the early 4th century BC.

In spite of great achievements in sculpture in the round, most of what has survived is in low relief, and a series of fine 6th–5th-century relief sarcophagi from Clusium, depicting dances, funeral games and banquets, or the journey of the dead to the underworld, are a major source of information on Etruscan everyday life. Superbly carved gravestones of the late mid-6th century are known from Clusium and Settimello, but the disk- and horseshoe-shaped gravestones of the Bologna, Fiesole, and Populonia graves have crude reliefs. (W.Cu./Ed.)

Sculpture developed but did not seek, as in Greece, to represent the idealized body of athletes and gods, attempting instead to represent the figure and features of the deceased (Figure 7). There was a continuing taste for real or fantastic animals such as lions, panthers, and sphinxes, and the Etruscan imagination seems to have been haunted by these beasts and demons, the vigilant guardians of the tombs.

Iberia. Whether in the form of great statuary or small votive images, Iberian figurative art was essentially religious and intended to represent sacred animals, deities, and their worshippers. Although much influenced by Greek and other sources, these works are vigorous and original, as may be seen from "La dama de Cerro de los Santos" in the Museo Arqueológico Nacional at Madrid and "La dama de Elche" in the Prado at Madrid (Figure 8). In the

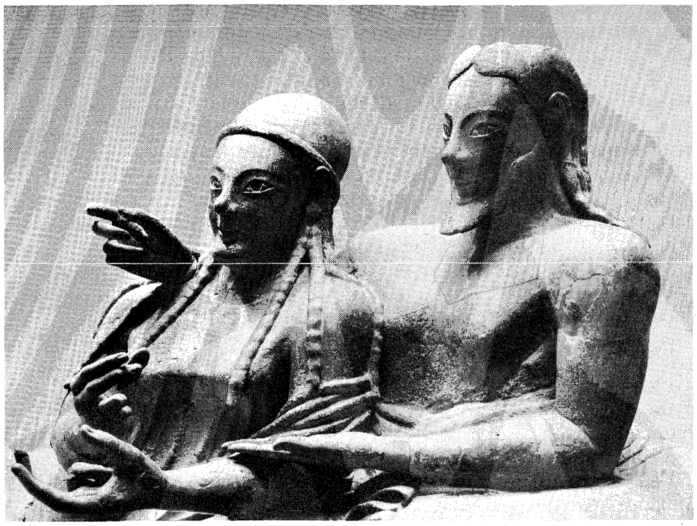

Figure 7: Detail of "Reclining Couple," clay sarcophagus from Caere, Italy, late 6th century BC. In the Museo Nazionale di Villa Giulia, Rome. Length of entire sarcophagus 2.01 m.

Alinari—Art Resource/EB Inc.

latter, a hieratic visage, with a severity not unlike some of the ideal heads of classical Greece, is adorned with a superabundance of heavy Iberian jewels. (R.Bl./Ed.)

Ancient Greek

Greek art no doubt owed much indirectly to the Minoan-Mycenaean civilization (now known in its later stages to have been Greek), which disintegrated at the end of the 2nd millennium BC, partly under the impact of a series of invasions from the Balkans. The period covered by this section, however, begins about 900 BC with the kaleidoscopic rearrangement of invaders and earlier inhabitants into a new pattern, which was followed by a steady artistic development—continuing without interruption down to the conquest of Greece by Rome in 146 BC. Even this diverted, rather than interrupted, the flow, and Greek artists continued to be predominant under the Roman Empire and beyond that into the Byzantine. But after Greece had become a Roman province, Greek art fell increasingly under the patronage of Romans and was devoted either to expressing Roman ideals or to reproducing older works of art. It is therefore reasonable to regard the later years of the 1st century BC, when the Roman Empire was forming, as the later limit of the period.

Five stages of Greek art

Within this period it is convenient to distinguish five stages of development. Their names are modern and arbitrary; the divisions between them are not equally sharp and do not apply equally to all parts of the Greek world, but they serve as a general guide to successive trends.

The first is the Geometric period (so-called from the rectilinear character of its art) from about 900 to about 800 BC, when Greece was self-contained and contact with the outside world was rare.

The second, the Orientalizing period, for about a century and a half from 800 BC, is one of contact with the East, a contact that had been broken by the upheavals at the end of the 2nd millennium.

The third period, the Archaic, from about 650 to about 480 BC, is characterized by the gradual absorption of Oriental elements and the rise and development of archaic Greek art.

The fourth period, from about 480 to about 330 BC, is known as the Classical; its beginning is marked by the rise of the sculptors Myron, Phidias, and Polyclitus and the painter Polygnotus, and its end, by the work of Scopas, Praxiteles, and Lysippus. (The word classical, which originally meant simply first-class, can also be used either in a narrower sense than this to denote only the Phidian age—*i.e.,* 50 years in the middle of the 5th century BC—or in a broader sense to cover the whole of post-Mycenaean Greek art from Geometric to late Roman.)

The fifth period is the Hellenistic, from about 330 BC, when the conquests of Alexander the Great opened new areas to the Greeks and the division of his kingdom among his Greek successors after his death in 323 diffused Greek art over the greater part of the known world, down to the late 1st century BC. Hellenistic symbolism and Hellenistic technical skill continued as living traditions under the Romans.

Statues were of limestone, marble, bronze, gold and ivory, terra-cotta, and wood. After the Archaic period the use of wood and of limestone seems to have been rare, as was the use of terra-cotta for statues of large size, although it should be noted that sculpture in the first and last of these materials tended to be ephemeral. The group of Orpheus and the two harpies that was restored at the J. Paul Getty Museum, Malibu, California, in the 1980s is astonishing not only for its quality but also for its size, and yet many other such figures may have been produced. Full-size statues of gold and ivory were rare at all times because of their cost; statues with gilded wooden bodies and marble extremities were sometimes made instead. For statuettes, ivory and amber, limestone, marble, wood, gold, silver, bronze, and terra-cotta were used; of these, terra-cotta was by far the most common, bronze and marble less so, and the rest rare. Extremely valuable because they can often be dated with accuracy are the types of sculpture used for the decoration of buildings: acroteria (*i.e.,* figures on the tops or ends of gables); figures in the low triangular field of the pediment under the gable (both of these are usually almost in the round); sculptured panels (metopes) of the Doric frieze, which are usually in high or very high relief; and the continuous Ionic frieze, which is usually in low relief.

Sources of modern knowledge of Greek sculptures

Of the many thousands of statues produced during the period in which Greek art flourished, not more than a few dozen survive, and those mostly mutilated. Knowledge of the history of Greek sculpture depends partly on these and partly on the architectural sculptures—both of high importance, since they are original. Much can also be learned about the general development of sculptural style from the small bronzes, often of very high quality, and from the terra-cottas. Of the small bronzes many, and of the terra-cottas very many, have survived, but they were made by independent artists and did not copy contemporary statues closely. The great bulk of evidence comes from copies made by Greeks, for Roman patrons, of originals now destroyed. Such evidence is invaluable but not entirely reliable. There is also literary evidence, but much of this is also second-hand or dates from long after the period in which the sculptures in question were made.

THE GEOMETRIC PERIOD

In the 9th century BC Greece was settling down again after upheavals and migrations both into and out of the mainland. It seems that invaders from the north brought with them the germs of an artistic style that developed into the Greek Geometric tradition.

In addition to the pottery, the Geometric period produced some terra-cottas and many small bronzes. The bronzes tended to be flat at first but became more solid and less angular as casting direct from wax models superseded cutting from bronze plates. Birds and other animals, especially horses, were popular and often admirably done; men, perhaps because their form commanded less imaginative interest, were not so successfully rendered; in the later stages of geometric art, groups of some complexity were attempted—a doe with her fawn, a man fighting (or greeting) a centaur, even a lion hunt complete with dogs. (B.As./Ed.)

THE ORIENTALIZING PERIOD

Sculpture of the Orientalizing period was profoundly affected by technical and stylistic influences from the East. In about 700 BC, the Greeks learned from their Eastern neighbours how to use molds to mass-produce clay relief plaques. Widely adopted, this technique helped to establish in Greece a stereotyped convention for figure representation, even in freestanding, unmolded sculptures; and a strong Eastern stylistic influence ensured that the convention was Oriental in flavour—in most cases a frontal pose with stiff patterned hair and drapery rendered in a strictly decorative manner. The adoption of this convention, which has come to be known as Daedalic style (after Daedalus, the legendary craftsman of Crete, where the style especially flourished), put an end to the development of naturalism and freedom in miniature sculptures that had shown promise in the Geometric period, and eventually became representative of even major Greek sculpture in the mid-7th century BC.

The Daedalic style

Hirmer Fotoarchiv, Munchen

In about 640 BC, however, a second Eastern influence began to be felt. As with the gigantic architecture of Egypt, the Greeks were impressed with the monumentality of Egyptian statuary, larger than life-size and executed in hard stone instead of the limestone, clay, or wood to which the Greeks had been accustomed. The Greeks learned the techniques of handling the harder stone in Egypt, and at home they turned to the fine white marble of the Cyclades islands (mainly Paros and Naxos) for their materials. It was at this time that the first truly monumental examples of Greek sculpture appeared. The idiom and proportions were at first still Daedalic. By about 630 BC, however, first in the islands and later in mainland Greece, they were carving freestanding figures of naked men that were copies of types formerly seen only in minor art and that owed something in proportion and details of pose to the common Egyptian standing figures. This new series of life-size or larger marble youths (kouroi) reveals rapid developments in technique and style, notably a transition from the Daedalic past to greater naturalism through the new monumental manner (Figure 9). The earliest of these figures were, as might be expected, dedications in sanctuaries, especially on the island of Delos, but some were grave markers, as on another island, Thera. At the same time, the older style was used for relief decoration of temples in Crete and Greece, particularly at Mycenae.

The kouros figure

THE ARCHAIC PERIOD

The kouroi, which had become standardized as freestanding statues of naked youths with hands to sides and one leg advanced, were the most representative examples of Archaic sculpture (Figure 9). At first their proportions were based on theory rather than observation; much the same was true of the anatomical details, which were treated as separate patterns applied to the figure with no proper understanding of their physiological relationships. Growing awareness of natural forms, although still without systematic study of the model, together with technical

The Archaic kouros and kore

mastery, led to a realism that is striking in comparison with the Daedalic pieces of the Orientalizing period (Figure 10). Still, the overriding considerations of proportion and pattern were never subordinated to nature. Only in the years just before the Persian invasion of 480 BC did some sculptors recognize the organic structure of the body and succeed in showing a truly relaxed pose, with the weight shifted onto one leg and the hips and torso consequently tilted to break the rigid symmetry of the characteristic kouros of the Archaic period (Figure 11).

In the female counterpart of the kouros, the kore, Archaic sculptors were again preoccupied with proportion and pattern—the pattern of drapery rather than of anatomy (Figure 12). Ionian (Chios, Samos) and island (Naxos) sculptors took the lead in developing decorative schemes for rendering the fall and splay of the folds of the loosely draped Ionic dress (chiton) and overmantle (himation). These patterns, like the anatomy of the kouroi, suggest nature rather than copy it; the strict logic of dressmaking is never observed by the sculptor, who uses the natural gesture of pulling a long skirt up and to one side first to produce a pleasing pattern of folds and only later to reveal the contours of the legs and body beneath. Most of the korai, like the kouroi, stood as dedications in sanctuaries, the richest series being from the Acropolis at Athens (these were overthrown by the Persians and then piously buried by the returning Athenians). Few of these statues were grave markers.

Archaic architectural sculpture

In the addition of sculpture to architecture, the determining factor was usually its position on the building. On a Doric temple, for instance, the metope frieze offered a series of rectangular plaques for reliefs that could accommodate two or three figures. There was a tendency in the Archaic period to let the action run on from one metope to the next, regardless of the intervening triglyph, a practice that was later abandoned. Above the frieze, the pediments formed by the gabled roof provided an awkward field—a long, low triangle. The sculptors of early temple pediments met the problem by depicting separate groups of different sizes (Figure 13), as at Corcyra (Archaeological Museum, Kérkira, Greece), or by devising monster bodies to fill the shallow corners, as in Athens (Acropolis Museum, Athens). Later, the advantages of using fighting groups with falling and fallen bodies were discovered; this type is represented at Athens and Aegina (Munich). The later Archaic pedimental figures were executed virtually in the round, standing against or just free from the background of the gable. Because these figures, unlike the kouroi and korai, were often in violent action, it may have been through meeting the problems of architectural sculpture that the artist arrived at a better understanding of the dynamics of the human body.

Work in relief also was used on gravestones, chiefly in Athens, for decorative bases of columns and for the frieze decoration on Ionic buildings, of which the best examples are from the Siphnian Treasury at Delphi (Archaeological Museum, Delphi), constructed shortly before 525 BC. The shallow relief on these works is little more than drawing rendered partly in the round; but the sculptor soon learned how, even in the shallowest relief, to indicate depth by overlapping figures and by bringing details up into the front plane. A dark-painted background helped the illusion; but the effect of the lavish use of colour on flesh, drapery, and backgrounds cannot now be readily appreciated since so little of it has survived in more than ghostly traces.

THE CLASSICAL PERIOD

The Severe style

Early Classical (c. 500–450 BC). This brief period is more than a mere transition from Archaic to Classical; in the figurative arts a distinctive style developed, in some respects representing as much of a contrast with what came afterward as with what went before. Its name—Severe style—is in part an indication that the "prettiness" of Archaic art, with its patterns of drapery and its decisive action, has been replaced by calm and balance. In vase painting and in sculpture, this new tone is evident in the composition of scenes and in details such as drapery, where the fussy pleats of the Archaic chiton give place to the heavy, straight fall of an outer robe called the peplos. The finest artists transformed the verve of the late Archaic

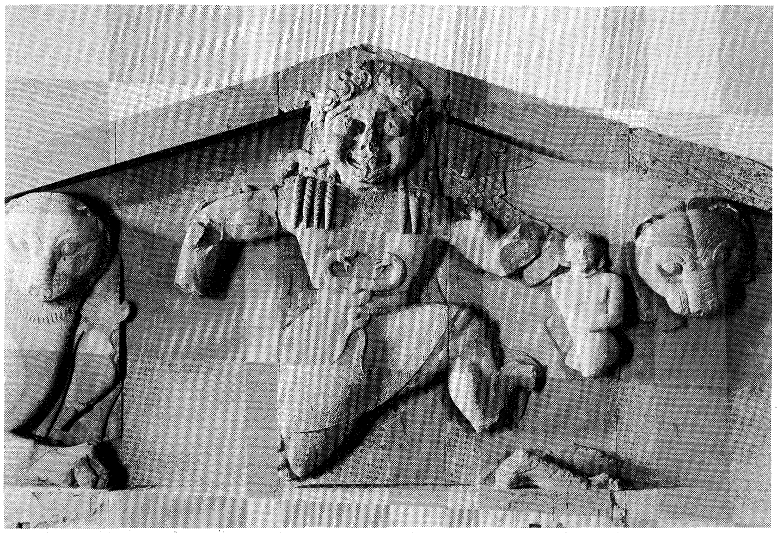

Figure 13: Gorgon from the west pediment of the Temple of Artemis, Corcyra (Corfu), Greece, limestone, *c.* 580 BC. In the Archaeological Museum, Kérkira, Greece.

By courtesy of the Deutsches Archaologisches Institut, Athens

style into more delicate expressions of emotion, and some were clearly checking their work more deliberately against the living model.

The early Classical period saw an impressive series of sculptural works that were excellent in their own right and significant in the continuing development of technical expressive skill and naturalism such as the relief carvings of the so-called Ludovisi Throne (Figure 14). Moreover, for the first time individual artists—and their contributions to technical and stylistic development—can in some cases be positively identified through Roman copies and written descriptions of their works.

Works of the Olympia Master

The finest examples of early Classical architectural sculpture are the works of the Olympia Master, an unidentified artist who decorated the pediments and frieze (Archaeological Museum, Olympia) of the Temple of Zeus at Olympia. In the east pediment, which shows men and women preparing for a chariot race, his figures display the sobriety and calm characteristic of the early Classical period. The men stand in the new, relaxed pose (the weight of the body being carried mainly by one leg) that was to be used by most sculptors throughout the period; and the women wear the peplos, its broad, heavy folds lending severity to the static composition. The west pediment, with a scene of struggling men and centaurs, has something of the rigid formality of the Archaic spirit, but here—and in the metopes that show the labours of Heracles—the artist has acutely observed differences of age in the human bodies and differences of expression—pain, fear, despair, disgust—in the faces (Figure 15). This was something new in Greek sculpture, and, in fact, cannot be readily matched in other works of this period.

The works of Myron

In freestanding sculpture—at this time, more commonly bronze than marble—the works of Myron (of Eleutherae, in Attica), identified through copies, were among the most celebrated of the period. Myron's most famous work is the "Discobolos" (discus thrower), of which a Roman copy (Museo Nazionale Romano) survives. Another of Myron's works surviving in copy is a sculpture of Athena with the satyr Marsyas (Athena in Städtische Galerie, Frankfurt am Main; Marsyas in Lateran Museums, Rome). The interplay of mood and action between the figures in this freestanding group is new, foreshadowed only by the now lost group of the Tyrantslayers erected in Athens at the end of the 6th century. Because bronze was often looted and corrodes easily, the majority of freestanding sculptures from this period have been lost. Some, however, have been rediscovered in the 20th century, the "Poseidon" (National Archaeological Museum, Athens) and the "Charioteer" from Delphi (Archaeological Museum, Delphi), for instance, although they have been eclipsed in fame by the still more remarkable pair of warriors dredged from the

sea in 1972 and displayed in the Museo Nazionale, Reggio di Calabria. The finer of these latter bronzes (Figure 16), although it probably represents a mortal, has a supernatural glamour and a ferocity quite unlike the calm solemnity conventionally admired in Classical works. This derives partly from the glowing surface of the swelling musculature and the use of inlay for eyes, teeth, and lips.

The idealization of man

High Classical period (c. 450–400 BC). Since Roman times, Greek art of the second half of the 5th century BC has been generally regarded as the high point in the development of the Classical tradition. It was the most refined expression of the Greek view of their gods as men and of their men as partaking of the divine. The aesthetic result of this concept was that the bestial or supernatural was abjured in representations of the divine; thus, even a Greek monster, such as the centaur, seems plausible as an image combining humanity and divinity. To some degree, the idealization of human figures was facilitated by the Greeks' traditional concern with proportion and pattern. As a result of the value placed on the ideal image, the representation of extremes (of age or youth, for example, or of deep emotion) and of individuality was ignored or little practiced. Even figures engaged in violent or painful action have a calm, detached expression that modern observers may find chilly and unfeeling. Another reflection of the value placed on the ideal image is an increasing preoccupation with the "heroic nude." From an early phase of Greek art, the artist had shown his interest in man as man rather than as individual. In the Archaic period, the artist studied the visual pattern of the naked male body. When anatomical competence was complete, it was still the abstraction, the pattern, that dictated that his subjects be nude; for it is certain that the average Greek dressed for everyday life and for battle and that only in the exercise ground or the racetrack was the naked body freely revealed.

During the high Classical period, Athens resumed a position of importance as an artistic centre of the Greek world after years of inactivity. Once most of the Greek homelands were secure from the Persian threat, the funds that had been provided to Athens by the Greek states to lead their defense were turned by the statesman Pericles to the embellishment of Athens itself, and a program of rebuilding temples in the city and countryside was begun. This task attracted sculptors, masons, and other artists to Athens from all over the Greek world. It is largely the work of these artists, under the guidance of Athenian masters, that determined what is now recognized as the high Classical style.

The statues of Phidias and Polyclitus

Of the several types of sculpture that flourished during the high Classical period, major statuary is least represented in surviving examples. Phidias, the most influential sculptor of the period, made two huge cult images plated with gold and ivory, the statue of Athena for the Parthenon and a seated statue of Zeus for the temple at Olympia that was one of the seven wonders of the ancient world. These works amazed and overawed viewers through all antiquity, but no adequate copies survive. Another important sculptor of the period, whose work can be seen through copies, was Polyclitus, from Argos. Polyclitus embodied his views on proportion in his "Doryphoros" ("Spear Bearer"), called "The Canon" because of its "correct" proportions of one ideal male form. Unlike freestanding statues, architectural sculpture from the high Classical period has survived in abundance. The Parthenon sculptures must have been executed by many different hands, but, because the overall design was by Phidias, the composition and details undoubtedly reflect his style and instructions. The pedimental figures and frieze, especially, display the Classical qualities of idealization (Figure 17). These allow an approximate assessment of Phidias' style and the importance of his contribution to the establishment of the Classical idiom. About the time that full employment for sculptors in Athens on the Parthenon came to an end, there began a distinguished series of carved relief gravestones for Athenian cemeteries. The general type had been familiar in Archaic Athens, and the practice continued in other parts of Greece through the early Classical period, mainly in the islands and in Boeotia. The new Attic series, with calm and dignified groups of figures in generalized settings of domesticity or

leave-taking, exploited effectively the rather impersonal calm in figure and features of the Classical conventions.

The other important class of sculpture, much of which has survived in the original, is the dedicatory—votive reliefs or major works like the "Nike" ("Victory") found at Olympia, made by Paeonius. This work, and others that belong to the last years of the century, such as the frieze from the balustrade of the temple of Athena Nike on the Acropolis at Athens, give a clear indication of progress and change in sculptural style. In the representation of the female body, never before a subject of particular interest to the sculptor (with the distinguished exception of the Olympia Master), true femininity was at last achieved through observation; in these works the figures are no longer like male bodies with the more obvious female characteristics added, which had generally been true of earlier works. Drapery, which had for its patterns been an important element of female figures in the Archaic period, has a heaviness, almost a life of its own in the Parthenon sculptures. By the end of the century, in the Nike balustrade, it is shown pressed tight against the body revealing the forms of the limbs and torso clearly beneath, with brittle, dramatic folds standing clear of the surface. This last style, together with the new approach to the rendering of women's bodies, led quickly to a deliberately sensual effect in statuary and hastened the decline of the unemotional Classical conventions.

Developments in rendering the female body

Late Classical period (c. 400–323 BC). The 4th century saw a dramatic increase of wealth in Greece but less in the hands of the warring states of the 5th century and more concentrated on the periphery of the Greek world—with the western colonies, the eastern Greeks, who continued in close touch with the friendlier Persian provinces, and the increasingly powerful Macedonian kingdom in the north. Macedonian power, culminating in Alexander the Great's annexation of the whole Persian Empire in the third quarter of the 4th century, was to transform Greek art as effectively as it did Greek life and politics. Even before Alexander's accession, however, the seeds of change were sown. The many new centres and patrons for artists may have made it easier for them to break with Classical conventions established in 5th-century Athens or by dominant 5th-century artists like Polyclitus. The trend was toward greater individuality of expression, of emotion, and of identity, leading eventually to true portraiture. The last was encouraged by the ambitions and pride of rulers such as the Macedonian kings or by the royal houses of Hellenized provinces in the western Persian Empire. To the same sources can be traced the new interest in monumental tomb construction. Men were aspiring more openly to divinity, and Greek art was no barrier to its explicit expression. It is clear, however, that artists were conscious of the values that were set in the 5th century, and by no means did they act as revolutionaries in styles or techniques. The development of Greek art was swift but smooth, and personalities lent impetus to the development rather than changing its flow dramatically.

The sculpture of Praxiteles

Three names dominate 4th-century sculpture, Praxiteles, Scopas, and Lysippus. Each can be appreciated only through ancient descriptions and copies, but each clearly contributed to the rapid transition in sculpture from Classical idealism to Hellenistic realism. Praxiteles, an Athenian, demonstrated a total command of technique and anatomy in a series of sinuously relaxed figures that, for the first time in Greek sculpture, fully exploited the sensual possibilities of carved marble. His Aphrodite (several copies are known), made for the east Greek town of Cnidus, was totally naked, a novelty in Greek art, and its erotic appeal was famous in antiquity. The "Hermes Carrying the Infant Dionysus" (Archaeological Museum, Olympia) at Olympia, which may be an original from his hand, gives an idea of how effectively a master could make flesh of marble (Figure 18). The reputation of Scopas, from the island of Paros, came from the intensity of expression with which he imbued his figures. Fragments of his work at Tegea (National Archaeological Museum, Athens) show his technique in the deep-sunk eye sockets that characterize his faces and that transform the hitherto passionless features of Classical sculpture into studies of intense emotion. Praxiteles and Scopas seem to typify the new spirit that can readily be discerned in surviving original sculptures. The "Demeter of Cnidus" (British Museum, London; perhaps by the Athenian sculptor Leochares) is Classical in mood, but the features are Praxitelean; and in the reliefs on the Mausoleum (British Museum, London) at Halicarnassus (on which both Scopas and Leochares are said to have worked), the vigour of the battle scenes is heightened by both the intensity of the features and a new, rather flamboyant use of drapery. On Athenian grave reliefs the Classical calm gave place to expressions of controlled but deep emotion. These are styles that can be recognized in places far from Greek soil, as in the relief sarcophagi fashioned by the Greeks for the kings of Sidon in Phoenicia.

The sculpture of Lysippus

Lysippus, from Sicyon in the northern Peloponnese, was Alexander's favourite sculptor. He was true to the Classical tradition in demonstrating his views on proportion by sculpturing athlete figures in different poses, although his types have heavier bodies and smaller heads than those of the Classical standard set down by Polyclitus. But he adds something to these single figure studies; for the first time they are composed in such a way that the viewer is

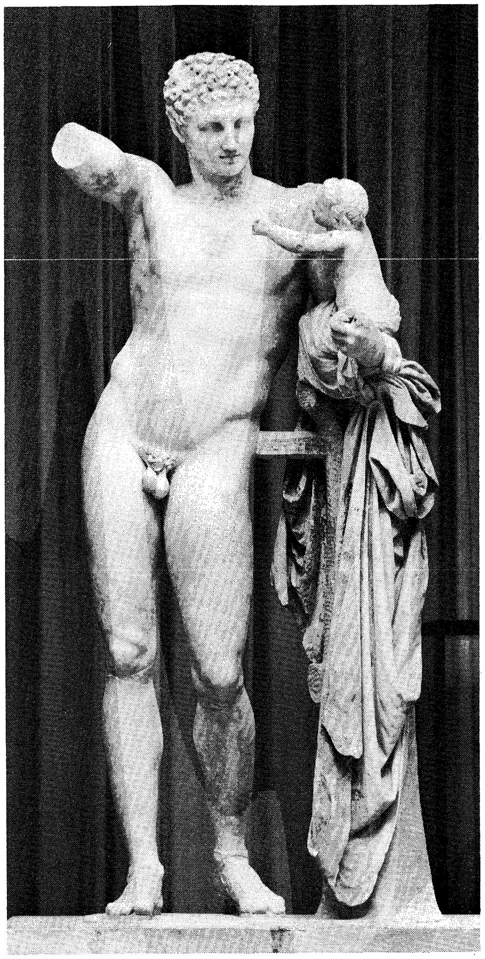

Figure 18: "Hermes Carrying the Infant Dionysus," marble statue by Praxiteles, *c.* 350–330 BC (or perhaps a fine Hellenistic copy of his original). In the Archaeological Museum, Olympia, Greece. Height 2.15 m.

Hirmer Fotoarchiv, Munchen

invited to move around them, and they are not tied to a single optimum viewpoint, as even Praxiteles' figures had been. This was an important innovation in the history of sculpture.

Another innovation, in the development of which Lysippus must also have played a vital part, is portraiture; he carved likenesses of Alexander. Nevertheless, portraits of contemporaries were still exceptional, and many early portraits are semi-idealized studies of the great philosophers, statesmen, or poets of the Classical period. And yet, it is clear that by now the use of live models was commonplace, as can be judged from the works or copies that survive and from stories of Praxiteles' use of his mistress Phryne as a model or of Lysippus' brother taking casts from life. By the time of Alexander most of the important problems in the realistic or dramatic treatment of features, pose, and drapery had been solved, leaving to later generations an opportunity only to exaggerate anatomy or expression or to devise sculptural groups of yet greater complexity. Fourth-century sculptors, led by Praxiteles, Scopas, and Lysippus, gathered and expressed the best of what had been learned before of anatomy, pattern, and composition; by adding emotional appeal they can be said to have achieved the logical culmination of the Classical tradition, in which Phidian sculpture in the 5th century was but one brilliant and influential episode.

Hellenistic period. Styles of Hellenistic sculpture were determined by places and schools rather than by great names. Pergamene sculpture is exemplified by the great reliefs from the altar of Zeus (Figure 19), now in East Berlin, and copies of dedicatory statues showing defeated Gauls (Figure 20, bottom). These, like the well-known "Nike of Samothrace" (Figure 21), are masterful displays of vigorous action and emotion—triumph, fury, despair—and the effect is achieved by exaggeration of anatomical detail and features and by a shrewd use of the rendering of hair and drapery to heighten the mood. The "Laocoon" group (Vatican Museums), a famous sculpture of the Trojan priest and his two sons struggling with a huge serpent, probably made by Rhodian artists in the 1st century AD but derived from examples of suffering figures carved in the 1st century BC, is a good example of this applied to a freestanding group (Figure 20, left); and the "Belvedere Torso" (Vatican Museums), much admired in Renaissance Italy, of the effective emphasis of anatomy (Figure 20, right). In vivid contrast, a fully sensual treatment of the female nude was achieved by careful surface working of the marble, and the accentuation of femininity by the incorporation of sloping shoulders, tiny breasts, and high full hips. It is the Hellenistic Aphrodite, such as the "Venus de Milo" (Figure 22), who proliferates in Roman copies. The sculptural groups such as Laocoon were novel, demanding a palatial or sanctuary setting and far removed from earlier two-figure groups or the more nearly comparable but one-view pedimental compositions. The new realism extended to the portrayal of old age, decrepitude,

New realism in sculpture

disease, low life, and even the grotesque. Alexandria, in its major and minor (clay) works of sculpture, seems to have been one of the important schools in this genre. For the first time in Greek art, babies were rendered as other than reduced adults. In portraiture, the idealizing tendencies of the 4th century were still strong, and portraits of kings or poets were overlaid by conceptions of kingship or artistry. It was to take Roman patronage to enforce a more brutal realism in portraiture of contemporaries.

Copies and stylistic revivals

Two of the most significant developments in Hellenistic sculpture, however, had nothing to do with the evolution of new styles or types of compositions. The first was the production of accurate copies of earlier works, which began by about 100 BC, in part occasioned by the demand from the Roman West. This production stimulated interest in the styles of the great Classical sculptors and helped to determine the decidedly Classical atmosphere of early imperial art. The second, related development is the creation of original works deliberately in the style of the late Archaic, early Classical, or full Classical periods. This archaizing can be seen as both a reaction against the more exuberant Hellenistic sculptural styles and a response to the new interest in the Classical past.

Greece and Rome. It was Hellenistic art that the great Roman Republic and its early empire came to know and to covet. It was already to some degree familiar to them from the work of the western Greeks in Italy and Sicily, and the Romans formed a closer acquaintance with it in the court of Alexandria and from the profits of their diplomacy and warfare. The flow of works of art and artists to the west began, and the classical styles of early imperial Rome are exactly those of the late Hellenistic Greek world, in many instances executed by the same artists. Thus, in the early empire the majority of known artists' signatures are those of Greeks. The adoption of Greek art by the Roman Empire ensured its continuity in the Western tradition and its eventual transmission, through the Renaissance revival, to the modern world.

(Jo.Bo./Ed.)

Roman and Early Christian

There are many ways in which the term ancient Roman art can be defined, but here, as commonly elsewhere, it is used generally to describe what was produced throughout the part of the world ruled or dominated by Rome until

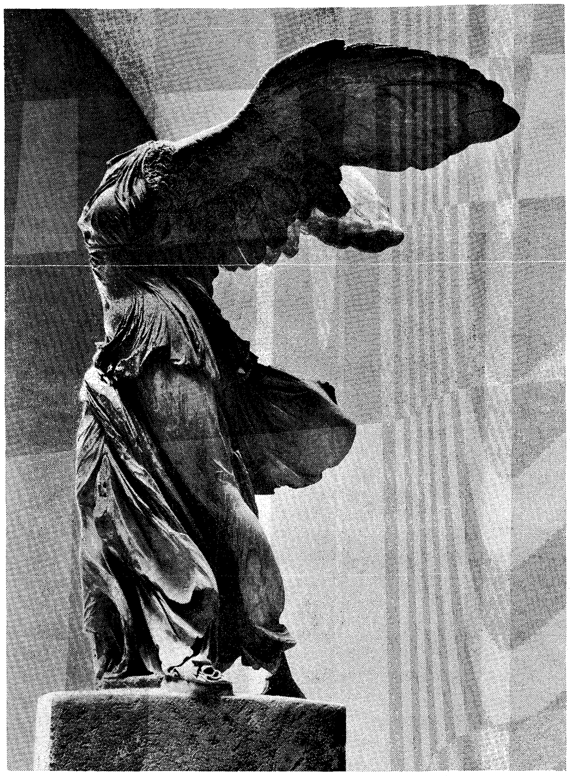

Figure 21: "Nike of Samothrace," marble statue, *c.* 200 BC. In the Louvre, Paris. Height 2.44 m.

J.E. Bulloz

around AD 500, including Jewish and Christian work that is similar in style to the pagan work of the same period.

Greek influences

The Romans were always conscious of the superiority of the artistic traditions of their neighbours. Such works of art as were made in or imported into Rome during the periods of the monarchy and the early republic were produced almost certainly by Greek and Hellenized Etruscan artists or by their imitators from the cities of central Latium; and throughout the later republican and the imperial epochs many of the leading artists, architects, and craftsmen had Greek names and were Greek, or at any rate Greek-speaking. References in ancient literature and signatures of artists preserved in inscriptions leave no doubt on this point. According to tradition, the earliest image of a god made in Rome dated from the 6th century BC period of Etruscan domination and was the work of Vulca of Veii. A magnificent terra-cotta statue of Apollo found at Veii (Figure 23) may give some notion of its character. In the 5th, 4th, and 3rd centuries BC, when Etruscan influence on Rome was declining and Rome's dominion was spreading through the Italian peninsula, contacts with Greek art were no longer chiefly mediated via Etruria but, instead, were made directly through Campania and Magna Graecia; paintings and "idealizing" statues of gods and worthies mentioned in literature as executed in the capital during this period were clearly the works of visiting or immigrant Greek artists. The plundering of Syracuse and Tarentum at the end of the 3rd century BC marked the beginning of a flow of Greek art treasures into Rome that continued for several centuries and played a leading role in the aesthetic education of the citizens.

Literature shows that by the middle of the 2nd century BC the Roman forum was thronged with honorific statues of Roman magistrates, which, although none of them has survived, may be assumed to have been carved or cast by Greeks because no native Roman school of sculptors of that time is known. And it is significant that the earliest account of Roman realistic portraits of private individuals is contained in the Greek historian Polybius' description of ancestral *imagines* ("masks") displayed and worn at patrician funerals—a description written about the middle of the 2nd century BC, when the tide of Greek artistic influence was sweeping into Rome and Italy from countries east of the Adriatic, where a highly realistic late-Hellenistic portrait art, which sometimes depicted Roman or Italian subjects, had already blossomed.

Three art forms that expressed the Roman spirit

The first appearance of three art forms that expressed the Roman spirit most eloquently in sculpture can be traced to the Hellenistic Age. These forms are realistic portraiture showing a preference for the ordinary over the heroic or legendary, in which every line, crease, wrinkle, and even blemish was ruthlessly recorded; a continuous style in narrative art of all types; and a three-dimensional rendering of atmosphere, depth, and perspective in relief work and painting. Of these three art forms there is no evidence in the early art of pre-Hellenistic central Italy; and it would be safe to guess that, if Rome had not met them in the homelands of Greek art, it would never have evolved them in its great art of imperial times. But Rome's own contributions to art, if of a different order, were vitally important. Its historical aims and achievements furnished late Hellenistic artists with a new setting and centre, new subjects, new stimuli, a new purpose, and a new dignity. Rome provided the external circumstances that enabled architects, sculptors, painters, and other craftsmen to exploit on a much more extensive scale than before artistic movements initiated in the Hellenistic world, and Rome became a great new patron of art and a great new wellspring of inspiration and ideas.

THE LAST CENTURY OF THE REPUBLIC

Funerary masks

Ancestral *imagines,* or funerary masks, made of wax or terra-cotta, had become extremely individualized and realistic by the middle of the 2nd century BC. The source of this realism is in the impact on Rome of late-Hellenistic iconography; although this use of masks was rooted

in ancient Roman social and religious practice, there is no basis for a belief that the Romans and Etruscans had, from early times, been in the habit of producing death masks proper, cast directly from the features of the dead. It was undoubtedly their funerary customs that predisposed the Romans to a taste for portraits; but it was not until around 100 BC that realistic portraiture, as an art in its own right, appeared in Rome as a sudden flowering, and to that time belong the beginnings of the highly realistic heads, busts, and statues of contemporary Romans—in marble, stone, or bronze—that have actually survived. Coin portraits of public personages, whose names and dates are recorded, greatly assist in determining a chronological sequence of the large-scale likenesses, the earliest of which can be attributed to the period of Sulla (82–79 BC). The style reached its climax in a stark, dry, linear iconographic manner that prevailed around 75–65 BC and that expressed to perfection current notions of traditional Roman virtues; of this manner, a marble head of an elderly veiled man in the Vatican is an outstanding illustration (Figure 24, top left). Shortly thereafter, an admiration for earlier phases of Greek art came into fashion in the West, and verism was toned down at the higher social levels by a revival of mid-Hellenistic pathos and even by a classicizing trend that was to stamp itself upon Augustan portraits. Meantime, in sepulchral custom, the ancestral bust had become an alternative to the ancestral mask, a development exemplified in a marble statue of a man wearing a toga and carrying two such busts in the Capitoline Museums at Rome (Figure 24, bottom); and portrait busts and figures carved on numerous stone and marble grave stelae (slabs or pillars used for commemorative purposes), characteristic of the late republican epoch, suggest the persistence of a preference for severe pose in middle-class and humbler circles. Furthermore, there are some 1st-century-BC portraits that suggest that the making of death masks proper (arguably a sophisticated idea) was occasionally practiced at this time (Figure 24, top right). None of the vivid Etruscan portraits, such as a bronze orator popularly called the "Arringatore" (Museo Archeologico) at Florence (Figure 25) and a terra-cotta married pair on the lid of a cinerary chest (for ashes of the dead) in the Museo Etrusco Guarnacci, at Volterra, is earlier than *c.* 100 BC; works of that type may be reckoned as provincial imitations of the new metropolitan, 1st-century-BC portrait style.

Narrative reliefs

There are no narrative reliefs from Rome that can confidently be assigned to a date before 100 BC. The only definitely dated 2nd-century-BC relief depicting an episode from contemporary Roman history, a frieze with the Battle of Pydna on Lucius Aemilius Paulus' victory monument at Delphi, was worked in 168 BC in Greece. The most familiar republican example of this form of art as practiced in the West is frieze decoration (partly in the Louvre, and

partly in the Glyptothek at Munich) from the so-called Altar of Ahenobarbus, which has been shown to have no sure connection either with an altar or with any of the Ahenobarbi. In these, prosaic documentation of Roman census procedure is juxtaposed with depictions of Greek sea nymphs, a conjunction of literalism and borrowed poetry typical of subsequent Roman art.

Funerary narrative sculpture

Funerary narrative sculpture of the late republic is exemplified in a monument of the Julii, at Saint-Rémy (Glanum), France. The base of this structure carries four great reliefs with battle and hunt scenes that allude not only to the mundane prowess of the family but also to the otherworldly victory of the souls of the departed over death and evil, since figures of the deceased, accompanied by personifications of death and victory, merge into one of the battle scenes. It is possible that these highly pictorial reliefs were partly based on lost Hellenistic monumental paintings, for southern Gaul had direct connections with Greek lands east of the Adriatic.

THE EMPIRE

Augustan Age. The hallmark of portraits of Augustus is a naturalistic classicism. The rendering of his features and the forking of his hair above the brow is individual. But the Emperor is consistently idealized and never shown as elderly or aging. A marble statue from Livia's Villa at Prima Porta (in the Vatican), which presents him as addressing, as it were, the whole empire, is the work of a fine Greek artist who, while adopting the pose and proportions of a classical Hellenic statue, perfectly understood how to adopt these to the image that Augustus cultivated as emperor (Figure 26). On his ornate cuirass (armour protecting the chest and back), Augustus' aims and achievements are recorded symbolically in a series of figure groups. A marble portrait statue found on the Via Labicana (Museo Nazionale Romano) represents the Emperor as heavily draped and veiled during the act of sacrificing as *pontifex maximus* ("chief priest"); and a bronze head from Meroe in The Sudan (British Museum), the work of a Greco-Egyptian portraitist, depicts him as a Hellenistic king. Of the female portraits of the period, one of the most charming is a green basalt head (Louvre) of the Emperor's sister, Octavia, with the hair dressed in a puff above the brow and gathered into a bun behind—a popular coiffure in early Augustan times. In many respects, the noblest of all Roman public monuments that were adorned with sculpture is the Ara Pacis Augustae ("Augustus' Altar of Peace"), founded in 13 BC and dedicated four years later (Figure 27). It stood in the Campus Martius and has been restored, with different orientation, not far from its original site. On its reliefs—significantly of Luna marble, a white marble quarried in Italy and not, as had earlier been the case, imported from Greece—it set a standard of distinction surpassed by no later work, with the harmonious blending of contemporary history, legend, and personification, of figure scenes and decorative floral motifs. The altar proper was contained within a walled enclosure, measuring about 38 by 34 feet ($11\frac{1}{2}$ by $10\frac{1}{2}$ metres), with entrances on east and west. On the upper part of the external faces of the south and north precinct walls ran a frieze representing the actual procession (of Augustus, members of his family, officers, priests, magistrates, and the Roman people) to the altar's chosen site on its foundation day (July 4, 13 BC), when sacrifice was offered in thanksgiving for the Emperor's recent return to Rome from the provinces. On either side of the western entrance was a depiction of Augustus' prototype Aeneas sacrificing on his homecoming to the promised land of Italy, and, since Augustus was also hailed as Rome's second founder, a depiction of the suckling of the twins, Romulus and Remus, by the she-wolf. The eastern entrance was flanked by personifications of Roma and of Mother Earth with children on her knees flanked by figures symbolizing air and water (Figure 27, bottom). On the exterior of the

walls, beneath all these figure scenes, was a magnificent dado filled with a naturalistic pattern of acanthus, vine, and ivy, perhaps a translation into marble of a gorgeous carpet or tapestry used in the ceremony. Swags of fruit and flowers that decked the interior faces of the precinct walls may represent real swags that were hung on the temporary wooden altar erected for the foundation sacrifice. The procession was continued in a much smaller frieze on the inner altar, from which figures of Vestal Virgins and of sacrificial victims and their attendants have been preserved. Delightful studies of imperial and other children and such homely incidents as conversations between persons taking part in the procession introduce an element of intimacy, informality, and even humour into this solemn act of public worship. The Ara Pacis, in fact, sums up all that was best in the new Augustan order—peace, serenity, dignity without pompousness, moderation and absence of ostentation, love of children, and delight in nature. The style of the altar's floral decoration strongly suggests that the sculptors who carved it were Greeks from Pergamum.

Julio-Claudian period. The imperial portraiture of Tiberius and Caligula was generally precise but academic work, but some of the female court portraits reflect not only the fashions for elegant simplicity and extreme elaboration in female coiffure but also a subtle poetry. Two possible extremes of tone are clearly marked by the contrasting busts of Claudius and Nero, the former uncomfortably uncompromising, the latter flatteringly Hellenic. In the relatively few public monuments dating from this period to include sculpture, none reveals any novel development.

Flavian period. In the emperor Vespasian's portraits, something of the old, dry style returned. This can be observed in his striking likeness on one of two historical reliefs (Vatican Museums) that were unearthed in Rome near the Palazzo della Cancelleria. A similarly sketchy and impressionistic handling of the hair is found on the emperor Titus' portraits, whereas the third Flavian emperor, Domitian, affected a more pictorial hairdo in imitation of the coiffure introduced by Nero. Still more picturesque are the female hair styles of the time, which display piles of corkscrew ringlets or tight, round curls (Figure 28). The Cancelleria reliefs date from the close of Domitian's reign and depict, respectively, Vespasian's triumphal entry and reception in Rome in AD 70 and Domitian's *profectio* ("setting out"), under the aegis of Mars, Minerva, and Virtus, for one of his northern wars. They are worked in a two-dimensional, academic, classicizing style that is in marked contrast with the vivid, three-dimensional rendering of space and depth, with brilliant interplay of light and shade, on the panels of the Arch of Titus in the Roman Forum. The latter reliefs, which present two excerpts from Titus' triumph in Palestine, were carved in the early 80s. The late Domitianic classicizing manner appears again in the frieze of the Forum Transitorium, which the emperor Nerva completed. This conflict of relief styles within the Flavian period is but one illustration of the ceaseless, unpredictable ebb and flow of different aesthetic principles throughout the history of imperial art.

Age of Trajan. In portraits of Trajan, a deepening of the bust, which was already seen in the later Flavian period, was carried a stage further; there is a new fluidity in the molding of the face; in the hair, which is plastered down across the brow, there is a partial revival of the late republican linear style. Aesthetically, one of the finest known likenesses of the Emperor is a marble head from

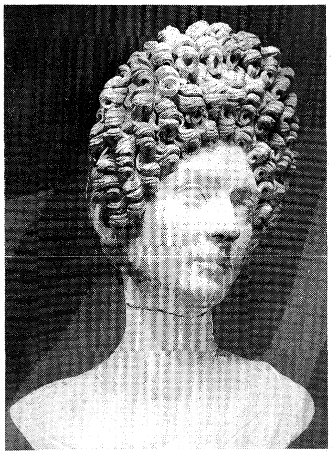

Figure 28: Portrait of a woman of the Flavian period, marble, *c.* AD 90. In the Capitoline Museums, Rome. Life-size.

Cesare Faraglia

Ostia (Ostia Museum). On his monumental column there is a series of less idealized and probably more faithful renderings of his features. The coiffures of Trajanic ladies are, if anything, even more elaborate and extravagant than those of their Flavian predecessors.

Reliefs of Trajan's Column

The reliefs of Trajan's Column, illustrating the two Dacian campaigns of 101–102 and 105–106 and winding up the shaft in a spiral band of Parian marble three feet (one metre) wide, are generally recognized to be the classic example of the continuous method of narration in Roman art. The episodes merge into one another without any punctuation, apart from an occasional tree; Trajan appears again and again in different situations, activities, and costumes. A statuesque figure of Victory separates the histories of the two wars. There are 23 spirals and about 2,500 figures. A high level of technical accomplishment is maintained throughout, and the interest and excitement of the theme never flag. Since the figures of men and animals had to be distinguished from a distance, they are inevitably overlarge in proportion to their landscape and architectural settings; and in order to avoid awkward empty spaces along the upper edges of the band and to preserve an allover, even, tapestry-like effect, background figures in the scenes are reared in bird's-eye-view perspective above the heads of those in the foreground. These carvings must be visualized as once brightly painted, with weapons and horse trappings added in metal. The sources of the scenes were possibly wartime sketches made by army draftsmen at the front, but the fusing together of those isolated pictures into a single scroll was the work of a single master artist, perhaps Apollodorus of Damascus, who designed the whole complex of Trajan's forum, basilica, and column.

The column (the interior of which contains a spiral staircase; Figure 29) had first been intended primarily as a lookout post for viewing Trajan's architectural achievements—his forum and its adjacent markets, to accommodate which he sliced away the slope of the Quirinal Hill. By the time of its dedication in 113, when the relief bands had been added and an eagle planned for the top of the capital, it had become a war memorial. Finally, it became Trajan's future tomb, crowned by his statue (which was later replaced by that of St. Peter) and containing a funerary chamber for the urns holding his and his consort's ashes.

Arch of Constantine

To the last years of Trajan's reign or to the early years of that of his successor should be attributed four horizontal panels that adorn the main passageway and the attic ends of the Arch of Constantine in Rome. If fitted together they would form a continuous frieze of three main scenes, which are, from left to right, an imperial triumphal entry, a battle, and the presentation to the Emperor of prisoners and the severed heads of captives by Roman soldiers. It seems clear that these sculptures were made between around 115 and 120, perhaps for the Temple of Divus Trajanus and Diva Plotina that was erected by Hadrian just to the north of the column. The presence on this frieze of chain-mail corselets, rarely seen on Trajan's Column, seems to indicate that that type of armour, so common under the Antonines (see below *Antonine and Severan periods*), first came into general use in late Trajanic or early Hadrianic times. These reliefs do not depict realistic fighting, as do those of the column, but a kind of ideal or dramatized warfare, with the Emperor himself participating in the melee and the soldiers wearing plumed and richly embossed parade helmets; the scenes melt into one another with total disregard of spatial and temporal logic.

Trajan's arch at Beneventum

A third example of Trajanic monumental sculpture is the relief decoration of the Arch of Trajan at Beneventum (Benevento), which is covered with pictorial slabs, the subjects of which are arranged to carry out a carefully balanced and nicely calculated order of ideas. Those on the side facing the city and on one wall of the passageway present themes from Trajan's policy and work for Rome and Italy; those on the side toward the country and on the other wall of the passageway allude to his achievements abroad. With two exceptions, where a pair of scenes forms a single picture, each panel is a self-contained unit. The reliefs already show something of the classicizing, two-dimensional character of Hadrianic work. Indeed, it seems likely that, although the arch itself was either decreed or dedicated in 114 or 115, some of the panels in which Hadrian is given a peculiar prominence were not carved until the early years of the latter's principate.

The frieze of a great, circular Tropaeum Trajani, set up in the Dobruja (Romania) to commemorate victories over the Dacians, contains a series of metopes (a decoration in a Doric frieze) carved with figure scenes in a naïve, flat, linear style that suggests the hands of army artists of provincial origin.

Age of Hadrian. In the iconography of the age of Hadrian, certain Hellenizing features—the wearing of a

short Greek beard by the males and the adoption by the females of a simple, classicizing coiffure—are harmonized with new experiments. The depth of the bust increases, there is greater plasticity in the modelling of the face, the men's curly hair and beards are pictorially treated, and the irises and pupils of the eyes are marked in. Many marble portraits of the Emperor survive from all over the empire, but of his likenesses in bronze only one is extant—a colossal head recovered from the Thames River in London (British Museum), torn from a statue erected in the Roman city and probably the work of a good Gaulish sculptor. Portrait statues of Hadrian's Bithynian favourite, Antinoüs, reveal a conscious return in the pose and proportions of the body to Classical Greek standards, combined with a new emotionalism and sensuousness in the rendering of the head.

Monumental reliefs of the age of Hadrian

The monumental reliefs of Hadrian's day cannot vie with those of his predecessors. The most interesting and perhaps the earliest of them are two horizontal slabs once exposed in the Roman Forum but later transported to the shelter of the Curia. Both carry on one side similar figures of victims for the Suovetaurilia sacrifice and on the other side different historical scenes: in the one case, Hadrian doling out the *alimenta* ("poor relief") to Roman citizens, in the presence of a statuary group of Trajan and Italia with children; in the other case, the burning of debt registers. At one end of each of these scenes is carved a figure, on a base, of the legendary Greek musician Marsyas, whose statue in the Forum may once have been in part enclosed by the panels. In the background of both historical pictures are carved in low relief various buildings in the Roman Forum that can be identified. The two scenes display the characteristically Hadrianic two-dimensional style, as do three large panels (Palazzo dei Conservatori, Rome), with the Emperor's head restored and depicting an imperial triumphal entry, an *adlocutio,* and an apotheosis, respectively—somewhat rigid, academic works. Eight medallions gracing the Arch of Constantine give pleasantly composed and lively, if Hellenizing, pictures of sacrifice and hunting (Figure 30). Some of them depict Antinoüs accompanying the Emperor, whose portraits have been recut as likenesses of Constantine the Great and of his colleague Licinius. Finally, historical reliefs found at Ephesus (now in the Neue Hofburg, Vienna)—one of the very few examples of provincial state reliefs that have survived—may be claimed as late Hadrianic (not as of the period of Marcus Aurelius, to which many critics have assigned them).

In Rome and Italy during the second quarter of the 2nd century, interment began to supersede cremation as a method of disposing of the dead, and Hadrian's reign saw the beginnings of a long line of carved sarcophagi that constituted the most significant class of minor sculptures down to the close of the ancient Greco-Roman world.

Antonine and Severan periods. Portraits of Antonine imperial persons, of which a bronze equestrian figure of Marcus Aurelius on the Capitol (Figure 31) and a great marble bust of Commodus as Hercules in the Palazzo dei Conservatori are perhaps the most arresting examples, display a treatment of hair and beard, deeply undercut and drilled, that grew ever more pictorial and baroque as the 2nd century advanced. This produced an impression of nervous restlessness that contrasts with the still, satin smoothness of the facial surfaces, particularly in the iconography of Commodus. To all this picturesqueness, Septimius Severus added yet another ornamental touch—the dangling, corkscrew forelocks of his patron deity, Sarapis. The female hairstyles of the time are characterized first by a coronal of plaits on top (Faustina the Elder), next by rippling side waves and a small, neat bun at the nape of the neck (Faustina the Younger, Lucilla), and then by stiff, artificial, "permanent" waving at the sides and a flat, spreading "pad" of hair behind (Crispina, Julia Domna).

State reliefs

Of the state reliefs of this epoch, the earliest are on the base (in the Vatican) of a lost column set up in honour of Antoninus Pius and Faustina the Elder. The front bears a dignified, classicizing scene of apotheosis: a powerfully built winged figure lifts the Emperor and Empress aloft, while two personifications, Roma and Campus Martius, witness their departure. On each side is a *decursio,* or military parade, in which the riders farthest from the spectator appear not behind the foot soldiers but high above their heads—a remarkable instance of the bird's-eye-view per-

Alinari—Art Resource/EB Inc.

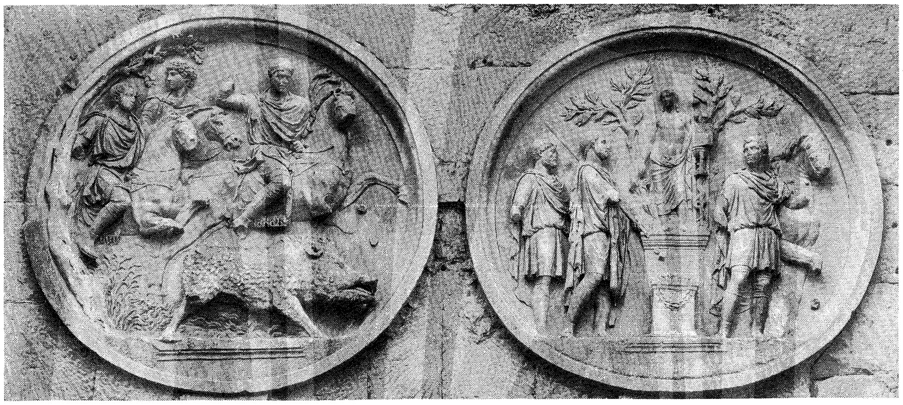

Figure 30: Medallions from the Arch of Constantine, Rome; medallions date from AD 117–138.

spective carried to its logical conclusions. All the figures in these side scenes are disposed on projecting ledges, a device employed again about 20 years later on Marcus Aurelius' Column. Eleven rectangular sculptured panels—similar to those on the Arch of Trajan at Beneventum but displaying greater crowding of figures, livelier movement, and a pronounced effect of atmosphere and depth—depict official occasions and ceremonies in the career of Marcus. Three of these are in the Palazzo dei Conservatori, Rome (Figure 32); the other eight are on the attics (low stories or walls above the cornice of the facade) of the Arch of Constantine. These two sets of panels represent two separate series and may have been carved for two (now lost) distinct triumphal arches. The contrast in style between the spiral reliefs of Marcus Aurelius' Column, put up under Commodus and depicting Marcus Aurelius' northern campaigns, with those of its Trajanic predecessor, is a measure of the change of mood that the Roman world experienced during the course of the 2nd century. The diminished proportions of the squat, doll-like figures, their herding together in closely packed, undifferentiated masses, their angular, agitated gestures, and the stress laid throughout on the horror and tragedy of war suggest that the empire is facing an unknown future with diminished security and that man is at the mercy of some unaccountable power, the supreme embodiment of which is an awe-inspiring winged, dripping figure, personifying the rainstorm that saved the Roman army from perishing from thirst. Again, in the imperial *adlocutiones* that punctuate this frieze, where the Emperor stands in a strictly frontal pose high above the heads of his audiences, can be seen a remarkable return (but probably not a conscious return) to the conventions employed in primitive art for expressing the concept of the ruler as transcendental being.

The spirit of the times is reflected no less vividly in carved sarcophagi. Their themes—familiar myths, battles, hunts, marriages, and so on—allude allegorically to death and the destiny of the soul thereafter. The classicizing, statuesque tradition is also maintained in late 2nd- and early 3rd-century columned sarcophagi, originating in the workshops of Asia Minor but freely imported into, and sometimes imitated in, Rome and Italy. On such pieces single figures or small groups of figures occupy niches between colonnettes. Among the most impressive examples is a great sarcophagus at Melfi, in Puglia, Italy, with a couch-shaped lid, on which the figure of a girl lies prostrate in the sleep of death.

Mansell—Alinari from Art Resource/EB Inc.

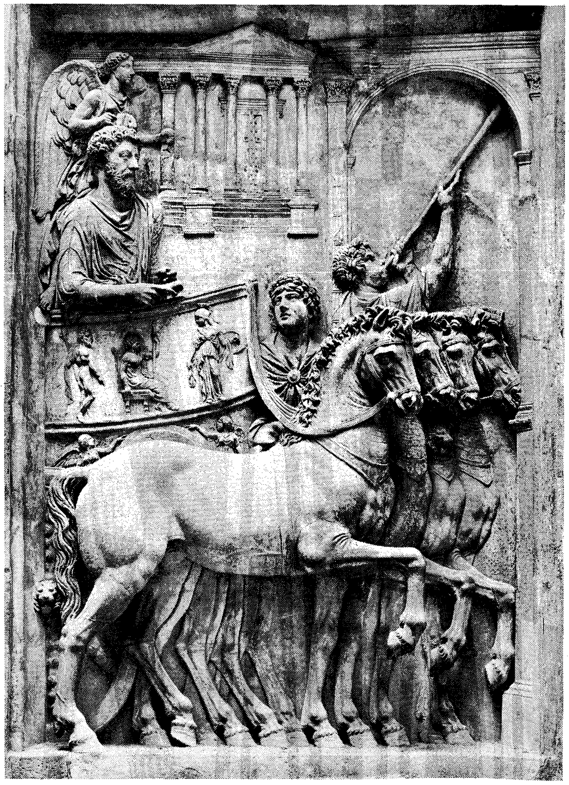

Figure 32: Marcus Aurelius in a quadriga (four-horsed chariot) entering Rome in triumph, from a marble relief in the Palazzo dei Conservatori, Rome, c. AD 176. Height 3.23 m.

The novel features that have been noted in the reliefs of Marcus Aurelius' Column were worked out more completely in those of the official monuments set up to honour Septimius Severus, both in Rome and abroad. In the arch erected in 203 at the northern end of the Roman Forum are found crowded masses of small figures in broad bands of relief, perhaps reflecting a style of documentary painting; in the smaller Porta Argentariorum in Rome, erected by bankers and cattle dealers in honour of the Emperor in the following year, there are stiff, hieratic, funeral poses; and above all in the still more remarkable four-way arch set up at Leptis (Lepcis) Magna in Tripolitania to commemorate a visit of about 203 is a pier decorated with a stylized bird's-eye view of an Oriental city under siege and (also on the piers) weirdly elongated representations of captives. The deeply undercut and drilled vine-scroll ornament here and in the Severan basilica nearby is similar to that found in Asia Minor, whence sculptors had doubtless been imported.

The tension between naturalism and schematization

3rd and 4th centuries. A new tension between naturalism and schematization marks the history of late-antique portraiture. In likenesses of Alexander Severus, the facial planes are simplified, and the tumbling curls of the 2nd-century baroque have been banished in favour of a skullcap treatment of the hair and sheathlike rendering of the beard. Toward the middle of the 3rd century, under Philip the Arabian and Decius, this clipped technique in hair and beard was combined with a return to something of the old, ruthless realism in the depiction of facial furrows, creases, and wrinkles. For a time, Gallienus reinstated the baroque curls and emotional expression, but in the later decades of the century the schematic handling of hair, beards, and features reappeared. Finally, in the clean-shaven faces of Constantine the Great and his successors of the 4th and early 5th centuries, the conception of a portrait as an architectonic structure came to stay; and the naturalistic, representational art of the Greco-Roman world was exchanged for a hieratic, transcendental style that was the hallmark of Byzantine and medieval iconography (Figure 33). The hair is combed forward on the brow in rigid, striated locks, and the eyes are unnaturally enlarged and isolated from the other features. The face is so formalized that the identification of any given portrait becomes a problem. A colossal bronze emperor (near the church of S. Sepolcro, Barletta), for example, has been given the names of several different rulers of the late 4th and early 5th centuries. Throughout these centuries the favourite female coiffure shows a plait or twisted coil of hair carried across the back and top of the head from neck to crown, while under Constantine there was a brief revival of the two Faustinas' styles.

Throughout the 3rd and 4th centuries, carved sarcophagi carry on the story of relief work. Aesthetically, the most notable 3rd-century example is an allover tapestry-like battle piece (Ludovisi Collection, Museo Nazionale Romano, Rome), which possibly was made for Decius' son Hostilian.

Of 3rd-century state reliefs in Rome, virtually nothing has survived. Narrow historical friezes carved for the Arch of Constantine, completed for the celebrations of his *decennalia* (10th anniversary of his reign) in 315, show dwarfish, dumpy, niggling figures. Both these reliefs and those of the slightly earlier Arch of Galerius at Thessalonica look as though they had been worked by artists whose experience had been confined to the production of small-scale sculptures. The last examples of Roman carving are reliefs on the base of an obelisk of Theodosius in the Hippodrome at Constantinople, where the Emperor and members of his court, ranged in rigid, hieratic poses, watch the shows. Few original portions are extant of the spiral relief bands that entwined columns of Theodosius and Arcadius in Constantinople.

Minor forms of sculpture. Of the minor forms of sculpture, none is more attractive than the art of modelling—

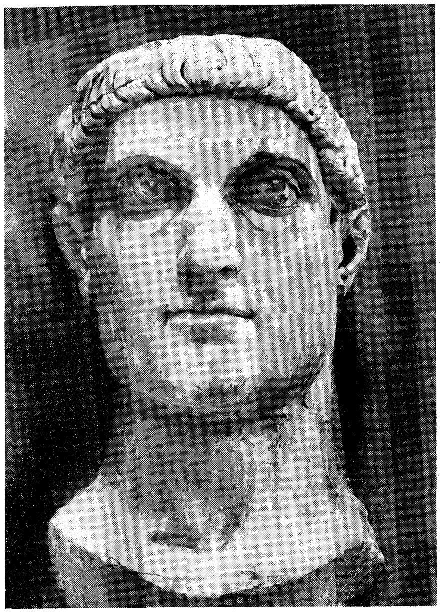

Figure 33: Marble colossal head of Constantine the Great, part of the remains of a giant statue from the Basilica of Constantine (formerly the Basilica of Maxentius) in the Roman Forum, Rome, *c.* AD 313. In the Capitoline Museums, Rome. Height of the head 2.41 m.

Stucco work

in relief or in the round—in fine, white stucco. Decorative stucco work was cheaper and easier to produce than carving in stone or marble. Soft and delicate in texture, it was equally elegant whether left white or gaily painted. In domestic architecture it was a useful alternative or accessory to painting; notable are such examples as a pure white, exquisite vault decoration showing ritual scenes with small-scale figures, from a late republican or early imperial house near the Villa Farnesina in Trastevere (Museo Nazionale Romano); handsome pairs of large white griffins, framed in acanthus scrolls against a vivid red ground, in the late republican House of the Griffins on the Palatine; and a frieze depicting the story of the *Iliad,* in white figures on a bright blue background, in the House of the Cryptoporticus, or Homeric house, at Pompeii. For the use of this technique in palaces, the figure work in Domitian's villa at Castel Gandolfo in the Alban hills can be cited; it can be found in such public buildings as the Stabian and Forum baths and the Temple of Isis at Pompeii. The loveliest and most extensive stucco relief work in a semiprivate shrine is that in the underground basilica near the Porta Maggiore, Rome, where the scenes all allude to the world beyond the grave, to the soul's journey to it, and to the soul's preparation for it in this life (Figure 34). Some of the best surviving stuccos are in tombs: the tomb of the Innocentii and the tomb of the Axe under the church of S. Sebastiano on the Via Appia; the tombs of the Valerii and the Pancratii on the Via Latina (in the latter, stucco work is attractively combined with painting in the flat); and the tomb of the Valerii under St. Peter's, Rome, where the interior walls of both the main and subsidiary chambers are almost completely covered with recesses, niches, and lunettes (semicircular or crescent-shaped spaces) containing stucco figures. The Vatican tomb of the Valerii must be reckoned as a classic place for the study of this delightful and all too scantily represented branch of Roman art.

Ivory and wood carving

Ivory was another popular material for minor sculpture. It was worked in the round, in relief, and in such forms as small portraits, figurines, caskets, and furniture ornaments, of which the carved plaques composing the throne, or "Cathedra of Maximianus," at Ravenna (probably 6th century) provide a notable instance. The consular and other diptychs comprise one of the most distinctive types of ivory relief work in the 4th and 5th centuries. Among them are masterpieces that kept alive the traditions of Hellenistic carving, such as a diptych of the Symmachi and Nicomachi families (one leaf of which is in the Victoria and Albert Museum, London, and the other in the Musée de Cluny, Paris), and some outstandingly fine examples of late antique portraiture, such as the Probus diptych at Aosta (Cathedral treasury) with a double portrait of Honorius, the Felix diptych in Paris (dated 428), and one of Boethius, consul in 487, at Brescia (Civico Museo dell'Età Cristiana). Fine examples of wood carving are panels with biblical scenes on the 5th-century door of the church of Sta. Sabina on the Aventine.

Gem carving

Many types of carving in precious stones were practiced by Roman-age craftsmen, and it is to them that the credit goes for the majority of intaglios that have survived from ancient times. (Intaglios are engraved or incised figures depressed below the surface of the stone so that an impression from the design yields an image in relief.) The widespread taste for them is reflected in the many existing glass-paste imitations reproducing their subjects, which include portraits of both imperial and private persons, and a large variety of divine and mythological groups and figures, personifications, animals, etc. Many bear the signatures of Greek artists.

The most impressive series of Roman gems consists of cameos representing imperial persons. These are miniature reliefs cut in precious stones with different coloured strata (so that the relief is of a different colour from the ground), whereas intaglios, like the ancient seals mentioned earlier, were reliefs, as it were, in reverse, cut into the surface so that a true relief only emerges from an impression. Among the earliest surviving examples of the great imperial cameos are the Blacas onyx (British Museum, London), portraying Augustus in the guise of Jupiter; the Gemma Augustea, a sardonyx (an onyx with parallel layers of sard) in the Kunsthistorisches Museum, Vienna, and the Grand Camée de France, a sardonyx in the Bibliothèque Nationale, Paris, which were probably carved under Caligula and present, respectively, the apotheosis of Augustus and of Tiberius, the latter with Divus Augustus, also; and a sardonyx cameo of Claudius with Jupiter's aegis (Royal Art Collection at Windsor Castle). Late antique examples of the craft are a rectangular sardonyx (city library at Trier), portraying Constantine the Great and members of his house and an onyx with busts of Honorius and Maria (Rothschild Collection, Paris).

Other varieties of carving in precious stones are represented by a miniature head of a girl (British Museum) wearing the hair style of Messalina and Agrippina the Younger, which is cut in *plasma;* an onyx vase in the Braunschweigisches Landesmuseum, Braunschweig, possi-

bly of the 1st century, depicting an emperor and empress as Triptolemus and Demeter; and a late-antique vase, carved in honey-coloured agate and decorated front and back with a naturalistic vine and with the head of Pan, cupped in acanthus, on either shoulder (Walters Art Gallery, Baltimore).

"Cameo glass"

Closely akin to cameos and vessels cut in precious stones are their substitutes in opaque "cameo glass," worked in two layers, with the designs standing out in white against a dark-blue or bright-blue background. To this class belong a blue vase from Pompeii (Museo Archeologico Nazionale), with Cupids gathering grapes; the Auldjo Vase (British Museum, London), with an exquisitely naturalistic vine; and the celebrated Portland Vase, also in the British Museum, the scenes on which have always been the subject of scholarly controversy but are generally supposed to depict myths relating to the afterlife. Similar imitations of carving in precious stones are late antique *diatreta* ("cage cups"), the decoration of which is cut back from the outer surface of the mold-cast blank. This openwork ornamentation sometimes represents the crisscross meshes of a net, while on other vessels it consists of an elaborate figure scene, the design in either case being very deeply undercut and, for the most part, only connected with the background by short shanks of glass. Of the figured examples, the most spectacular surviving specimens are a dark-blue *situla* ("bucket") with a hunting scene (treasury of St. Mark's, Venice) and a dull-green cup presenting the story of Lycurgus ("Rothschild Vase," British Museum). Of the other types of glass with figured decoration, molded cups with gladiatorial and circus scenes are characteristic of the early-imperial period; and the 4th-century glassworker's craft is represented by vessels with cut or incised designs. Among the most important centres of glass production under the empire were Syria, Alexandria, and the Cologne region.

Figured pottery

Figured terra-cotta tablewares (terra sigillata—a term often incorrectly stretched to cover plain wares) were cheaper versions of costly decorated silverwares. During the last century of the republic and in the early decades of the 1st century of the empire, Arretium (Arezzo) was the most flourishing centre of the manufacture of a fine type of red-gloss pottery (Figure 35). As signatures on the pots reveal, Italian firms often employed Greek and Oriental craftsmen, and the mythological and floral themes of the vessels' molded ornamentation owe much to the inspiration of Hellenistic art.

Gaulish pottery

From shortly before the mid-1st century AD onward, the markets enjoyed by Italian fabrics were captured by the products of potteries now established in southern, central, and eastern Gaul. These manufactured cheaper, more mass-produced, and aesthetically inferior red-gloss and black-gloss wares, popularly known as "Samian," some varieties of which continued into the 4th century. The decoration of Gaulish pots was, for the most part, molded; but some vessels carry applied motifs made in individual molds, and others show designs incised to counterfeit cut glass. Yet another type of ornament was carried out in the barbotine technique, by which relief work was produced by trailing liquid clay across the surface of the pot. As regards the content of the decoration, themes from daily life were added to traditional subjects based on Greco-Roman mythology and on natural history. The *E* barbotine hunt cups (produced mainly at Castor, Northamptonshire) are the highlight of the native Romano-British potter's craft.

A late-antique class of red-gloss pottery, known as late A ware, with scenes in relief from Greek mythology and from Roman spectacles, was manufactured in a southern Mediterranean area, probably Egypt. (J.M.C.T./Ed.)

EARLY CHRISTIAN

Early in the 20th century it was thought that Christian art began after the death of Christ or, at least, in the second half of the 1st century AD. But later discoveries and studies showed that a truly Christian art—that is, with a style quite distinctive from Pagan Roman art—did not exist before the end of the 2nd or beginning of the 3rd century. When it ended, or rather developed into something else, is harder to say. Early Christian art penetrated all the provinces of the Roman Empire, adapting itself to existing pagan art. It subsequently created its own forms, which varied according to local stylistic evolution. The new capital at Constantinople (ancient Byzantium), founded by the emperor Constantine the Great (306–337), was to be an important centre of art. The art produced there, now known as Byzantine art, extended throughout the entire Christian East. It is customary to distinguish early Christian art of the West or Latin part from the Christian arts of regions dominated by the Greek language and to consider the latter as proto-Byzantine, while acknowledging, however, a certain latitude in the initial date of this separation: 330, the foundation of Constantinople; 395, the separation of the Greek part of the empire from its Latin sector; or, finally, the reign of Justinian (527–565). The transition from the earlier to the later art discussed in the next sections took place at different times in different locations; therefore, there can be no precise chronological boundary. Only after Justinian's reign did many Eastern regions submit to the ascendancy of the art of Constantinople, following until the 6th and even the 7th century the paths traced by Christian art in its beginnings. In the West the end of Early Christian art is easier to determine. Closely tied to Roman art, it finished with the collapse of the empire at the end of the 5th century. Then, transformed into a multitude of regional art styles, it assimilated various influences from the East and from the barbaric peoples who superseded their Roman masters.

The vague boundaries of this art in time and space make a definition of its character difficult. Its style evolved from the current Greco-Roman art. The new elements lay not in form but in content: places of worship very different from pagan temples, iconography drawn from the Scriptures. As the hold of the church over public and private life grew, these new elements tended to set traditional subjects completely aside. Early Christian art, while deeply rooted in Greco-Roman art, became a new entity, as distinct from ancient art as from that of the Middle Ages. An obvious difference is the absence of monumental public sculpture. Early Christian sculpture was limited to small pieces and private memorials and only gradually became incorporated into ecclesiastical architecture.

Sarcophagi. The imagery of sarcophagi followed an evolution similar to that of the catacomb paintings. The same biblical and Gospel subjects were introduced into pagan or neutral compositions. In the second or third quarter of the 3rd century, the oldest Christian sarcophagi were hardly distinguishable from the pagan. On one at Sta. Maria Antiqua, Rome, a seated philosopher reading a scroll, a praying figure, and a "Good Shepherd" are "Christianized" by the scenes that accompany them on either side: Jonah resting and the Baptism of Christ. Thus, a sarcophagus from the Via Salaria (Rome, Vatican Museums), which represents the same subjects except for the truly Christian scenes, can be called "Christian" only with reservation.

During the 4th century this iconography was enriched and became more strictly narrative; the miracles of Christ, fully described, were included, the crossing of the Red Sea

Further development of Christian iconography on carved sarcophagi

was often depicted in a long frieze, and the episodes of the Passion of Christ—his arrest, his trial before the Jewish council, his presentation to Pilate, and the Way of the Cross—often extended along the faces of the sarcophagi. The Crucifixion itself was represented only by a bare cross, surmounted by a crown enclosing the monogram of Christ: thus, the symbolic image of the triumph over death. This hesitation to portray the dead Christ on the Cross, an ignominious mode of punishment reserved by the Romans for slaves and abject criminals, disappeared only gradually during the course of the 5th and 6th centuries.

The largest group of Early Christian sarcophagi was found in Rome and its vicinity, although others were found elsewhere in the Mediterranean region. The classicizing style of the first half of the 3rd century became vulgar and a little crude around 300, but it became progressively refined in the time of Constantine and his sons. To the years from 340 to 370 belong the best Roman works: the sarcophagi called the "Two Brothers" (Museo Cristiano), that of Junius Bassus, dated 359, another with columns (both in the grotto of St. Peter's, Rome), that of the "Three Good Shepherds" (Vatican Museums), and, finally, one in S. Sebastiano, Rome, which contains several rare scenes from the story of Lot. While bearing witness to a renaissance of Classical style, they are laden with a new spirituality. A final flourishing occurred near the end of the 4th century in Milan with the decoration of a sarcophagus (S. Ambrogio), which combined an elegant finesse in the figures (due probably to Greek influence) to the vigour of the Roman style.

The sarcophagi of the Middle East and of Ravenna belong principally to the 5th and 6th centuries and to a different artistic tradition. Those of Constantinople and of Asia Minor are fewer in number and lack stylistic homogeneity. Several examples (*e.g.,* sarcophagus of a child and another of the Apostles, end of the 4th century, both in the Arkeoloji Müzeleri, Istanbul) have a harmonious beauty inspired by Classical Greek art; others are in a totally different and more popular style. The sarcophagi of Ravenna, which first appear at the end of the 4th century, stand midway between the Greek art of the East and Latin art. That of Bishop Liberius (4th–5th centuries) of Ravenna at the church of S. Francesco is close to the classicizing Roman sarcophagi in the handling of figures, while the composition—Christ and the Apostles isolated under arcades—finds its models in Asia Minor. Successive waves of Eastern influence affected local style, producing in the 5th century an art distinct from that of the rest of Italy and the Middle East.

Ivory carving. The Christianization of the decorative arts was a slower process than that of monumental art. The presence of pagan imagery on small, movable objects, usually intended for secular use, was less shocking than on the walls and floors of religious buildings. Because many of these objects were made of precious materials, most of them have disappeared. Only ivories are preserved in considerable number. On a small coffer from Brescia (Civico Museo Romano), second half of the 4th century, Gospel scenes cover the four sides and the top, surrounded by a border of biblical subjects similar to those whose presence has been noted in the paintings of the catacombs and on the sarcophagi. The figures are characterized by a gentle beauty and are close to those of certain Roman sarcophagi of the middle and third quarter of the 4th century. Ivories such as the holy women at the tomb and the Ascension of Christ in the Museo d'Arte Antica, Castello Sforzesco in Milan and in the Bayerisches Nationalmuseum in Munich (Figure 36); six miracles of Christ, divided between the two leaves of a diptych, now in Berlin and in Paris; a coffer in London (British Museum) that bears one of the oldest, if not the oldest, representations of Christ on the cross; and a reliquary found at Pola, Istria, Yugoslavia—all belong to a group of ivories that were produced either in Rome or in northern Italy from the end of the 4th to the middle of the 5th century. In the second half of the 5th century the quality of ivory carving declined in the West; it improved, however, at Constantinople and perhaps other eastern cities, such as Antioch and Alexandria.

Ivories in classical style

The Middle Ages

EASTERN CHRISTIAN

The Byzantine era really began with the transference of the capital of the Roman Empire from Rome to the site of ancient Byzantium on the Bosporus in the year AD 330, the new capital thereafter being called Constantinople, after its founder, the emperor Constantine I. Constantine had 17 years earlier been responsible for recognizing Christianity, and from the outset he made it the official religion of the new city. The art dedicated to the service of the faith, which had already begun to develop in the days when Christians were oppressed, received official recognition in the new centre and was also subjected to a number of new influences, so that it owed a debt on the one hand to Italy and Rome and on the other to Syria and Asia Minor, where Oriental elements were prominent. It must not be forgotten that the population of Constantinople and its neighbourhood was Greek, not Latin, so that the poetic and philosophical outlook of the Greek world was itself a very considerable influence.

Constantinople and the Byzantine Empire. Sculpture underwent changes very similar to those in architecture. The decorative work in Hagia Sophia illustrates its nature. In the Classical world naturalistic representation had prevailed; at Hagia Sophia the forms are still basically representational, but they are treated in an abstract manner, more advanced in degree than at St. Polyeuktos. Capitals of the period are similarly stylized even when they use bird or animal forms, for these are usually treated as part of an overall balanced pattern. With this tendency toward stylization in architectural sculpture, it is not surprising to find that three-dimensional, representational sculpture was progressively going out of fashion. Portrait sculptures had been made of most of the early emperors, and the texts report that a mounted figure of Justinian I topped a column in front of Hagia Sophia. But that was the last of the series; figural compositions in high relief had adorned sarcophagi, and similar reliefs had found a place on the walls of churches, but virtually none of these dates from later than Justinian's reign. Instead, flat slabs with low-

Developing stylization in architectural sculpture relief ornament akin to that on the capitals and cornices of Hagia Sophia, some of it even purely geometric, came into vogue. These slabs were used for the lower sections of windows or to form a screen between the body of the church and the sanctuary; they were later to develop into the high structures called iconostases, which eventually became universal in Orthodox churches.

Ivories. The minor sculptural arts are essential to any treatment of medieval sculpture in general, partly because more is known about them and partly because some of the most able masters of the period preferred to work on small-scale objects, and patronage was ready to support them. Most important are the ivories. They comprise a wide variety of types, ranging from small pyxides—circular vessels used in the liturgy—to large-scale works made up of a number of separate panels, like the famous throne of Maximian (Figure 37), the Archbishop of Ravenna, at Ravenna (*c.* 550; Museo Arcivescovile, Ravenna). Most usual, however, were the flat plaques used as diptychs, book covers, etc. Considerable numbers of these, dating mostly from the late 5th and early 6th centuries, have been preserved. After about the middle of the 6th century, however, ivories become rarer: very few can be dated to the period between the reign of Justinian and the revival of Byzantine art in the 9th century.

Diptychs, or two-panel ivories, seem to have been very popular both for use as book covers and for ceremonial purposes. The most impressive of them were imperial. In these each leaf was made up of five panels; on the central one was a portrait of the emperor; at the sides were standing figures of the consuls; below were scenes, usually of tribute bearers; and above were angels upholding a bust of Christ. They thus illustrated the Byzantine ideas of hierarchy, Christ above and the world below, dominated by the emperor as Christ's vice-regent. The finest of them, known as the Barberini ivory (Figure 38, left), is in the Louvre and probably depicts Anastasius I (491–518); another, of his wife, the empress Ariadne, is divided between several collections.

Consular diptychs

More numerous today are the diptychs that were issued by the consuls on coming to office. Their fabrication ceased when the office of consul was abolished by Justinian in 541; though by no means are all the consuls portrayed before that time, leaves of the diptychs issued by a large number of them survive. Each leaf consisted of a single plaque. The earlier ones, like that of Probus (408), are still Roman in style; but those dating from just before and just after 500, which constitute the majority, are in a different style, either more ornate or very much simpler. The more elaborate ones are well represented by leaves of the consul Flavius Anastasius (517), in the Cabinet des Médailles, Bibliothèque Nationale, Paris (Figure 38, right); they show the consul enthroned, with lively circus scenes below. The plainer type is represented by a consular diptych of Justinian dated 521 (six years before his accession as emperor), now exhibited in the Castello

Sforzesco at Milan, where the decoration is confined to rosettes at the four corners and a medallion with a Latin inscription at the centre.

Most of the official ivories were probably carved at Constantinople, but it seems likely that others, which were intended for more general use or for the church, may well have been done elsewhere. Rome, Milan, Alexandria, and Antioch in Syria were all important centres, and there has been a good deal of dispute among experts as to where many of the ivories were made. Maximian's throne, the most elaborate of them all, has been assigned to Alexandria, Constantinople, and even to Ravenna itself; and there has been argument as to whether the consular diptychs were carved at Constantinople, Rome, or Alexandria. There is, however, unanimity with regard to certain types. Thus, a number of rather small plaques bearing decorations in a clumsy but expressive style can safely be assigned to Palestine, and probably to Jerusalem; another group, characterized by a similar search for realism but by greater technical proficiency, can perhaps be attributed to Antioch. A leaf in the British Museum, with the Adoration of the Magi above and the Nativity below, illustrates the first type; a composite diptych used as a book cover, now at Ravenna, represents the second. Each of its leaves is made up of five panels, like those of the imperial diptychs, but here Christ occupies the central one, and there are scenes from the Gospels and the Old Testament all around.

Alexandrian school

Work of a more polished type, where classical scenes, single figures, or, less often, events from the Bible are the subjects, has been associated with Alexandria. At one time this city was regarded as the primary centre of production, and numerous ivories of major importance were attributed to it, notably the throne of Maximian. The panels that compose the latter are in various styles and are certainly not all of the same school. Those on the sides, depicting scenes from the life of Joseph, are vivid and expressive, whereas those on the front, showing John the Baptist, prophets, and ornamental scrollwork, are grand and elegant. It is possible that the artist who did the Joseph scenes was trained in Alexandria, but most of the rest of the work is now generally regarded as Constantinopolitan, and it was probably there that the throne was carved, wherever the craftsmen had been trained. Also typical of Constantinople, especially during the rule of Justinian, is a large panel in the British Museum representing the archangel Michael. The treatment of this youthful figure and his drapery is in a style reminiscent of classic Greek art, but this is happily combined with ornate decoration and a hieractic composition.

A few ivories bearing secular scenes may also be assigned to the capital; one of the most important is a diptych in the Hermitage at Leningrad with depictions of animal combats in the circus.

Classification of mid-Byzantine ivories

A fragment of a sceptre in the name of Leo VI (886–912) at the Staatliche Museen Preussischer Kulturbesitz, Berlin, a panel showing the crowning of Constantine VII Porphyrogenitus by Christ (944) in Moscow, and one with the crowning of Romanus II (945) in the Cabinet des Médailles, Paris, can be dated exactly. But in most cases, dates can only be suggested on the basis of style. The ivories have been classified under a number of headings in a monumental survey made by A. Goldschmidt and K. Weitzmann. They term their first group that of Romanus and associate a number of ivories with that showing his crowning, mentioned above; they include triptychs with the deesis on the central panel in the Vatican, the Palazzo Venezia at Rome, and the Louvre, the last known as the "Harbaville Triptych" (Figure 39, left), as well as panels at Dresden, Venice, Vienna, and elsewhere.

Goldschmidt and Weitzmann's second group is built up around an ivory in the church of Sta. Francesca at Cortona, Italy, which bears the name of Nicephorus II Phocas (963–969). It includes among others a fine triptych with the Virgin on the central panel, at Luton Hoo, Bedfordshire, England. The faces are broader and heavier than those on ivories of the Romanus group. Other groups are distinguished not so much on the basis of date as by form or style, such as groups termed the "painterly" and the "framed," while a more obvious group is composed of caskets. The majority of examples are dated to the later 10th or earlier 11th centuries, but manufacture of objects in this group apparently continued at least until the early 12th century, the later ones being either more linear in style, like a panel with the Baptist and four Apostles in the Victoria and Albert Museum, London, or the figures being very much elongated, as in a St. John at Liverpool. High relief and deep undercutting were apparently in special favour early in the 11th century.

Though the caskets were no doubt often carved by the same people who carved the plaques, they constitute an independent group not only because of their form but also because they are nearly all adorned with secular motifs that have been drawn from Classical literature. The panels bearing the scenes are framed in bands adorned with rosettes or sometimes human heads in profile; because of this, the caskets are often termed rosette caskets. The most exquisite in execution, if also mannered in style, is one in the Victoria and Albert Museum known as the Veroli casket (Figure 39, top). A few caskets of different type are also known; one at Florence has the rosette borders, but they frame panels bearing Christ, the Virgin, and saints; one at Troyes, France, has no rosette borders, while its side panels show horsemen of Persian type and, at the ends, phoenixes that are distinctly Chinese. During the later part of the 12th century, soapstone plaques became more common than ivories, probably for economic reasons, but they bore low-relief decorations in a very similar style. (D.T.R.)

Georgia. A distinct Georgian sculptural tradition did not emerge until the advent of Christianity, which stimulated a demand for a large number of carved stone reliefs. The earliest of these were based on Early Christian models. In the 8th and 9th centuries the high-relief figures of Early Christian art gave way to figures rendered in wholly linear fashion. In the 10th and 11th centuries the reliefs became gradually more plastic and expressive until they were again freed, to a considerable degree, from the background. At the same time there was an increasing interest in the disposition of figures in a harmonious design. By the 12th century, however, sculptors were beginning to look more to ornamentation than to figural representation. Repetition of themes characterized most of Georgian sculpture in subsequent centuries. Sculpture of all periods was always smaller than life-size.

Linear and plastic treatment of reliefs

Armenia. The stone construction of Armenian churches lent itself to carved decorations, and architectural sculpture was more extensively used in Armenia than in any other country of the Middle East, except Georgia. The reliefs of the 4th-century hypogeum (a subterranean structure hewn out of rock) at Aghts along with those on numerous funerary stelae (upright slabs of inscribed stone) antedating the Arab conquest exemplify the early stages of stone sculpture. Beginning with the 6th century, and perhaps even earlier, floral and geometric motifs as well as figure representations were carved around the windows of the churches, between the arches of the blind arcades, and on the lintels and the lunettes over the doors. Decorative ornaments became increasingly intricate during the later periods.

The outstanding example in Armenian art of the use of architectural sculpture is the Church of the Holy Cross, built in the early 10th century on the island of Aghthamar in Lake Van (Figure 40); this is the earliest medieval example, either in the East or in the West, of a stone building entirely covered with relief sculpture. Around the dome and on the four facades may be seen a variety of animals, vine and other floral scrolls, and large figures of saints and scenes from the Old Testament. A portrait of King Gagik I Artsruni, offering to Christ a model of the church he had erected, appears on the west facade. Such donor portraits, sometimes carved in the round as at Ani, were one of the characteristic features of the decoration of Armenian churches.

Donor portraits

Coptic Egypt. Strictly speaking, the adjective Coptic, when it is applied to art, should be confined to the Christian art of Egypt from the time when the Christian faith may be recognized as the established religion of the country among both the Greek-speaking and Egyptian-speaking elements of the population. In this sense Coptic art is essentially that reflected in the stone reliefs, wood carvings, and wall paintings of the monasteries of Egypt, the earliest foundations of which date from the 4th and 5th centuries AD. It is, however, common practice to include within Coptic art all forms of artistic expression that, like the so-called Coptic textiles, need have no religious intent or purpose. The term has also been further extended to denote stylistic characteristics that can be traced back to the 2nd and 3rd centuries AD and perhaps earlier.

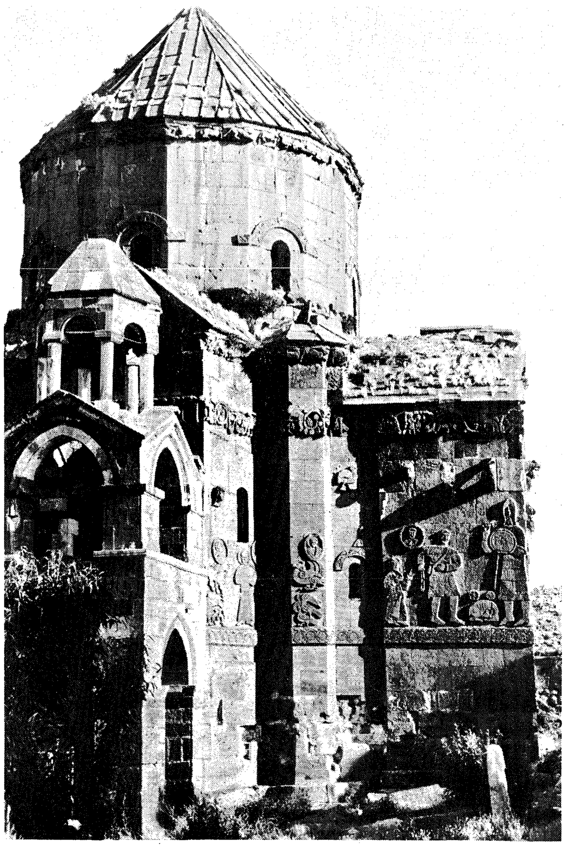

Figure 40: Church of the Holy Cross, Aghthamar, Lake Van, Armenia (now Turkey), early 10th century.
John Donat

A specifically Christian art was slow in developing: when it did emerge, it was not the product of a school of Christian artists inventing new forms of expression. It continued the style current in the country, evolving from the late antique art of Egypt, in which themes derived from Hellenistic and Roman art may or may not have been given new allegorical significance. There is little direct legacy from the art of pharaonic Egypt either in the style of execution or in the choice of decorative themes. The most obvious survival in Christian iconography is the peculiar looped form of cross derived from the ancient Egyptian writing of the word for life (*ankh*). Less convincing is the connection postulated between the concept of *Maria lactans* (representations of the Virgin nursing her child) and bronze and terra-cotta statues of the ancient Egyptian goddess Isis suckling the infant sun god Horus or between representations of saints on horseback and some late figures of the adult Horus in an identical pose.

Origins in ancient Egyptian and Greco-Roman art

The extent to which Egypt may have exerted a major creative influence on Christian art is uncertain in the absence of material remains of the Christian period from Alexandria, the great metropolis of Egypt from the time of the Ptolemies and a city that played an important and, at times, decisive role in the intellectual life of the early church. A series of Christian ivory carvings, of unrecorded provenance, is frequently referred to as Alexandrian on stylistic considerations and adduced as proof of a continuing artistic skill in the Hellenistic tradition.

Objects found in the hinterland depart from the Classical canons of proportion and mode of representation. Political and economic conditions in Egypt from the time of its incorporation in the Roman and, later, Byzantine empires doubtless account for much of the provincial appearance of Egyptian and Coptic art and the emergence of a freer, more popular folk style. Lack of the kind and degree of patronage that had been given by the pharaohs, Ptolemies, and, to some extent, Roman emperors to the old religion of Egypt meant an impoverishment of schools of skilled craftsmen, avoidance of costlier materials, and a decline in the high standard of finish. Particularly noticeable is the absence of carving in the round, of work of monumental scale, and of the use of the harder ornamental stones that had been characteristic of pharaonic art.

Characteristic Coptic stylistic features are to be observed in tombstones from the Delta site of Terenuthis. These depict the dead man frontally posed beneath a gabled pediment of mixed architectural style, hands extended at right angles from the body and bent upward from the elbow in the orans (praying) position, a pose that appeared frequently in the earliest Christian art in Rome. There is no firm evidence, however, that the community was Christian. Similarly, the series of architectural elements carved in relief from Oxyrhynchus and Heracleopolis may not all be from Christian buildings. The earlier material from Heracleopolis, dating probably from the 4th century, is notable for its figure subjects drawn from classical mythology, carved in a deep relief that leaves them almost freestanding, producing an effective play of light and shade. As such reliefs were painted, the absence of fine detail in the carving was less noticeable.

Much of the material available for a study of Coptic sculpture has not been found in context, and, in the absence of assured information concerning its provenance and of circumstantial evidence for dating (even in the cases of pieces from known sites), it is impossible to provide a detailed account of the development of Coptic sculpture. In general, the figures are stiff in pose and movement; there is a tendency for the carving to become flat, and there is little in the way of narrative scenes drawn from biblical stories. The most successful carvings are probably the impressive variety of decorated capitals, particularly from the monasteries of Apa Jeremias at Ṣaqqārah and of Apa Apollo at Bāwīṭ. Among them are basket-shaped examples decorated with plaitwork, vine and acanthus leaves, and animal heads. The form imitates a style introduced into Constantinople by the emperor Justinian I, and it is clear that, in the hinterland of Egypt, there was during the 6th century certain artistic influence on Coptic art from Byzantium, despite religious and political differences. Contemporary Byzantine influence seems to have been at work on other architectural elements at Bāwīṭ, as, for example, in the finely carved limestone pilaster depicting, on one side, a geometric and floral pattern surmounted by a saint and, on the other, vine scrolls and birds below an archangel. (A.F.Sh.)

Carved capitals

WESTERN CHRISTIAN

With the dissolution of the Roman Empire in the West, cultural hegemony passed to the Eastern Empire, but older traditions remained in western Europe and intermingled with several invaders—Germanic tribes arriving from the north and Christians arriving from Constantinople as well as from Rome. The Merovingian art of the Franks, which was culturally predominant throughout Europe in the 6th century, survives principally in grave relics, such as jewelry, hollowware, and the like.

In Italy the Lombards, who invaded the country in 568, propagated Germanic art, but there is a strong Mediterranean influence in the sculpture—stone plaques for choir screens, altars and altar canopies, sarcophagi, and details of architecture, for example; the abstract decorations, many of them interlaced motifs, were to be blended with more and more Byzantine elements (Figure 41). The creatures and vegetation become almost impossible to recognize—they aspire, as it were, to be ornamental stone writing rather than representation. Similar ornaments were also applied in stucco; for example, in S. Salvatore at Brescia and especially in the famous Tempietto at Cividale del Friuli (both 8th century). At Cividale del Friuli, standing figures of saints have been incorporated in decoration in which the Byzantine influence is obvious.

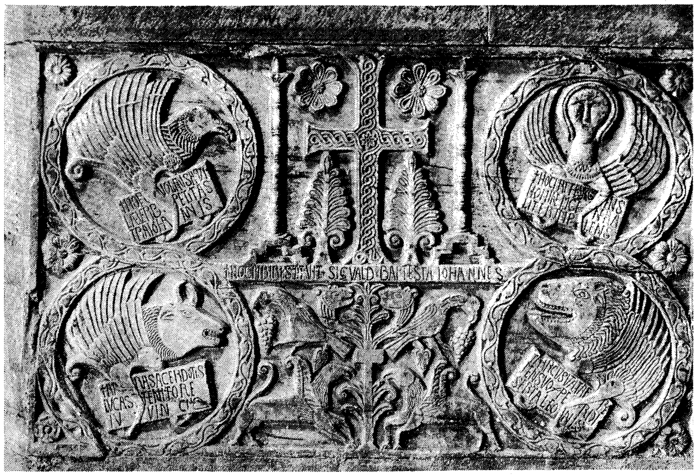

Figure 41: Marble relief inscribed by the Patriarch Sigwald, part of the canopy over the baptismal font in the cathedral of Cividale, Italy, 762–776. 0.91 m × 1.52 m.

In Ireland, monumental crosses represented the Celtic Christian tradition, and similar Anglo-Saxon crosses may be found in England (Figure 42). The abstracted decoration recalls the relief style in Italy, but here the surface is not a flat plane but is packed with round, knoblike projections that create a plastic rather than a glyphic effect.

Carolingian and Ottonian periods. The cultural revival of the Carolingian period (768 to the late 9th century), stimulated by the *academia palatina* at Charlemagne's court, is the first phase of the pre-Romanesque culture, a phase in which late Classical and Byzantine elements amalgamated with ornamental designs brought from the East by the Germanic tribes. The German Ottonian and early Salian emperors (950–1050), who succeeded the Carolingians as rulers of the Holy Roman Empire, assumed initially the Carolingian artistic heritage, although Ottonian art later evolved into a distinct style.

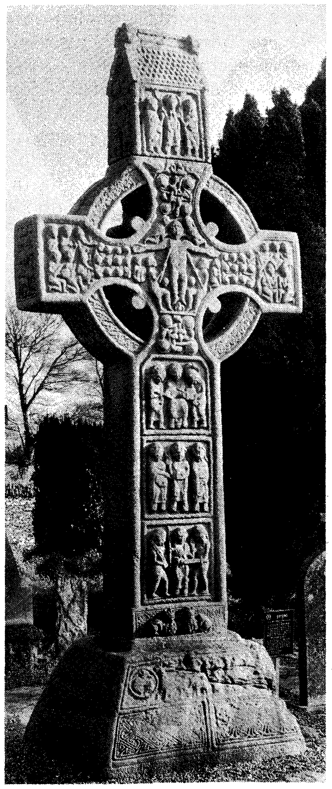

Figure 42: "Cross of Muirdach," Clonmacnoise, 923. Height 5.38 m.

Little Carolingian sculpture has survived, but in Ottonian days the sculpting of freestanding statues was taken up again, although the earliest specimens, serving as they did as reliquaries, were still closely related to the silversmith's and goldsmith's art; for example, the famous statue of "Sainte-Foy" at Conques (France) and the "Golden Madonna" at Essen. The wooden "Gero Crucifix" (about 73.6 inches [187 centimetres] high; cathedral of Cologne; Figure 43), which was carved before 986, already reveals a certain realism in the representation of the shape of the body, in contrast to the contemporary crucifix of Gerresheim (before 1000). The so-called Bernward Crucifix at Ringelheim (Germany) is between the two. The reliefs on the wooden doors of Sankt Maria im Kapitol at Cologne display an affinity with the mid-11th-century Romanesque ivories of the Meuse district. The Carolingian bronze doors in Aachen were imitated at Mainz, where Bishop Willigis had similar portal wings made for his cathedral. He was far surpassed, however, by Bernward at Hildesheim, who had the still extant door wings of the cathedral (1015) decorated with typological images in parallel, scenes from the Old and the New Testament; in theme, the images go back to early Christian examples Bernward had seen in Italy, but the force of the gestures and the use of unadorned surface as dramatic interval in the episode of Adam and Eve reproached by the Lord has no precedent in the history of art (Figure 44). The influence of Classical art manifests itself clearly in the so-called Christ's Column (12.8 feet [3.9 metres] high; *c.* 1020; St. Michael's, Hildesheim), which, with its figures spiralling around the shaft, reminds one of the triumphal columns of Trajan and Marcus Aurelius. Originally, it was crowned by a cross. As belonging to the art associated with Bernward, one must also reckon the seven-branched candlestick in the Minster of Essen (90.6 inches [230 centimetres] high; before 1011) and the bronze crucifix at Essen-Werden (42.5 inches [108 centimetres] high; *c.* 1060), a late product of the same school.

"Christ's Column"

Romanesque. The term Romanesque—coined in 1818—denotes in art the medieval synthesis of the widespread Roman architectural and artistic heritage and various regional influences, such as Teutonic, Scandinavian, Byzantine, and Muslim. Although derived primarily from the remains of a highly centralized imperial culture, the Romanesque flowered during a period of fragmented and unstable governments. It was the medieval monasteries, virtual islands of civilization scattered about the continent, that provided the impetus—and the patronage—for a major cultural revival.

The bronze "Christ's Column" is a modest prophecy of the monumental spirit that would distinguish the sculptural decoration of the new monastic buildings rising in much of western Europe. Developed in the abbey doorways and on the pillars and capitals of cloisters, where the sculptor had to learn anew the technique of stone carving and of rendering the human figure, this spirit gradually grew stronger.

During the 11th century more and more churches were constructed in the Romanesque style, the massive forms of which are another indication of this sculptural instinct. Romanesque sculpture culminated in France in the great semicircular relief compositions over church portals, called tympanums. The example at Moissac (*c.* 1120–30), which represents the Apocalyptic vision with the 24 elders, is a particularly brilliant demonstration of how devices of style can so transform the objects of nature that they seem entirely purged of terrestriality (Figure 45). All the forms are suspended in a predominating plane that denies physical space. Differences in scale are masterfully exploited: the tiny figures of the elders are a foil to the looming image of Christ in the centre. With great consistency, every detail has been subjected to a process of stylization that produces rhythmic patterns in the drapery, hair, and feathers. The central figure is so flattened as to appear disembodied, while the two towering angels have been so attenuated that their bodies have lost all mass.

The astonishing variety that master sculptors such as Gislebertus, Benedetto Antelami, and Nicola Pisano achieved within the confining principles of Romanesque

style can be illustrated, on the one hand, by the tympanums of Burgundy, such as the spectral "Last Judgment" at Autun (Figure 46) or the "Pentecost" at Vézelay, and, on the other, by the less visionary sculpture of Provence, such as that of Saint-Trophime in Arles (Figure 47) or of the church in Saint-Gilles, which retain many of the forms and characteristics of Classical antiquity.

Another sculptural form that reappeared in Europe during the latter part of the Romanesque period was sepulchral sculpture, in which a sculptured figure of the deceased was cut or molded on top of a sarcophagus or on the sepulchral slab set into the floor of an abbey or cloister. (J.J.M.T./Ed.)

Gothic

Origin of the term Gothic

The difficulty with many anatomies of Gothic art is that they become involved in attributing a meaning to Gothic that it is incapable of sustaining. It is not, for one thing, a medieval word; instead, it is an invention of the 16th century attributed, as it were, posthumously, by historians after the Gothic style had been trampled into virtual insensibility by the Italian Renaissance. The word refers to the Teutonic tribes who were thought to have destroyed Classical Roman art and were thus considered barbarians. But nobody in the 13th century thought of himself as Gothic. The fact is that the literature of art criticism is virtually nonexistent in the Middle Ages. Certainly people talked about art, patrons valued it, connoisseurs appraised it. But the terms in which this was done must now, for the most part, be a matter of speculation or imagination. There was not necessarily anything mysterious about this. It is common to suppose that medieval discussions on art were infused with a degree of spirituality. This is probably mistaken. There is, for instance, little that is spiritual about financing the building of a gigantic cathedral. It is certain that clergymen preached sermons about art, giving it a spiritual and symbolic interpretation. It is also true that, since a large proportion of art served a religious function, artists were, in some sense, "servants of God." But they were also the servants of far more worldly considerations, such as earning a living or achieving a reputation, and these should never be discounted in any imaginative re-creation of the medieval artist's existence.

EARLY GOTHIC

Portal sculpture

Throughout this period, as in the Romanesque period, the best sculptors were extensively employed on architectural decoration. The most important agglomerations of figure work to survive are on portals, and, in this, once again, the church of Saint-Denis assumes great significance. The western portals (built 1137–40), part of a total facade design, combined features that remained common throughout the Gothic period: a carved tympanum (the space within an arch and above a lintel or a subordinate arch); carved surrounding figures set in the voussoirs, or wedge-shaped pieces, of the arch; and more carved figures attached to the sides of the portal. As it survives, Saint-Denis is disappointing; the side figures have been destroyed and the remainder heavily restored. The general effect is now more easily appreciated on the west front of Chartres cathedral.

If one compares the portals here (*c.* 1140–50; Figure 48, left) with those of early 13th-century Reims, one can see that the general direction of the changes in this early

period of Gothic sculpture was toward increased realism. The movement toward realism is not manifest in a continuous evolution, however, but in a series of stylistic fashions, each starting from different artistic premises and achieving sometimes a greater degree of realism but sometimes merely a different sort of realism. The first of these fashions can be seen in the sculpture on the west front of Chartres. That the Christ and the Apostle figures are in some sense more human than the Romanesque apparitions at Vēzelay and Autun (*c.* 1130) need hardly be argued. That the figures, with their stylized gestures and minutely pleated garments, are at all "real" is doubtful. That their forms are closely locked to the architectural composition is clear. The features of the Chartres sculpture had a wide distribution; they are found, for example, at Angers, Le Mans, Bourges, and Senlis cathedrals. There are stylistic connections with Burgundy and also with Provence. The fashion lasted from *c.* 1140 to 1180.

The centre of development for the second style lay in the region of the Meuse. The activity of one of the chief artists, a goldsmith called Nicholas of Verdun, extends at least from the so-called Klosterneuburg altar (1181) into the early years of the 13th century. His style is characterized by graceful, curving figures and soft, looping drapery worked in a series of ridges and troughs. From these troughs is derived the commonly used German term for this style—*Muldenstil.* This drapery convention is essentially a Greek invention of the 4th century BC. It seems likely that Nicholas seized the whole figure style as a tool to be used in the general exploration of new forms of realism. It remained extremely popular well into the 13th century. A rather restrained version of the style decorated the main portals of the transepts (the transversal part of a cruciform church set between the nave and the apse or choir) of Chartres (*c.* 1200–10; Figure 48, centre). It is also found in the earliest sculpture (*c.* 1212–25) of Reims cathedral (Figure 48, right) and in the drawings of the *Sketchbook* of Villard de Honnecourt (*c.* 1220).

In the opening years of the 13th century yet another type of realism emerged. It seems to have originated at Notre-Dame, Paris (*c.* 1200), and to have been based on Byzantine prototypes, probably of the 10th century. The looping drapery and curving figures were abandoned; instead, the figures have a square, upright appearance and are extremely restrained in their gestures. Figures in this style are found at Reims, but the major monument is the west front (*c.* 1220–30) of Amiens cathedral (Figure 49, left).

The Joseph Master

Once again, the style changed. On the west front of Reims worked a man called after his most famous figure, the Joseph Master (Figure 49, right). Working in a style that probably originated in Paris *c.* 1230, he ignored the restraint of Amiens and the drapery convolutions of the *Muldenstil* and produced (*c.* 1240) figures possessing many of the characteristics retained by sculpture for the next 150 years: dainty poses and faces and rather thick drapery hanging in long V-shaped folds that envelop and mask the figure.

Another aspect of this quest for realism was the spasmodic fashion throughout the 13th century for realistic architectural foliage decoration. This resulted in some astonishingly good botanical studies—at Reims cathedral, for example.

The effects elsewhere in Europe of this intense period of French experiment were as piecemeal and disjointed as the effects of the architectural changes. In England, the concept of the Great Portal, with its carved tympanum, voussoirs, and side figures, was virtually ignored. The remains of a portal the style of which may be connected with Sens cathedral survive from St. Mary's Abbey, York, England (*c.* 1210). Rochester cathedral (*c.* 1150) has carved side figures, and Lincoln cathedral (*c.* 1140) once had them. The major displays of English early Gothic sculpture, however, took quite a different form. The chief surviving monument is the west front of Wells cathedral (*c.* 1225–40), where the sculpture, while comparing reasonably well in style with near-contemporary French developments, is spread across the upper facade and hardly related at all to the portal.

In Germany, the story is similar. On the border between France and Germany stands Strasbourg, the cathedral of which contains on its south front some of the finest sculpture of the period (*c.* 1230). A very fine and delicate version of the *Muldenstil,* it comes reasonably close to the best transept sculpture of Chartres. But it differs in two important respects. Predictably, its architectural framework is entirely different; and it has the slightly shrill emotional character, common in German art, that represents an effort to involve and move the spectator. Shrill emotionalism is again found at Magdeburg cathedral in a series of "Wise and Foolish Virgins" (*c.* 1245) left over from some abandoned sculptural scheme. Influenced by Reims rather than Chartres, the sculpture of Bamberg cathedral (*c.* 1230–35; Figure 50, left) is a heavier version of the *Muldenstil* than that at Strasbourg. But of all this German work, by far the most interesting complex is in the west choir (*c.* 1250) of Naumburg cathedral (Figure 50, right). Here, the desire for dramatic tension is exploited to good effect, since the figures—a series of lay founders in

Jean Roubier

contemporary costume—are given a realistic place in the architecture, alongside a triforium gallery. Naumburg also has a notable amount of extremely realistic foliage carving.

It is hard to say what a French mason would have made of this English and German work. With the major Spanish work of the period, however, he would have felt instantly at home. Burgos cathedral has a portal (1230s) that is very close to the general style of Amiens, and its layout is also, by French standards, reasonably conventional.

HIGH GOTHIC

Late sculptural developments of the early Gothic period were of great importance for the High Gothic period. The Joseph Master at Reims and the Master of the Vierge Dorée at Amiens both adopted a drapery style that, in various forms, became extremely common for the next century or more; both introduced into their figures a sort of mannered daintiness that became popular. These features appear in an exaggerated form in some of the sculpture for the Sainte-Chapelle, Paris.

On the whole, this period saw the decline of architectural sculpture. Given the emphasis placed on geometric patterning by the Rayonnant style, perhaps this is not surprising. A few portals, such as those on the west front of Bourges cathedral, were completed, but they have a very limited interest. The field of sculpture that expanded with great rapidity was the more private one, represented by tombs and other monuments.

For this, the family feeling of Louis IX was partly responsible. By making sure that both his remote ancestors and his next of kin got a decent burial—or reburial—he was responsible for an impressive series of monuments (the remnants of which are now chiefly in Saint-Denis) executed mainly in the years following 1260. Although earlier examples and precedents may be found, Louis IX had a large share in popularizing the idea of the dynastic mausoleum, and many other important people followed suit.

The monuments executed for St. Louis have come down in such a battered state (almost entirely as a result of the destruction wrought during the French Revolution) that it is difficult to generalize about them. One can say, however, that Louis's masons popularized two important ideas. One was the tomb chest decorated with small figures in niches—figures generally known as weepers, since they often represented members of the family who might be presumed to be in mourning. Later, in the early 14th century, the first representations appear of the heavily cloaked and cowled professional mourners who were normally employed to follow the coffin in a funeral procession. The second innovation introduced by Louis's masons lay in the emphasis given to the effigy. Around 1260 the first attempts were made to endow the effigy with a particular character. This may not have involved portraiture (it is obviously hard to be sure), but it did involve a study of different types of physiognomy, just as the botanical carving of the early Gothic period had involved a study of different kinds of leaves.

A somewhat similar story may be told of English sculpture during this period. The architectural carving found at Westminster Abbey (mainly of the 1250s) has much of the daintiness of contemporary French work, although the drapery is still more like that of the early Chartres or Wells sculpture than that of the Joseph Master. The baggy fold forms of the Joseph Master rarely appear in England before the sculptured angels of the Lincoln Angel Choir (after 1256).

Architectural sculpture in England probably remained more interesting than the continental equivalent because first-rate masons continued to work in this field in England until the end of the 13th century. Hence, around 1295 one can still find a work such as the botanical carving of Southwell Chapter House. Even in the 14th century, there are such architectural and sculptural curiosities as the west front of Exeter cathedral. Sculptural interest, however, in buildings such as Gloucester Cathedral Choir (begun soon after 1330), where the effect depends on traceried panels, is virtually nonexistent; and the "leaves of Southwell" were succeeded almost at once by an extremely dull form of foliage commonly known as "bubbleleaf,"

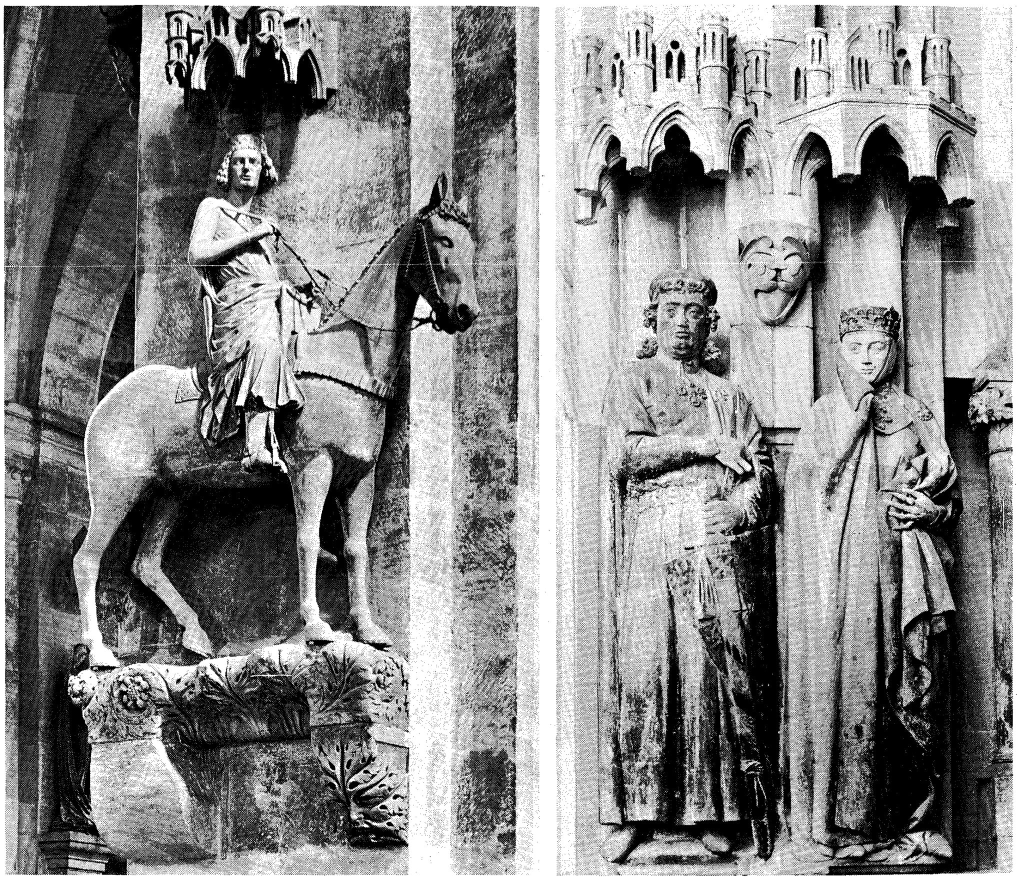

Figure 50: *German Gothic sculpture.*

which remained more or less standard for the 14th and 15th centuries.

Monuments of Westminster Abbey

As in France, much of the virtuosity in carving went into private tombs and monuments. The best surviving medieval mausoleum is Westminster Abbey, where a large number of monuments in a variety of mediums (especially purbeck, bronze, alabaster, and freestone) is further enhanced by some of the floors and tombs executed by Italian mosaic workers introduced by Henry III. Especially well preserved is the tomb of Edmund Crouchback, earl of Lancaster (died 1296), which has a splendid canopy and retains some of its original colouring.

As in the early Gothic period, the west of England produced some highly original work that appears to stand outside the normal canon of European development. The earliest monument in this series is the tomb of Edward II (*c.* 1330–35), which is notable for one of the most elaborate surviving medieval canopies. It is preceded stylistically by the wooden canopies of stalls in Exeter cathedral and thus is likely to be a translation into stone of carpenters' work. It was followed by a series of monuments, in Tewkesbury and elsewhere, extending into the 15th century and then dying out.

German High Gothic sculpture is represented by some rather dainty, elegant figures, enveloped in curving and bulky drapery, around the choir of Cologne cathedral (consecrated in 1322). There is also some impressive figure sculpture on the west front of Strasbourg cathedral (begun after 1277). It is strongly influenced by the Joseph Master of Reims but also by the earlier Gothic sculpture of Strasbourg itself. Although it varies in style, much of it is far more expressive than the related French work. The sculptors seem to have been trying to capture an emotive mood.

Spanish High Gothic architectural sculpture is probably less interesting but, by French standards, is more conventional than the German. Major portals exist at León (13th century) and Toledo (14th century) cathedrals, which conform more or less to the rather elegant and mannered French style. Spain also possesses a considerable number of interesting tombs from this period.

Italian Gothic. The figurative arts in Italy during the period 1250–1350 have a strong line of development. The most important 13th-century sculptors were Nicola Pisano (1210/20–1278/84) and his son Giovanni (*c.* 1245–after 1314). Both worked mainly in Tuscany, and both executed pulpits that rank as their major completed works. Nicola's style, as seen in the Pisa Baptistery (1259–60) and Siena cathedral (1265–68) pulpits, was heavily influenced by Classical sculpture—especially by the facial types and the methods of constructing pictorial relief compositions (Figure 51). Nevertheless, his reliefs resemble 13th-century sculpture, particularly in the handling of the drapery. Moreover, in moving from Pisa to Siena, one is conscious of a transition from a strongly antique style to something much closer to northern Gothic sculpture. Nicola's use of Classical ideas was in some way linked with a search for a more realistic style. It forms, in this respect, an interesting parallel to the *Muldenstil* work of Nicholas of Verdun, who was active in the Mosan region from the late 12th to the early 13th century.

The sculptural style of Giovanni does not develop from that of his father. His pulpit in S. Andrea Pistoia (completed 1301), for instance, is technically less detailed and refined but emotionally much more dramatic. While it is possible that the emotionalism of his work was inspired by Hellenistic sculpture, it is also possible that Giovanni had travelled in and been influenced by the north, especially Germany.

Giovanni's first major independent work was a facade for Siena cathedral (*c.* 1285–95). The lower half alone was completed, and it survives in the present building along with a large proportion of Giovanni's imposing figure sculpture. It is quite dissimilar to French facades,

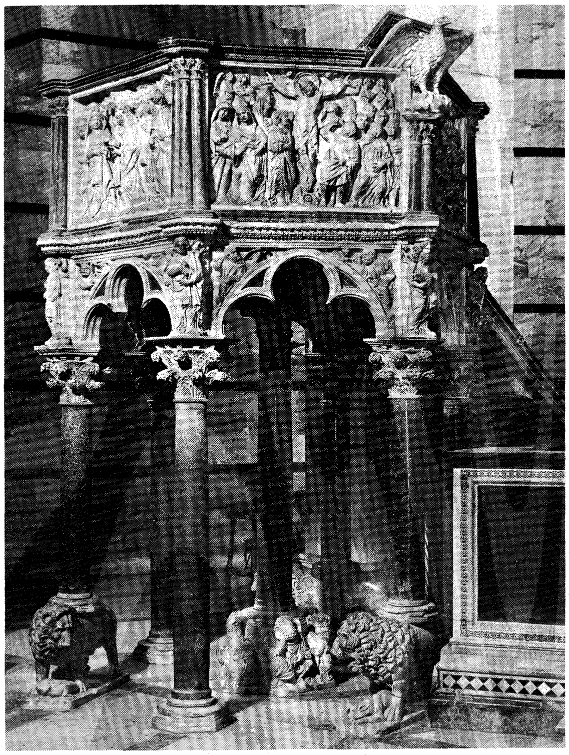

Figure 51: Marble pulpit by Nicola Pisano, 1259–60. In the Pisa Baptistery.

Alinari—Art Resource/EB Inc.

although the placing of the main sculpture above the portals finds an elusive parallel in Wells cathedral, in England (*c.* 1225–40).

Influence of the Pisano workshop

The fame of Nicola's workshop spread to other areas of Italy. For S. Domenico in Bologna, his workshop made a shrine for the body of St. Dominic (1260s). And in Milan, a shrine for the body of St. Peter Martyr was made for S. Eustorgio (1335–39) by Giovanni di Balduccio in a style derived from the Pisano workshop. The most famous Pisano "exports," however, were Arnolfo di Cambio, who worked for the papal court in Rome *c.* 1275–1300, and Tino di Camaino, who worked at the Neapolitan court *c.* 1323–37.

Arnolfo's style is the more difficult to understand. Although he worked alongside Giovanni Pisano during the 1260s, their works have little in common. Arnolfo's sculpture is very solid and impassive. He excelled at formal, static compositions, such as were required for church furniture and for tombs. He designed the funerary chapel as well as the tomb of Pope Boniface VIII and like the Pisanos was architect as well as sculptor; indeed, he was the first architect of the new cathedral of Florence (founded 1296).

Tino di Camaino went south after a training in Siena and a successful career in Tuscany. Sometimes his style approaches the elegance and sweetness of northern 14th-century sculpture, but there is generally a residual heaviness, especially in the faces, that reminds one of his origins in the Pisano circle. He was famous as a tomb sculptor, and the largest collection of his monuments is in Naples (much of the sculpture, however, was executed by his workshop). The tombs make an interesting comparison with those of the French and English royal houses. At another mausoleum (of the Scaliger family), at Verona, the figure sculpture is reminiscent of the Pisano style, but the decorative canopy work is more elaborate and closer to northern art.

The workshop of the facade of Orvieto cathedral and the work of the sculptor and architect Andrea Pisano (no relation to Nicola and Giovanni) are less clearly connected with the Pisano tradition. The facade of Orvieto was designed by the Sienese Lorenzo Maitani *c.* 1310. The sculptural decoration is in varying styles, the best of which is an extraordinarily low and delicate relief that gives an almost pictorial quality.

Andrea Pisano is known chiefly through the bronze doors completed for the Baptistery of Florence cathedral during the 1330s. The scenes of the life of St. John the Baptist are set in quatrefoils (a four-lobed foliation), a common High Gothic decorative motif. Within this awkward shape, the episodes are composed with masterly skill. Although nothing certain has been established about the training of Andrea Pisano, his background is likely to have been similar to that of some of the Orvieto sculptors. The main difference is the evident impact of Giotto's painting, which led Andrea to make his figures rather stocky and solid.

Andrea had a son, Nino Pisano, about whom little is known but from whose hand a group of Madonnas survives. They are interesting in that they veer strongly in the direction of daintiness and sweetness and, to this extent, look more northern than almost any other group of Italian sculpture before the early work of Lorenzo Ghiberti.

International Gothic. The plastic arts are harder to understand in this period, because they have been far more frequently the subject of wanton destruction. Enormous quantities, for example, of goldsmiths' work owned by the French royal family have almost entirely vanished. A few of the remaining pieces testify to the quality of the work, which is beautifully finished and gaily coloured in the technique of *en ronde bosse* enamelling—for example, the "Thorn Reliquary" (*c.* 1400–10; British Museum, London), and the "Goldenes Rössel" at the Stiftskirche, Altötting, Germany (1403).

More seriously, large quantities of private monumental sculpture have been lost in France and the Low Countries. The main sculptor of the French royal family in the second half of the 14th century was a native of Valenciennes, André Beauneveu. His reputation was so widespread that he rather surprisingly earned a mention in the chronicles of Jean Froissart. He produced a large number of monuments, especially for King Charles V, of which several effigies survive (Figure 52). This sculpture, while technically good, is somewhat pedestrian and hardly serves as a prelude to the work of Claus Sluter, who worked for Charles V's brother Philip the Bold, duke of Burgundy.

Claus Sluter

Sluter's surviving work is mainly at Dijon, France, where he was active from about 1390 to about 1406. His figure style is very strongly characterized and detailed and, at times, emotional. This suggests that his origins are German and that he may have come from the region of Westphalia. The intrusive realism of Sluter's work, however, is

Giraudon—Art Resource/EB Inc.

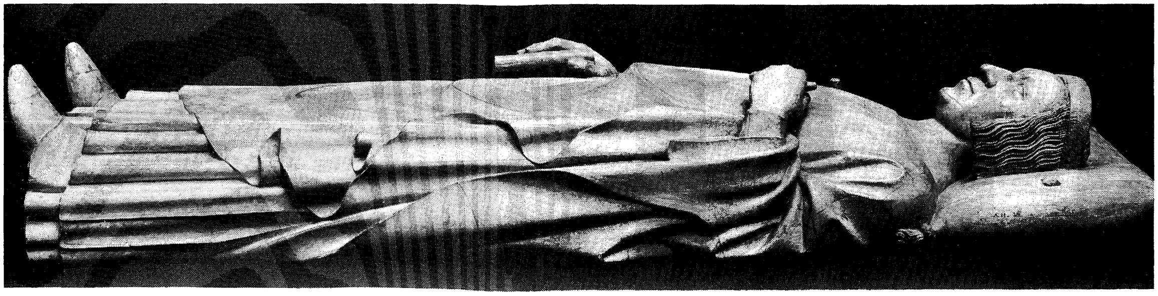

Figure 52: Tomb of Charles V in the abbey of Saint-Denis, France, by André Beauneveu, 14th century.

also symptomatic of a gradual change in sculptural style during this period. The strong characterization of the faces of his figures finds parallels in the near-contemporary triforium busts and Přemyslid tombs in St. Vitus' Cathedral in Prague. Sluter's drapery style, which veers dramatically away from the somewhat reticent elegance of previous court sculpture, also has parallels in the east. Bohemia and Austria possess a series of Madonna figures (*Schöne Madonnen*) swathed in extremely elaborate and artificial drapery arrangements.

The International Gothic sculptural style forms an interesting prelude to developments in Italy, especially to the early work of Donatello and the gradual introduction of Classical ideas into sculpture, for these ideas can be seen as part of a search for an alternative to the elegance of International Gothic. How far Florentines had any knowledge of northern developments is not clear. Ghiberti certainly knew a little about them; moreover, the task of rebuilding Milan cathedral during this period (*c.* 1400) brought large numbers of northern masons across the Alps. As yet, however, the extent to which the sculpture on Milan cathedral was influenced by northern ideas has not been determined.

England stands apart from much of the development represented by Sluter's style. The royal tombs in Westminster Abbey, which extend up to Richard II (died 1400), do not reflect changes subsequent to the phase of André Beauneveu. Further, a fashion for bronze effigies, going back to the effigy of Henry III (1291–93), persisted in England. But whatever the regional idiosyncracies, Westminster tombs, existing as a group in situ, provide a somewhat faded and battered impression of what these great collections of medieval family monuments looked like.

LATE GOTHIC

In the years around 1400, when International Gothic flourished, Italian and northern artists had achieved some sort of rapprochement. Under the renewed influence of antique art, Italy drew away again, and it was not until the 16th century that the north showed any real disposition to follow suit in the imitation of Classical models. While painting and architecture of the 15th century have a reasonably well-defined development, sculptural development is harder to trace—partly because much crucial work (especially in the Low Countries) has been destroyed. It is clear, however, that elaboration rather than restraint was the rule—indeed, the exceptions to the rule (mainly found in France) stand out. This taste for the highly complicated and elaborate—especially in Spain and Germany—was encouraged by the dual influences of painting and architecture. Like the painters, the sculptors enjoyed giving extremely realistic detail and expression to their figures; and, like the architects, they enjoyed complicated tracery work, often encasing their compositions in tabernacle-like enclosures of brilliantly fantastic architecture. To 20th-century eyes, the result may seem overloaded and the total impression exhausting; but in its time the work of, for example, Michael Pacher or Veit Stoss must have been admired precisely for the way in which the sculptor used every conceivable opportunity to display his virtuosity.

The taste for the elaborate

One interesting characteristic of the late Gothic period deserves comment: the increase in the amount of art produced by foreign artists for countries such as Hungary, Poland, and Scotland. Competition between countries for the work of the best artists was not new. Throughout the Middle Ages artists travelled widely. In the 13th century Villard de Honnecourt went from northern France to Hungary, and Roman marble workers journeyed to Westminster. In the period *c.* 1400 there was much interchange between northern and southern Europe. In the 15th century, this general pattern was confirmed; the Netherlandish sculptor Gerhaert Nikolaus von Leyden, for instance, became court sculptor in Vienna, and the Italian sculptor and architect Andrea Sansovino served the Portuguese court in the 1490s. There is also the work of the Franconian sculptor Veit Stoss for the Polish court at Cracow (*c.* 1480) and the work of Bernt Notke of Lübeck for Aarhus (Denmark), Tallinn (Estonia), and Stockholm (*c.* 1470–90). Numerous other objects could be added. More specifically, there is the altar executed by Meister Francke of Hamburg for Helsingfors (1420s) and Hugo van der Goes' panels for the Palace of Holyrood, near Edinburgh (1470s).

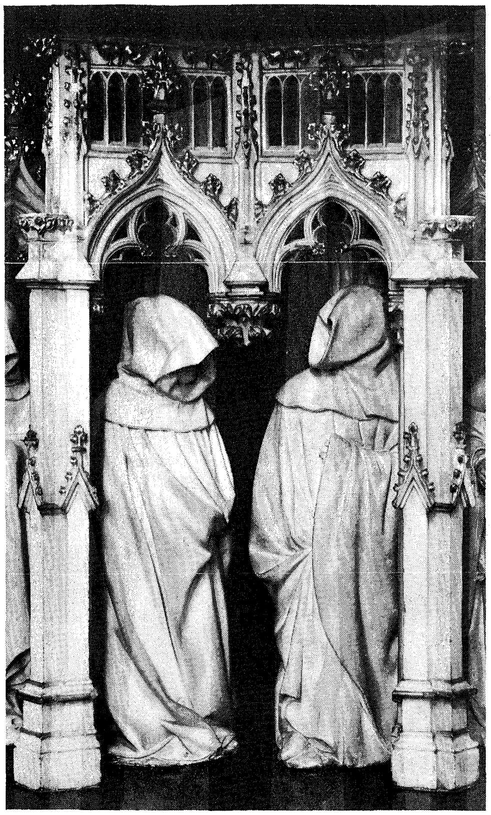

Figure 53: Weepers from the tomb of Philip the Bold, by Claus Sluter and Claus de Werve, completed 1411. In the Musée des Beaux-Arts, Dijon, France. Height 40.6 cm.
R. Remy

Sluter's work for the court of Burgundy lasted about 15 years. During this time, he worked on three major items: the main portal of the chapel of the Charterhouse near Dijon; inside the chapel, the tomb of his patron, Philip the Bold (Figure 53); and a large Calvary group for the Charterhouse cloisters. When he died in 1406, the continuance of his work was assured by the employment of his nephew and heir, Claus de Werve, until his death in 1439. Further, the pattern of the finally completed tomb of Philip the Bold became famous immediately and was frequently imitated all over Europe.

The forcefulness and boldness of Sluter's sculpted figures is combined with elaborate decorative work—on the canopy of the tomb of Philip the Bold, for example. A similar decorativeness is found in the contemporary carved Dijon altarpieces of Jacques de Baerze. The combination remained more or less constant for the rest of the Gothic period.

The spread of this style is hard to trace. In Germany, the most interesting artists worked in the second half of the century. Two of the more important sculptors were Gerhaert Nikolaus von Leyden and Michael Pacher of Brunico. They were followed by a number of virtuoso southern German artists: Veit Stoss of Nürnberg, Tilman Riemenschneider of Würzburg (Figure 54), and Adam Kraft of Nürnberg. In northern Germany, the most original figure was Bernt Notke of Lübeck. Much of the fantastic decorative involvement of his work may now seem overwhelming. The love of realistic detail is well illustrated by Notke's monumental group of St. George and the Dragon (St. Nicholas' Church, Stockholm; Figure 55), where the dragon's spines are made from real antlers. The group as a whole is, of course, of wood, a medium that could be employed to create intricate, open, thin, and spiky forms impossible in stone.

Bernt Notke of Lübeck

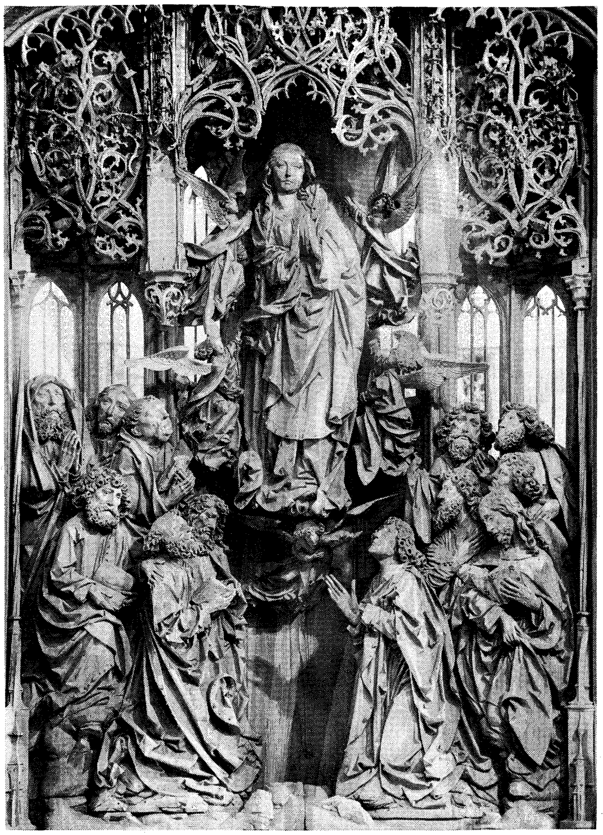

Figure 54: "The Assumption of the Virgin," part of the Altar of the Virgin by Tilman Riemenschneider, 1505–10. In the Herrgottskirche, near Creglingen, Germany.

On the whole, the sculpture produced in France seems to show more decorative restraint. Certainly, the chief French works surviving take the form of large groups, as in the Tonnerre "Entombment" (1450s), or of architectural schemes in which the decoration is clearly subordinate to the figures, as in Châteaudun, Castle Chapel (*c.* 1425).

Restraint is also notable in the chantry chapel of Richard Beauchamp, earl of Warwick (*c.* 1450; Warwick), which has some obvious motifs taken over from the workshop of Sluter. But many of the chantry chapels so common in 15th-century England—for instance, the Henry V Chantry, Westminster Abbey (1440s), or the chantries of John Alcock (*c.* 1488) and Nicolas West (*c.* 1534) at Ely cathedral—show an extraordinary mixture of sculpture and tracery work more reminiscent, as an expression of taste, of Germany or Spain.

The full impression of such profusion can now best be judged from the Chapel of Henry VII (*c.* 1503–*c.* 1515; Westminster Abbey), which is unique in England for the amount of sculpture that has been preserved.

Spanish 15th-century sculpture also tended to be extremely ornate. A number of huge, carved high altarpieces survive—for instance, in the cathedrals of Burgos (1486–88) and Toledo (begun 1498). Some of the altar pieces, like that at Toledo, were designed and executed under the direction of German or Netherlandish artists (Figure 56).

The change from late Gothic to Renaissance was superficially far less cataclysmic than the change from Romanesque to Gothic. In the figurative arts, it was not the great shift from symbolism to realistic representation but a change from one sort of realism to another.

Architecturally, as well, the initial changes involved decorative material. For this reason, the early stages of Renaissance art outside Italy are hard to disentangle from late Gothic. Monuments like the huge Franche-Comté chantry chapel at Brou (1513–32) may have intermittent Italian motifs, but the general effect intended was not very different from that of Henry VII's Chapel at Westminster. The Shrine of St. Sebaldus at Nürnberg (1508–19) has the general shape of a Gothic tomb with canopy, although much of the detail is Italianate. In fact, throughout Europe the "Italian Renaissance" meant, for artists between about 1500 to 1530, the *enjolivement,* or embellishment, of an already rich decorative repertoire with shapes, motifs, and figures adapted from another canon of taste. The history of the northern artistic Renaissance is in part the story of the process by which artists gradually realized that Classicism represented another canon of taste and treated it accordingly.

But it is possible to suggest a more profound character to the change. Late Gothic has a peculiar aura of finality about it. From about 1470 to 1520, one gets the impression that the combination of decorative richness and realistic detail was being worked virtually to death. Classical antiquity at least provided an alternative form of art. It is arguable that change would have come in the north anyway and that adoption of Renaissance forms was a matter of coincidence and convenience. They were there at hand, for experiment.

The "rightness" of Classical antiquity

Their use was certainly encouraged, however, by the general admiration for Classical antiquity. They had a claim to "rightness" that led ultimately to the abandonment of all Gothic forms as being barbarous. This development belongs to the history of the Italian Renaissance, but the phenomenon emphasizes one aspect of medieval art. Through all the changes of Romanesque and Gothic, no body of critical literature appeared in which people tried to evaluate the art and distinguish old from new, good from bad. The development of such a literature was part of the Renaissance and, as such, was intimately related to the defense of Classical art. This meant that Gothic art was left in an intellectually defenseless state. All the praise went to ancient art, most of the blame to the art of the more recent past. Insofar as Gothic art had no critical literature by which a part of it, at least, could be justified, it was, to that extent, inarticulate. (A.Ma./Ed.)

The Renaissance

ITALY

The revival of Classical learning in Italy, which was so marked a feature of Italian culture during the 15th century, was paralleled by an equal passion for the beauty of Classical design in all the artistic fields; and when this eager delight in the then fresh and sensuous graciousness that is the mark of much Classical work—to the Italians of that time, seemingly the expression of a golden age—became universal, complete domination of the Classical ideal in art was inevitable.

This turning to Classical models was less sudden and revolutionary than it seemed. Throughout the history of Romanesque and Gothic Italian art, the tradition of Classical structure and ornament still remained alive; again and again, in the 12th and 13th centuries Classical forms—the acanthus leaf, moulding ornaments, the treatment of drapery in a relief—are imitated, often with crudeness, to be sure, but with a basic sympathy for the old imperial Roman methods of design. Nicola Pisano, at work in the mid-13th century, was but the first of many Italian artists, particularly sculptors, to turn definitely to Roman antecedents for inspiration.

Early Renaissance. Sculpture was the first of the arts in Florence to develop the Renaissance style. Some would date the beginning of the Renaissance to the sculptural competition in 1401 for the bronze doors of the Baptistery of the cathedral of Florence; others would propose the commission to Donatello and Nanni di Banco in 1408 for four seated saints for the facade of the cathedral. The competition reliefs for the bronze doors, submitted in 1402, reveal a change in attitude toward sculpture, and the figures of the Evangelists are the manifestation of that change. The development of Florentine sculpture roughly parallels the development in painting from a dignified monumental style to a relaxed sweetness, although there is no one in painting to approach the rich inventive genius of Donatello.

The genius of Donatello

Donatello, like his friends the architect Brunelleschi and the painter Masaccio, was one of the most outstandingly original artists in Western history. He undoubtedly was influenced by the concepts of antiquity current in Florence, but there was relatively little antique sculpture visible for him to study in his formative years. He first appears as a mature genius working on two of the major projects of the 15th century, the sculptural decoration of the cathedral of Florence and of the guild church of Or San Michele.

His "St. George," begun *c.* 1415 for the niche of the Armourer's Guild at Or San Michele, indicates the new direction in sculpture (Figure 57). Here he reveals such a deep knowledge of the human figure at rest and in movement that he may already have begun his investigation into proportion and the statics and dynamics of the human figure. But the tension between repose and action—the representation, in fact, of pause—also is a psychological achievement, hardly to be matched in earlier sculpture. It is noteworthy, too, that the monumental simplicity and power of the piece is achieved by such a subtle manipulation of the planes and such a technical virtuosity in

Alinari—Art Resource/EB Inc.

carving the marble that the observer is rarely concerned with the material. The figure is neither flesh nor stone; it simply is.

In the relief under the niche occupied by "St. George," Donatello introduced another great innovation that was to have unlimited repercussions in Florentine art. Relief has always been a problem for sculptors because it must follow a narrow path between the two-dimensionality of painting and the three-dimensionality of full-round sculpture. Donatello conceived of a very low relief in which the subtle modelling of planes suggests the illusion of depth and figures moving in space while still respecting the integrity of the plane. He continued to develop the potentialities of this relief style throughout his long career and strongly determined the kind of relief sculpture executed in Florence.

In his brief career Nanni di Banco was as prolific and inventive as Donatello. In his earliest works, such as the "Isaiah," he approached more closely the Classic ideal than did Donatello, and in his late work at the Porta della Mandorla he began to evolve a relaxed style that was to have its greatest impact after mid-century. About 1411–13 he executed the "Quattro Santi Coronati" ("Four Crowned Saints") for the niche of the woodworkers and stoneworkers guild at Or San Michele. In this commission he solved one of the most difficult problems facing the sculptor, that of the group conceived in the round. Although some of the figures still retain certain Gothicizing elements in the draperies and in the heads, the major impression is of a group of Roman senators born again in the Renaissance. The group is bound together by the spatial relation of one to the other and by a kind of mute conversation in which they are all engaged.

Ghiberti's "Gates of Paradise"

Lorenzo Ghiberti won the competition for the bronze doors of the Baptistery. He began work in 1403 and set the doors in place in 1424. Ghiberti's fame rests upon his second set of doors, the "Gates of Paradise" (1425–52). The gilded bronze reliefs are treated almost like paintings, for they are rectangular in format and contained within a frame. Unlike the earlier doors, in which the ground plane is simply a neutral backdrop, it is here treated in such a way that it suggests sky and space. Figures are placed in landscape or in perspectivally rendered architecture to suggest a greater depth to the relief than actually exists. At the time that he was executing his first set of bronze doors, Ghiberti undertook to cast the first life-sized bronze statue since antiquity, his "St. John the Baptist" (1412–16) for Or San Michele. Although the figure and its draperies reveal Ghiberti's strong adherence to a late Gothic style, with this work he moved technically into the Renaissance. The influence of Donatello and Nanni di Banco liberates the "St. Matthew" of 1419–22, for Or San Michele, from the older traditions. Ghiberti achieved fame in his own time as a bronze founder and as the master of the shop in which many sculptors and painters of the early Renaissance were trained.

The Sienese sculptor Jacopo della Quercia was the most important sculptor of 15th-century Siena. He executed the Fonte Gaia (1414–19), a public fountain for the Piazza del Campo, the main square of Siena, and was awarded the commission for a baptismal font in the baptistery of Siena cathedral. Always a procrastinating artist, he postponed work on the font to such a degree that the reliefs were finally awarded to other sculptors, including Donatello and Ghiberti. Jacopo's major work is the relief sculpture around the main portal of S. Petronio, Bologna (1425–38). The sculptural treatment of the low relief figures and the suggestion of a space adequate to contain them parallels the painting of Masaccio. The dramatic vigour and powerfully conceived forms had a great influence on the young Michelangelo.

Donatello dominated Florentine sculpture of the second quarter of the 15th century. He executed a series of prophets and a "Cantoria," or singing balcony, for the cathedral, saints for Or San Michele, decorative reliefs and bronze doors for the Old Sacristy of S. Lorenzo, and a bronze "David" (now in the Bargello, Florence) that comes closer to recapturing the spirit of antiquity than any other work of the early Renaissance—indeed, the very idea of a free-standing sculpture of a nude hero was without precedent since antiquity. During the decade 1443–53 Donatello was in Padua executing the equestrian statue of Gattamelata to stand in front of the church. Erasmo da Narni, called Gattamelata, was a condottiere, or leader of mercenary troops, who rose to a position of importance. The statue is an idealization of nature in both horse and rider and a reinterpretation of antiquity. Donatello certainly knew the antique statue of Marcus Aurelius in Rome during his stay there (1431–33). He uses the concept of antiquity, the pose of the antique bronze horses at St. Mark's in Venice, and the forms of the war-horse of his own time. The rider is clothed in quasi-antique armour and bears little or no resemblance to the effigy on Gattamelata's tomb inside the church. Donatello is not concerned with particulars but with the idealized and generalized aspects of man that reveal his potential nobility. The "Gattamelata" states the basic concept that almost all equestrian statues have followed since that time. Donatello's presence in Padua gave rise to a productive local school of bronze sculptors and workers, and his reliefs on the high altar there influenced painters and sculptors of northern Italy.

Donatello's "Gattamelata"

One of his first works upon his return to Florence was a wooden statue of Mary Magdalene for the baptistery of the cathedral. The nervous energy and conscious distortion of forms that may be detected in all his work becomes explicit in the emaciated figure clothed in her own hair. This same emotionalism and distortion is even more pronounced in his last work, the pulpits for the church of S. Lorenzo in Florence.

Antonio Pollaiuolo expresses in his sculpture the same sort of muscular activity and linear movement as in his painting—he has the energy but not the interest in emotion found in Donatello. His small bronze "Hercules and Antaeus" (*c.* 1475; Bargello, Florence) is a forceful depiction of the struggle between these two powerful men from classical mythology. The angular contours of the limbs and the jagged voids between the figures are all directed toward expressing tautness and muscular strain, and the work is one of the earliest examples of the statuette in modern times.

The popularity of small bronzes, usually of secular, often of pagan, subjects and sometimes objects of utility (inkwells, candleholders, and so on), increased in popularity toward the end of the century. The elegant, polished antique gods made by Antico in Mantua and the brilliantly modelled satyrs made by Riccio in Padua set a standard in such works that has never been excelled. Bronze statuettes were made by almost all the major sculptors of the 16th century in Italy.

The "sweet style" of the Florentine school

In complete contrast with Pollaiuolo, Desiderio da Settignano is perhaps best known for his portraits of women and children, although he also executed two public monuments of major importance in Florence—the tomb of Carlo Marsuppini in Sta. Croce (*c.* 1453–55) and the "Tabernacle of the Sacrament" in S. Lorenzo (1461). The tabernacle, which was probably assembled and completed by assistants after Desiderio's death, indicates the new trends taking shape in Florentine sculpture. The central panel employs a perspectivized space. The figures moving into that space are defined in a linear manner that emphasizes contours and billowing draperies to suggest movement. The lateral, full round figures of angels are modelled with a delicacy and subtlety of surface to create relaxed and sweet figures very different from Donatello's strong, virile early saints.

Antonio Rossellino collaborated with his older brother Bernardo on the tomb of Leonardo Bruni (*c.* 1445–49) in Sta. Croce but soon became the dominant personality in the family business. The great sculptural complex of the Cardinal of Portugal tomb (1461–66) in S. Miniato al Monte at Florence reveals the same general tendencies as Desiderio's contemporary work. The tomb is decorated with soft and relaxed angels and a tender Madonna and Christ Child in the roundel (Figure 58). Similar tendencies can be found in such artists as Agostino di Duccio, Mino da Fiesole, and Luca della Robbia.

Andrea del Verrocchio was more interested than these sculptors were in movement, which he expressed in a

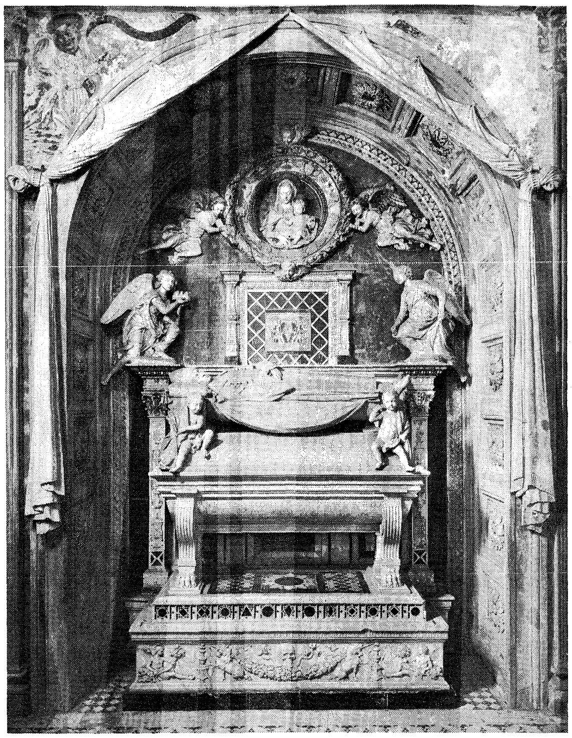

Figure 58: The Cardinal of Portugal tomb, marble sculptural complex by Antonio Rossellino, 1461–66. In the church of S. Miniato al Monte, Florence.

Alinari—Art Resource/EB Inc.

somewhat restrained manner. His group of "Christ and St. Thomas" for Or San Michele (*c.* 1467–83) solves the problem of a crowded niche by placing St. Thomas partly outside the niche and causing him to turn inward toward the figure of Christ. His large equestrian statue of Bartolomeo Colleoni (1483–88) in Venice descends from Donatello's "Gattamelata," but a comparison of the two works reveals Verrocchio's evidence of greater interest in movement. The "Putto with Dolphin" (*c.* 1479; formerly in the Palazzo Vecchio, Florence, but now replaced by a copy) is at once an exquisite fountain decoration, an antique motif restated in Renaissance terms, and the clearest statement of Verrocchio's interest in suggested movement. The child in the piece is seen to be turning; the movement is reinforced by the fish, and the suggestion of motion culminates in the actual movement of the water spouting from the dolphin's mouth. Verrocchio also reveals his indebtedness to Desiderio in the way he treats the surfaces.

High Renaissance and Mannerism. Sixteenth-century sculpture is dominated by the figure of Michelangelo. Although he was born and trained in the 15th century, his style and the bulk of his creations place him firmly in the 16th century. Michelangelo's example was so powerful that Mannerist Florentine artists such as Bartolommeo Ammannati and Baccio Bandinelli could only struggle feebly against it. Others, such as Vincenzo Danti, found it easier to succumb and to follow docilely. Jacopo Sansovino effectively escaped the influence of Michelangelo by transferring his activities to Venice. In Padua a group of bronze workers continued to develop the tradition of fantastic and often beautiful small bronzes that had its origins in Donatello's shop. It was only toward mid-century with artists such as Benvenuto Cellini or at the end of the century with Giambologna that Florentine sculpture found individuals who were able to assimilate Michelangelo's pervasive influence.

Michelangelo Buonarroti is said to have learned sculpture from the minor Florentine sculptor Bertoldo di Giovanni, who provided a link with the tradition of Donatello. An early work, the "Madonna of the Stairs" (*c.* 1492; Casa Buonarroti, Florence), reflects a type of Donatello Madonna and Donatello's very low relief. After the expulsion of the Medici from Florence, Michelangelo fled to Bologna; there he executed three figures for the tomb of S. Domenico and saw the powerful reliefs of Jacopo della Quercia. By 1496 he was in Rome, where he carved a "Bacchus," now in the Bargello, Florence. Michelangelo recaptures the antique treatment of the young male figure by the soft modulation of contours. The figure seems to be slightly off-balance, and the parted lips and hazy eyes suggest that he is under the influence of wine. The little faun also joins in the Bacchic revel by slyly stealing some grapes. In his first major sculptural work the 21-year-old artist succeeded in capturing the spirit of the antique as no artist before him had done. The "Pietà" (today in St. Peter's), commissioned by a French cardinal, was begun immediately upon the completion of the "Bacchus." The motif of the pietà is German in origin, but it is so completely transformed by Michelangelo that the work is one of the harbingers of the High Renaissance. The robes of the Madonna are exaggerated to create a solid base for the pyramidal composition. The figure of Christ is bent and twisted, in part to express the suffering of the crucifixion and in part to make it conform to the contours of the pyramid. All is directed toward creating a calm, dignified, and stable composition that expresses emotion and religious fervour by implication rather than by overstatement. The work is carried to a higher degree of finish than any of the succeeding works, and it is one of the few that Michelangelo signed.

Michelangelo's mastery of the antique

In 1501 Michelangelo was recalled to his native city of Florence to execute an over-life-size figure of "David." When the piece was completed, Michelangelo's contemporaries judged it too important to place out of sight high up on the cathedral, as had been originally proposed, and a committee voted to place it in front of the Palazzo Vecchio, the seat of Florentine civic government. Michelangelo's technical virtuosity is dramatically demonstrated by the fact that he extracted a figure about 14 feet (four metres) tall from a spoiled block. The youthful David was one of the symbols of Florence. Michelangelo sees him as a slightly awkward adolescent with large hands

Michelangelo's "David"

Alinari—Art Resource/EB Inc.

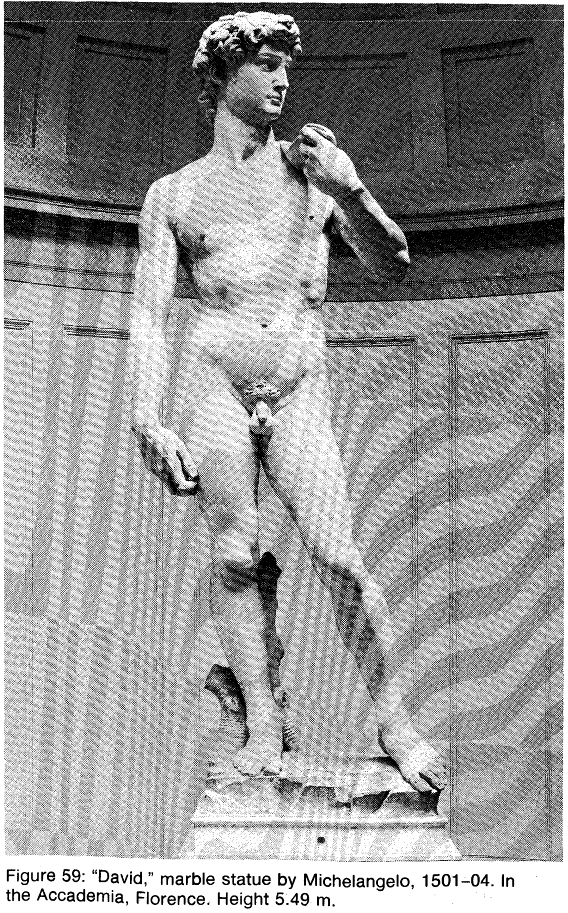

Figure 59: "David," marble statue by Michelangelo, 1501–04. In the Accademia, Florence. Height 5.49 m.

and feet, the body of a boy, and the head of a young man—a powerful figure who has not yet realized his full potential. The balance of the figure is subtly arranged to keep the bearing leg under the head while permitting the apparently nonbearing leg to be relaxed. The positions are reversed in the arms, giving the cross-axis balance of working and relaxed members. The head turns to the left to meet Goliath and the stone of the sling is concealed in the right hand. It is this subtle balance and adjustment of parts to create a unified and harmonious whole that places this work firmly in the High Renaissance style that was appearing simultaneously in painting and architecture (Figure 59).

While in Florence from 1501 to 1505, Michelangelo carved "Madonna and Child" for Notre-Dame in Brugge. He began but did not finish a "St. Matthew" for the cathedral, and he painted the "Holy Family" (*c.* 1503–05; Uffizi, Florence), his reply to Leonardo's eminently popular "The Virgin and Child with St. Anne." In competition with Leonardo he began but did not finish the "Battle of Cascina" for the Palazzo Vecchio. On command of Julius II he returned to Rome.

The Roman years (1506–16) are characterized by what Michelangelo later called the tragedy of the tomb. He had been called to Rome to execute a monumental sepulchre for Pope Julius II. The Pope's financial difficulties and the jealousies of the papal court diverted the artist from the tomb to the painting of the Sistine ceiling. The death of Julius in 1513 caused the heirs to press for a smaller tomb and rapid completion. After many years of negotiations, in 1545 a much-reduced version was set in place in S. Pietro in Vincoli, instead of in St. Peter's as originally planned. The figures by Michelangelo for the tomb are now widely scattered. Only the "Moses" remains in place from the original projects. This figure, which recalls so strongly Donatello's "St. John the Evangelist," was intended to be placed well above the observer's head and is so adjusted. The "Dying Slave" and the "Bound Slave" are now in the Louvre. The "Victory," also intended for the tomb, was executed *c.* 1532–34 in Florence, where it has remained. Four unfinished figures of slaves were carved before 1534 and remained in Florence, where they once formed part of the grotto decoration at the Pitti Palace.

With the election of Pope Leo X in 1513, Michelangelo was diverted from his projects and sent to Florence to design a facade for S. Lorenzo, a church under Medici patronage. Although Michelangelo promised that the facade would become the showplace of Italian sculpture, nothing came of the project. He was assigned instead to construct a tomb chapel as a pendant to Brunelleschi's Old Sacristy, and later to provide suitable housing for the Medici library in S. Lorenzo. While engaged in these projects Michelangelo was also put in charge of the fortifications of Florence prior to and during the siege of 1529. He complained, justly, that no one can plan and execute three projects simultaneously.

The Medici tombs (1520–34) gave the artist the opportunity to plan the architectural setting of his sculpture and to control both the light cast on the work and the position of the observer. Since the chapel was originally planned to contain the tombs of the Medici popes Leo X and Clement VII, it is best seen from behind the altar, where the papal celebrant of the mass for the dead would have stood. On the left is the tomb of Giuliano, on the right the tomb of Lorenzo, and before the observer the Madonna and Christ Child with the Medici patron saints, Cosmas and Damian; and beneath the two sarcophagi respectively lie the recumbent figures of "Night" and "Day," and "Dawn" and "Dusk."

The "Pietà," or "Deposition," in the museum of the cathedral of Florence dates from around 1550 and may have been intended by Michelangelo for use in his own tomb. The figure of Nicodemus is a self-portrait and indicates Michelangelo's deep religious convictions and his growing concern with religion. His final work, the "Rondanini Pietà" (1552–64), now in the Castello Sforzesco, Milan, is certainly his most personal and most deeply felt expression in sculpture. The artist had almost completely carved the piece when he changed his mind, returned to the block, and drastically reduced the breadth of the figures. He was working on the stone 10 days before he died, and the piece remains unfinished. In its rough state the "Rondanini Pietà" clearly shows that Michelangelo had turned from the rather muscular figure of Christ of his earlier works (as can be seen from the partially detached original right arm) to a more elongated and more dematerialized form.

Followers of Michelangelo

Whether in Rome or Florence, Michelangelo had a strong influence on sculptors of the 16th century. Vincenzo Danti followed closely in Michelangelo's footsteps. His bronze "Julius III" of 1553–56 in Perugia is derived from Michelangelo's lost bronze statue of Julius II for Bologna. Many of his figures in marble are only free variations on themes by Michelangelo. In much the same way, Baccio Bandinelli attempted to rival the monumentality of Michelangelo's "David" and the complexity of his "Victory" in the statue of "Hercules and Cacus" (1534), which was placed as a companion to the "David" in front of the Palazzo Vecchio. Bartolommeo Ammannati should be best known for his design of the bridge of Sta. Trinità in Florence, but his most visible work is the Neptune Fountain (1560–75) in the Piazza della Signoria, with its gigantic figure of Neptune turned toward the "David" in presumptuous rivalry.

Benvenuto Cellini through his celebrated autobiography has left a fuller account of his picturesque life than that of any other artist of the 16th century. He was in Rome from 1519 to 1540 and was one of the defenders of the pope during the siege of the Castel Sant'Angelo. In France from 1540 to 1545, he executed there the celebrated saltcellar for Francis I and the "Nymph of Fontainebleau" (Louvre). The saltcellar is at once an example of 16th-century conspicuous consumption and of Mannerist conceits in art. It is of solid gold, which is covered in part by enamels as though it were a base metal. It was designed for use as a functional object upon the King's table to hold nothing more than common table salt. On his return to Florence in 1545 Cellini received the commission to cast the bronze "Perseus," now in the Loggia dei Lanzi, Florence, which he describes in some detail in his *Autobiography.* The youthful figure of Perseus seems to retain some of the airiness from his flight on the winged sandals of Hermes. He holds aloft the head of the Medusa in an outstretched arm, thus creating an open composition that exploits to the full the potential of the bronze medium. Void is almost as important as solid in this light and airy composition that would have been unthinkable and impossible in marble. Cellini intended the figure to be seen from a variety of viewing points, a relatively new idea in sculpture of this sort, and he leads the observer around by the position of the arms and the legs.

Giambologna

Florentine sculpture at the end of the 16th century was dominated by the Fleming Giambologna and by his shop assistants. Giambologna went to Italy for study shortly after mid-century and settled in Florence in 1557. His earlier major work in Italy is the Fountain of Neptune (1563–66) in Bologna. By early 1565 he had also cast the earliest of his many versions of the bronze "Flying Mercury" that is his most famous creation. The ideas of Cellini's "Perseus" are here carried to their logical conclusion. The god borne along on the air by his winged sandals touches earth only on the slenderest base possible, which is, in fact, represented as a jet of air from the mouth of a wind god. The statue is perfectly balanced according to principles discovered early in the 15th century, yet the outthrust arms and legs give it a feeling of movement and of lightness. Giambologna understood Michelangelo's *figura serpentinata,* the upward spiralling composition, better than any sculptor of the 16th century. His marble group of the "Rape of the Sabines" (1579–83), in the Loggia dei Lanzi, Florence, interweaves three figures in an upward spiralling composition that prefigures the Baroque. Outside Florence, at the present Villa Demidoff in Pratolino, he carved a figure of the Apennines (1581) that seems to be a part of the living rock; it is an excellent example of late Mannerism, in which a paradoxical relationship between art and nature is often cultivated. As the favourite sculptor of the Medici, Giambologna and his prolific shop dominated Florentine sculpture at the end of the 16th century, training artists who were to carry late 16th-century ideas into the rest of Europe and prepare the way for the nascent Baroque. (J.R.Sp./Ed.)

Venetian sculpture

In sculpture, Venice was less independent of Florence and Rome than in painting. The major 16th-century impetus came from Jacopo Sansovino, a central Italian who arrived in Venice in 1527. Sansovino never adopted the full-scale Mannerism of Florence, and his style retained a High Renaissance flavour, but his pupils Danese Cattaneo and Alessandro Vittoria were selectively able to develop the more mannered aspects of Sansovino's style into a Venetian species of Mannerism.

Vittoria stands closer to Florentine style than his contemporaries in painting, particularly in his decorative work, and his small bronzes display a serpentine grace surpassed only by Giambologna in Florence. His marble figures are, however, often more directly expressive than those of Florentine sculptors. His altarpiece for S. Francesco della Vigna (1561–63) conforms with the attenuated canons of Mannerist elegance. In sculpture as in painting, the narrative Venetian style proved to be more easily adaptable to the demands of the Counter-Reformation than the abstract artiness of central Italian Mannerism. The work of Vittoria and of the painter with whom he was most closely associated, Palma il Giovane, seems to anticipate many of the characteristics of Baroque art.

MANNERIST SCULPTURE OUTSIDE ITALY

In the north of Europe, Giambologna's influence was paramount. Both Hubert Gerhart and Adriaan de Vries, the leading exponents of northern Mannerist sculpture, can be considered as followers of the expatriate Fleming. Gerhart worked (1583–94) for Hans Fugger at Kirchheim, Augsburg, and at Amsterdam under de Sustris, and for the archduke Maximilian I of Bavaria, at whose court he produced bronze figures of considerable accomplishment (1598–1613). De Vries joined Bartholomaeus Spranger in 1601 at Rudolf's court in Prague. His "Psyche with Three Cupids" (Nationalmuseum, Stockholm) is a characteristic example of his stylishness—a wonderful satin finish, spiralling complexity, and a soaring grace reminiscent of Giambologna's "Mercury" (Figure 60).

J.E. Bulloz

As in painting, France owed its early acquisition of Mannerist sculptural style to Italian artists at Fontainebleau, to Primaticcio's stucco style, and to Cellini. Jean Goujon began from this point of inspiration, and his decorations for the "Fountain of the Innocents" at the Louvre (1547–49) possess a sophisticated refinement *all'antica* unequalled by any non-Italian artist of the period (Figure 61).

The influence of Primaticcio's suave stucco decorations is even more apparent in the early work of the other great French sculptor of the century, Germain Pilon. This is not surprising since his elegant "Monument for the Heart of Henry II" was probably completed under Primaticcio's supervision. His statues for Primaticcio's Tomb of Henry II, however, show him moving toward greater naturalism and expressiveness. In his later works Pilon achieved a freedom of plasticity and feeling for texture that anticipated Baroque developments.

Spanish Renaissance sculpture at first relied heavily upon visiting Italians, led by Andrea Sansovino, but with the advent of Ordóñez, Diego de Siloé, and the painter-sculptors Machuca and Beruguete, a native Spanish school of Mannerism was formed. Like his father (the painter Pedro), Alonso Beruguete studied in Italy. On his return to Spain about 1517, he began to develop an elaborately pictorial style in sculptural complexes of great originality. The fluid quality of his designs reaches its peak in the surging motions of the "Transfiguration Altar" (1543–48) for Toledo cathedral. Beruguete's greatest successor at Valladolid was Pompeo Leoni, who collaborated with his father, Leone, on portraits of Charles V, composed in a disciplined and sternly Roman style, quite different from the expressive fluency of native Spanish sculpture that reemerged at the turn of the century in the few sculptures of polychromed wood by El Greco. (M.J.Ke.)

The Baroque period

ITALY

Early and High Baroque. At the beginning of the 17th century, sculpture in all of Italy, with the exception of Florence, was at a low ebb; and the dry, frankly propagandist nature of the decoration of the Borghese and Sistine chapels in Sta. Maria Maggiore, Rome, reveals this only

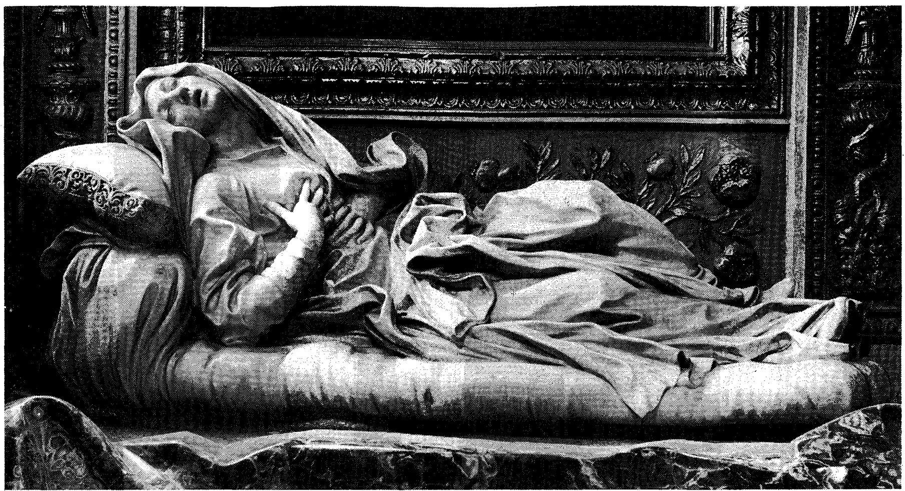

Figure 62: "Ludovica Albertoni," marble effigy by Gian Lorenzo Bernini, *c.* 1674. In the Altieri Chapel, S. Francesco a Ripa, Rome.
Anderson—Alinari from Art Resource/EB Inc.

too clearly. With Stefano Maderno and Camillo Mariani a slightly more imaginative interpretation of the demands of the Council of Trent is to be found, while certain aspects of the work of Pietro Bernini (1562–1629) were to have considerable influence on his son Gian Lorenzo. The first breath of the new Baroque spirit, however, is to be found in the immense vitality of the equestrian monuments in Piacenza (1612–25) by Francesco Mochi; and a comparable fiery vigour is the keynote of the fresco "Aurora" by Guercino in the Casino Ludovisi, Rome (1621–23). The forms are pierced and opened up, and the momentary, unstable poses, with draperies fluttering and tails lashing, give a vivid movement that releases the figures from the Mannerist spell.

No field was more congenial to the spirit of Baroque art than sculpture carried out on a conspicuous scale. The Baroque artist achieved dramatic pictorial unity by abolishing the traditional limits separating painting, sculpture, and architecture. The solid masses of sculpture and even of architecture were made to move in space by means of such motive forms as undulations; sculpture was transformed by such painter's devices as richly varied illusionistic textures, coloured materials, and irregularly dappling light effects.

The genius of Bernini

Gian Lorenzo Bernini, the greatest sculptor of the 17th and 18th centuries, established the sculptural principles for those two centuries in a series of youthful works of unrivalled virtuosity, as the "Apollo and Daphne." Stone was now completely emancipated from stoniness by open form and by an astonishing illusion of flesh, hair, cloth, and other textures, pictorial effects that had earlier been attempted only in painting. These qualities made what his contemporaries called his "speaking portraits" seem unprecedentedly alive; portrait sculpture for two centuries was a variation of these innovations. In the statue of St. Longinus in St. Peter's in Rome, Bernini created the characteristic formula of Baroque sculpture by throwing the draperies into a violent turmoil, the complicated and broken involutions of which are not rationally explained by the figure's real bodily movement but seem paroxysmally informed by the miracle itself. The passion with which he imbued his sculptured figures, capturing the most transitory states of mind, reached its apogee in the representation of the ecstasy of St. Teresa in the Cornaro Chapel, Sta. Maria della Vittoria, Rome (1645–52) and in the figure of the expiring Ludovica Albertoni (Figure 62) in the Altieri Chapel, S. Francesco a Ripa, Rome (*c.* 1674). The former is generally considered the masterpiece of Baroque religious sculpture and shows how Bernini could organize the arts of architecture, painting, and sculpture in an overwhelming assault on the senses that dispels the resistance of the intellect. This ambitious plan was typical of the mature Bernini, whose spiritual and artistic aspirations exceeded the scope of his early secular salon statues. His later works were largely religious and unprecedentedly vast in scale, as in the dazzling "Cathedra Petri," which covers the whole end of St. Peter's in Rome with a teeming multitude of figures.

The tombs of Bernini are magnificent spectacles in which symbolic figures, clothed in sweeping draperies, with rhetorical gesture and expressive features, share in some emotional experience, theatrically depicted. An example is the tomb of Alexander VII in St. Peter's, Rome. The pontiff, set in a great apse, kneels on a high pedestal about which Charity, Truth, Justice, and Wisdom weep disconsolately while Death, a skeleton, raises the great draperies of polychrome and gold that veil a darkened doorway. Another work, the fountain of the Triton in the Piazza Barberini, Rome, from which all clarity of profile or of shadow, all definiteness of plane, are removed, is also characteristic of Bernini's style, widely imitated throughout Europe.

Bernini's art was the basis of all Baroque sculpture, but his example was not always followed, and the work of his more restrained contemporaries, such as Alessandro Algardi (relief of "Meeting of Attila and Pope Leo," 1646–53, St. Peter's, Rome) and the Fleming François Duquesnoy, attracted more approval from theorists of art. The

latter's "St. Susanna" in Sta. Maria di Loreto in Rome, a figure after the antique but enlivened with Berninian textures, was originally made to look toward the observer and, with a gesture, to direct his attention to the altar. The distinction between art and life that the Mannerists had cultivated was banished by this active participation of the statue in the viewer's space and activities, another important innovation of Bernini.

Late Baroque. In late 17th-century painting, composition became increasingly decorative rather than structural, and there was a loosening of design in the individual figures as well. This dissolution is also to be found in sculpture of the period, such as in the proto-Rococo figures of Filippo Carcani (active 1670–90) in Rome and, to a lesser extent, in those of Filippo Parodi (1630–1702) in Genoa, Venice, and Naples. Outside Venice and Sicily the true Rococo made little headway in Italy.

A more or less classical late Baroque style, best exemplified by the heroic works of Camillo Rusconi in Rome, was dominant in central Italy through the middle of the 18th century. Rusconi's work had considerable influence outside Italy as well.

The latter half of the century saw the emergence of a much lighter and more theatrical manner in the works of Agostino Cornacchini and of Pietro Bracci, whose allegorical figure "Ocean" on the Fontana di Trevi by Niccolò Salvi (completed 1762) is almost a parody of Bernini's sculpture. Filippo della Valle worked in a classicizing style of almost French sensibility, but the majority of Italian sculpture of the mid-18th century became increasingly picturesque with a strong tendency toward technical virtuosity. Complex sculptured groups designed by Luigi Vanvitelli for the park of the palace at Caserta (*c.* 1770) are almost *tableaux vivants* ("living pictures") in a landscape setting, while the Cappella Sansevero de' Sangri in nearby Naples (decorated 1749–66) is one of the most important sculptured complexes of the time. Allegorical groups by Antonio Corradini and Francesco Queirolo vie with each other in virtuosity and include such conceits as fishnets cut from solid marble and the all-revealing shrouds developed by Giuseppe Sammartino. Florentine sculpture of the 18th century is less spectacular, and Giovanni Battista Foggini took back from Rome the compromise style of Ferrarza, while Massimiliano Soldani-Benzi seems to have been instrumental in the brilliant revival there of small-scale bronze statuettes. Giovanni Marchiori worked in Venice with an attractive painterly style, in part based on the wood carvings of Andrea Brustolon; and Giovanni

Maria Morlaiter ran the full gamut to a late 18th-century classicism close to the early works of the great Neoclassical sculptor Antonio Canova.

BAROQUE AND ROCOCO OUTSIDE ITALY

Spain. Spanish sculpture of the 17th and 18th centuries exhibits a greater continuity with late Gothic art than does the painting; and the Counter-Reformation demands for realism and an emotional stimulus to piety led to sculpture with glass eyes, human hair, and even real fabric costumes. Italian Renaissance sculpture had made a very limited impact in Spain, and with few exceptions this was in the court ambience only, while Spanish Baroque sculpture is almost entirely religious and of a fundamentally popular nature. Gregorio Hernández in sculptures like the "Pieta" (1617; Museo Nacional de Esculturas, Valladolid, Spain) revealed an emotional realism more Gothic than Baroque (Figure 65); but in the figures of Manuel Pereira there is a clear-cut monumentality and intense concentration comparable to that of Zurbarán. Both were active in Castile, though the main centre of sculptural activity was Seville and Granada, with Juan Martínez Montañés as the dominant personality. The intense realism and deep spirituality of his figures were followed by his pupil Alonso Cano; but in the figures of Cano's pupil Pedro de Mena, his simple monumentality is replaced by a more picturesque and theatrical gracefulness. José de Mora, also a pupil of Cano, took this process even further. But in general the 18th century saw a sad decline in Spanish sculpture.

Realism and emotionalism of religious sculpture

Flanders. In comparison with painting, the sculpture of the 17th century in the southern provinces is extremely disappointing. The Flemish sculptor François Duquesnoy spent almost all of his career in Rome, while those who remained in Flanders, such as his brother Hieronymus Duquesnoy the Younger, were mostly secondary artists influenced by Rubens. Artus Quellinus the Elder reveals a much more individual style, particularly in his decorations for the Town Hall in Amsterdam, and the tendency toward a painterly style is more pronounced in the work of his son Artus Quellinus the Younger, Rombout Verhulst, and Lucas Faydherbe.

Decline of Antwerp in the late 17th century

The end of the Twelve Years' Truce in 1621 had brought back Antwerp's old troubles, and the control of the Scheldt by the United Provinces was confirmed by the Peace of Westphalia (1648). Economic depression and French aggression in the second half of the 17th century combined to make the southern provinces increasingly provincial, while under the provisions of the Treaty of Utrecht (1713) and the Treaty of Rastatt (1714) the territories passed to Austria. Eighteenth-century painting and sculpture became increasingly weak and provincial, though fantastic pulpits carved by Hendrik Frans Verbruggen, Michel Vervoort, and Theodor Verhaegen provide a remarkable parallel to those in central Europe.

France. Duquesnoy was much admired in France, where the sculptors of Louis XIV (the "Sun King"), such as François Girardon, continued his tradition of setting correct and charming allusions to the antique in a pictorial and spatial context that is wholly Baroque. Girardon's tomb of the Cardinal de Richelieu, in the church of the Sorbonne, Paris, is illustrative of the Baroque monuments of France, calmer and more conservative than those of Italy. The dying cardinal, lying on his sarcophagus and originally gesturing in supplication toward the altar, is upheld by Religion and mourned by Science. The three figures, united by the lines of skillfully arranged draperies, are informed by a solemn and touching sentiment. The academic discipline imposed by the Sun King's ministers, especially Colbert, discouraged less tractable spirits, such as the passionate genius Pierre Puget. His unique expressions of anguish are couched in the physical terms of highly original works like the "Milo of Crotona"; here the composition of a figure rigid with pain is given an almost unbearable tension.

Antoine Coysevox, another of the sculptors of Louis XIV, had begun in the official "academic Baroque" style, but his later works, undertaken after the death of Colbert, are witnesses of the gradual acceptance of the Baroque in France, which now acquired the artistic leadership that Italy had long held over the rest of Europe. At the same time, the style was made lighter, gayer, and more ornamental, in accordance with 18th-century taste, as seen in the famous "Chevaux de Marly" by Guillaume Coustou now marking the entrance to the Champs-Élysées in Paris but designed for Marly, as part of the most innovative outdoor display of sculpture since the 16th-century gardens of Italy. Coustou's bust of his brother Nicolas has a characteristic freshness and informality whereby 18th-century artists avoided the grandeur they found pompous in the Berninian tradition.

This 18th-century style that reduced the Baroque to exquisite refinement was the art of the aristocratic salon and boudoir. The little marble "Mercure" (1741) of Jean-Baptiste Pigalle is almost wholly Berninian, except in its intimacy and deliberate unpretentiousness; even in Pigalle's most ambitious undertakings, the relative scale of the figures is much reduced and the whole composition opened up, in contrast to Bernini's tombs. Nevertheless, the narrative and indeed the allegory of his masterpiece, the tomb of the Maréchal de Saxe (1753; Saint-Thomas, Strasbourg), is as enthralling and memorable as any 17th-century sculpture, although the theme, significantly, no longer seems to be inspired by the Christian faith. At the same time, the more classical current of French sculpture continued and gained importance as the 18th century advanced. The clarified form and continuous, unbroken contours of Étienne-Maurice Falconet's marble "Bather" (1757) adapt the Classic tradition to a pretty and intimate Rococo ideal that is the quintessence of 18th-century taste. This Classicism was purified by Jean-Antoine Houdon, who avoided the playful air of the Rococo boudoir in his "Diana" (*c.* 1777) and his marble nude in the Metropolitan Museum of Art, New York City (1782). His portrait sculptures are the ultimate in the 18th-century refinement of Bernini's tradition.

Jean-Antoine Houdon

In the context of the rather restrained French sculpture of the 18th century, the blatant sensuality of Clodion (byname of Claude Michel) is the exception rather than the rule (Figure 66). Portrait busts by Jean-Baptiste Lemoyne and Pigalle follow the direction taken by Coysevox in his "Robert de Cotte," but Augustin Pajou and Houdon

soon abandoned the Rococo in favour of a Neoclassical approach. Edme Bouchardon, however, flirted only briefly with the Rococo and otherwise remained firmly attached to the classicizing tradition of French sculpture.

England. English sculpture of the early 17th century was very provincial, with Nicholas Stone and Edward Marshall the only English-born sculptors to rise above the general level of mediocrity. Their styles were based on contemporary Netherlandish sculpture with small admixtures of Italian influence; and after 1660 the uncomprehending borrowings of John Bushnell from Bernini serve only to make his figures look ludicrous. The most distinguished English-born sculptor of the second half of the 17th century was Edward Pierce, in whose rare busts is to be found something of Bernini's vigour and intensity. But the general run of English sculpture as represented by Francis Bird, Edward Stanton, and even the internationally renowned woodcarver Grinling Gibbons remained unexceptional. It was not until John Michael Rysbrack from Antwerp settled in England in *c.* 1720, followed by the Frenchman Louis-François Roubillac in *c.* 1732, that two sculptors of European stature were active in England. The busts and tombs of Rysbrack and Roubillac have a power and vitality previously unknown in English sculpture; they were responsible for the revival that took place in the 18th century.

Central Europe. While the influence of Giambologna persisted in some quarters, Hans Krumper and Hans Reichle produced bronze figures less indebted to the Classical tradition but with stronger individuality. Jörg Zürn, whose finest wood carvings are to be seen at Überlingen, and Ludwig Münsterman, in Oldenburg, continued in the Mannerist style, whereas Georg Petel, who came under the influence of Rubens, is almost the only sculptor to reveal the impact of the Baroque. Petel's importance lies mainly in his ivories, and Leonard Kern in Franconia developed a similar Rubensian style for his small statuettes.

Influence of Bernini

Painting and sculpture recovered slowly from the ravages of the Thirty Years' War, and some of the earliest reflections of the high Baroque of Bernini are to be found in the sculpture of Matthias Rauchmiller at Trier (1675) and Legnica (Liegnitz) in Silesia (1677).

Among sculptors in Austria the forces of Classicism were stronger; and the weak north Italian late Baroque styles of Giovanni Giuliani and Lorenzo Mattielli were supplanted by the cool elegance and classical refinement of Georg Raphael Donner. His preference for the soft sheen of lead gave Austrian Baroque sculpture one of its most distinctive features.

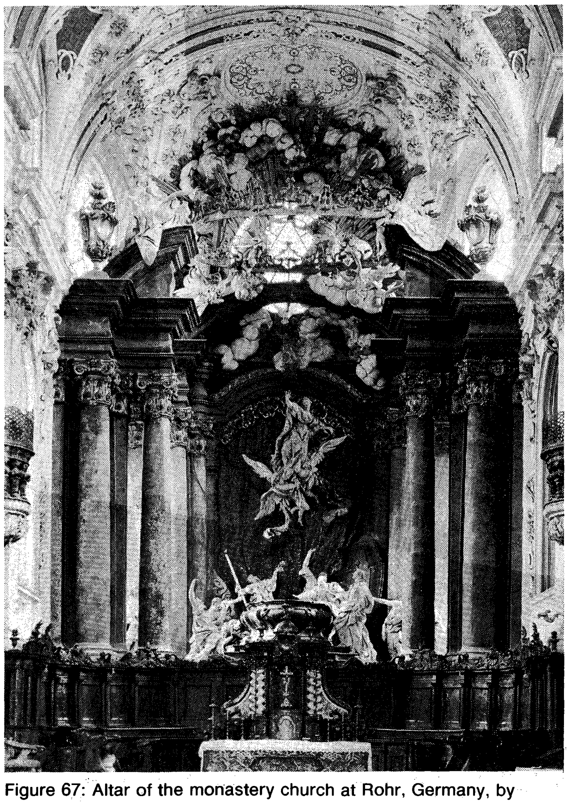

Figure 67: Altar of the monastery church at Rohr, Germany, by Cosmas Damian Asam and Egid Quirin Asam, 1718–25.

During the first four decades of the 18th century, Bohemian Baroque art developed almost independently of Vienna. The brilliant rugged stone sculptures of Matyás Bernard Braun and Ferdinand Maximilián Brokoff, with their dynamism and expressive gestures, were truly Bohemian in spirit.

Bavarian Baroque art in the hands of the brothers Egid Quirin Asam and Cosmas Damian Asam was almost entirely confined to churches, and their brilliant development of the theatrical illusionism of Bernini is achieved in the high altar (Figure 67) of the monastery church at Rohr, in Germany (1718–25), and in St. John Nepomuk in Munich (begun 1733). Cosmas Damian's style as a painter was influenced by Rottmayr as well as by the Italian masters whom he studied during his stay in Italy (1711–14), while the sculptural style of Egid Quirin was formed on the south German tradition of wood carving, as well as on Bernini.

The Saxon school

In Upper Saxony there was also a native tradition before the arrival of Permoser, represented by the heavy figures of Georg Heermann and Konrad Max Süssner, both of whom had been active in Prague in the 1680s. Balthasar Permoser was trained in Florence under Foggini, whence he was summoned to Dresden in 1689. His painterly conception of sculpture, derived from Bernini, is revealed in the complex "Apotheosis of Prince Eugene" (1721; Österreichische Galerie, Vienna) and above all in the sculptural decoration of the Zwinger in Dresden initiated during the second decade. Paul Egell was a pupil of Permoser in Dresden at the time of the Zwinger decorations, and in 1721 he was appointed court sculptor at Mannheim. Egell's elongated and refined Baroque figures were an effective counter to the Classicism of Donner, and his personality was decisive in Franconia and the Palatinate during the first half of the century.

Berlin under the Great Elector of Brandenburg had become an increasingly important centre, both politically and artistically; and the full-bodied Baroque style of Andreas Schlüter, as revealed by his equestrian monument to the Great Elector (1696–1708), now at Charlottenburg, was fully in sympathy with the time.

The Rococo style in Bavaria

No hard and fast division can be made between the Baroque and the Rococo in central and eastern Europe, either chronologically or stylistically. The first Rococo decorative ensembles in Germany, the Reiche Zimmer of the Residenz in Munich, were built by the Frenchman François de Cuvilliés in 1730–37, but in painting and sculpture the situation is more complicated. Ignaz Günther, the greatest south German sculptor of the 18th century, was trained under Johann Baptist Straub; the elongated forms of Egell's sculpture at Mannheim, however, deeply impressed him, and his development was toward an almost Mannerist grace and refinement. Günther was capable of the most extraordinarily sensitive characterization of surfaces, even when painted white; and this he combined with an interpretation of character comparable to the late Gothic sculptors, thus giving his figures a realism and immediacy that is almost uncanny. Apart from their lightness and vivacity, however, it is the figures' relationship to the altars on which they are placed that reveals their Rococo quality. Gone are the great coordinated ensembles of the Asams, and instead each figure has a totally separate existence of its own and a balance is only to be found when the church interior is taken as a whole.

Johann Michael Feichtmayr

Swabian sculpture of the period is characterized by the extremely successful partnerships between the sculptors and stucco artists. For Zwiefalten and Ottobeuren Joseph Christian provided the models from which Johann Michael Feichtmayr created the superb series of larger than life-size saints and angels that are the glory of these Rococo interiors. Feichtmayr was a member of the group of families from Wessobrunn in southern Bavaria that specialized in stucco work and produced a long series

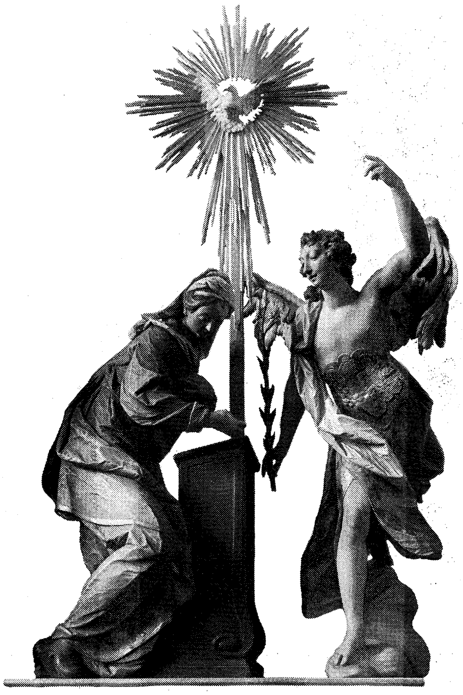

Figure 68: "The Annunciation," painted wood sculpture by Ignaz Günther, 1764. In the abbey church at Weyarn, Bavaria.

Bildarchiv Foto Marburg/Art Resource, NY

of masters, including Johann Georg Übelherr and Joseph Anton Feuchtmayer, whose masterpieces are the Rococo figures at Birnau on Lake Constance. The sculptor Christian Wenzinger worked at Freiburg im Breisgau in relative isolation, but his softly modelled figures have a delicacy that recalls the paintings of Boucher.

Until his death Johann Wolfgang van der Auvera was the most powerful personality in the field of sculpture in the area, but later Ferdinand Dietz at Bamberg pursued an increasingly individual Rococo style that often parodied the growing taste for Neoclassicism. Prussian Rococo sculpture was less distinguished, though the decorations of Johann August Nahl are among the most imaginative in Germany.

Austrian sculpture of the later 18th century, as represented by Balthasar Ferdinand Moll, inclined more toward a realistic Rococo style than to the Classicism of Donner; and, although the strange, neurotic genius Franz Xavier Messerschmidt began in this style, at the end of his career he produced a startling series of grimacing heads when he lived as a recluse in Bratislava.

Russia. The Baroque style as it was imported to Russia from western Europe by the imperial court never amounted to what might properly be termed a Russian Baroque period. A great influx of Western influence during this period, especially under the sponsorship of Peter the Great, did, however, dispel the predominance of Byzantine ideas and forms. The brilliant Baroque busts of Bartolomeo Carlo Rastrelli the Younger established during the early 18th century a distinguished tradition of Russian portrait sculpture that was maintained by Fedot Shubin. The parks and gardens of the Rococo palaces of the empress Elizabeth were adorned with sculpture, but the work was done almost exclusively by Italians and Frenchmen commissioned for the task.

Latin America. With the coming of Europeans to Central and South America, indigenous symbolism and sculptural forms blended with Renaissance realism, Baroque elegance, and subsequent stylistic currents. Indian traits appeared in such European-introduced sculptural forms as the stone crosses that were erected in churchyards; statues, whether by European sculpture or aboriginal pupils, depicted Jesus, the Virgin Mary, saints, and occasionally an earthly benefactor of the church. Materials were of wood, plant fibre pulp coated with canvas and gesso, or plaster. The statues often had real costumes and hair, glass eyes and teeth, and extremely realistic flesh—bloody, bruised, and torn—with taut muscles and distended veins. Gold halos or crowns were added and costume textures were imitated by the gold-leaf-and-paint estofado technique. Many of these were undoubtedly inspired by paintings brought from Europe.

Few sculptors are known by name from the colonial period and fewer attributions are possible. At least a dozen individuals can be identified in Mexico in the 16th century, however, and twice that number in the 17th; the best known are José Cora of Puebla and his nephew Zacarias, and Gudiño of Querétaro. Many were both sculptors and architects, a necessity of the times. In the 18th century considerable artistic stimulus was provided by the Spanish-born Neoclassicist Manuel Tolsa, first director of the Academy in Mexico City, first to produce an equestrian statue in the New World (of Charles IV), and teacher of many sculptors of subsequent fame. The second most important artistic centre of the colonial era was Quito, Ecuador, which was known particularly for its decorative sculpture.

The sculpture is marginally less provincial than the paintings, and, for example, the choir stalls carved by Pedro de Noguera and his assistants for Lima cathedral (1624–26) are of distinguished quality. The Baroque tradition tended to last until well into the 19th century in sculptures such as the robust figures of Antônio Francisco Lisboa (*e.g.*, "O Aleijadinho," or "The Little Cripple"), the greatest sculptor that Brazil has produced.

(P.C.-B./J.Hud./J.Hm./A.Vo./C.I.C./Ed.)

Neoclassical and Romantic sculpture

NEOCLASSICISM

The 18th-century arts movement known as Neoclassicism represents both a reaction against the last phase of the Baroque and, perhaps more importantly, a reflection of the burgeoning scientific interest in classical antiquity. Archaeological investigations of the classical Mediterranean world offered to the 18th-century cognoscenti compelling witness to the order and serenity of Classical art and provided a fitting backdrop to the Enlightenment and the Age of Reason. Newly discovered antique forms and themes were quick to find new expression.

The successful excavations contributed to the rapid growth of collections of antique sculptures. Foreign visitors to Italy exported countless marbles to all parts of Europe or employed agents to build up their collections. The accessibility of the sculpture of antiquity, in museums and private houses and also through engravings and plaster casts, had a far-reaching formative influence on 18th-century painting and sculpture. The great majority of ancient sculptures collected were Roman, although many of them were copied from Greek originals and were believed to be Greek.

In the writing of Johann Joachim Winckelmann, the great German historian of ancient art, Greek art had been considered immeasurably superior to Roman. It is curious, however, how little positive influence the marbles that Lord Elgin took to England from the Parthenon in Athens had on sculpture in western Europe, although they had a great influence on scholars. The ideals of Neoclassical sculpture—its emphasis on clarity of contour, on the plain ground, on not rivalling painting either in the imitation of aerial or linear perspective in relief or of flying hair and fluttering drapery in freestanding figures—were chiefly inspired by theory and by Roman neo-Attic works, or indeed by Roman pseudo-Archaic art. The latter class of art exerted an influence on John Flaxman, who was enormously admired for the severe style of his engravings and relief carvings.

"Decorum" and idealization. Academic theorists, especially those of France and Italy during the 17th century, argued that the costume, details, and setting of a work be as accurate as possible when representing a period and place in the historical past. The 18th century and, in particular, the Neoclassicists inherited this theory of "decorum" and, enabled by all the newly available archae-

ological evidence, implemented it more fully than had any of their precursors.

Question of the use of Classical or contemporary dress

A series of monuments to 18th- and early 19th-century generals and admirals of the Napoleonic Wars in St. Paul's Cathedral and Westminster Abbey demonstrate an important Neoclassical problem: whether a hero or famous person should be portrayed in Classical or contemporary costume. Many sculptors varied between showing the figures in uniform and showing them completely naked. The concept of the modern hero in antique dress belongs to the tradition of academic theory, exemplified by the English painter Sir Joshua Reynolds in one of his Royal Academy *Discourses:* "The desire for transmitting to posterity the shape of modern dress must be acknowledged to be purchased at a prodigious price, even the price of everything that is valuable in art." Even the living hero could be idealized completely naked, as in two colossal standing figures of Napoleon (1808–11; Apsley House, London, and Brera, Milan) by the Italian sculptor Antonio Canova. One of the most famous of Neoclassical sculptures is Canova's "Paolina Borghese as Venus Victrix" (1805–07; Borghese Gallery, Rome). She is shown naked, lightly draped, and reclining sensuously on a couch, both a charming contemporary portrait and an idealized antique Venus (Figure 69).

Relation to the Baroque and the Rococo. Classical academic theories circulating in the Renaissance, and especially in the 17th century, favoured the antique and those artists who followed in this tradition. The artists praised included Raphael, Michelangelo, Giulio Romano, and Annibale Carracci. The slightly later generation of writers added the name of the French painter Nicolas Poussin to the list. The exuberance and "fury" of the Baroque must be avoided, it was argued, because they led to "barbarous" and "wicked" works. Continuing in this tradition, Winckelmann, for example, argued that the Italian Baroque sculptor and architect Bernini had been "misled" by following nature.

Anti-Baroque feeling

Such hostility to Baroque works, however, did not immediately eradicate their influence on 18th-century artists, as can be seen, for example, in an early work by Canova, "Daedalus and Icarus" (1779; Museo Civico Correr, Venice), executed before he had been to Rome. In Canova's tomb of Pope Clement XIV (1784–87; SS. Apostoli, Rome), the Pope, seated on a throne above a sarcophagus, is treated in a dramatically realistic style with hand raised in a forceful gesture reminiscent of papal tombs of the 17th century.

Rococo influence

Although the Neoclassical artists and writers expressed contempt for what they regarded as the frivolous aspect of the Rococo, there is a strong influence of French Rococo on the early style of some of the Neoclassical sculptors. Étienne-Maurice Falconet, Flaxman, and Canova all started to carve and model with Rococo tendencies, which were then gradually transformed into more Classical elements.

Hostile critics of Neoclassical sculpture have tended to compare such works to "a valley of dry bones." Some artists misunderstood the advocacy of Winckelmann and his school to imitate ancient art. Winckelmann meant—as did 17th-century theorists before him, and writers such as Shaftesbury and Jonathan Richardson, who influenced him considerably—imitation to be a means of discovering ideal beauty and conveying the spirit of the original. He did not advocate servile copying of the antique. Unfortunately, spiritless copies were made, and these led to a proliferation of the Neoclassical style and its classification as "frigid." In sculpture some of the important commissions

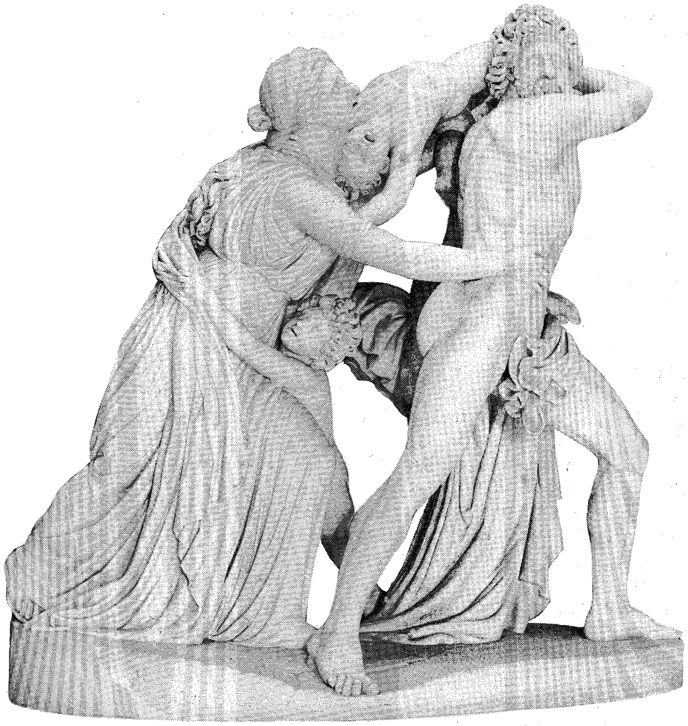

Figure 71: "Fury of Athamas," marble sculpture by John Flaxman, 1790–92. In Ickworth, Suffolk.

A.F. Kersting

regrettably resulted in this lifeless concept of Neoclassicism. Among the examples are large marbles of Christ (Figure 70), John the Baptist, and the Apostles by the Danish sculptor Bertel Thorvaldsen in the Church of Our Lady, Copenhagen (1821–27 and 1842). Thorvaldsen's marbles, unlike Canova's, lose little when seen only as plaster casts, and indeed the surface of the sculpture was deliberately left neutral and the act of carving left to others.

Classical serenity and restraint

Gestures and emotions in Neoclassical works are usually restrained. In bacchanalian scenes the gaiety is held in check, never bursting into exuberance. In a tragic scene, Andromache does not shed a tear as she mourns the death of Hector. When Flaxman did attempt terror, as in the marble "Fury of Athamas" (1790–92; Ickworth, Suffolk), the violence is forced and unconvincing (Figure 71). Indeed, there hardly exists in any Neoclassical sculptor's work a convincing image of rage. The concept of antique calmness permeated European art. Canova with his "Hercules and Lichas" (1796; Galleria Nazionale d'Arte Moderna, Rome) produced a large marble of exaggerated expression beyond his normal range and to some extent beyond his abilities. Like Flaxman, he was far more successful when carving images of delicacy, bordering on charm.

Prominent early British Neoclassicist sculptors included John Wilton, Joseph Nollekens, John Bacon the Elder, John Deare, and Christopher Hewetson, the last two working mostly in Rome. The leading artist of the younger generation was John Flaxman, professor of sculpture at the Royal Academy and one of the few British artists of the period with an international reputation. The last generation of Neoclassicists included the sculptors Sir Richard Westmacott, John Bacon the Younger, Sir Francis Chantrey, Edward Hodges Baily, John Gibson, and William Behnes.

While Neoclassicism in France was dominated by painting and architecture, the movement did find a number of notable exponents in sculpture. These included Claude Michel, called Clodion, creator of many small Classical figures, especially nymphs; Augustin Pajou; and Pierre Julien. Pigalle's pupil Jean-Antoine Houdon was the most famous 18th-century French sculptor, producing many Classical figures and contemporary portraits in the manner of antique busts. Other contemporary sculptors included Louis-Simon Boizot and Étienne-Maurice Falconet, who was director of sculpture at the Sèvres factory. The slightly younger generation included the sculptors Joseph Chinard, Joseph-Charles Marin, Antoine-Denis Chaudet, and Baron François-Joseph Bosio. The early sculpture of Ingres's well-known contemporary François Rude was Neoclassical.

Important among central European sculptors early in the period was Johann Heinrich von Dannecker. Subsequent Neoclassicists included Johann Gottfried Schadow, who was also a painter but is better known as a sculptor; his pupil, the sculptor Christian Friedrich Tieck; the painter and sculptor Martin von Wagner; and the sculptor Christian Daniel Rauch.

Canova

The most important Italian Neoclassicist was Antonio Canova, the leading sculptor, indeed by far the most famous artist of any sort, in Europe by the end of the 18th century. Canova's position in the following 20 years may be compared only with that enjoyed by Bernini in the 17th century. The differences between their careers, however, are of great importance. Only at the commencement of his career did Bernini carve gallery sculpture for princely collectors, but the majority of Canova's works belong to this category. Both artists remained resident for most of their life in Rome, but whereas Bernini was controlled by the popes and only rarely permitted to work for foreign potentates, Canova's principal patrons were foreigners, and he supplied sculpture to all the courts of Europe. A fine sculptor of varying styles, including austere, sentimental, and horrific, Canova produced an extensive body of work that includes Classical groups and friezes, tombs, and portraits, many in antique dress. He was also a painter, regrettably bad. His pupil and collaborator, Antonio d'Este, is one of the more interesting of the lesser Italian Neoclassical sculptors. Other Neoclassical sculptors in Rome included Giuseppe Angelini, best known for the tomb of the etcher and architect Giambattista Piranesi in the church of Sta. Maria del Priorato, Rome.

In Milan, Camillo Pacetti directed the sculptural decoration of the Arco della Pace. The work of Gaetano Monti, born in Ravenna, can be seen in many northern Italian churches. The Tuscan sculptor Lorenzo Bartolini executed some important Napoleonic commissions. The "Charity" (Pitti Palace, Florence) is one of the more famous examples of his later Neoclassicism. It should be noted, however, that he did not see himself as a Neoclassical artist and that he challenged the idealism that was favoured by Canova and his followers.

The Swede Johan Tobias Sergel, court sculptor to the Swedish king Gustav III, and the Dane Bertel Thorvaldsen, who lived most of his life in Rome, were among the best known Neoclassical sculptors in Europe. Thorvaldsen was the chief rival to Canova and eventually replaced him in critical favour. His work was more severe, sometimes even archaizing in character, and his religious sculpture, most notably his great figure of Christ in the Church of Our Lady in Copenhagen, exhibits a deliberately chilling, sublime style that still awaits sympathetic reassessment. Among his more notable pupils was the Swedish sculptor Johan Byström.

The principal Neoclassicists in Spain were the painter José de Madrazo y Agudo and the sculptor José Alvarez de Pereira y Cubero.

Both leading Russian Neoclassicists were sculptors. Ivan Petrovich Martos studied under Mengs, Thorvaldsen, and Batoni in Rome and became a director of the St. Petersburg Academy. His best works are tombs. Mikhail Kozlovskij contributed to the decoration of the throne room at Pavlovsk.

Apart from the painter Benjamin West, who worked almost entirely in London, the leading Neoclassicists among American artists were sculptors. William Rush produced standing Classical figures including those formerly decorating a waterworks in Philadelphia (now in the Pennsylvania Academy of Fine Arts). In the middle years of the 19th century there came into prominence four sculptors: Horatio Greenough, who executed several government commissions in Washington, D.C.; Hiram Powers, known particularly for his portrait busts; Thomas Crawford, who did monumental sculpture; and William Wetmore Story,

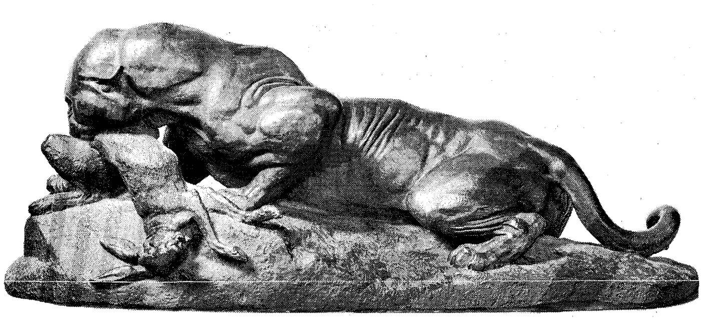

Figure 72: "Jaguar Devouring a Hare," bronze sculpture by Antoine-Louis Barye, 1850–51. In the Louvre, Paris. 41.9 cm × 95.2 cm.

Alinari—Art Resource/EB Inc.

who lived and worked in Rome, where he was associated with several other prominent 19th-century Americans.

(D.I.)

19TH-CENTURY SCULPTURE

In the 19th century sculptors throughout the Western world were affected in an unprecedented way by the great public annual exhibitions organized by the Academies. Great patrons at court or among the nobility could still play a very important part in making an artist's reputation, but publicity from these exhibitions was crucial. Among examples of sculptures that attracted sensational publicity of this sort are François Rude's "Neapolitan Fisherboy" (1834; Louvre), Hiram Powers' "Greek Slave" (1843), Auguste Clésinger's "Woman Bitten by a Snake" (1847; Louvre), and Randolf Rogers' "Nydia the Blind Girl" (1858).

In all these sculptures except the last the subject is more or less nude. In all except the first there is a strong narrative interest. In these respects they resemble the prize pieces set by the French Royal Academy of Painting and Sculpture and by its numerous imitators. Unlike those prize pieces, however, these works drew for their subjects not upon Greek or Roman mythology or history: Nydia is a Roman girl but taken from a modern novel about Pompeii, and the Greek slave is a contemporary Christian girl taken captive by the Turks. The old clichés about "academic" sculpture in the 19th century are hopelessly inadequate. The Academies in their educational program often encouraged a heroic but restrained Neoclassicism—their exhibitions, on the other hand, encouraged an appeal to novelty, to sentiment, and to sensationalism (often of an unfortunate kind), involving subjects from modern life and modern literature.

The exhibition piece was often a plaster cast of the original clay model. Several versions in marble or bronze were then made if there was the demand. These would be acquired for the sculpture galleries, conservatories, or gardens of great collectors, as well as for museums, which, for the first time, included collections of modern art. In reduced form they might also make an appearance amid the crowded furnishings of fashionable drawing rooms. Upon the chimneypiece perhaps some miniature scene of jungle violence modelled by Barye and cast in bronze might be displayed, while behind the ferns a marble nude would shrink in vain from male scrutiny.

The proliferation of domestic sculpture was made possible by a series of technical innovations chiefly associated with Paris. Improved reducing machines greatly facilitated the half-size replication of exhibition pieces, and the reproduction of such works on a still smaller scale as bronze statuettes; new methods of sand-casting meant that these bronzes were also available in larger editions and at a lower cost. The reproduction of terra-cotta sculpture also thrived in Paris as it had done in the late 18th century; busts of men of letters and women of fashion, together with groups of seductive nymphs, were always the most popular subjects. The miniature sculptures (often also reproductions of larger works) in biscuit porcelain, which had also been produced in 18th-century Paris, also continued to be popular in England for a while, as well as France.

Exalted notions of the artist's role, inculcated by the Academies and dramatized by Romantic literature, did little to encourage sculptors to involve themselves with what was often described as "mere" ornament. Mechanical methods—more and more sophisticated machinery for turning and pointing, as well as reducing machinery and novel techniques of casting—were often employed with great success. This resulted, however, not only in more bad sculpture than before but also in more badly carved and cast ornament in architecture, furniture, and metalwork. In Paris, however, the fertile genius of Albert Carrier-Belleuse particularly excelled in devising such objects as gasoliers supported by pretty girls in a luxurious style that combined elements from the art of the 16th, 17th, and 18th centuries. In England, Alfred Stevens, inspired by the versatility of the Italian Renaissance, was happy to devote himself to the design of cutlery and fire grates, and, at the end of the century, Alfred Gilbert, creator of the most remarkable metropolitan fountain since the Renaissance (the Eros in Piccadilly Circus), also became the first sculptor of the foremost rank since Cellini to devote himself wholeheartedly to the art of the goldsmith.

Perhaps the least successful aspect of 19th-century sculpture was the large-scale relief panels and pedimental ornaments and niche stances on churches and public buildings—the individual styles encouraged by the exhibition were inappropriate, and traditional styles tended to be artificially resurrected. The subject matter was often selected for negative purposes—to avoid offense, to seem impressive, to fill gaps. The unsuitability of this sort of task for the artist with a romantic sense of independence is obvious, and the situation did once arise, in the case of David d'Angers, of a sculptor's choosing his own program for one of the great public buildings in Paris (the Panthéon) against the wishes of his patrons. This same sense of independence also made for difficult relations between sculptors and architects. The quarrels between the architect of the Paris Opéra and Jean-Baptiste Carpeaux were typical; what was atypical was the success of Carpeaux's festive high relief of nymphs in abandoned dance (completed in 1869).

Another type of public sculpture—the portrait, typically in bronze, erected in a town square or other public space—

DEVANEY STOCK PHOTOS

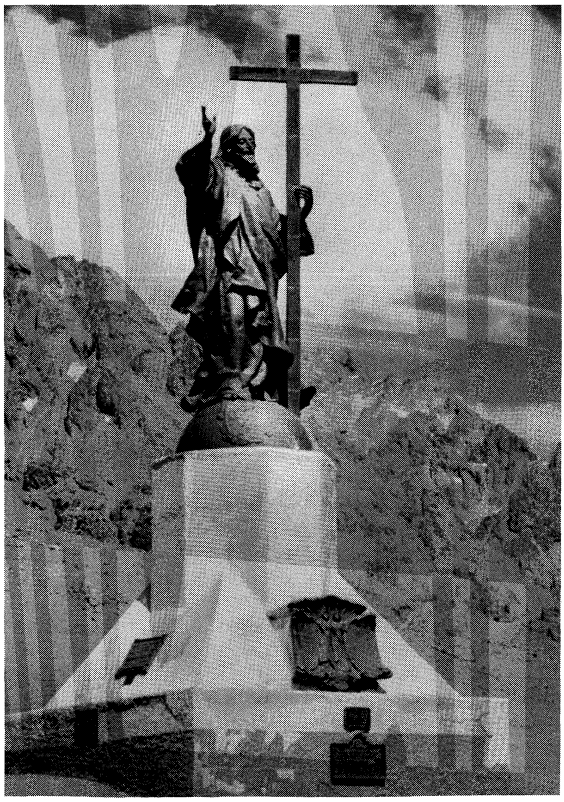

Figure 73: "Christ of the Andes" by Mateo Alonso, 1902. In the Uspallata Pass on the border between Argentina and Chile.

Commemorative portrait sculpture

flourished in the 19th century as it had not done since the first centuries AD. The first prominent sculptures of this sort commemorating nonroyal figures since antiquity seem to have appeared in Britain. The statues of Nelson by Sir Richard Westmacott erected in Liverpool and Birmingham soon after the subject's death were followed by statues of political heroes such as Fox and Pitt. By the end of the century, even relatively minor generals, philanthropists, or entrepreneurs were commemorated in this manner—almost invariably at the expense of public subscribers. The rest of Europe eventually followed this English example.

The young countries of the New World—the United States and later the republics of Latin America—commemorated with statues heroes whom they perceived as national saviours and founders. It may be that statues of Nelson excited as much patriotic sentiment as those of Washington or Bolívar, but Nelson could not embody the nation as the others did, nor certainly could any statue of a European monarch. For Europe national pride could best be promoted by an appeal to the past. Among the most remarkable public sculpture of the 19th century must certainly be counted Carlo Marochetti's "Duke Emmanuel Philibert" (1833, Turin) and Christian Daniel Rauch's "Frederick the Great" (1836–51, East Berlin) and the several statues of Joan of Arc in France. These were works of not simply historical but also topical and political significance, as indeed was the colossal "Christ of the Andes" by Mateo Alonso erected in 1902 on the border of Chile and Argentina. Abstractions were also endowed with a more urgent ideological content than in former centuries. In France, at least in the great "Triumph of the Republic" by Jules Dalou (unveiled in 1899 in the Place de la Nation), these could be animated with genuine passions. This is not true of the Statue of Liberty in New York City, which has nonetheless made an impact on the popular imagination.

Funeral sculpture

In the 19th century, funeral sculpture was as completely revolutionized as public sculpture. Whereas previously it had only really been in England that a large section of the wealthier classes had enjoyed the privilege of erecting substantial sculptured memorials, the opening up of large landscaped municipal cemeteries made this possible elsewhere. These cemeteries, of which the finest examples are in Paris and in Italy, were free from ecclesiastical censorship, and new themes quickly developed that were appropriate for an age of doubt and of desperate faith. The sentimentality and sensationalism of the annual exhibition were found here also, and so too was much exhibitionist virtuosity devoted to depicting the veiled faces and figures of ascending souls and their androgynous angelic escorts, as well as to recording bourgeois haberdashery.

This virtuosity is largely associated with Italian sculpture; and in a sense the Italians continued to dominate sculpture throughout the Western world after the death of Canova, by supplying the skilled carvers who were everywhere employed to translate into marble ideas worked out in clay. The greatest sculptors of the 19th century tended to play a smaller part than any of their predecessors in the actual carving, and the most vital sculpture of the period is preeminently plastic: when one thinks of the broken surfaces of the portrait busts by Carpeaux, for example, or of the precarious balances, open forms, and eloquent contours of Gilbert's statuettes, one thinks of wax and clay.

(N.B.P.)

Modern sculpture

19TH-CENTURY BEGINNINGS

The origins of modern art are usually traced to the mid-19th-century rejection of Academic tradition in subject matter and style by certain artists and critics. Painters of the Impressionist school that emerged in France in the late 1860s sought to free painting from the tyranny of the subject and to explore the intrinsic qualities of colour, brushwork, and form. This expansive notion of visual rendering had revolutionary effects on sculpture as well. The French sculptor Auguste Rodin found in it a new basis for life modelling and thus restored to the art a stylistic integrity that it had hardly possessed for more than two centuries.

Auguste Rodin

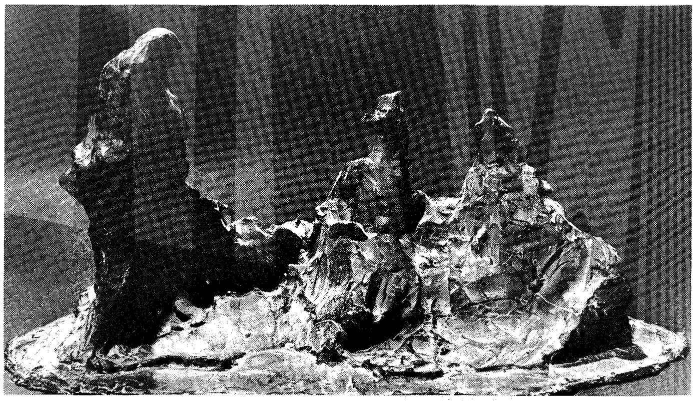

Figure 74: "Conversation in a Garden," wax-covered plaster sculpture by Medardo Rosso, 1893. In the Galleria Nazionale d'Arte Moderna, Rome. Height 43.2 cm.

Rodin's highly naturalistic early work, "The Age of Bronze" (1877), is effective because the banal studio pose of a man leaning on a staff produced an unconventional and expressive gesture when the staff was removed. From Honoré Daumier, Rodin had learned the bold modelling of surfaces that are emotive rather than literal; the statue is only a rough approximation that avoids the definitive finish of earlier sculpture and remains in a state of becoming. Eventually, Rodin even worked with mere fragments such as broken torsos, and he enormously enlarged the range of figure composition. The mass, until then the principal vehicle of sculptural composition, was explosively opened by these methods; in contrast to earlier sculpture, which depended on the interplay of solid and void, Rodin's works are fused with the surrounding space. These methods evolved in his many works, such as "Adam" (1880), "Eve" (1881), and others, originally conceived as a part of the masterpiece of modern sculpture, "The Gates of Hell," undertaken by Rodin in 1880 and never really completed. It was inevitable that the translucent nature of the marble surface should engage the attention of Rodin, and even though he always prepared the models in clay and left the execution in stone to assistants, such marbles as "The Kiss" (1885), when properly exhibited with light partly from the rear, appear to glow with the incandescence of their passionate intensity.

(J.Hud./J.Hm.)

Although the art of Rodin appears conservative in comparison to the painting of the time, in that he continued to use literary themes while painting did not, the new style that he evolved did much to revive sculpture's significance as an expressive medium, and his importance to 20th-century sculpture can hardly be overestimated. His fresh search and revelation of the basic movements of modern life had a profound influence on the generation of European sculptors who followed him.

Among Rodin's contemporaries, Edgar Degas, whose sculpture, begun in the 1880s, was an intimate study of movement and light, in several respects predicts 20th-century developments. Rodin's Italian counterpart, Medardo Rosso, lived in Paris during the 1880s; his work was known and owned by Rodin (Figure 74). Less gifted than Rodin but interested in the same problems, Rosso used wax in such a way that light was suffused through sensitively modelled portraits, and labile forms were created to express the flux that he felt was a condition of modern life. In Italy Rosso influenced Arturo Martini and through him Giacomo Manzù, Marino Marini, and Alberto Viani.

THE 20TH CENTURY

Rodin's successors

The ablest of Rodin's many pupils were Émile-Antoine Bourdelle and Charles Despiau. Bourdelle's "Hèraklès Archer" (1910) is an attempt to continue Rodin's active postures; but the results are melodramatic, and the forms are heavy and less sensitively modelled. Despiau, who

Collection, The Museum of Modern Art, New York, given anonymously

was director of Rodin's shop from 1907 to 1914, also responded to the interest in Classicism; his best work, "Girl from the Landes" (1904), was a balance of individual traits in the Rodin tradition, combined with graceful poses and well-rounded forms.

Two of the many other young sculptors attracted to Paris by Rodin's fame were Wilhelm Lehmbruck and Constantin Brancusi. Lehmbruck's early work has the soft modelling by touches of clay characteristic of the time, as in his "Mother and Child" (1907) and "Bust of a Woman" (1910). Brancusi's "Sleeping Muse" (1908) and the small "Bust of a Boy with Head Inclined" (1907) reflect Rodin's later interests in the expressiveness of modelling as opposed to strenuous gesture. Pablo Picasso and Henri Matisse were also early disciples of Rodin, as was Jacob Epstein, particularly in his naturalistic and psychologically incisive portraits.

Avant-garde sculpture (1909–20). In the second decade of the 20th century the tradition of body rendering extending from the Renaissance to Rodin was shattered, and the Cubists, Brancusi, and the Constructivists emerged as the most influential forces. Cubism, with its compositions of imagined rather than observed forms and relationships, had a similarly marked influence.

One of the first examples of the revolutionary sculpture is Picasso's "Woman's Head" (1909). The sculptor no longer relied upon traditional methods of sculpture or upon his sensory experience of the body; what was given to his outward senses of sight and touch was dominated by strong conceptualizing. The changed and forceful appearance of the head derives from the use of angular planar volumes joined in a new syntax independent of anatomy. In contrast to traditional portraiture, the eyes and mouth are less expressive than the forehead, cheeks, nose, and hair. Matisse's head of "Jeanette" (1910–11) also partakes of a personal reproportioning that gives a new vitality to the less mobile areas of the face. Likewise influenced by the Cubists' manipulation of their subject matter, Alexander Archipenko in his "Woman Combing Her Hair" (1915) rendered the body by means of concavities rather than convexities and replaced the solid head by its silhouette within which there is only space.

Brancusi's "Bird in Space"

Brancusi also abandoned Rodin's rhetoric and reduced the body to its mystical inner core. His "Kiss" (1908), with its two blocklike figures joined in symbolic embrace, has a concentration of expression comparable to that of primitive art but lacking its spiritualistic power. In this and subsequent works Brancusi favoured hard materials and surfaces as well as self-enclosed volumes that often impart an introverted character to his subjects. His bronze "Bird in Space" became a *cause célèbre* in the 1920s when U.S. customs refused to admit it duty free as a work of art (Figure 75).

Raymond Duchamp-Villon began as a follower of Rodin, but his portrait head "Baudelaire" (1911) contrasts with that by his predecessor in its more radical departure from the flesh; the somewhat squared-off head is molded by clear, hard volumes. His famous "Horse" (1914), a coiled, vaguely mechanical form bearing little resemblance to the animal itself, suggests metaphorically the horsepower of locomotive drive shafts and, by extension, the mechanization of modern life. Duchamp-Villon may have been influenced by Umberto Boccioni, one of the major figures in the Italian Futurist movement and a sculptor who epitomized the Futurist love of force and energy deriving from the machine. In "Unique Forms of Continuity in Space" (Figure 76) and "Head + House + Light" (1911), he carried out his theories that the sculptor should model objects as they interact with their environment, thus revealing the dynamic essence of reality.

Jacques Lipchitz came to Cubism later than Archipenko and Duchamp-Villon, but after mastering its meaning he produced superior sculpture. In 1913, after several years of conservative training, he made a number of small bronzes experimenting with the compass curve and angular planes. They reveal an understanding of the Cubist reconstitution of the bodies in an impersonal quasi-geometric armature over which the artist exercised complete autonomy. Continuing to work in this fashion, he produced "Man with a Guitar" (Figure 77), and "Standing Figure" (1915), in which voids are introduced, while in the early 1920s he developed freer forms more consistently based on curves.

Lehmbruck's mature style emerged in the "Kneeling Woman" (1911) and "Standing Youth" (1913), in which his gothicized, elongated bodies with their angular posturings and appearance of growing from the earth give

expression to his notions of modern heroism. In contrast to this spiritualized view is his "The Fallen" (1915–16), intended as a compassionate memorial for friends lost in the war.

Constructivism and Dada. Between 1912 and 1914 there emerged an antisculptural movement, called Constructivism, that attacked the false seriousness and hollow moral ideals of academic art. The movement began with the relief fabrications of Vladimir Tatlin in 1913. The Constructivists and their sympathizers preferred industrially manufactured materials, such as plastics, glass, iron, and steel, to marble and bronze. Their sculptures were not formed by carving, modelling, and casting but by twisting, cutting, welding, or literally constructing: thus the name Constructivism.

Sculpture as invention

Unlike traditional figural representation, the Constructivists' sculpture denied mass as a plastic element and volume as an expression of space; for these principles they substituted geometry and mechanics. In the machine, where the Futurists saw violence, the Constructivists saw beauty. Like their sculptures, it was something invented; it could be elegant, light, or complex, and it demanded the ultimate in precision and calculation.

Seeking to express pure reality, with the veneer of accidental appearance stripped away, the Constructivists fabricated objects totally devoid of sentiment or literary association; Naum Gabo's work frequently resembled mathematical models, and several Constructivist sculptures, such as those by Kazimir Malevich and Georges Vantongerloo, have the appearance of architectural models. The Constructivists created, in effect, sculptural metaphors for the new world of science, industry, and production; their aesthetic principles are reflected in much of the furniture, architecture, and typography of the Bauhaus.

The Dadaist assemblage

A second important offshoot of the Cubist collage was the fantastic object or Dadaist assemblage. The Dadaist movement, while sharing Constructivism's iconoclastic vigour, opposed its insistence upon rationality. Dadaist assemblages were, as the name suggests, "assembled" from materials lying about in the studio, such as wood, cardboard, nails, wire, and paper; examples are Kurt Schwitters' "Rubbish Construction" (1921) and Marcel Duchamp's "Disturbed Balance" (1918). This art generally exalted the accidental, the spontaneous, and the impulsive, giving free play to associations. Its paroxysmal and negativist tenor led its subscribers into other directions, but Dadaism formed the basis of the imaginative sculpture that emerged in the later 1920s.

Conservative reaction (1920s). In the 1920s modern art underwent a reaction comparable to the changes experienced by society as a whole. In the postwar search for security, permanence, and order, the earlier insurgent art seemed to many to be antithetical to these ends, and certain avant-garde artists radically changed their art and thought. Lipchitz' portraits of "Gertrude Stein" (1920) and "Berthe Lipchitz" (1922) return volume and features to the head but not an intimacy of contact with the viewer. Tatlin and Alexander Rodchenko broke with the Constructivists around 1920. Jacob Epstein developed some of his finest naturalistic portraiture in this decade. Rudolph Belling abandoned the mechanization that had characterized his "Head" (1925) in favour of musculature and individual identity in his statue of "Max Schmeling" of 1929. Matisse's reclining nudes and the "Back" series of 1929 show less violently worked surfaces and more massive and obvious structuring.

Aristide Maillol continued refining his relaxed and uncomplicated female forms with their untroubled, stolid surfaces. In Germany, Georg Kolbe's "Standing Man and Woman" of 1931 seems a prelude to the Nazi health cult, and the serene but vacuous figures of Arno Breker, Karl Albiker, and Ernesto de Fiori were simply variations on a studio theme in praise of youth and body culture. In the United States adherents of the countermovement included William Zorach, Chaim Gross, Adolph Block, Paul Manship, and Wheeler Williams.

Sculpture of fantasy (1920–45). One trend of Surrealist or Fantasist sculpture of the late 1920s and the 1930s consisted of compositions made up of found objects, such as Meret Oppenheim's "Object, Fur Covered Cup" (1936). As with Dadaist fabrications, the unfamiliar conjunction of familiar objects in these assemblies was dictated by impulse and irrationality and could be summarized by Isidore Ducasse's often-quoted statement, "Beautiful . . . as the chance meeting on a dissecting table of a sewing machine with an umbrella."

Of greater artistic importance was the sculpture of a second group that included Alberto Giacometti, Jean Arp, Lipchitz, Henry Moore, Barbara Hepworth, Picasso, Julio González, and Alexander Calder. Although these sculptors were sometimes in sympathy with Surrealist objectives, their aesthetic and intellectual concerns prohibited a more consistent attachment. Their art, derived from visions, hallucinations, reverie, and memory, might best be called the sculpture of fantasy. Giacometti's "Palace at 4 A.M." (Figure 78), for example, interprets the artist's vision not in terms of the external public world but in an enigmatic,

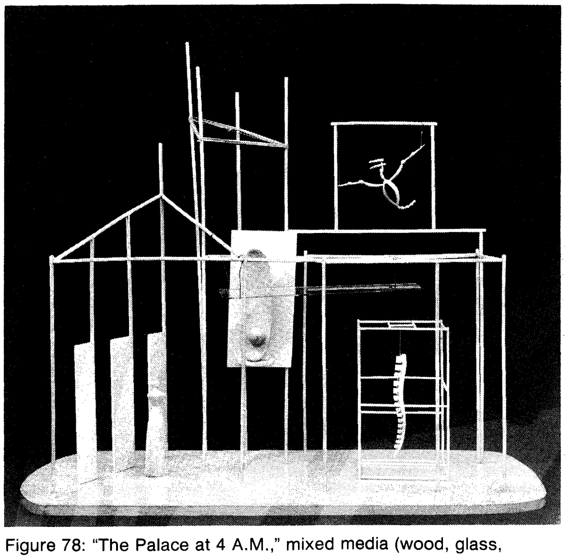

Figure 78: "The Palace at 4 A.M.," mixed media (wood, glass, wire, and string) by Alberto Giacometti, 1932–33. In the Museum of Modern Art, New York City. 63.5 × 71.8 × 40 cm.

private language. Moore's series of "Forms" suggest shapes in the process of forming under the influence of each other and the medium of space. The appeal of primitive and ancient ritual art to Moore, the element of surprise in children's toys for Calder, and the wellsprings of irrationality from which Arp and Giacometti drank were for these men the means by which wonder and the marvelous could be restored to sculpture. While their works are often violent transmutations of life, their objectives were peaceful, "... to inject into the vain and bestial world and its retinue, the machines, something peaceful and vegetative." ([Jean] Hans Arp, *On My Way,* Documents of Modern Art, vol. 6, p. 123, George Wittenborn, Inc., New York, 1948.)

Other sculpture (1920–45). The sculpture of Moore, Gaston Lachaise, and Henri Laurens during the 1920s and '30s included mature, ripe human bodies, erogenic images reminiscent of Hindu sculpture, appearing inflated with breath rather than supported by skeletal armatures. Lachaise's "Montagne" (1934–35) and Moore's reclining nudes of the '30s are identifications with earth, growth, vital rhythm, and silent power. Prior to Moore and the work of Archipenko, Boccioni, and Lipchitz, space had been a negative element in figure sculpture; in Moore's string sculptures and Lipchitz' transparencies of the 1920s, it became a prime element of design.

Moore's reclining nudes

Lipchitz' figure style of the late 1920s and '30s is inseparable from his emerging optimistic humanism. His concern with subject matter began with the ecstatic "Joy of Life" (1927). Thereafter his seminal themes were of love and security and assertive passionate acts that throw off the inertia of his Cubist figures. In the "Return of the Prodigal Son" (1931), for example, strong, facetted curvilinear volumes weave a pattern of emotional and aesthetic accord between parent and child.

The American sculptor John B. Flannagan rendered animal forms as well as the human figure in a simple, almost naive style. His interest in what he called the "profound subterranean urges of the human spirit in the whole dynamic life process, birth, growth, decay and death" (quoted in Carl Zigrosser, *Catalog for the Exhibition of the Sculpture of John B. Flannagan,* p. 8, The Museum of Modern Art, New York, 1942) resulted in "Head of a Child" (1935), "New One" (1935), "Not Yet" (1940), and "The Triumph of the Egg" (1941).

Somewhat more mystical are Brancusi's "Beginning of the World" (1924), "Fish" (1928–30), and "The Seal" (1936). As with Flannagan, the recurrent egg form in Brancusi's art symbolizes the mystery of life. Nature in motion is the subject of Alexander Calder's mobiles, such as "Lobster Trap and Fish Tail" (1939) and others suggesting the movement of leaves, trees, and snow. In the history of sculpture there is no more direct or poetic expression of nature's rhythm.

Developments after World War II. "The modern artist is the counterpart in our time of the alchemist-philosopher who once toiled over furnaces, alembics and crucibles, ostensibly to make gold, but who consciously entered the most profound levels of being, philosophizing over the melting and mixing of various ingredients" (Ibram Lassaw, quoted by Lawrence Campbell in *Art News,* p. 66, The Art Foundation Press, New York, March 1954). While work in the older mediums persisted, it was the welding, soldering, and cutting of metal that emerged after 1945 as an increasingly popular medium for sculpture. The technical and expressive potential of uncast metal sculpture was carried far beyond the earlier work of González and Picasso.

By courtesy of the trustees of the Tate Gallery, London

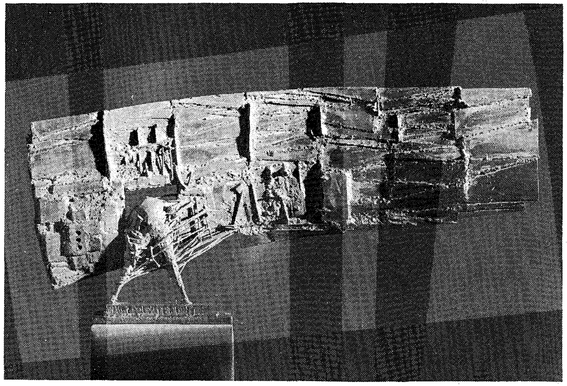

Figure 79: "The Man of Saint-Denis," by César (Baldaccini), 1958. In the Tate Gallery, London. Height 50.8 cm.

The appeal of metal is manifold. It is plentifully available from commercial supply houses; it is flexible and permanent; it allows the artist to work quickly; and it is relatively cheap compared to casting. Industrial metals also relate modern sculpture physically, aesthetically, and emotionally to its context in modern civilization. As the American sculptor David Smith has commented, "Possibly steel is so beautiful because of all the movement associated with it, its strength and functions. Yet it is also brutal, the rapist, the murderer and death-dealing giants are also its offspring" (quoted in Garola Giedion-Welcker, *Contemporary Sculpture,* Documents of Modern Art, vol. 12, p. 123, George Wittenborn, Inc., New York, 1955).

The technique of metal sculpture

The basic tool of the metal sculptor is the oxyacetylene torch, which achieves a maximum temperature of 6,500° F (3,600° C; the melting point of bronze is 2,000° F). The intensity and size of the flame can be varied by alternating torch tips. In the hands of a skilled artist the torch can cut or weld, harden or soften, colour and lighten or darken metal. Files, hammers, chisels, and jigs are also used in shaping the metal, worked either hot or cold. The sculptor may first construct a metal armature that he then proceeds to conceal or expose. He builds up his form with various metals and alloys, fusing or brazing them, and may expose parts or the whole to the chemical action of acids. This type of work requires constant control, and many sculptors work out and guard their own recipes.

Other sculptors such as Peter Agostini, George Spaventa, Peter Grippe, David Slivka, and Lipchitz, who were interested in bringing spontaneity, accident, and automatism into play, returned to the more labile media of wax and clay, with occasional cire-perdue casting, which permit a very direct projection of the artist's feelings. By the nature of the processes such work is usually on a small scale.

A number of artists brought new technique and content to the Dadaist form of the assemblage. Among the most important was the American Joseph Cornell, who combined printed matter and three-dimensional objects in his intimately sealed, often enigmatic "boxes."

Another modern phenomenon, seen particularly in Italy, France, and the United States, was the revival of relief sculpture and the execution of such works on a large scale, intended to stand alone rather than in conjunction with a building. Louise Nevelson, for example, typically employed boxes as container compartments in which she carefully disposed an assortment of forms and then painted them a uniform colour. In Europe the outstanding metal reliefs were those by Alberto Burri, Gio and Arnaldo Pomodoro, César (Figure 79), Zoltán Kemény, and Manuel Rivera.

New views of nature. Development of metal sculpture, particularly in the United States, led to fresh interpretations of the natural world. In the art of Richard Lippold and Ibram Lassaw, the search for essential structures took the form of qualitative analogies. Lippold's "Full Moon" (1949–50) and "Sun" (1953–56; commissioned by the Metropolitan Museum of Art, New York City, to hang in its room of Persian carpets) show an intuition of a basic regularity, precise order, and completeness that underlies the universe. Lassaw's comparable interest in astronomical phenomena inspired his "Planets" (1952) and "The Clouds of Magellan" (1953).

In contrast to the macrocosmic concern of these two artists were the interests of sculptors such as Raymond Jacobson, whose "Structure" (1955) derived from his study of honeycombs. Using three basic sizes, Jacobson constructed his sculpture of hollowed cubes emulating the modular, generally regular but slightly unpredictable formal quality of the honeycomb.

Isamu Noguchi's "Night Land" is one of the first pure landscapes in sculpture. David Smith's "Hudson River

Landscape" (1951), Theodore J. Roszak's "Recollections of the Southwest" (1948), Louise Bourgeois's "Night Garden" (1953), and Leo Amino's "Jungle" (1950) are later examples.

In the 1960s a number of sculptors, particularly in the United States, began to experiment with using the natural world as a kind of medium rather than a subject. Among the more notable examples were the American Robert Smithson, who frequently employed earth-moving equipment to alter natural sites, and the Bulgarian-born Christo, whose "wrappings" of both natural and man-made structures in synthetic cloth generated considerable controversy. The name environmental sculpture has come to denote such works, together with other sculptures that constitute self-contained environments.

The human figure. Since figural sculpture moved away from straightforward imitation, the human form has been subjected to an enormous variety of interpretations. The thin, vertical, Etruscan idol-like figures developed by Giacometti showed his repugnance toward rounded and smooth body surfaces or strong references to the flesh. His men and women do not exist in felicitous concert with others; each form is a secret sanctum, a maximum of being wrested from a minimum of material. Reg Butler's work (*e.g.,* "Woman Resting" [1951]) and that of David Hare ("Figure in a Window" [1955]) treat the body in terms of skeletal outlines. Butler's figures partake of nonhuman qualities and embody fantasies of an unsentimental and aggressive character; the difficulties and tensions of existence are measured out in taut wire armatures and constricting malleable bronze surfaces. Kenneth Armitage and Lynn Chadwick, two other British sculptors, make the clothing a direct extension of the figure, part of a total gesture. In his "Family Going for a Walk" (1953), for example, Armitage creates a fanciful screenlike figure recalling wind-whipped clothing on a wash line. Both Chadwick and Armitage transfer the burden of expression from human limbs and faces to the broad planes of the bulk of the sculpture. Chadwick's sculptures are often illusive hybrids suggesting alternately impotent De Chirico-like figures or animated geological forms.

Luciano Minguzzi admired the amply proportioned feminine form. Minguzzi's women (*e.g.,* "Woman Jumping Rope" [1954]) may exert themselves with a kind of playful abandon. Marini's women (*e.g.,* "Dancer" [1949]) enjoy a stately passivity, their quiescent postures permitting a contrapuntal focus on the graceful transition from the slender extremities to the large, compact, voluminous torso, with small, rich surface textures.

The segmented torso, popular with Arp, Laurens, and Picasso earlier, continued to be reinterpreted by Alberto Viani, Bernard Heiliger, Karl Hartung, and Raoul Hague. The emphasis of these sculptors was upon more subtle, sensuous joinings that created self-enclosing surfaces. Viani's work, for example, does not glorify body culture or suggest macrocosmic affinities as does an ideally proportioned Phidian figure; his torsos are seen in a private way, as in his "Nude" (1951), with its large body and golf ball-sized breasts.

A.C. Cooper Ltd.

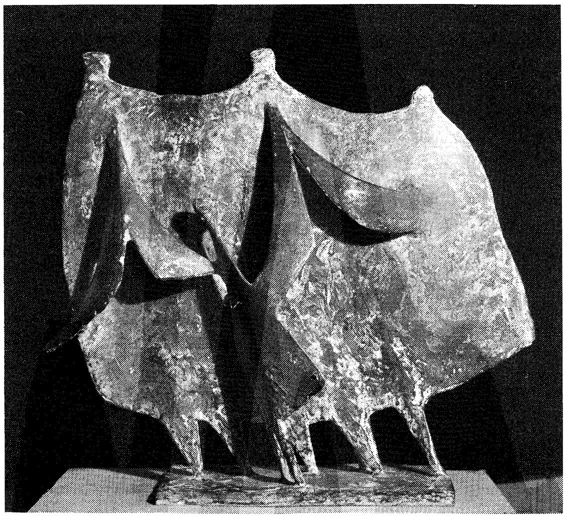

Figure 80: "Family Going for a Walk," bronze sculpture by Kenneth Armitage, 1953. In a private collection. Height 74 cm.

Among the most impressive figure sculptures made in the United States in the late 1950s were those by Seymour Lipton. Their large-scale, taut design and provocative interweaving of closed and open shapes restore qualities of mystery and the heroic to the human form.

The American George Segal emerged from the Pop movement of the 1950s and '60s as a major figurative sculptor. His plaster casts from live models, usually left white and indistinctly featured, are often situated in mundane settings of actual furniture or other objects.

The works of the French-born American artist Marisol contrast sharply with Segal's in their boxlike forms, onto which highly individualized features are usually painted. In the 1970s and '80s, Duane Hanson, another American, took Segal's live-model casting technique a step further with his startlingly naturalistic, fully pigmented cast fibreglass figures.

Archaizing, idol making, and religious sculpture. After World War II several sculptors became interested in the art of early Mediterranean civilizations. The result was a conscious archaizing of the human form with the intent of recapturing qualities of Cycladic idols, early Greek and Egyptian statuary, and some aspects of late Roman art.

Moore's admiration for archaic Greek sculpture produced "Draped Reclining Figure" (1952), which shows his return to the solid form and the suggestion of power and force by using drapery as a tense foil for the volumes that press against it. His "King and Queen" (1952–53) resulted from further excursions into the archaic Greek myth world.

The interest in recreating idols or totems was continued by Arp in his "Idol" (1950) and by Noguchi in his Stone Age-type sculptures for the Connecticut General Life Insurance Company (Hartford). By creating presences that elude rational definition, these artists restored to art its ancient aura of myth, mystery, and magic in an age that consistently disclaims their existence.

Modern religious sculpture

The argument that modern sculpture is inappropriate for religious requirements is disproved by works of Lipchitz, Lassaw, and Herbert Ferber. In keeping with the Jewish preference for nonfigural art, Ferber's ". . . and the bush was not consumed" (1951), commissioned by a synagogue in Millburn, New Jersey, comprises clusters of branches and boldly shaped weaving flames, invisibly suspended in a powerful and intimate vision that absorbs its viewers with its hypnotic rhythm. Lassaw's "Pillar of Fire," for the exterior of a synagogue in Springfield, Massachusetts, also has a mesmerizing pattern recalling the illusory images sometimes seen in flames. Lipchitz' sculpture of the "Virgin of Assy" (1948–54) was commissioned for the Catholic church at Assy, France.

Moreover, an increasing number of gifted sculptors are providing handsome liturgical objects and decorations, such as Harry Bertoia's shimmering reredos, Lipton's work for a synagogue in Tulsa, Oklahoma, and Roszak's sculptured spire for Kresge Chapel on the campus of the Massachusetts Institute of Technology, Cambridge.

Public and private memorials. After World War II there was a flood of public memorial sculpture, and in Europe especially many of the commissions were carried out by modern sculptors. A striking war memorial in Italy is Mirko Basaldella's gate for the monument to the Roman hostages killed in the Ardeatine Caves (1951). For its full effect the gate must be seen in connection with the rugged masonry wall to which it is attached. The gate was cast in metal and fashioned in a tangled, thicket-like pattern that suggests the painfully difficult passage from life to death for those who died in the caves.

Another imposing memorial is Ossip Zadkine's monument to the bombing of Rotterdam, a figure recoiling from the violence that descended from the sky. In Moore's "Warrior with a Shield" a soldier defiantly raises his shield and mutilated body toward the ill-starred heavens during the Battle of Britain. Epstein's public monument to "Social Consciousness" (1952–53), in Fairmount Park,

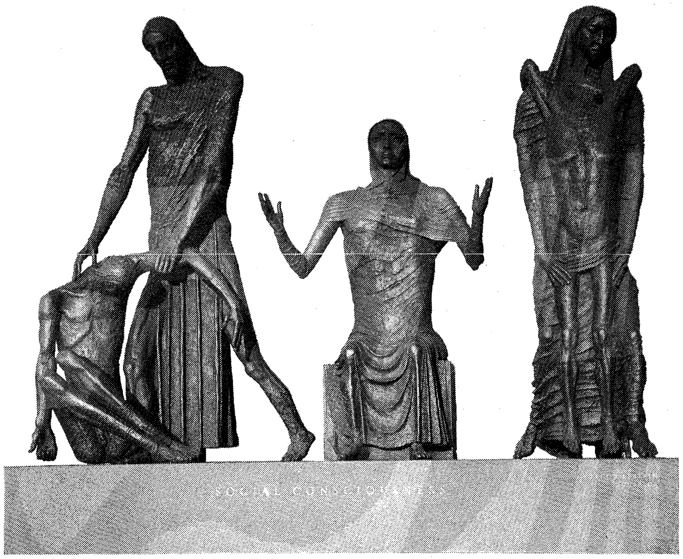

Figure 81: "Social Consciousness," bronze sculpture by Jacob Epstein, 1952–53. In Fairmount Park, Philadelphia. Height 3.9 m.

By courtesy of Philadelphia Museum of Art, Ellen Phillips Samuel Memorial, Fairmount Park Art Association

Philadelphia, treats the helplessness of those confronted with pressures over which they have no control. In contrast to the invulnerable champions of academic art, these sculptures image the hero in distress.

Modern sculpture and architecture

Other developments. Despite the rapid and exciting developments in both architecture and sculpture, the two have seldom been meaningfully and integrally united. The architecture of Le Corbusier, Frank Lloyd Wright, Pier Luigi Nervi, Ludwig Mies van der Rohe, and others occasionally shows strong sculptural qualities, but relatively rarely were their surfaces planned to receive sculpture. Freestanding sculptures such as those created by Gabo, Pevsner, De Rivera, Calder, and Noguchi have been used to provide intimacy and visual relief from the severity of the "cult of the cube" in architecture. The architectural firm of Skidmore, Owings & Merrill successfully used Bertoia's brilliant screens and Noguchi's sculptures and garden ideas; Roszak's "Eagle" for the American embassy in London and Moore's changeable reliefs on the London Time and Life Building held out hope for further thoughtful integration of the arts.

Also of great moment is the phenomenon of the sculptor-designer who has produced important changes in furniture and industrial design. Max Bill's school in Ulm, Germany, showed great promise. Playground facilities have been revolutionized by such designs as those made by Noguchi for Creative Playthings Inc. in the United States and the slides, hollowed forms, and climb apparatus of Egon Moeller-Nielson for parks in Stockholm. Noguchi, Moholy-Nagy, Bill, Bertoia, and many other modern artists contributed to the breakdown of the distinction between the object of utility and the work of art. Not since Gothic times has sculpture shown such promise of becoming an extensive and important part of human existence. (A.E.El./Ed.)

In Italy, traditional trends in sculpture are reflected in the brilliant accomplished modelling of Giacomo Manzù; Marino Marini, devoting himself almost entirely to the single theme of horse and rider, gave a bald realistic style an oddly apocalyptic force. The rough-hewn monumentality of the figures of the Austrian carver Fritz Wotruba is characteristic of this phase. Joannis Avramidis, also working in Vienna, turned figures into clusters of simplified formal echoes; the third sculptor of the Viennese group, Rudolf Hoflehner, who worked in iron, transformed them into symbolic presences. The segmental iron sculpture of the Spaniard Eduardo Chillida deals with a more limited and powerful range of forms.

Robert Rauschenberg in the United States sought to place his subtly calculated "combines" in the gap between reality and art, contrasting the significance of paint with the borrowed imagery and objects that are juxtaposed to it. Another American, Claes Oldenburg, began by reconstructing common things out of the random pictorial substance of Abstract Expressionism; his later reconstructions of the rigid furniture of life are tailored out of limp plastic sheeting, and the paradox oddly extends one's knowledge of the objective world.

In the reliefs of the Venezuelan Jesús Raphael Soto, the shifting paradoxes of vision are given a delicate order. Aside from this, the widespread work in kinetic mediums, such as that of Nicholus Takis, during the 1960s formed a separate genre, winking and shuddering on its own, most nearly linked to the Surrealist tradition.

Other sequels of the general rationalization and concentration of artistic means have been more fertile. In the hands of the U.S. painters Kenneth Noland and Frank Stella, painting discovered new shapes, both within the rectangular canvas and beyond it. The new value that was given to the painted plane did not benefit painting only. The British painter Richard Smith deployed it in three dimensions in painted constructions that re-create impressions of commercial packaging in terms of the spatial imagination of the arts. Sculpture, reequipped with colour, developed remarkably, and Anthony Caro led a group of British sculptors in exploration of spatial modulation and formal analogy. (La.G.)

BIBLIOGRAPHY

General: An excellent general history of world art is HUGH HONOUR and JOHN FLEMING, *A World History of Art* (1982; U.S. title, *The Visual Arts: A History*), which examines sculpture in relation to the other arts. H.W. JANSON, *History of Art* (1962; 2nd ed., 1977), is also recommended. Among books that discuss sculpture of many periods, RUTH BUTLER, *Western Sculpture: Definitions of Man* (1975), is unusually valuable. So, too, is F. DAVID MARTIN, *Sculpture and Enlivened Space* (1981). For the techniques of sculpture see W. VERHELST, *Sculpture: Tools, Materials, and Techniques* (1973); and RUDOLF WITTKOWER, *Sculpture* (1977). The making of bronze sculptures, omitted from the latter, is brilliantly elucidated by JENNIFER MONTAGU, *Bronzes* (1963, reissued 1972). ERWIN PANOFSKY, *Tomb Sculpture* (1964), traces from ancient Egypt to about 1800 some of the major themes of one very important class of Western sculpture.

Ancient Mediterranean: Sculpture in the early civilizations of southern Europe is seldom studied separately, but it is featured in the following general works: JOHN BOARDMAN, *Pre-Classical* (1967, reissued 1979); R.W. HUTCHINSON, *Prehistoric Crete* (1962); A. ARRIBAS, *The Iberians* (1964); N.K. SANDARS, *Prehistoric Art in Europe* (1968); and SPYRIDON MARINATOS, *Crete and Mycenae* (1960).

Greek, Hellenistic, Etruscan, and Roman art: An authoritative and comprehensive account of ancient Greek art (which, for the most part, means Greek sculpture) is MARTIN ROBERTSON, *A History of Greek Art* (1975). For a succinct introduction to sculpture only, see JOHN BARRON, *Introduction to Greek Sculpture* (1981, reissued 1984). For the Archaic period, G.M.A. RICHTER, *Archaic Greek Art Against Its Historical Background* (1949), is still valuable; for the so-called Classical period, BRUNILDE S. RIDGWAY, *Fifth Century Styles in Greek Sculpture* (1981), is a good detailed guide; and for the later periods, MARGARETE BIEBER, *The Sculpture of the Hellenistic Age*, 2nd rev. ed. (1981), is highly useful. For the ancient literature on art, see J.J. POLLITT, *The Art of Greece 1400–31 B.C.: Sources and Documents* (1965). Etruscan sculpture is best discussed in OTTO J. BRENDEL, *Etruscan Art* (1978). Sculpture features prominently in the most lively general books on Roman art: R. BIANCHI BANDINELLI, *Rome: The Centre of Power* (1970; originally published in Italian, 1969), and *Rome: The Late Empire* (1971); and RICHARD BRILLIANT, *Roman Art* (1974). Of more limited scope but great interest is JOCELYN M.C. TOYNBEE, *Art in Roman Britain* (1962). See also J.J. POLLITT, *The Art of Rome c. 753 BC–AD 337: Sources and Documents* (1966, reissued 1983).

Early Christian and early medieval: Good general surveys of the early Christian period that include some discussion of sculpture are ERNST KITZINGER, *Byzantine Art in the Making* (1977); JOHN BECKWITH, *The Art of Constantinople*, 2nd ed. (1968); ANDRÉ GRABAR, *The Beginnings of Christian Art: 200–395* (1967, originally published in French, 1966); STEVEN RUNCIMAN, *Byzantine Style and Civilization* (1975); and CYRIL A. MANGO, *The Art of the Byzantine Empire 312–1453: Sources and Documents* (1972). This last volume, together with ERNST KITZINGER, *Early Medieval Art* (1940; rev. ed., 1983), concerns also the early medieval period. Among more specialized studies

of sculpture in the early Christian period, JOHN BECKWITH, *Coptic Sculpture* (1963); and JOSEPH NATANSON, *Early Christian Ivories* (1953), should be mentioned. For general information on the early medieval period, see PETER LASKO, *Ars Sacra 800–1200* (1972); GEORGE HENDERSON, *Early Medieval* (1972); and GEORGE ZARNECKI, *Art of the Medieval World* (1975). Valuable studies specifically on sculpture include GEORGE H. CRICHTON, *Romanesque Sculpture in Italy* (1954); HERMANN LEISINGER, *Romanesque Bronzes* (1956); FRITZ SAXL, *English Sculptures of the Twelfth Century* (1954); and M.F. HEARN, *Romanesque Sculpture: The Revival of Monumental Stone Sculpture in the Eleventh and Twelfth Centuries* (1981).

Gothic: Many of the ideas expressed in this section of the article are treated at greater length in ANDREW MARTINDALE, *Gothic Art* (1967). General studies of Gothic art include GEORGE HENDERSON, *Gothic* (1967); JOAN EVANS (ed.), *The Flowering of the Middle Ages* (1966, reissued 1984); and JOHAN HUIZINGA, *The Waning of the Middle Ages* (1924, reissued 1976; 12th Dutch ed., 1973). For the imagery of the period, the reader is referred to ÉMILE MÂLE, *The Gothic Image: Religious Art in France of the Thirteenth Century* (1958, reissued 1972; trans. of 3rd French ed., 1910), and *Religious Art from the Twelfth to the Eighteenth Century* (1949, reissued 1970; originally published in French, 1945). A useful anthology of the literary sources of the period is TERESA G. FRISCH, *Gothic Art 1140–1450* (1971). For a general treatment of English Gothic sculpture, see LAWRENCE STONE, *Sculpture in Britain: The Middle Ages,* 2nd ed. (1972); for France, MARCEL AUBERT, *La Sculpture française au moyen âge* (1947); and for Italy, JOHN POPE-HENNESSY, *Italian Gothic Sculpture,* 2nd ed. (1972).

Renaissance: There are numerous general books on Renaissance art, especially on Renaissance art in Italy, but sculpture is seldom adequately discussed in them. The best introduction to the sculpture is JOHN POPE-HENNESSY, *Italian Renaissance Sculptures,* 2nd ed. (1971). As a succinct guide to the sculpture in Florence, the most consistently important centre in Europe at this time, CHARLES AVERY, *Florentine Renaissance Sculpture* (1970), is recommended. Renaissance sculpture in northern Europe is discussed in ANTHONY BLUNT, *Art and Architecture in France: 1500–1700* (1953); WOLFGANG STECHOW, *Northern Renaissance Art: 1400–1600* (1966); GERT VON DER OSTEN and HORST VEY, *Painting and Sculpture in Germany and the Netherlands: 1500–1600* (1969); and MICHAEL BAXANDALL, *The Limewood Sculptors of Renaissance Germany* (1980). For Spain and Portugal, see GEORGE KUBLER and MARTIN S. SORIA, *Art and Architecture in Spain and Portugal and Their American Dominions: 1500–1800* (1959).

Baroque and Rococo: The best brief general discussion of Western art of this period is MICHAEL KITSON, *The Age of Baroque* (1966, reissued 1976), which includes some consideration of sculpture. For Italian Baroque sculpture, a better guide than POPE-HENNESSY (above) is provided by the sections on sculpture in RUDOLF WITTKOWER, *Art and Architecture in Italy: 1600–1750,* 3rd rev. ed. (1973, reissued 1982). ROBERT ENGGASS, *Early Eighteenth-Century Sculpture in Rome,* 2 vol. (1976); and the first two volumes (1977 and 1981) of FRANÇOIS SOUCHAL, *French Sculptors of the 17th and 18th Centuries,* must also be mentioned. For 18th-century France, the sections by Michael Levey on sculpture in MICHAEL LEVEY and WEND GRAF KALNEIN, *Art and Architecture of the Eighteenth Century in France* (1972), are excellent. For English sculpture, see the admirable account in MARGARET WHINNEY, *Sculpture in Britain: 1530–1830* (1964). For Spain, Portugal, and Latin America, see KUBLER and SORIA (above); HAROLD E. WETHEY, *Colonial Architecture and Sculpture in Peru* (1949, reprinted 1971); and PAL KELEMEN, *Baroque and Rococo in Latin America* (1951).

Neoclassicism and the 19th century: An excellent general account of Neoclassicism, which includes much of value on sculpture, is HUGH HONOUR, *Neoclassicism* (1977). For England, see DAVID G. IRWIN, *English Neoclassical Art* (1966); BENEDICT READ, *Victorian Sculpture* (1982); SUSAN BEATTIE, *The New Sculpture* (1983); and WHINNEY (above). For France and Italy, see GERARD HUBERT, *La Sculpture dans l'Italie Napoléonienne* (1964); JANE VAN NIMMEN and RUTH MIROLLI, *Nineteenth Century French Sculpture* (1971), an admirable introduction; and PETER FUSCO and H.W. JANSON (eds.), *The Romantics to Rodin* (1980), also a good introduction. A superb general introduction—perhaps the only truly comprehensive one—to Western sculpture of the 19th century is H.W. Janson's contribution to ROBERT ROSENBLUM and H.W. JANSON, *Art of the Nineteenth Century* (1984; U.S. title, *19th Century Art*).

Modern: There are numerous general introductions to modern art, but most give little space to sculpture. The best books devoted to modern sculpture are ALBERT E. ELSEN, *Modern European Sculpture: 1918–1945* (1979); HERBERT READ, *A Concise History of Modern Sculpture* (1964); and FRED LICHT, *Sculpture: 19th and 20th Centuries* (1967). Some recent developments are described in ALLEN KAPROW, *Assemblage: Environments and Happenings* (1966); and UDO KULTERMANN, *The New Sculpture* (1968; originally published in German, 1967). For a prominent sculptor's compelling but contentious account of what sculpture consists of, see WILLIAM TUCKER, *The Language of Sculpture* (1977).

(N.B.P.)

Sensory Reception

Sensory reception is the means by which an organism is able to react to changes in its external or internal environment, in particular through the activation of specific parts, which transform the energy change involved into vital processes. In many instances, environmental changes are transmitted from the receptor organ to other parts of the body by specialized cells, but in unicellular organisms such transformations are made by specialized organelles, such as light-sensitive "eye spots" or cilia sensitive to mechanical disturbances. In all higher animals, sensory reception is the special function of sensory neural elements, which "translate" changes into nerve impulses. The biological significance of such a feature is that it allows an organism to make appropriate reactions to changed circumstances; without such provisions it would be in constant danger of injury or death at the slightest environmental alteration. In general, the more highly evolved the organism, the greater the number of environmental changes sensed and the more precisely each is analyzed. Some organisms, however, possess special senses developed for perceiving environmental changes not registered by, nor relevant to, other species.

The purpose of this article is to examine the various sensory capacities of living organisms, to explain the mechanisms of sensory function, and to consider the adaptive advantages of sensing. Human sensory reception is presented in a separate section, followed by a detailed treatment of human vision and hearing. Diseases and impairments of function of these latter two vital senses are also discussed.

This article is divided into the following major sections:

ANIMAL SENSORY RECEPTION

Nature and functions of sensory systems

CLASSIFICATION OF SENSORY SYSTEMS

According to location of receptors. In general, sense cells, or receptors, located superficially in an organism receive signals from outside the organism and are parts of the exteroceptive system. Receptors located inside the body receive signals from changes taking place inside the body and belong to the interoceptive system. On activation, sense cells cause reactions appropriate to their location; they are said to respond with their local sign. For example, a decapitated frog reacts to stimulation of the skin by precisely directed limb movements aimed at wiping away the stimulus. Local sign in man is expressed by a conscious awareness of the spot being stimulated, as when a person locates a thorn in the skin. This is not true for vision, hearing, and smell, however, the sources of which are localized away from the body surface. Although some authorities believe that projection in space is learned, especially in man, for most animals such ability seems to be innate. In many cases, interoceptors stimulate channels that are never brought into consciousness; the presence of a local sign is thus shown only by the appropriateness of the resulting reactions. Internal pain is remarkable in that it is usually "misdirected" (referred) to the body surface in well-established patterns, according to its origin, a considerable help in medical diagnosis.

According to type of stimulus. More than one type of energy applied to a sense cell can, if strong enough, generate a nerve impulse, which will be interpreted by the central nervous system (CNS) as a change in the specific energy to which the cell is sensitive and will cause the same results as if the appropriate stimulus were present. Thus, a specific reflex action can be brought about by natural stimulations, such as touch of the skin, as well as by electrical stimulation of the nerve fibres activated by such touch. Each type of sense cell thus causes a specific output reaction and a specific sensation, which is the modality perceived. In other words, if the optic nerve could be functionally connected to the ear and the acoustic nerve to the eye, lightning would be heard and thunder seen.

Selectivity with regard to specific energy changes comes about in diverse ways, the simplest of which is the localization of the sense cell in such a way that it is protected from unwanted stimuli and by the use of accessory structures that make it extremely sensitive to the wanted one. The sense cells in the eye, for instance, are protected from any but the most severe changes in mechanical pressure; at the same time, the eye's optical properties focus the incoming light on the layer of sense cells constituting the retina. The hair cells of the ear, which are very sensitive to rapid changes in air pressure because of the ear's structure, are also well protected from other mechanical disturbances by shock-absorbing fluid.

Another main factor that differentiates types of sense cells is the presence of specific receptor sites for reacting with the energy to which they are specifically sensitive. Certain cells, for example, can be specifically stimulated by a given substance and no other, at least in the small concentrations required for reaction. Cells with such narrow reaction ranges are rare, however; more often, each cell has a wider spectrum, as is the case of the photoreceptors of the eye with regard to colour. Photoreceptors comprise three types of cell, each with a definite optimum but reactive to well-overlapping band widths, thereby providing for a range of colour vision. In other cases, it is the threshold (the lowest energy level) to any given stimulus that varies in different cells; this variation provides for measurement of the intensity of the stimulus. In many cases, however, intensity is coded by the frequency of the nerve impulses each receptor sends to the central nervous system.

The actual amounts of energy that can be transformed into a nerve impulse are sometimes amazingly small. One or a few photons of light absorbed may suffice not only for reception and transformation into a nerve impulse in several optic fibres but also for visual perception.

Photoreceptors

Photoreceptors are sensitive to light changes. They contain photopigments for absorption of light. The variety of photopigments in different cells determines the number of colours that can be distinguished. It is interesting to note that in insects, among other animals, colour sensitivity is extended into the ultraviolet range, though it is short in the red range. Cells especially sensitive to infrared radiation are found in the remarkable pit organs of vipers, which enable the snake to locate warm-blooded prey from a distance even when it freezes into immobility.

In the skin of warm-blooded animals, nerve endings, with or without accessory structures, are present that react especially to warming or to cooling.

Taste and smell

Well-known organs of chemical reception are those of smell and of taste. Except in cases in which there is great specificity to one substance, as, for example, the sex attractant in insects, the spectrum of chemoreceptive cells is broad. The sense of taste was long thought to be mediated by narrow, separate fibres for acid, bitter, sweet, and sour sensations; this viewpoint is now being replaced by one in which the spectra are considerably wider. Frogs have been shown to have taste cells that react specifically to distilled water. Chemoreceptors are also present as interoceptors, a well-known example being the carotid body in certain vertebrates; this organ monitors oxygen pressure in the carotid artery, which supplies the brain with blood.

Mechanoreceptors are the most widespread type of sense receptor and the most varied with regard to localization, sensitivity, and type of nerve-impulse firing. There are numerous subdivisions of the mechanoreceptive sense, such as touch, pain, sound, gravity, and muscle tone. Examples in humans include the naked nerve endings in the cornea of the eye; the Pacinian corpuscles in the skin, with their multilayered sheathlike covers; and the hair cells in the inner ear. Impulse formation may continue for as long as stimulus lasts, thus giving a continuous (tonic) type of discharge, or be limited and proportional to the rate of change of the stimulus, thus producing an abrupt (phasic) discharge. A remarkable type of mechanoreceptor occurs in the elastic organs of crustacean legs; movement-sensitive cells fire for the time a joint moves in one direction, and others fire for the opposite movement.

Electroreception

Electroreception is known only in certain fishes. Electrosensitive cells are accompanied by an organ that sends out small or large voltage changes. The sense cells occur along the long axis of the fish, enabling it both to discover food objects in the surrounding water and to locate other fish. This system is a great aid for navigation in murky water (see ELECTRICITY AND MAGNETISM: *Bioelectric effects*).

Certain animals appear to be able to orient to environmental changes for which no specific sense cells are known. Among these, magnetism is the most outstanding example. In fish, magnetic fields may well be received by electroreceptors. In insects and birds, which seem to perceive magnetic fields, no special sense cells have been implicated. The wide variety of phenomena considered as extrasensory perception in man may be based on direct influence on central-nervous elements, thus bypassing sensory input channels.

EVOLUTION OF SENSORY SYSTEMS

Specific sensory abilities do not show a clear evolutionary progression, most likely because the development of any type of sense depends on many other factors in the total ecology of a given organism. Vision, for instance, is sometimes poor or absent in a species of a class in which other members have a highly developed visual system: examples include cave-dwelling species, relatives of sighted emergent species.

Mechanical stimuli are effective in all forms of life. Specialized organs, however, appear very early in animal evolution; such organs include gravity and light receptors in jellyfish. In more advanced members of the phyla Mollusca and Arthropoda, greatly developed sense organs occur, some of which show an amazingly close resemblance to vertebrate organs; *e.g., Octopus* eyes and semicircular canals (for equilibrium). There is always a close relationship between the presence of highly developed sense organs and a region of the central nervous system; the latter is needed to "process" the incoming information in order to abstract the cues of importance to a given animal. The fact that such elaborate systems exist does not exclude the possibility of much shorter and simpler pathways, which provide for more localized and quicker reactions; for instance, the blink reflex, caused by the sudden approach of an object to the eye, bypasses the visual cortex of the brain.

INTEGRATION OF SENSORY INFORMATION

Although sensory information must be coded into a flow of nerve impulses for transmittal over distances, interactions between adjacent sense cells and sensory neurons also occur. Nerve cells can influence each other by mutual connections that result in membrane potential changes (electrical differences) in one when the other is stimulated. Similar effects are often caused by nerve impulses. When a number of nerve cells (neurons) with adjacent receptive fields are activated, it is common to find that the ones receiving the strongest stimulation suppress the response of those that are stimulated less. This action leads to a sharper difference at boundaries of stimulated and nonstimulated areas; thus, contrasts can be enhanced by this process, known as lateral inhibition. Certain sense cells have the property of being active, usually at a low rate, when not stimulated. This activity can then be either increased or decreased by appropriate stimuli. It is by such means that neurons indicating visual movements in one direction or sounds changing from one frequency to another obtain their selectivity. Such elaborations can be performed at different levels of the central nervous system. In the higher

Lateral inhibition

mammals, for instance, the fibres forming the optic nerve are mainly of two types, with small visual fields, one in which light in the centre of the field excites while light in the surrounding field inhibits, and vice versa. In animals even as highly developed as the rabbit, more complex integration has taken place in the visual periphery, and optic fibres can indicate such features as the movement of oriented lines in specific directions, which in cats and monkeys does not seem to occur before units in the brain have sampled the incoming information.

From this and other information it is clear that the use the animal makes of its senses is highly correlated with the type of sensory integration taking place in the nervous system. The ways by which a given stimulus is analyzed are varied and as yet only partially understood. It is, however, possible to build models that can be of mutual benefit for engineering and sensory information processing. By feeding back part of the incoming signal to earlier steps in the information processing, stability is greatly enhanced both in organisms and in machines. (C.A.G.W.)

Mechanoreception

Sensitivity to mechanical stimuli is a common endowment among animals. In addition to mediating the sense of touch, mechanoreception is the function of a number of specialized sense organs, some found only in particular groups of animals. Thus, some mechanoreceptors act to inform the animal of changes in bodily posture, others help detect painful stimuli, and still others serve the sense of hearing (see below *Sound reception*).

Slight deformation of any mechanoreceptive nerve cell ending results in electrical changes, called receptor or generator potentials, at the outer surface of the cell; this, in turn, induces the appearance of impulses ("spikes") in the associated nerve fibre. Laboratory devices such as the cathode-ray oscilloscope are used to record and to observe these electrical events in the study of mechanoreceptors. Beyond this electrophysiological approach, mechanoreceptive functions are also investigated more indirectly—*i.e.*, on the basis of behavioral responses to mechanical stimuli. These responses include bodily movements (*e.g.*, locomotion), changes in respiration or heartbeat, glandular activity, skin-colour changes, and (in the case of man) verbal reports of mechanoreceptive sensations. The behavioral method sometimes is combined with partial or total surgical elimination of the sense organs involved. Not all the electrophysiologically effective mechanical stimuli evoke a behavioral response; the central nervous system (brain and spinal cord) acts to screen or to select nerve impulses from receptor neurons.

Man experiences sharp, localized pain as a result of stimulation of "pain spots" (probably free nerve endings) in the skin, and dull pain, usually difficult to localize, associated with inner organs. The sensory structures of pain spots in the skin differ from other receptors in that they respond to a wide range of harmful (noxious or nociceptive) stimuli. Excessive stimulation of any kind (*e.g.*, mechanical, thermal, or chemical) may produce the human experience of pain. Apart from eliciting this subjective feeling of pain, stimulation of pain receptors in the human skin is objectively characterized by such signs of emotional expression as weeping and by efforts to withdraw from the stimulus. The reflex withdrawal of his hand from a burning stimulus may begin even before the person becomes conscious of the pain sensation.

Experience of pain in animals

Judging from objective criteria, responses to painful stimuli also occur in nonhuman animals, but, of course, any subjective experience of pain sensation cannot be directly reported. Still, the question of painful experience among animals is of considerable interest because investigators (*e.g.*, medical researchers) are often obliged to subject laboratory animals to treatments that would elicit complaints of pain from a man. If a cat's tail is accidentally stepped on, the pitiful screeching and efforts to withdraw are so strikingly similar to human reactions that the observer is led to attribute the experience of pain to the animal. If one treads accidentally on an earthworm and observes the animal's apparently desperate struggles to get free, he might again be inclined to suppose that the worm feels pain. This sort of "mind reading," however, is inherently uncertain and may be grossly misleading.

The following observations illustrate some of the difficulties in making judgments of the inner experiences of creatures other than man. After the spinal cord of a fish has been cut, the front part of the animal may respond to gentle touch with lively movements, whereas the trunk, the part behind the incision, remains motionless. A light touch to the back part elicits slight movements of the body or fins behind the cut, but the head does not respond. A more intense ("painful") stimulus, however (for instance, pinching of the tail fin), makes the trunk perform "agonized" contortions, whereas the front part again remains calm. To attribute pain sensation to the "painfully" writhing (but neurally isolated) rear end of a fish would fly in the face of evidence that persons with similarly severed spinal cords report absolutely no feeling (pain, pressure, or whatever) below the point at which their cords were cut.

Aversive responses to noxious stimuli nevertheless have a major adaptive role in avoiding bodily injury. Without them, the animal may even become a predator against itself; bats and rats, for instance, chew on their own feet when their limbs are made insensitive by nerve cutting. Some insects normally show no signs of painful experience at all. A dragonfly, for example, may eat much of its own abdomen if its tail end is brought into the mouthparts. Removal of part of the abdomen of a honeybee does not stop the animal's feeding. If the head of a blow-fly (*Phormia*) is cut off, it nevertheless stretches its tubular feeding organ (proboscis) and begins to suck if its chemoreceptors (labellae) are brought in touch with a sugar solution; the ingested solution simply flows out at the severed neck.

At any rate, responsiveness to mechanical deformation is a basic property of living matter; even a one-celled organism such as an amoeba shows withdrawal responses to touch. The evolutionary course of mechanoreception in the development of such complex functions as gravity detection and sound-wave reception leaves much room for speculation and scholarly disagreement.

RECEPTION OF EXTERNAL MECHANICAL STIMULI

The sense of touch. Sensitivity to direct tactual stimulation—*i.e.*, to contact with relatively solid objects (tangoreception)—is found quite generally, from one-celled organisms up to and including man. Usually the whole body surface is tangoreceptive, except for parts covered by thick, rigid shells (as in mollusks). Mechanical contact locally deforms the body surface; receptors typically are touch spots or free nerve endings within the skin, often associated with such specialized structures as tactile hairs. The skin area served by one nerve fibre (or sensory unit) is called a receptive field, although such fields overlap considerably. Particularly sensitive, exposed body parts are sometimes called organs of touch—*e.g.*, the tentacles of the octopus, the beak of the sandpiper, the snout of the pig, or the human hand.

Stimulation of the human skin with a bristle reveals that touch (pressure) sensation is evoked only from certain spots. These pressure spots, especially those on hairless parts (*e.g.*, palm of the hand, or sole of the foot), are associated with specialized microscopic structures (corpuscles) in the skin. Pressure spots are most densely concentrated on the tip of the human tongue (about 200 of them per square centimetre, or 1,300 per square inch), roughly twice their concentration at the fingertip. A characteristic feature of many tactile sense organs is their rapid and complete adaptation (*i.e.*, temporary loss of sensitivity) when stimulated. Still, in man a distinction can be made between transient and more prolonged pressure sensations.

Relatively little research has been done with regard to the physiology of individual tangoreceptors in vertebrates. The Pacinian corpuscle of higher vertebrates, however, has been studied in isolation (see *Human sensory reception* below, for illustrations). These corpuscles, found under the skin, are scattered within the body, particularly around muscles and joints. Local pressure exerted at the surface or within the body causes deformation of parts of the corpuscle, a shift of chemical ions (*e.g.*, sodium, potassium), and the appearance of a receptor potential at the nerve ending. This receptor potential, on reaching sufficient (threshold) strength, acts to generate a nerve impulse within the corpuscle. Among insects, movements of tactile hairs have been shown (sometimes specifically) to affect the receptor potential and the impulse frequency in the connected nerve fibre.

Many vertebrates and invertebrates can localize with some precision points of tactual stimulation at the body surface. People typically can still distinguish two sharpened pencil points, or similar pointed stimuli, when the points are separated by as little as about one millimetre (0.04 inch) at the tip of the tongue. (When moved closer together, the two points are perceived as one.) The human two-point threshold is about two millimetres at the finger tip, reaching six or seven centimetres (2.4–2.8 inches) at the skin of the back. Such tactual ability serves blind people when they read raised type (Braille) with their fingers. Closely related functions include the ability to distinguish between tactile stimuli that differ qualitatively; for example, between a rough and a smooth surface. This ability is even observable in the ciliate *Stylonychia* (a one-celled relative of *Paramecium*).

Reading Braille

Sensory contact with the ground below often informs animals about their spatial position. Nocturnal animals (for example, some eels) find shelter during the day by keeping as much of their skin as possible in contact with solid objects in the surroundings (thigmotaxis). Animals that live in running water usually maintain their position as they turn and swim head-on against the current (rheotaxis). Study of rheotaxic behaviour reveals that the sensory basis almost exclusively depends on visual or tactile stimuli (or both) arising from the animal's movements relative to the solid bottom or surroundings. The long antennae of many arthropods (*e.g.,* crayfish) and the lengthened tactile hairs (vibrissae) on the snouts of nocturnally active mammals (*e.g.,* cat, rat) serve in tactually sensing objects in the vicinity of the animal's body, extending and enriching the adaptive function of the sense of touch.

Lateral-line organs. *Mechanoreceptor function.* All of the primarily aquatic vertebrates—cyclostomes (*e.g.,* lampreys), fish, and amphibians—have in their outer skin (epidermis) special mechanoreceptors called lateralline organs. These organs are sensitive to minute, local water displacements, particularly those produced by other animals moving in the water. In this way, approaching organisms are detected and localized nearby before actual bodily contact takes place. Thus the lateral lines are said to function as receptors for touch at a distance, serving to perceive and locate prey, approaching enemies, or members of the animal's own species (*e.g.,* in sexual-display behaviour).

From *Experientia* (1952)

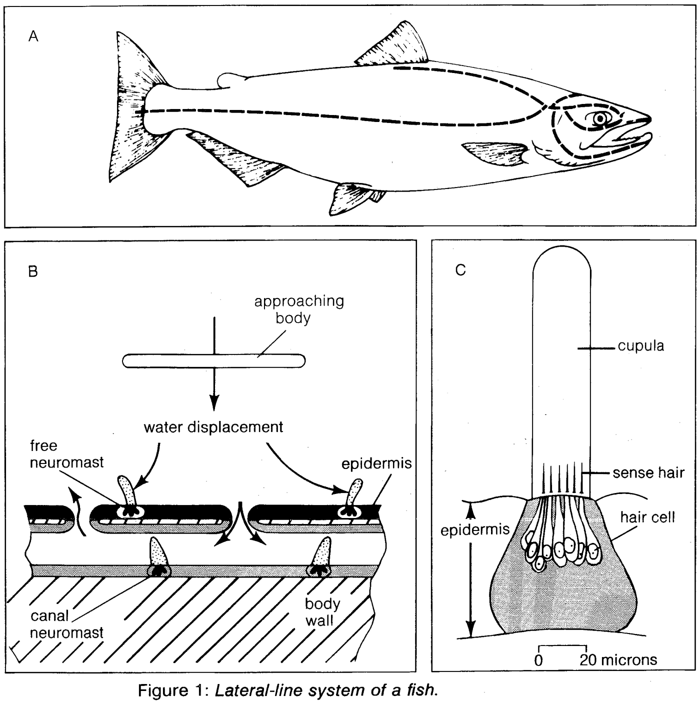

Figure 1: *Lateral-line system of a fish.*
(A) Bodily location of lateral lines; (B) longitudinal section of a canal; (C) superficial neuromast.

Each epidermal organ, called a sense-hillock or neuromast (Figure 1C), consists of a cluster of pear-shaped sensory cells surrounded by long, slender supporting cells. The sense hairs on top of the sensory cells project into a jellylike substance (the cupula) that bends in response to water displacement. The cupula stands freely in the surrounding water, grows continuously (*e.g.,* as a human fingernail), and wears away at the top. Sense organs of this type are distributed along definite lateral lines on the head and body of the animals (Figure 1A), developing in the outer layer of cells (ectoderm) of the embryo from a thickening called the lateral placode. From the central part of the same placode the sensory cells of inner-ear structures (the labyrinth) arise. The common embryologic origin and structural similarities of mature neuromasts and labyrinthine cell groups have led to the designation of all of these organs as the acoustico-lateralis system. The nerves to all the sense organs of the system arise from a common neural centre (called the acoustic tubercle in the wall of the brain's medulla oblongata). Among such amphibians as frogs, lateral-line organs and their neural connections disappear during the metamorphosis of tadpoles; as adults they no longer need to feed under water. The higher land-inhabiting vertebrates—reptiles, birds, and mammals—do not possess the lateral-line organs; only the deeply situated, labyrinthine sense organs persist.

The sensory cell of a neuromast bears one relatively long hair (kinocilium) and about 50 shorter ones (stereocilia). The kinocilium is inserted eccentrically on top of the sense cell; the stereocilia are arranged in parallel rows. In about half of the hair cells of a neuromast, the kinocilium is found on one (and the same) side of the cell; in the remaining hair cells it is found on the opposite side. In most cases these are cranial and caudal side, respectively. In the clawed frog (*Xenopus*), each group of hair cells in a neuromast connects to its own nerve fibre; hence there are two fibres per sense organ. The hair cells send a continuous series of neural impulses toward the acoustic tubercle in the absence of adequate external stimulation. A longitudinal water current along the toad's body surface, however, selectively increases or decreases the frequency of impulses from the cranial and caudal cells, depending on whether the flow is from head to tail or vice versa; current directed at right angles to such neuromasts has no effect. The impact of the moving water moves the cupula to deform the sensory hairs. Even minute cupula displacements of less than one thousandth of a millimetre are clearly effective in altering the impulses.

Detection of water currents

In *Xenopus,* as well as in other animals that have lateral-line organs, there are also some neuromasts with their hair cells asymmetrical at right angles to the head-tail axis. These add directional sensitivity so that other animals moving nearby in the water are well distinguished and localized. The postulated function of the lateral-line organs in the reception of low-frequency propagated pressure waves ("subsonic sound") has not been verified behaviorally. At very short distances, however, a vigorous low-frequency sound source stimulates the lateral-line system on the basis of acoustical near-field effects (water particle displacements), just as does any moving or approaching object.

Cyclostomes, many bony fishes, and all the aquatic amphibians studied have only superficial ("free") neuromasts of the kind described above. In the development of most fish, however, a number of structures called lateral-line canals (Figure 1B) are formed as a secondary specialization. They begin as grooves that develop in the epidermis along the main lateral lines; thus, a number of formerly free neuromasts are taken down to the bottom of each groove. The walls of the grooves then grow together above the neuromasts. Eventually the grown-together walls form canals under the epidermis, containing in their walls a series of canal neuromasts and a chain of openings to the outside (canal pores) along the lateral lines. The cupulae are changed in form, fitting the canal somewhat like swinging doors. The canal is filled with a watery fluid. Stimulation occurs essentially in the same way as with free neuromasts: local, external water displacement is transmitted via one or more canal pores to produce a local shift of the canal fluid to move cupulae. The sense cells in the canal neuromasts are polarized in the direction of the canal.

Canal specialization is particularly well developed in lively species of fish that swim more or less continuously and in bottom dwellers that live in running or tidal waters. Canalization has been interpreted as a case of adaptive evolution, serving to avoid the almost continuous, intense stimulation of free neuromasts by water flowing along the fish body during swimming or, in the case of relatively inactive bottom dwellers, by the external currents. These coarse water displacements probably mask subtly changing stimuli from detection by the lateral-line organs on the surface of the animal's body. Canal neuromasts are shielded in large degree from these masking currents.

Locating prey, predators, and sexual partners

The lateral-line organs function mainly in locating nearby moving prey, predators, and sexual partners. Usually these objects must be much closer than one length of the animal's body to be detected in this way; even intense stimuli are hardly ever detected beyond five body lengths away. Lateral-line function in rheotactic orientation against currents is restricted mainly to inhabitants of small currents such as mountain brooks, where marked differences of water-flow velocity affecting the fish body locally are likely to occur. Compared to their use of other sensory functions (*e.g.,* vision) the animals depend little on ability to sense extremely close, resting objects (obstacles) through the lateral lines. Obstacle detection of this kind does not arise from reflection of water waves; rather, the pattern of water displacement around the moving fish abruptly undergoes deformation at the near approach of an obstacle as the result of compression; the fish encounters a sudden rise in water resistance in the immediate vicinity of the obstruction. Nor do the lateral-line organs function to regulate or coordinate the animal's movements on the basis of the water flow or pressure variations along its body produced by swimming; neither do they serve for the reception of water-transmitted propagated sound waves (hearing).

Ampullary lateral-line organs (electroreceptors). Perhaps the most interesting specialization of the lateralline system is the formation in several groups of fish of deeply buried, single electrically sensitive organs. Such structures, for example, are found on the head of all the elasmobranchs (*e.g.,* sharks and rays), and are called ampullae of Lorenzini. Similar organs include those on the head of *Plotosus,* a marine bony fish (teleost); structures called mormyromasts in freshwater African fish (mormyrids) and in electric eels (gymnotids); what are named small pit organs of catfishes (silurids); and possible related organs in several other fish groups. These are known as ampullary lateral-line organs, and they have features in common. The sensory cells are withdrawn from the body surface, lack kinocilia, and have no mechanical contact with the surrounding water through a cupula. The latter attribute, indeed, is typical for all the acousticolateral end organs, except ampullary sense organs, in which the sense cells lie within the wall of a vesicle (or ampulla) that opens to the surface through a tubelike duct. Ampulla and duct are filled with a gelatinous substance that has excellent electrical conductivity.

Fish with ampullary sense organs are found to be remarkably sensitive to electrical stimuli—*i.e.,* minute, local potential differences in the surrounding water at their body surface. In behavioral experiments with sharks and rays, sensitivity to changes of 0.01 microvolt per centimetre (one microvolt = 1/1,000,000 of a volt) along the body surface has been found for the ampullae of Lorenzini. Similar, though somewhat higher, values have been recorded from the ampullary nerve fibres. A decrease in voltage at the opening of the ampulla causes an increase of the spontaneous nerve-impulse frequency; an increase in voltage at the opening produces the opposite response. Through their electrical sensitivity, such fish can detect and locate other organisms in darkness, in turbid water, or even when these organisms are hidden in the sand or in the mud of the bottom.

Electrical "radar"

Sharks, rays, and most catfishes are able to detect electrical changes (biopotentials) emanating from other organisms. The freshwater mormyrids and eels, on the other hand, have special signal-emitting electric organs. They produce a series of weak electric shocks (up to a few volts), sometimes quite regularly and frequently; for example, about 300 shocks per second in the mormyrid fish *Gymnarchus.* In this way, a self-generated electric field is created in the immediate surroundings. Any appropriate object (for example, a prey animal with good conductivity in relation to fresh water) will cause a deformation of the electric field and can thus be detected in a radar-like manner through the sensitive ampullar electroreceptors.

Some theorists suggest that initially mechanoreceptive lateral-line organs evolved into electroreceptors. At any rate, evidence of a certain double sensitivity—to mechanical and to electrical stimuli—has been observed in electrophysiological experiments with Lorenzinian ampullae. This double sensitivity has not been found, however, in behavioral experiments; alterations in behaviour indicate that ampullary lateral-line organs merely serve the animal as electroreceptors in adapting to the environment.

Other varieties of mechanoreception. *Surface waves.* Several species of animals living at or near the water surface use surface waves or ripples emanating from potential or struggling victims to locate their prey quickly: examples are the toad *Xenopus,* several fish species, and such insects as the back swimmer (*Notonecta*) and the water strider (*Gerris*). The whirligig beetle (*Gyrinus*) also uses surface ripples to avoid collisions with obstacles and companions. The sensory structures involved range from specialized tactile hair receptors (trichobothria) to internally located cells (proprioceptors) in movable body appendages and lateral-line organs.

Water and air currents. Special water-displacement receptors found in lobsters (*Homarus*) are most reminiscent of the lateral-line organs in vertebrates. Water-current receptors also enable several kinds of bottom-dwelling invertebrates to orient themselves (rheotaxis) in rivers and tidal currents. Many predators among these animals also respond chemically (see *Chemoreception* below), moving against the current (positive rheotaxis) until the prey is reached. In this way, for example, certain marine snails easily find their particular prey (sea anemones). Similarly among insects, the chemical "smell" of prey or of potential sex partners elicits a tendency to move against the wind (anemotaxis) until the source of the chemical stimulus is found. Several types of air-current receptors (true mechanoreceptors) on the heads of insects enhance such chemoreceptive behaviour. In flying locusts, an air current directed appropriately toward the head elicits compensatory reflex flight movements. The receptors involved (groups of hair sensilla on the head) mediate small corrections in the maintenance of straight flight; major guidance, however, derives from the insect's visual contact with the ground below.

Vibration reception. Adaptation and recovery occur most rapidly among touch receptors, and they tend to respond well to repeated stimulation, even of relatively high frequency. Thus, a person can feel whether an object is vibrating; above a threshold frequency of about 15 cycles per second (cps), discretely perceived tactual stimuli seem to fuse into a quite new and distinct vibratory sensation. The upper frequency limit of this vibration sense is found at several thousand cps among normal individuals, with sensitivity being maximal in the range of 200 cps (above a threshold amplitude of about 100 millimicrons). Just as pitch is discriminated in hearing, differences of about 12 to 15 percent in vibration frequencies can be distinguished by most people.

Specialized vibration receptors

Vibration sensitivity is not limited to man; fish, for instance, also may respond to low-frequency water vibrations with tactile receptors. In addition, several kinds of animals have special vibration receptors. In some insects, a group of specialized structures (chordotonal sensilla) in the upper part of each tibial segment of the leg signal vibrations from the ground below. In the cockroach, the threshold amplitude for vibrational stimuli of this kind has been found to be less than 0.1 millimicron. Birds have special receptors (corpuscles of Herbst in the tibiotarsal bone of the leg) with which they can detect slight vibrations of the twig or branch on which they sit. Perhaps birds are alerted at night in this way to approaching predators; maximal sensitivity is at about 800 cps, and the threshold amplitude is close to 20 millimicrons. Spiders also use their vibration sense to locate prey in the web.

Generalized hydrostatic pressure. Several types of aquatic animals are sensitive to small changes of hydrostatic, or water, pressure. Among fish, this applies particularly to the order Ostariophysi (Cypriniformes), which includes about 70 percent of all the freshwater species of bony fishes. The swimbladder in these animals is connected with the labyrinth (sacculus) of the inner ear through a chain of movable tiny bones, or ossicles (weberian apparatus). Alterations in hydrostatic pressure change the volume of the swimbladder and thus stimulate the sacculus. These fish can easily be trained to respond selectively to minute increases or decreases in pressure (for example, to a few millimetres of water pressure), indicating that they have a most refined sense of water depth. All of these fish are so-called physostomes, which means that they have a swimbladder duct through which rapid gas exchange with the atmosphere can occur; many live in relatively shallow water. The hydrostatic-pressure sense can function to inform the animals about their distance from the surface or about the direction and velocity of their vertical displacement. It also appears that improvement and refinement of the sense of hearing arises through the swimbladder's connections via the weberian apparatus with the labyrinth.

Sensing of hydrostatic pressure

The sensitivity of several kinds of crustaceans to relatively small hydrostatic-pressure changes (as low as five to 10 centimetres [two to four inches] of water pressure) is most remarkable because these animals have no gas-filled cavity whatsoever. The mechanism by which the stimuli are detected remains a puzzling question, although information about changing water depth during tidal ebb and flow clearly would seem to have adaptive value.

RECEPTION OF INTERNAL MECHANICAL STIMULI

Some proprioceptors (internal receptors) for mechanical stimuli provide information about posture and movements of parts of the body relative to each other; others contribute to an undisturbed course of coordinated muscular actions (*e.g.,* in locomotion). Best known from studies of vertebrates and arthropods, some are tonic proprioceptors (serving to maintain muscle tone in posture); others are of the phasic type (serving movement); still others have a mixed phasic-tonic character. In principle, proprioceptors can be stimulated adequately by pressure or stretching during active movements of the animal (reafferent stimulation) as well as through passive external pushing and pulling (exafferent stimulation). One passive factor, particularly in land-inhabiting animals, is gravity as it acts on bodily tissues or organs. Proprioceptors thus not only serve reflex adjustments in posture and relatively automatic movements of parts of the body with respect to each other (as in driving an automobile) but they also provide gravitational information about the position of limbs or of the whole body in space. To the extent that they are gravity detectors, these sensory structures are properly called external receptors (exteroceptors instead of proprioceptors). For receptors that are diffusely located within the body, a clean distinction between proprioceptive and possible exteroceptive function (gravity reception) is experimentally practicable only under conditions of weightlessness, as in space travel.

Vertebrates. *Muscle spindles.* Well-known proprioceptors of all the four-limbed vertebrates studied are the muscle spindles occurring in the skeletal (striate) muscles; fish muscles show structurally simpler but functionally comparable receptors. Each muscle spindle in mammals consists of a few slender, specialized (intrafusal) muscle fibres that are surrounded by a sheath of connective tissue filled with lymph fluid (Figure 2). The muscle spindle itself is surrounded by and arranged parallel to the ordinary (extrafusal) muscle fibres. Each intrafusal fibre consists of contractile (motor) parts at both ends and a noncontractile sensory midsection that serves as a receptor for stretch (changes of length and tension). There is double (primary and secondary) sensory innervation in mammals, but the secondary endings are lacking in lower vertebrates. Even when the animal is at rest, both types of endings are active (under the tension of normal muscle tonus). Additional stretch (lengthening) of the intrafusal midsection increases the nerve impulse frequency, and relaxation (shortening) causes a decrease. The primary (phasic-tonic) ending responds quickly; responses of the secondary (tonic) endings are slower.

The length of the muscle spindle as a whole varies with the contraction phase and the length of the muscle to which it belongs. The length of the sensory midsection, however, may change more or less independently because its motor nerve endings function apart from the innervation of the extrafusal muscle fibres. Thus the ratio of extrafusal–intrafusal contraction determines whether or not a change of length in the midsection will occur during muscle activity. There are reasons to suppose that midsection stretch remains more or less unchanged during self-initiated ("voluntary") movements; reafferent stimulation of muscle spindles would be avoided in this way. But as soon as an unexpected (exafferent) stretch of a muscle occurs—for example, when a leg pushes against an obstacle during locomotion—the midsections stretch to produce an increase of impulse frequency. This neural activity elicits a compensatory reflex contraction of the stretched muscle, as in the knee jerk during medical examinations: a blow beneath the kneecap causes stretch of a thigh muscle, stimulation of its muscle spindles, and a compensatory jerking contraction of the same muscle.

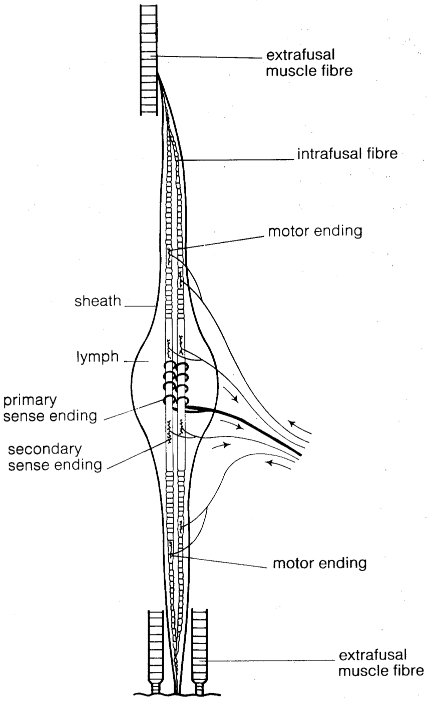

Figure 2: Mammalian muscle spindle.

Knee jerk

Tendon organs. Branched nerve endings on vertebrate tendons (not far from their point of attachment to muscle) also respond to stretch; however, they are decidedly less sensitive than are muscle spindles. These tendon organs produce no impulses under the stretch of normal, resting muscle tonus. Neither is there a mechanism preventing reafferent stimulation of tendon organs, nor does it make any difference whether the stretch is brought about by active muscle contraction or passively following external influence. In both cases tendon receptors respond according to the intensity of the stretch; their response causes relaxation of the attached muscle and may serve (among other functions) to prevent anatomical damage.

Human awareness of posture and movement of parts of the body with respect to each other (kinesthetic sensations) is attributable neither to muscle spindles nor to tendon organs. The sensations are based on stimulation of sensory nerve endings of various types at the joint capsules and of stretch receptors in the skin. There are also mechanoreceptors in the walls of some blood vessels (*e.g.*, in the aorta and the carotid sinus); these are sensitive to blood-pressure changes and play a regulatory role in the circulatory system.

Invertebrates. Among invertebrates, the arthropods exhibit the most readily distinguished proprioceptors, called muscle-receptor organs and chordotonal proprioceptors. Both types of structure occur in crustaceans as well as in insects. Adequate stimuli are variations in length and tension (stretch).

Muscle receptor organs. Although they structurally and functionally resemble the muscle spindles of vertebrates, arthropod muscle receptor organs are always situated outside of the muscles proper. Numerous branches of multipolar primary nerve cells are connected with the noncontractile midsection of specialized muscle fibres, both ends of which are contractile and have an efferent (motor) innervation. In crustaceans, the muscle receptor organ contains two elements: a slowly contracting, nonadapting tonic fibre and a quickly contracting, rapidly adapting phasic element.

Chordotonal proprioceptors. Widely distributed among arthropods, chordotonal receptor organs are thin, elastic, innervated strands of connective tissue, stretched between adjacent segments of the body or of leg joints. The sensory endings of a few bipolar primary nerve cells, each provided with a spiny sensillum (scolopidium), are attached to the strand. Chordotonal proprioceptor organs generate neural impulses that show them to contain both phasic movement receptors and tonic pressure receptors; sometimes two varieties of each. Thus there are receptors that selectively respond only during flexion, only in the flexed position, only during stretch, or only in the stretched state of the given strand. Several kinds of insects, apart from their clearly proprioceptive-chordotonal functions, have other chordotonal elements that serve as typical exteroceptors. Sense organs of this type (tympanic and subgenual organs in legs, organs of Johnston in the antennae) may function in the reception of sound waves, of vibrations in the ground, or of other external mechanical stimuli. Many insects also have a special type of chordotonal-proprioceptor structure (campaniform sensilla) not found in crustaceans. Sensory endings of primary nerve cells are connected with thin, dome-shaped (campaniform) spots on the exoskeleton. These campaniform sensilla respond to external stimuli such as local tensions and deformations of the body surface. They function in the regulation of such movements as the beating of wings in locusts. Similarly functioning proprioceptors (lyriform organs) are also observed among spiders.

In insects, body posture and movements of individual body parts with respect to each other can be detected through groups of external tactile hairs implanted near the joints between adjacent skeletal elements. Some function as rotation receptors or exteroceptors to detect the direction of gravity.

Among other invertebrates, the cephalopod *Octopus* clearly exhibits proprioceptive abilities, though specific receptors have not yet been identified. These animals, however, seem unable to integrate proprioceptive data in the central nervous system with other sensory information in learning. Thus an octopus readily can be taught to discriminate between two small cylindrical objects (both provided with longitudinal ribs) if the ribs on one of them are somewhat coarser than those on the other. But the animal cannot learn to distinguish between cylinders of the same size if the ribs are equally coarse and if they are longitudinal on one and transverse in the other; nor can it learn to discriminate between small objects of different form or different weight. This indicates that an octopus cannot learn any discrimination that depends on sensory information about the position of the arms and suckers making contact.

Octopus learning

MAINTENANCE OF EQUILIBRIUM

Active maintenance of equilibrium during bodily movement (*e.g.*, in locomotion) requires appropriate sensory functions. Although many animals usually maintain their bodies with the long axis horizontal (backside up), man being a notable exception, there are frequent departures from the usual position. A fish may dive steeply downward and a man may alter his normal orientation by lying down at full length. In no case, however, need there be any loss of equilibrium. Every deviation means an equilibrium disturbance and evokes compensatory reflex movements, not only a deviation from the usual position as in most laboratory experiments.

Maintenance of equilibrium is based upon contact of the animal with the external world; several sensory systems may play a role in this context. When an animal moves over a solid surface, tactile stimuli usually predominate as cues. It has been noted above how proprioceptors in vertebrates and arthropods can also contribute to spatial orientation; bodily tissues under gravity weigh vertically down and stimulate internal mechanoreceptors in a way that depends on, and varies with, the animal's spatial position. When they are out of contact with the ground, many animals orient themselves in space by keeping their back (dorsal) side turned up toward the light. Visual cues also can serve equilibration; for example, through compensatory body movements (optomotor reflexes) brought about by the shifts of the image of the environment over the retina of the eye. For the receptors mentioned thus far, however, equilibration is not the unique function. There are other sensory structures that are genuine organs of equilibrium in that they primarily and exclusively serve orientation of posture and movement in space.

Secondary cues

Gravity receptors. Because of the constancy of its magnitude and direction, gravity is most suitable in providing animals with cues to their position in space. The sense organs involved (statoreceptors) usually have the structure of a statocyst, a fluid-filled vesicle containing one or more sandy or stonelike elements (statoliths). Sensory cells in the wall of the vesicle have hairs that are in contact with the statolith, which always weighs vertically down. Hence, depending on the animal's position, different sense cells will be stimulated in statocysts with loose statoliths (Figure 3A); or the same sense cells will be stimulated in different ways in statocysts with a statolith loosely fixed to the sense hairs (Figure 3B).

From W. von Buddenbrock, *Vergleichende Physiologie*

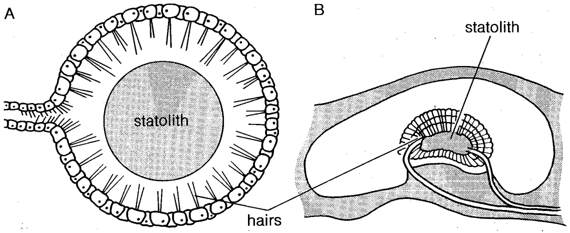

Figure 3: *Statocyst gravity receptors.*
(A) With a free-moving statolith, as in a mollusk (scallop), and
(B) with statolith loosely fixed to hair cells, as in a crustacean (opossum shrimp).

Statocysts are found in representatives of all of the major groups of invertebrates: jellyfish, sandworms, higher crustaceans, some sea cucumbers, free-swimming tunicate larvae, and all the mollusks studied thus far. Analogous receptors that occur generally in vertebrates are the ear's utriculus and probably (to a degree) also two other otolith organs (sacculus and lagena) of the ear (labyrinth). Statocysts (including vertebrate labyrinthine statoreceptors) develop embryologically from local invaginations of the body surface. In primitive evolutionary forms, the interior of the statocyst is in open communication with the surrounding sea and thus is filled with water; statoliths usually are sand particles taken up from outside. In a few animal groups, this developmental stage is only found during the larval phase, the initial opening to the exterior being closed in the adult animal. In more advanced forms, the liquid content (statolymph) and the statoliths are produced by cells in the wall of the organ. This specialized type of closed statocyst is found in many snails, in all the cephalopods such as the squid (except *Nautilus*), and in the vast majority of vertebrates (from bony fishes up to and including mammals).

Geotactic behaviour

Statocyst function may be studied by observing compensatory reflexes under experimental conditions. When the position of a laboratory animal is appropriately changed, movements of such body parts as the eyes, head, and limbs can be observed. Such movements tend to counteract the imposed change and to restore or to maintain the original position. Evidence of statoreceptor function is provided if these reflexes are abolished after surgical elimination of both statocysts. Many animals exhibit locomotion that is gravitationally directed vertically down or up (positive or negative geotaxis, respectively). Geotactic behaviour may be experimentally altered by whirling the animal in a centrifuge to change the direction and to increase the intensity of the force exerted on the sensory hairs by the statoliths. Molting crustaceans shed the contents of their statocysts along with their exoskeleton. If such an animal is placed in clean water containing iron filings, it takes up new iron statoliths instead of the usual sand grains. By moving a magnet to vary the direction of the force exerted by the metal statoliths, the animal can be made to adopt any resting position, even to stay upside down. Statoliths can be washed out of the open statocysts of a shrimp without damaging the sensory hairs. When the hairs are pushed in different directions with a fine water jet, the shrimp exhibits compensatory reflexes. In this way, it has been shown that each statocyst signals a change of position around the animal's long axis; the same reaction is found to occur after removal of the statocyst on one side only. Electrical impulses in the statocyst nerve can be recorded while the animal is in different spatial positions, or during experimental deflection of the sensory hairs. Such experiments reveal that both vertebrates and decapod crustaceans (*e.g.*, shrimp) exhibit spontaneous and statolith-induced neural activity in the lining (epithelium) of the gravity receptor.

Spontaneous activity. The sensory epithelium of a statocyst is spontaneously active, initiating a continuing series of impulses directed toward the central nervous system (even when the statoliths are experimentally removed from the statocyst). This resting frequency of neural activity is fairly constant and completely independent of the animal's position in space. In vertebrates and in crustaceans, spontaneous activity of the left statocyst affects the central nervous system to produce a tendency of the animal to roll to the right about its long axis; spontaneous activity of the right statocyst prompts a tendency to roll to the left. Normally, these rolling tendencies neutralize each other in the central nervous system, not becoming manifest unless the statocyst on one side of the body is functionally eliminated by complete surgical removal, by destruction of its sensory epithelium, or by cutting its nerve. This intervention permits the influence of the spontaneous activity generated in the remaining statocyst to be felt, and the animal tends to roll toward the operated side. Unilateral (one-sided) removal of the statoliths alone, however, does not produce such an effect so long as the sensory cells in the epithelium remain intact. The rolling tendency of a unilaterally operated animal usually diminishes little by little in the course of hours or days, until it finally disappears completely. If the remaining statocyst is then removed, rolling occurs again, but this time to the other (last operated) side. This tendency also diminishes and disappears with time. Apparently the unbalancing effect of the spontaneous influx from a statocyst is gradually counteracted in some unknown way by the central nervous'system.

Statolith influences. Vertebrates and crustaceans have statoliths that are loosely connected to the sensory hairs by a sticky substance. With such a mechanical arrangement, the statolith stimulates the sensory cells by parallel (shearing) motion rather than by pressure or pull at right angles to the epithelium. The effects are demonstrable in experiments with fish, based on the dorsal-light orientation noted above. In a laboratory darkroom, if light shines at a fish from one side, the animal assumes an oblique position. While the fish tends to turn on its side (with its back side to the light), gravity tends to keep it vertical; the oblique position is the result. In a whirling centrifuge, the pressure exerted by the statoliths may be increased. When this is done, the fish rights itself almost precisely to the degree that the shearing force exerted by the statoliths is held constant.

Otolith organs in vertebrates

In vertebrates, statoreception is localized in the head within the labyrinth, particularly within the utriculus, one of the three statolith (or otolith) organs (Figure 4). The statolith is surrounded by a gelatinous substance akin to the cupula of the lateral-line organs. In most higher vertebrates, the head moves rather flexibly because it is not rigidly connected to the trunk. Thus information coming from the utriculi has to be neurally integrated centrally with impulses from proprioceptors that signal the position of the head with respect to the limbs and trunk (for example, neck receptors), if the animal is to orient its head and body appropriately in space.

The roles played by the remaining otolith organs of the labyrinth (sacculus and lagena) in statoreception remain unclear. Their sensory epitheliums (maculae) are roughly at right angles to each other and to that of the utriculus. In view of their arrangement, it was once supposed that the three otolith organs of the labyrinth would serve to detect position in three spatial planes (indeed, the three semicircular canals do serve to detect rotation in different planes). It has been found, however, that the sacculus and the lagena (as far as it is present) can be put out of function bilaterally in representatives of all the classes of vertebrates without causing overt equilibration disturbances. On the other hand, some secondary statoreceptor function has been demonstrated for these otolith organs in all the animals from fish up to and including man.

In the special case of flatfishes (*e.g.*, halibut, sole, flounder), the normal upright position in the juvenile stage changes to one of swimming and lying on one side as an adult. The eye from that side migrates to the upper surface; but the situation of both labyrinths remains unchanged. Hence, the originally horizontal maculae of the utriculi are now oriented vertically. In these fish, the sacculi (usually the major organs of hearing in bony fishes) indeed may be shown to serve as statoreceptors. At any rate, the same otolith organ may function in one fish species as an organ of hearing and in another as a gravity receptor; clearly, both functions depend on basically identical mechanical stimulation.

As receptors belonging to the acousticolateralis system, the otolith organs of vertebrates have hair cells of the same type that is found in lateral-line neuromasts. Under the electron microscope, the sensory hair cells show a pattern of polarization (arrows in Figure 4) throughout the macula, indicating the directions in which the shearing otolith should have an activating or an inhibiting influence. Results of physiological investigations thus far performed agree well with these deductions.

Statocyst research among crustaceans

Among the invertebrates, most statocyst research has been done with such decapod crustaceans as lobsters.

From Cold Spring Harbor Symposia on Quantitative Biology (1965)

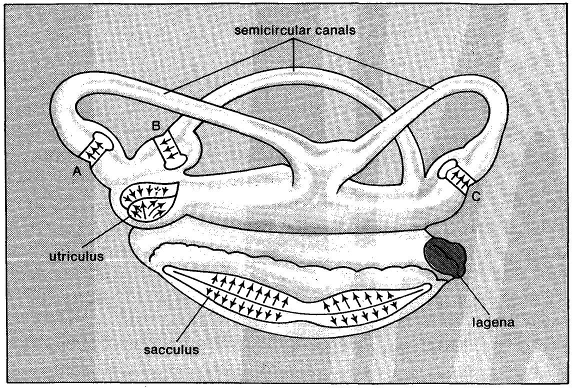

Figure 4: Right labyrinth of a codlike fish called the burbot, seen from above. Ampullae of anterior, horizontal, and posterior semicircular canals are lettered A, B, and C, respectively. Arrows show direction of hair-cell polarization.

The working mechanism of their statocysts conforms with the physiological principles of vertebrate statoreception discussed above. The results of electrophysiological investigations support the conclusions drawn from behavioral observations. In some crustacean statocysts (for example, in the lobster, *Homarus*), special statoreceptors are found that signal the same bodily position differently, depending on the direction of movement through which it was reached (hysteresis effect). The part played by the statocyst in equilibration has been investigated in several other invertebrate groups, among them jellyfish, sandworms, and such mollusks as scallops, common snails, sea hare, and octopus. Each sensory cell from the vertical macula in a statocyst of the octopus bears up to 200 kinocilia, and all the cilia of each cell are polarized in the same direction. On the macula as a whole, there is a radiating polarization pattern, the activating direction pointing everywhere from the centre to the margin. Compensatory eye reflexes resulting from tilting the animal head down or head up around a transverse axis reveal a hysteresis effect. After unilateral-statocyst removal, mollusks do not tend to roll toward the operated side (as do vertebrates and crustaceans) but toward the side of the remaining statocyst.

The almost complete absence of statocysts in insects is remarkable in view of evidence that many of them have a high degree of sensitivity to the direction of gravity. Receptors involved are specialized tufts of tactile hairs at the external body surface; in the honeybee, such groups of hairs are notably found between head and thorax and between thorax and abdomen. The adaptive function of these static (gravity) receptors becomes manifest in the honeybee "dance language" performed on a vertical comb in the hive. The angle between the dancing bee and the perpendicular seems to direct other bees to sources of nectar and pollen.

Rotation receptors. In addition to having tonic statoreceptors (signalling position with respect to gravity), several groups of animals have purely phasic rotation receptors that respond only to angular acceleration or deceleration, as produced on a turntable. Vertebrates, cephalopods (*e.g.*, squid), and decapod crustaceans (*e.g.*, lobsters) have special rotation receptors at the inner surface of the fluid-filled organ of equilibrium (labyrinth or statocyst). This fluid lags inertially with respect to the wall of the organ at the onset and arrest of every rotation. Among crustaceans, such as crabs or lobsters, the rotation receptors incorporate relatively long, delicate hairs that extend more or less at right angles to the wall freely into the statocyst fluid. The hairs respond quickly to fluid motion, swaying around their point of attachment and returning slowly through their elasticity to resting position. Their stimulation causes compensatory reflexes of the eyestalks or of the whole animal.

Eyestalk reflexes can be readily observed when a blinded, legless crab is rotated while flat on a turntable. These reflex movements are called nystagmus. At the onset of rotation to the right, both eyestalks move at about the rotation rate to the left by way of compensation until they reach their maximal deviation. In most cases, one or more jerky movements of the eyestalks in the opposite direction are observed per rotation during the initial period (quick, restoring nystagmus phases). In general, however, the eyestalks remain deviated opposite to the direction of rotation for several revolutions of the turntable. During prolonged constant-velocity rotation, the crab's eyestalks return to their symmetrical position; at this point, inertial lag in the statolymph is reduced to the degree that the fluid finally rotates together with the statocyst wall. Sudden arrest of the turntable under these circumstances causes afternystagmus: the eyestalks move promptly to the right (at about the same velocity as they moved to the left at the onset of rotation) until their maximal deviation toward this side is reached. After a quick jerk in the opposite direction, the eyes continue their slow movement to the right, and in this way as many as three or more after nystagmus jerks may occur with decreasing intensity. Such aftereffects may last many seconds, but finally the eyestalks return slowly to their symmetrical position. All of these nystagmic effects from such horizontal rotation are abolished in a blinded crab, however, after bilateral elimination of the long, delicate statocyst hairs by their denervation or by cauterization of the hair bases.

Rotation of a blinded crab

In vertebrates, rotation reception occurs within the labyrinth. Each labyrinth has three semicircular canals arranged in planes at right angles to each other (Figure 4); the canals communicate with the utriculus. One end of each canal is widened into an ampulla, and the sensory cells (hair cells) are arranged in a row on a ridge (crista) of the ampullar wall. The crista is oriented at right angles to the plane of the canal, and the extended hairs of its sensory cells are imbedded in a jellylike cupula that reaches to the opposite wall of the ampulla. Endolymph displacement through a canal makes the cupula move aside, as if it were a swinging door. In vertebrates, the inertial lag of the endolymph at the onset of rotation is very brief, the fluid catching up with the angular velocity of the labyrinth within a fraction of a second. An ampulla with its crista and cupula is reminiscent of a lateral-line canal neuromast, except that all of the hair cells of a crista are polarized in the same direction. In the cristae belonging to the vertical semicircular canals the kinocilium is implanted at the side facing the canal; in the horizontal cristae all of the sensory cells are polarized toward the opposite side (facing the utriculus). This structural arrangement is in keeping with differences between the vertical and the horizontal canals observed in behavioral and electrophysiological experiments.

A turn of the animal's head around the vertical axis to the left increases the neural-impulse frequency (activation) in the left horizontal crista; a turn of the head to the right causes a frequency decrease (inhibition). Opposite effects occur at the same time in the right horizontal crista. Recordings from the different crista nerves, while the animal is being rotated successively around all three major body axes, show the horizontal crista to respond only to rotation of the animal around its vertical axis; the vertical cristae, however, respond to rotation about all three axes. Behavioral data (compensatory eye reflexes) provide similar results, except that the eyes fail to exhibit an observable response associated with the vertical semicircular canals during rotation around the vertical axis. Stimulation of the vertical cristae under these circumstances gives rise to the simultaneous contraction of antagonistic pairs of eye muscles; hence the absence of a compensatory eye rotation.

In decapod crustaceans, particularly crabs, the statocyst is anything but a simple spherical vesicle; it has a very complicated shape with several curved invaginations and projections. In a small corner in the lowest (most ventral) part of the crab statocyst, a cluster of minuscule sand particles (statoliths) is found in contact with specialized (hooked) hairs. Apart from these hook-hair gravity receptors, there is a single, slightly curved row of relatively straight "thread" hairs atop an oval invagination in the middle of the lower statocyst wall. These hairs are the rotation receptors described above in the blinded crab revolving on a turntable. Bilateral elimination of the thread hairs alters the reflexes of the eyestalks. Instead of reacting immediately, at the very onset of rotation, in the absence of thread hairs on both sides, the eyes initially maintain their symmetrical position. They start their compensatory movement only after rotation has begun or at the end of rotation after the animal has reached a new, steady position. Furthermore, the velocity of this compensatory eye movement seems to be independent of the rate of angular acceleration or deceleration. The delayed nature of the response suggests that loss of rotation sensitivity about horizontal axes results from thread-hair elimination.

That the thread hairs are indeed responsive to rotation about all three major body axes is supported by a number of observations. Bilateral elimination of the impulses from the statolith hairs (position receptors) by selective nerve cutting, for example, does not affect the animal's response to rotation around the vertical axis. Despite their loss of impulses from position receptors, crabs subjected to angular acceleration or deceleration about either horizontal axis exhibit the normal compensatory eyestalk reflexes at the very onset of rotation. When a new (inclined) position of the animal is maintained, the eyestalks again become

Eyestalk reflexes

symmetrical, although complete return to symmetry may require several minutes. On the other hand, when both thread hairs and statolith hairs are eliminated, all such rotation and position reflexes of the eyestalks and related aftereffects are abolished. After unilateral elimination of the thread hairs or removal of one entire statocyst in a blinded crab, both eyes still react to rotation around the vertical axis in both directions. When electrical recordings are made of the activity of the primary sensory neurons innervating the thread hairs, similar results are obtained, the receptors responding only to angular acceleration and deceleration. They are spontaneously active, and the neural response to rotation that is superimposed upon the spontaneous background consists of a coded sequence of impulse-frequency increases and decreases. The same reception unit responds to acceleration about all three major axes.

The statocysts of cephalopods (nautilus, squid, octopus) rival the complexity of crab statocysts. In addition to the perpendicular macula with its statolith (for gravity reception), the octopus has three cristae (containing many hair cells with two-directionally polarized kinocilia) arranged approximately at right angles to each other. Rotation (turntable) experiments and surgical removal of statocyst receptors have shown that the octopus cristae function as rotation receptors. Nystagmus and afternystagmus persist almost unchanged after unilateral statocyst removal, but they are completely abolished after the additional removal of the second statocyst in a blinded octopus. In the cuttlefish (*Sepia*), the statocyst is structurally even more complicated; besides three cristae, it has three maculae (statolith organs) also arranged in different planes.

Rotation receptors of a different type are found in some groups of insects. Dragonflies (for example, *Aeshna*) have external hair receptors between the head and thorax. If a gust of wind turns the animal around its long axis during flight, the relatively heavy head lags with respect to the thorax. The resulting stimulation of the hair receptors in the neck region elicits compensatory flight reflexes and restores the insect to a normal position. These receptors do not respond to static head displacements. In the Diptera (true flies), the posterior knobbed "wings" (halteres) serve as flight stabilizing rotation receptors. During flight, the halteres beat in a vertical plane, synchronously with the forewings. Rotational instability is gyroscopically counteracted by the beating action. Receptors are campaniform sensilla at the base of the haltere. (S.Di.)

Thermoreception

Thermoreception is a process in which different levels of heat energy (temperatures) are detected by living things. Temperature has a profound influence upon living organisms. Active life among animals is feasible only within a narrow range of body temperatures, the extremes being about 0° C and 45° C. On the Fahrenheit scale the same range is 32° F and 113° F. Limitations depend on the freezing of tissues at the lower temperature and on the chemical alteration of body proteins at the higher end of the range. Within these limits the metabolic rate of the animal tends to increase and decrease in parallel with its body temperature.

Body temperature and metabolism among more highly evolved animals (*e.g.,* birds and mammals) are relatively independent of direct thermal influences from the environment. Such animals can maintain considerable inner physiological stability under changing environmental conditions and are adaptable to substantial geographic and seasonal temperature fluctuations. A polar bear, for example, can function both in a zoo during summer heat and on an ice floe in frigid Arctic waters. This kind of flexibility is supported by the function of specific sensory structures called thermoreceptors (or thermosensors), which enable the animal to detect thermal changes and to adjust accordingly.

Temperature of the body directly reflects that of the environment among cold-blooded (poikilothermic) animals, such as insects, snakes, and lizards. These creatures maintain safe body temperatures mainly by moving into locations of favourable temperature (*e.g.,* in the shade of a desert rock). Warm-blooded (homoiothermic) organisms, such as the polar bear, normally keep practically constant body temperature, independent of environment. Homoiothermic animals, including man, are able to control their body temperature not only by moving into favourable environments but also through the internal regulatory (autonomic) effects of the nervous system on heat production and loss. Such autonomic adjustments depend on lower brain centres; the behavioral (movement) responses require the function of the brain's outer layers (the cerebral cortex).

Cold-blooded and warm-blooded animals

A variety of behavioral responses is elicited through stimulation of thermoreceptors, including changes in body posture that help regulate heat loss and the huddling together of a group of animals in cold weather. In some species, thermoreceptors are also involved in food location and sexual activities. Bloodsucking insects, such as mosquitoes, are attracted by thermal (infrared) radiations of warm-blooded hosts; such snakes as pit vipers can locate warm prey at considerable distance by means of extremely sensitive infrared receptors. Man has achieved the widest range of adaptability to extremes in temperature, since his technology allows him to protect himself under a considerable variety of thermal conditions on earth and even in outer space.

Perceptual aspects of thermoreception are found in evidence that man and other animals have conscious temperature sensations and emotional experiences of thermal comfort and discomfort (see below *Human sensory reception*). The effects of temperature on productive efficiency and behaviour (*e.g.,* on one's ability to think) have led to the installation of heat-regulating equipment in homes, public buildings, factories, and similar shelters for people, livestock, and other animals.

Thermoreception can be studied in different ways: (1) on the basis of reports of temperature sensations and thermal comfort by human subjects; (2) through observations of behavioral responses to variations in temperature by all kinds of animals; (3) by the measurement of compensatory autonomic responses (*e.g.,* sweating or panting) to thermal disturbances in the environment; and (4) by recording electrical impulses generated in the nerve fibres of thermoreceptors in laboratory animals and human subjects.

GENERAL PROPERTIES OF THERMORECEPTORS

The concept of thermoreceptors derives from studies of human sensory physiology, in particular from the discovery reported in 1882 that thermal sensations are associated with stimulation of localized sensory spots in the skin. Detailed investigations reveal a distinction between hot spots and cold spots; that is, specific places in the human skin that are selectively sensitive to warm stimuli or to cold. To this extent the different thermoreceptors exhibit sensory specificity. Modern neurophysiological methods show thermoreceptors also to be biophysically specific, in that they include nerve endings that are excited only by or primarily by thermal stimuli.

Early investigations of thermoreception

Extending far beyond the context of conscious temperature sensation as reported by humans, the biophysical definition holds for any thermoreceptive structure. Clearly, electrical responses from thermoreceptors are observable whether conscious sensations are reported by the animal (as in the case of a person) or whether they are not (as in the case of a laboratory rat). Although they are closely related, the concepts of sensory and biophysical specificity are not identical, the criterion being the quality of inner experience (sensation) in the first case and the quality of the neurally effective stimulus in the second. To make the distinction clear, a receptor that is neurally excited by cooling as well as by the application of a chemical (*e.g.,* menthol) might be classified only as a specific (cold) thermoreceptor in terms of human sensation; biophysically, however, it manifestly is a chemoreceptor as well (see below *Chemoreception*).

Most of the modern understanding of thermoreceptors is based on biophysical (electrophysiological) investigations. This approach, introduced in 1936 for recording the electrical signals from single thermosensitive nerve fibres in the tongue of the cat, had been applied by 1960 to similar recordings from single thermoreceptors in the skin of human subjects. Such investigations are made by dissecting single nerve fibres under the microscope and placing them on electrodes or by inserting very fine wires (*e.g.,* tungsten microelectrodes) directly into the intact nerve or receptor. As in the case of other sensory nerve fibres, the electrical signals generated by the activity of thermoreceptors are brief impulses of about one millisecond duration and roughly constant amplitude. They follow in a more or less regular sequence, modulations (changes) in the frequency of which reflect differences in the intensity of the stimulus. (Frequency modulation is widely applied in such devices as radios for information processing.) Sensory structures are called specific thermoreceptors if they respond biophysically to temperature stimuli yet are practically insensitive to such other kinds of stimulation as mechanical pressure.

Cold receptors and warm receptors

The general properties of thermoreceptors in the external parts of the body are found to be similar for any species of animals investigated. Thermoreceptors can be divided into well-defined classes as cold and as warm receptors. At constant temperatures (within an appropriate range), cold receptors are continuously active electrically, the frequency of the steady discharge (static response) depending on temperature. In most cases the static activity reaches a maximum at temperatures between 20° and 30° C (68° and 86° F). On sudden cooling to a lower temperature level, the cold receptors respond with a transient increase in frequency (dynamic response); if the lower temperature is maintained, the frequency drops to a level of static discharge in adaptation. When the receptor is warmed up again, a transient decrease in electrical activity is seen, after which the frequency rises again and finally adapts to the initial static value. Warm receptors are also continuously active at constant temperatures, with a maximum at 41° to 46° C (about 106° to 115° F). On sudden temperature changes, warm receptors respond in the opposite direction from that of cold receptors, temporarily overshooting adaptation frequency on warming and showing transient inhibition on cooling. Thermoreceptors are thus selectively sensitive to specific ranges of temperature as well as to rate of temperature change.

Some receptor cells in the skin of fishes and amphibians respond both to mechanical and to thermal stimulation. In the skin of cat, monkey, and man, receptors have been found that are excited both by mechanical stimuli and by cooling. It seems, however, that these nerve endings are primarily mechanoreceptors (see above *Mechanoreception*), their sensitivity to cooling being much lower than that of specific cold receptors.

THERMORECEPTORS IN INVERTEBRATES

Insects placed on a surface that provides a temperature gradient (warmer at one end and cooler at the other) often congregate in a narrow band of temperature, providing behavioral evidence of sensitive thermoreception. Honeybees (*Apis mellifera*) normally choose a temperature range of 35° ± 1.5° C (95° ± 2.7° F); when repeatedly replaced at the warm end of the gradient, individual bees follow their average chosen temperature within ±0.25° C (±0.45° F). Bees also accurately regulate temperature in the hive between 35° and 36° C (95° and 97° F) by behavioral patterns (*e.g.,* beating wings to circulate air) in the brood season.

Among invertebrates other than arthropods, the leech (*Hirudo medicinalis*) can make temperature discriminations with an accuracy of 1° C (about 1.8° F). The slug (*Agriolimax reticulatus*) reacts at temperatures below 21° C (70° F) by increased locomotor activity in response to 0.3° C (0.5° F) cooling over a period of five minutes.

The temperature sensitivity of bloodsucking arthropods (*e.g.,* lice) is considerably greater than that of nearly all other arthropods; the warmth of the victim's body is the primary influence in stimulating and guiding such blood feeders. The so-called castorbean tick (*Ixodes ricinus*), which sucks blood from sheep, responds when its front legs, which are the primary site of thermal sensitivity, are warmed up by 0.5° C (0.9° F). The bloodsucking assassin bug (*Rhodnius prolixus*) responds with direct movement toward any warm stimuli; *e.g.,* when a glass tube warmed 15° C (27° F) above air temperature is kept within about four centimetres (1.5 inches) of its antennae. Similarly, mosquitoes (*Aedes aegypti*) fly readily to a warm, odourless, inanimate surface as if it were that of a warm-blooded creature. The mosquito's antennae are probably the site of the thermosensors, and the animals manifest sensitivity to changes in air temperature of about 0.5° C. In most insects the thermoreceptors appear to be located in the antennae, since they show impairment of thermoreceptive behaviour when part or all of the antennae are removed. Behavioral studies represent a rather gross method of localizing thermosensitive structures, however. A more direct approach to thermoreceptor function in insects has been achieved by electrophysiological methods. Microelectrodes with tips of very small diameter are inserted near the presumed thermosensitive cells. Any electrical nerve impulses elicited by temperature stimuli are amplified and recorded. This method permits, for example, the study and identification in various insects of receptors that are sensitive to cooling. Cockroaches (*Periplaneta americana*) have two whiplike antennae consisting of 120 to 180 ring-shaped segments that grow thinner and longer with increasing distance from the animal's head. There are about 20 cold receptors per antenna; these are located on the thicker segments (Figure 5), with rarely more than one per segment. Each cold receptor consists of a delicate hairlike structure (sensillum) emerging from a ring-shaped wall. The cold sensilla are mechanically protected by large bristles covering the segments of the antenna. At constant temperatures the cold receptor is continuously active, the average maximum frequency of its discharge being about 16 impulses per second at a temperature near 28° C (82° F). At higher and lower temperatures, the steady frequency becomes lower. When the receptor is rapidly cooled, its discharge frequency rises steeply up to 300 impulses per second and then declines gradually to a much lower constant level. On rapid warming, the opposite response is seen; *i.e.,* there is a transient inhibition of the receptor discharge, followed by a gradual restoration of the steady activity. The cold receptor is thus sensitive to constant temperatures as well as to the rate of temperature changes.

Studies with micro-electrodes

From *Zeitschrift fur Vergleichende Physiologie* (1968)

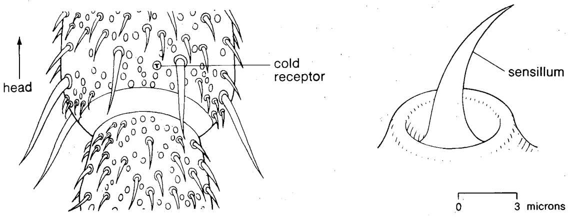

Figure 5: (Left) Portion of cockroach antenna showing location of cold receptor. (Right) Magnification of a single cold receptor of a cockroach.

Caterpillars of various moths (*Lasiocampidae, Saturniidae, Sphingidae*) have cold-receptor cells in their antennae and mouthparts (maxillary palps). Electrophysiological investigations with microelectrodes suggest that just three receptor cells located in the third antennal segment and probably not more than one receptor cell in the maxillary palp are sensitive to cooling. At constant room temperatures, static neural activity from such cells is observed; this activity increases in frequency when the temperature is lowered. During rapid cooling, the frequency rises steeply to a transient maximum of up to 300 impulses per second, while rapid warming produces a temporary inhibition of the discharge. Since only a few cells out of the 20 or 30 that comprise the thermoreceptor structure exhibit the typical electrical response to cooling, specific thermoreceptive function among caterpillars is strongly indicated.

Electrophysiological evidence for the presence of thermosensitive structures also is available for the antennae of honeybees and of migratory locusts (*Locusta migratoria migratorioides*). Temperature-induced changes in the spontaneous electrical activity within the central nervous system of honeybees also have been recorded. Other sensory structures in these animals also can be influenced by temperature, but their primary functions appear to be chemoreceptive or mechanoreceptive.

THERMORECEPTORS IN VERTEBRATES

Fish. Many species of modern bony fish (teleosts) are sensitive to very small changes of temperature of the water in which they live. Various marine teleosts, such as the cod (*Gadus gadus*), have been trained to swim half out of water up a long sloping trough in response to changes of as little as 0.03° to 0.07° C (0.05° to 0.13° F) in the temperature of the water flowing over them.

More detailed conditioning experiments with freshwater fish show that they can distinguish warm from cold, discrimination being made on the basis of thermal change rather than on absolute temperature. Temperature sensitivity persists in these animals when the nerve supplying the lateral line (see *Mechanoreception* above) is cut but is abolished after transection of the spinal cord. When freshwater fish are trained to seek food in response to a change in water temperature, they are found to discriminate differences of less than 0.1° C (0.2° F). Goldfish (*Carassius*) have been trained to discriminate between warm and cold metal rods that have been placed in their tanks. Consistent responses are obtained only when the rod is at least 2° C (3.5° F) colder or warmer than the water. Practically the whole surface of the fish, including the fins, is found to be thermosensitive.

Temperature discrimination in goldfish

This mode of temperature discrimination need not be ascribed to the function of specific thermoreceptors; it could depend on skin receptors that are sensitive to combined mechanical and thermal stimulation. Indeed, electrophysiological recordings from nerve fibres originating in the skin of fish support the latter view. Changes in the electrical activity of these fibres are elicited only when the skin is touched by some solid object; yet the frequency of this mechanically elicited neural discharge is heavily influenced by the temperature of the object used in touching the fish.

From *Journal of Physiology* (1956)

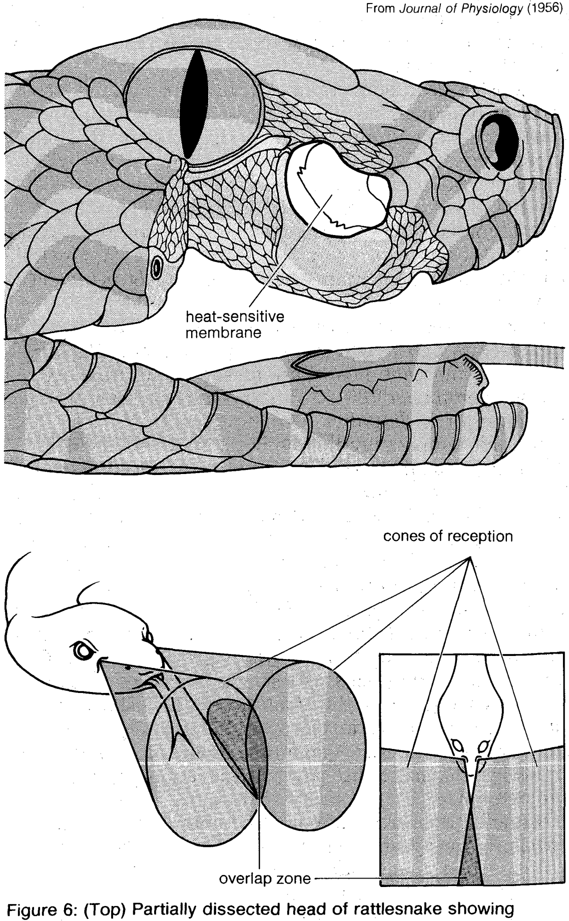

Figure 6: (Top) Partially dissected head of rattlesnake showing heat-sensitive membrane inside pit organ. (Bottom) Cones of reception, directions from which heat energy can be detected (see text).

Elasmobranchs, such as rays and sharks, have distinctive sense organs, called ampullae of Lorenzini, that are highly sensitive to cooling. These organs consist of small capsules within the animal's head that have canals ending at the skin surface. The capsules and their canals are filled with a jellylike substance, sensory-receptor cells being situated within each capsule. Recordings of impulses from single nerve fibres supplying the ampullae of Lorenzini in rays (*Raja*) and dogfish (*Scyliorhinus*) reveal steady activity of the receptors at constant temperatures between 0° and 30° C (32° and 86° F), the average frequency maximum appearing near 19° C (66° F). Rapid cooling causes transient overshooting of the stabilized discharge frequency, while rapid warming produces transient inhibition of the impulses. In some single fibres, cooling by 3° C (5.5° F) leads the frequency to overshoot by about 100 impulses per second. It remains an open question, however, whether the ampullae of Lorenzini are to be called specific thermoreceptors, since they also respond to mechanical stimuli and to weak electrical currents.

Amphibians and reptiles. Rattlesnakes (*Crot alus*) and related species of pit vipers (Viperidae) have a pair of facial pits (Figure 6), sense organs on the head below and in front of the eyes, which are most sensitive thermoreceptors indeed. The pit organs act as directional distance receptors and make it possible for the reptile to strike at warm prey even when the snake's eyes and nose are covered and its tongue has been cut off. Each pit is a cavity about five millimetres deep, equally as wide at the bottom, and narrowing toward the opening at the surface of the head. Inside and separated from the bottom by a narrow air space is a densely innervated membrane of about 10 microns thickness stretching between the walls of the pit. A direct connection between the air space beneath the membrane and the open air maintains equal pressure on both sides of the membrane. Warm-sensitive receptors distributed over the membrane consist of treelike structures of uninsulated (unmyelinated) nerve fibres. Infrared radiation (heat energy) reaches the membrane from an external source through the narrow opening of the pit, permitting the snake not only to detect heat but also to localize coarsely the position of the stimulus. The fields of direction (cones of reception) from which each pit can receive infrared radiation from the environment extend to the front and sides of the head, with a narrow zone of overlap in the middle, as shown in Figure 6.

Under resting conditions, there is an irregular, steady discharge of nerve impulses from the pit organ. Rapid warming by as little as 0.002° C (0.004° F) at the nerve endings elicits a significant increase in impulse frequency; cooling produces an inhibition of the resting discharge. In contrast to the warmth receptors in mammals, the reptile's pit receptors are practically insensitive to steady temperatures, despite their high sensitivity to rate of thermal change. The distinctive consequence in the snake's adaptive behaviour is that gradual variations in air temperature tend to occur without detection, only the more rapid changes in infrared radiation being discriminated. Sensitivity to rapid temperature changes is enhanced by the very limited heat capacity of the receptive membrane (since it is so thin). When an animal that is 10° C (18° F) warmer than the environmental background appears for half a second at a distance of 40 centimetres (about 16 inches) in front of the snake, the heat energy radiated is enough to elevate significantly the frequency of receptor discharge in the pit organ. Indeed, behavioral experiments show that under these conditions the snake is able to discover warm prey through the victim's infrared radiations.

Detection of warmth of their prey by snakes

As poikilotherms, reptiles have practically no internal neural or metabolic mechanisms for maintaining their body temperature within physiologically safe limits. Nevertheless, such reptiles as snakes and lizards are able to keep their body temperature near these safe levels through behavioral regulation (*i.e.*, by moving to cooler or warmer places as necessary). The body temperatures of two samples of lizards (*Sceloporus magister* and *Cnemidophorus tesselatus*), for example, were found to be 34.9° ± 0.6°

C (94.8° ± 1.1° F) and 41.3° ± 0.2° C (106.3° ± 0.4° F), respectively, although the average air temperatures were 33° C (91° F). Highly accurate regulation is recorded for a snake (*Crotalus cerastes*) that moved partially in and out of its burrow into the sun to maintain a body temperature of 31° to 32° C (88° to 90° F) over several hours. The desert iguana (*Dipsosaurus dorsalis*) regulates its body temperature largely by behavioral mechanisms to achieve and hold body temperatures near 38.5° C (101.3° F). These adjustments by iguanas include postural orientation to solar radiation both inside and outside burrows and altered thermal contact of the body surface with the soil. Although supporting direct evidence remains to be more fully developed, it appears that reptiles have thermosensitive nerve structures in the brain as well as in the skin.

There is some electrophysiological evidence of thermal sensitivity among amphibians, but only to relatively large temperature changes. The lateral-line organs in frogs (*Xenopus laevis*), which, as in fish, are sensitive to minute water turbulence, also respond to static temperatures and to temperature changes. Whether these responses have any adaptive, behavioral significance for temperature detection remains to be demonstrated. It has been reported, however, that a frog placed in a pan of cool water will not jump out as the pan is heated, if the temperature changes are gradual enough. Indeed, frogs are recorded to remain in the water this way until they are boiled to death.

Birds. Birds are homoiothermic, normally maintaining their body temperature within a range of less than 1° C (1.8° F). Investigations of temperature regulation in birds suggest the existence of thermosensors both in the lower part of the brain (hypothalamus) and in the skin.

Direct electrophysiological evidence of thermoreceptors has been obtained in the tongues of chickens and in the skin of pigeons by recording from individual fibres of nerves serving the receptors. At a constant temperature of 20° C (68° F), a high level of static activity was observed for cold receptors in the chicken's tongue. When the temperature of the tongue was maintained at 44° C (111° F), individual cold fibres showed a low, steadystate frequency of two to four impulses per second. A temperature drop of 9° C (16° F) was found to elicit an initial response of 30 impulses per second, which gradually declined to a new static frequency of eight impulses per second. Rewarming of the tongue resulted in a cessation of detectable electrical activity for several seconds; no specific warm receptors were found. There is some electrophysiological evidence of cold and warm receptors in the skin of pigeons.

Mound building to regulate nest temperatures

Megapodes, large-footed birds such as the Australian mallee fowl (*Leipoa*), or brush turkey, bury their eggs. They depend on the thermal sensitivity of their face or mouthparts to guide their efforts in controlling the temperature of the eggs during hatching. The eggs are incubated in mounds where heat is generated through the fermentation of rotting vegetation and by irradiation from the sun. For extended periods of time the male bird is busy covering and uncovering the eggs, normally keeping the temperature almost constant at 34° ± 1° C (93° ± 2° F) over the unusually long incubation period (as much as 63 days) that characterizes this family of birds.

Mammals. Detailed information is available from electrophysiological investigations of single thermosensitive nerve fibres in the skin of mammals, particularly cats and monkeys. The nose of a cat contains numerous cold and warm receptors that are highly specific in responding to thermal stimuli; they are not excited by mechanical deformation of the skin. As a rule, each thermoreceptor is connected with a single nerve fibre. By using very finely tipped thermal stimulators, investigators can locate precisely the sites of warm and cold receptors in the skin; the details of the underlying cellular structure at these spots have been studied by electron microscopy. At the site of a cold-sensitive spot in the cat's nose, a thin, myelinated (insulated) nerve fibre penetrates the dermis and divides into several unmyelinated branches about 70 microns beneath the skin surface (Figure 7). The tips of these branches have been shown to be the cold-sensitive nerve endings proper; they come into close contact with the basal cells of the epidermis. In most cases the nerve endings are embedded in small concavities on the lower surface of the basal cells. Warm receptors remain to be identified; they appear to be situated in a deeper layer of the skin. In monkeys and, presumably, in man, warm receptors are innervated by unmyelinated nerve fibres (diameter one micron, impulse conduction velocity of 0.5 to 1.5 metres [1.5 to five feet] per second); cold fibres are served either by unmyelinated fibres or by thin myelinated fibres (diameter two to four microns, conduction velocity three to 20 metres [ten to 66 feet] per second).

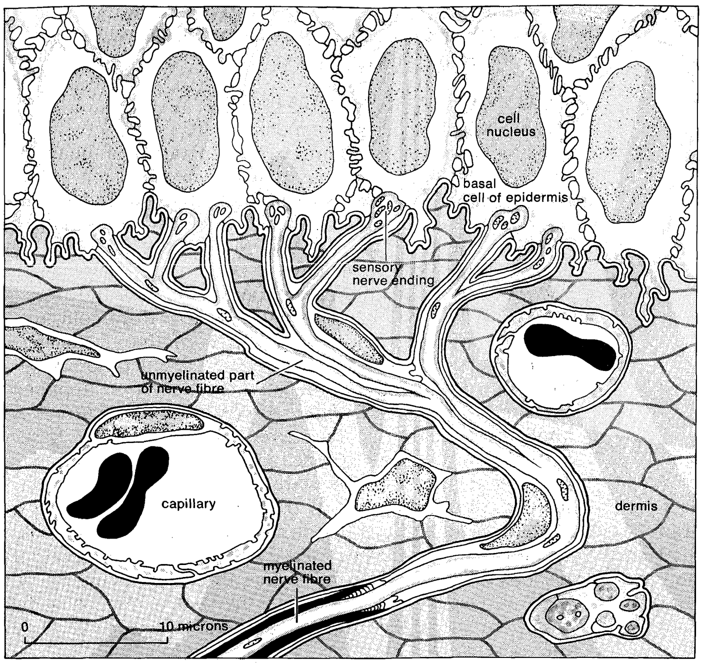

Figure 7: Cold receptor in the skin of a cat as seen with electron microscope.

At constant skin temperatures in the normal range, cold fibres in mammals are found to be continuously active. The average maximum frequency of the static discharge is observed at 27° C (81° F), the extreme limits of the normal range of static activity being 5° and 42° C (41° and 108° F). At skin temperatures above 45° C (113° F), cold receptors again can be activated. This so-called paradoxical discharge corresponds to the similar paradoxical sensation of cold in man when a hot object is touched or the hand is put into hot water. On sudden cooling, temporary overshooting can be 30 times higher than the static frequency of eight impulses per second. Warm receptors in the cat's nose start to show their activity at skin temperatures of 30° C (86° F) and reach an average maximum of 35 impulses per second at 46° C (115° F). Above this temperature the discharge suddenly falls off.

Similar populations of cold and warm receptors have been found in monkey skin, which has an additional group of warm fibres distinguished by an average static maximum at 41° C (106° F). The transient overshooting of warm-receptor activity can be several times higher than the static maximum frequency. When cold stimuli of the same magnitude (*e.g.*, 3° C [37° F]) are rapidly applied to the warmer skin, the degree of overshooting reaches a maximum at a skin temperature of 27° C (81° F). This temperature corresponds to that which elicits maximum static discharge from the cold fibres. Overshooting on rapid warming of warm receptors follows the same general rule: the temporary maximum occurs at temperatures for which the static discharge frequency also appears at a maximum.

Distinctive properties of cold receptors are found in hibernators. European hamsters (*Cricetus cricetus*) tend to maintain body temperatures of about 5° C (41° F) during hibernation. Further cooling, however, elicits arousal reactions from the animal that indicate thermoreceptive function is intact. Electrophysiological investigations have shown that myelinated cold fibres serving the hamster's nose are continuously active at very low temperatures, having a static maximum near 4° C (39° F). In contrast to these findings, myelinated cold fibres in mammals that do not hibernate are blocked at temperatures below 10° C (50° F).

Relatively little is known about the processing of information from skin thermoreceptors in the central nervous system (brain and spinal cord). Responses to cooling the tongue have been recorded from single nerve cells (neurons) of the brain's thalamus in monkeys. In addition to a few brain neurons that are excited both by mechanical stimulation and cooling of the tongue, there are also numerous nerve cells in the thalamus that respond only to cooling. The latter neurons exhibit a static discharge in the temperature range (at the tongue) between 15° and 44° C (59° and 111° F), the maximum frequency being at 21° to 31° C (70° to 88° F). Rapid cooling of the tongue causes considerable transient overshooting in frequency from thalamic nerve cells over the entire range of preadapting temperatures used; by contrast, warming of the tongue results in a transient inhibition but not an increase in the rate of a discharge of any nerve elements in the brain. Thus, the activity of thalamic nerve cells activated by cooling the tongue closely reflects the behaviour of the peripheral (*e.g.,* tongue or skin) cold receptors. Even in the outer layers of the brain (cerebral cortex), nerve cells that respond specifically to cooling of the skin have been found. Other individual cortical neurons in the cat, however, receive signals not only from peripheral thermoreceptors but from mechanoreceptors and taste receptors as well.

Thermal information processing in the monkey brain

Cats can be trained to respond behaviorally to thermal stimulation (*e.g.,* they will press a bar or lever). These experiments reveal cats to be relatively insensitive in discriminating warm and cold stimuli applied to the furred skin of the trunk or the legs, requiring temperature differences amounting to several degrees Celsius. This does not necessarily mean that cats have no finer thermal sensitivity than their grossly observable behaviour suggests. Indeed, autonomic regulatory responses, such as increased blood flow to the ear, can be elicited by mild warming of the paws, even though such warming is inadequate as a signal for training behavioral responses. In contrast to the low thermal sensitivity of their skin elsewhere in the body, cats have been found to manifest behavioral responses when the nose and upper lip are warmed or cooled by only 0.1° to 0.2° C (0.2° to 0.4° F). This corresponds to levels of thermal sensitivity of the face in human subjects and also is in accordance with electrophysiological evidence of high thermal sensitivity of the cat's nasal region.

Mammalian thermoreceptor structures, each containing elements sensitive to warm and cold, are to be found in the skin, in the deep tissues of the body, and in the hypothalamus and spinal cord. While much of the evidence of thermosensors in the central nervous system derives from experiments in neural temperature regulation within the body, in 1963 microelectrodes were used to record directly the activity of thermosensitive neurons in the frontal part of the cat hypothalamus. Many investigations made with this method show that most neural elements in the cat and rabbit hypothalamus are practically insensitive to directly applied temperature stimuli. There are, however, two smaller populations of thermosensitive neurons, one of which responds to local warming and the other to local cooling of the brain tissue.

Warm-sensitive brain neurons in cats and rabbits increase the frequency of their static impulse discharge in direct proportion to the degree that hypothalamic temperature is raised above normal. Similarly, the cold receptors there respond with an increase in impulse frequency when the temperature of the hypothalamus falls below the normal value for the animal's body. Since temperature in the deeper tissues of the body (*e.g.,* the brain) varies quite slowly, the activity of hypothalamic thermosensors seems to be almost entirely a function of the level of temperature alone and not of the rate of temperature change. By contrast, the thermoreceptors in mammalian skin are highly sensitive to rapid changes in temperature. Intervening elements in the nervous system have been identified that integrate temperature signals from the hypothalamus and from the skin. Thermosensors are also found to be localized in the midbrain of rabbits and in various parts of the spinal cord in guinea pigs and dogs. These findings are in good agreement with observations that thermoregulatory responses such as shivering or panting can be influenced by local temperature changes in the spinal region of the animal.

Signals from hypothalamic thermosensors, from deep-body thermosensors, and from those in the skin are integrated in thermoregulatory centres located mainly in the mammal and bird hypothalamus. The integrated signals provide information about the inner (core) temperature of the body and about thermal changes at the periphery (body surface). Such information serves to activate internal mechanisms that maintain body temperature within the normal range of values. When signals from warm receptors (especially from those in the hypothalamus) prevail over signals from cold sensors, such heat-loss mechanisms as sweating, panting, and widening of blood vessels (vasodilatation) in the skin act to reduce body temperature. When signals predominate from cold receptors (particularly from those in the skin), heat-conservation mechanisms are initiated. Heat production rises as muscles expend energy in shivering and through other metabolic reactions (nonshivering thermogenesis); heat loss is reduced by mechanisms that narrow the blood vessels (vasoconstriction) in the skin and that fluff out hairs or feathers to enhance thermal insulation. All these involuntary, or autonomic, regulatory changes continue even without the function of the cerebral cortex; thus, they do not require consciousness, persisting during light anesthesia or during sleep.

Sweating, panting, and shivering

In human beings, the function of thermosensors is closely involved in the highly emotional experiences of thermal comfort and discomfort. Whereas temperature sensations are mainly related to the activity of warm and cold receptors in the human skin, thermal comfort and discomfort reflect the general state of the thermoregulatory system, involving signals not only from thermoreceptors in the skin but from thermoreceptors in deep-body regions and in the hypothalamus as well. Thus, the same temperature at the skin can be experienced as comfortable or uncomfortable, depending on the thermal condition of the person's whole body. When one is overheated, an ice bag applied to the head may be perceived as pleasant; but, if someone is generally chilled just to the point of shivering, the same cold stimulus can be most unpleasant. (H.He.)

Chemoreception

All animals react to chemicals in the environment, initially through a sensory process called chemoreception. The process begins when chemical stimuli come in contact with chemoreceptors, specialized cells in the body that convert (transduce) the immediate effects of such substances directly or indirectly into nerve impulses. A nerve cell (neuron) that makes a direct conversion is called a primary receptor; a cell that is not a neuron but that responds to stimulation by inducing activity in an adjacent nerve cell is called a secondary receptor.

CLASSES OF CHEMORECEPTORS

In man two distinct classes of chemoreceptors are recognized: taste (gustatory) receptors, as found in taste buds on the tongue; and smell (olfactory) receptors, embedded high in the lining (epithelium) of the nasal cavity. These respond to different classes of chemicals: gustatory receptors to water-soluble materials (*e.g.,* salt) in direct contact with them and olfactory receptors to generally water-insoluble, vaporous materials that may arise from a distant source, such as a neighbour's kitchen. The receptors themselves are also different; gustatory receptors are specialized epithelial cells (secondary receptors) with neurons branching among them, while olfactory receptors are nerve cells (primary receptors) with fibres leading to the brain.

In all air-breathing vertebrates (*e.g.,* reptiles, birds, and mammals) the two classes of chemoreceptors are easily identifiable. In fish gustatory organs are on the fins and even the tail, as well as in and near the mouth, all still

Fish that taste with their tails

recognizable as taste buds. The nostrils in fish do not usually open into the mouth, but they are lined with olfactory epithelium. Much lower concentrations of chemicals are needed to elicit responses in fish for smell than for taste. These concentrations are similar to those for air breathers, permitting separate identification of the chemical senses for aquatic and terrestrial vertebrates.

For some invertebrates (*e.g.,* worms), however, distinctions between taste and smell receptors may not emerge. Chemoreceptors of these animals are structurally different from those of vertebrates, and their locations on the body are different. It has been held that invertebrate animals have only one chemical sense, with different sensitivities for various chemicals, as measured by the lowest concentrations (thresholds) of chemicals that can be received. Terrestrial invertebrates, particularly insects, do exhibit separable chemoreceptive capacities, however; additional study seems likely to reveal similar distinctions for other invertebrates. For these animals, the terms distance chemoreceptors and contact chemoreceptors are preferred by many biologists over the terms (*e.g.,* smell and taste) used in human physiology. Separation of these seems feasible because contact chemoreceptors are usually stimulated by nonvolatile, water-soluble chemicals, while distance chemoreceptors typically respond to volatile, oil-soluble chemicals. In addition, thresholds for stimulation of distance chemoreceptors are usually very much lower than those for contact chemoreceptors. Generally the behavioral results of contact chemoreception are feeding, mating, or the deposit of eggs, while those of distance chemoreception are orientation or movement of the animal toward or away from a volatile chemical.

Aquatic animals and terrestrial species with mucus-secreting skins are generally sensitive to chemicals all over the body, reacting with avoidance. This sensitivity has been called the common chemical sense. Man and other terrestrial vertebrates have a remnant of this receptor system that responds to irritants in the mucous membranes of the mouth, eyes, and genital organs. Common chemical receptors are thought to be free nerve endings (branching structures, or dendrites, of nerve cells) in the skin or in moist membranes. Even on the basis of relatively few studies, the common chemical sense is known to be separable from the sense of pain, and thus it is considered as a separate sensory capacity.

Receptors for humidity, particularly well studied in insects, may or may not be chemoreceptors. There is no question that some animals can orient toward or away from regions of high or low atmospheric humidity. The question is whether this is true hygroreception (*i.e.,* stimulation of the receptor by moisture-saturation deficit) or is stimulation by water acting as an odorous chemical. While the matter is far from settled, it seems that some insects and possibly mammals actually may be able to smell water, while others have true hygroreceptors.

Flavour

In common speech the word taste refers to what is more correctly designated as flavour. For man, flavour sensations represent integration by the central nervous system (*e.g.,* the brain) of a complex of stimuli: gustatory, olfactory, common chemical, tactile, thermal, even painful. When carefully studied in other species (*e.g.,* a few other mammals and a few insects), reactions to foods seem to be similar to those of man, with multidimensional stimulation involved in food preferences.

ADAPTIVE FUNCTIONS OF CHEMORECEPTION

For most animals, chemical stimuli are leading sources of information about the environment; even man relies heavily on chemoreception for food selection. Species identification, mate finding, courtship, and mating are also chemically directed among most animals.

Food procurement. Foods are generally located by reception of odours they emit, sampled for palatability by both contact and distance chemoreception, fed upon only if they supply appropriate chemical stimuli during feeding, and laid aside either when the animal is full or when the animal's threshold of response for the stimulating chemical rises above the intensity of stimulation provided by the foods.

At least four classes of chemicals are recognized that affect feeding behaviour: (1) attractants: odours eliciting movement *toward* the source; (2) repellents: odours that prompt the animal to move *away* from the source; (3) feeding stimulants (phagostimulants): tastes and odours that induce the animal to feed; and (4) feeding deterrents (antifeedants): tastes and odours that inhibit feeding behaviour. Chemicals in foods that attract animals or that induce feeding are not necessarily nutritionally valuable in themselves; in food plants, the stimulants often are so-called secondary plant substances (*e.g.,* odorous essential oils) that provide little nourishment. Among animals that are preyed upon as food, the stimulants are often traces of odorous materials present on the body surface. Indeed, animals will feed on nutritionally worthless materials that have been experimentally impregnated with appropriate phagostimulants. Ordinarily, however, specific feeding stimulants are part of an animal's natural food (see also BEHAVIOUR, ANIMAL: *Feeding Behaviour*).

Symbiotic relationships. Most parasites do not just blunder onto their hosts but, rather, orient themselves toward suitable animals or plants. Little is known about the guiding stimuli for most parasites, but for some the odour of the host acts as an attractant, and the taste of the host's body surface functions as a feeding stimulant. Parasitic wasps that lay their eggs on wood-boring insects, for example, locate their targets in logs through olfactory signals. The wasp then drills into the log with a complex egg-laying structure (ovipositor) on the end of which are contact chemoreceptors that allow the insect to sample the prospective host to determine whether or not it is already parasitized. Animals that establish nonparasitic (mutualistic or commensalistic) relationships also find each other by chemical clues; or at least the mobile member of a pair finds the nonmobile member through chemoreception. Sea anemones that attach themselves to shells housing hermit crabs, for example, detect the proper shells with contact chemoreceptors on their tentacles. Annelid worms that are commensal (feeding together) with starfish or sea urchins to which they cling locate the latter by chemicals given off by the hosts.

Chemoreception among parasitic wasps

Communication. Many animals release chemicals that influence other individuals behaviorally or at least physiologically. Usually produced by glands, these chemical communication signals have been named pheromones because they seem to act somewhat like hormones inside an animal's body. Females of some moths, for example, produce scents that attract males from great distances (a behavioral effect). Queen honeybees give off a chemical (so-called queen substance) that suppresses ovarian development in worker bees (a physiological effect). Basically the general classes of information that are coded in chemical signals are concerned with species or individual identification, with social communication, and with sexual or reproductive activity.

Ovarian suppression in bees

In aggregating as groups or in dispersal, animals depend on their ability to identify species or individuals. Thus, honeybees scent-mark their own hive and areas around it with odours that uniquely identify that particular insect community for its members. Many mammals are individually territorial, marking the boundaries of their territories with special glandular secretions (*e.g.,* deer), with body odours (*e.g.,* bears), or with urine (*e.g.,* dogs).

Chemical signals facilitate cooperation among social insects and many mammals. When their colony is endangered, for instance, ants, bees, and wasps alert the group with alarm odours. They also deposit chemicals that serve as guidance signals to indicate the way to sources of food or to living quarters.

Most of the sexual signals that animals produce at all stages of mating are chemical. Females of many mammalian species, for example, produce specific odours that attract only males of the same species. Male bumblebees mark leaves or sticks with a scent that induces females of their species to tarry for mating. In many species mating itself is stimulated in one or both sexes by special chemicals produced by the partners. Male tree crickets, for instance, produce a glandular secretion on which the female feeds during mating.

Orientation. Besides being oriented toward or away from food or mates, many animals are guided to suitable habitats by chemicals emanating from plants or from other environmental features. Fish such as salmon, which return from the ocean to lay their eggs in fresh water, generally come back to the specific stream where they themselves were hatched, guided by the odour of the stream. Other fish recognize their nesting areas by odours produced by plants in the vicinity.

Protection against predators. A most effective form of chemical protection is found in marine slugs and snails that produce strong acid secretions when disturbed. These secretions can injure other animals. Many species of animals produce chemicals that are repellent without necessarily being dangerous; for example, stinkbugs, millipedes, skunks, and some earthworms produce strongly smelling or bitter-tasting secretions when disturbed. An animal that causes a predator to become ill long after contact is not thereby directly protected. If the prey has a special taste or smell, however, the predator that samples it and later sickens learns to avoid the taste or smell, thus sparing other members of the species upon which it might otherwise prey.

Repellents of stinkbugs and skunks

CHEMORECEPTORS IN LOWER INVERTEBRATES

Detailed evidence of chemoreception is available for only insects and mammals. Indeed, chemoreception has been studied in depth for only three or four species of insects and four or five species of mammals. For most animals data for secure generalizations are lacking.

Protozoa. Protozoans, even though they are single-celled, behave as if they had a nervous system. They are sensitive to chemicals in the environment and usually select some foods in preference to others. Carbon dioxide dissolved at low concentrations attracts many protozoans and may be the agent that leads them to foods. Some protozoans (*e.g., Spathidium*), however, can locate specific foods at a distance, presumably by a chemical sense. Ciliates (*e.g., Paramecium*) are most sensitive to chemical stimulation at the anterior (front) end; the receptors are probably special cilia (hairlike structures). *Paramecium* takes nonfoods, such as carmine particles, but soon "learns" to stop this, the change in behaviour persisting for some days. In some ciliates (*e.g., Vorticella*) that reproduce by exchanging genetic material between individuals (conjugation), a motile partner (conjugant) swims to a stationary individual. The swimmer is attracted from up to a millimetre away by a chemical produced by the fixed partner. All of these behaviour patterns performed by only one cell are nevertheless similar to those of multicellular animals.

Cnidaria. Chemoreception is doubtless the most crucial receptive capacity of cnidaria (*e.g., Hydra* and jellyfish), but little is known about the organs involved. Sensitivity to food chemicals is greatest near the mouth and tentacles, but specialized organs remain to be described. Almost all receptors are free nerve endings in the integument (body surface). *Hydra* exhibits feeding behaviour when stimulated by such chemicals as reduced glutathione or tyrosine. This reaction occurs in about half of the tests with weak solutions (1×10^{-6} molar) of these substances. Reduced glutathione acts similarly on the Portuguese man-of-war (*Physalia*) and some other coelenterates called marine hydroids. Amino acids other than tyrosine induce a feeding response in some coelenterates: valine and glutamine in sea anemones and proline in some hydroids and corals.

The feeding sequence of coelenterates is highly coordinated, despite the presence of only a very primitive kind of nervous system called a nerve net. Contact with food causes discharge of stinging or entangling structures (nematocysts), the reaction being released by a combination of chemical and tactile stimuli. The tentacles then draw the prey into the mouth. This response may be evoked by release of glutathione or amino acids from the injured prey.

Other behaviour patterns of coelenterates have been little studied. Anemone fish (*e.g., Amphiprion*) live safely among the tentacles of sea anemones that kill other fishes. Seemingly the mucous coat of the anemone fish develops a chemical that inhibits the discharge of nematocysts, although other interpretations of observations made so far are possible. Many marine coelenterates that live in immobile groups shed sperms or eggs (depending on their sex) synchronously, the activity probably being regulated by chemicals given off by some individuals that trigger discharge in others. A swimming sea anemone, when touched by a starfish that feeds upon it, releases its hold and swims away. Identification of the predator starfish is specifically chemical. Reactions of coelenterates to chemical stimuli are far from stereotyped, a wide range of responses being observable.

Platyhelminthes. Flatworms (Platyhelminthes) have two major life-styles—free-living (turbellarians) and parasitic (tapeworms and flukes)—and their reactions vary accordingly.

For some free-living flatworms (*e.g.,* freshwater planarians) the locations of chemoreceptors in the body are known, but their structure is not. Planarians locate foods at a distance, and their behaviour during this process indicates that earlike protuberances (the auricles) on the head bear the receptors. Water currents elicit orientation movements, the animals crawling upstream when thus stimulated, as if they were making an olfactory response. Removal of a structure called the auricular groove abolishes planarian responses to foods; the receptor organs in the groove are thought to be ciliated glandular patches of nerve cells. Upon reaching food, the worm makes contact with its anterior end and with the tip of its pharynx (proboscis). Ingestion then may or may not occur, the reaction resembling selective taste (gustatory) responses of other animals. The tip of the worm's proboscis has receptors; indeed, an isolated pharynx cut away from the rest of the body will feed on appropriate foods.

Flatworms have been experimentally subjected to stimulation with many pure chemicals, most at concentrations not likely to be encountered in nature. The animals are usually attracted by relatively weak solutions and repelled by high concentrations. They respond to natural food juices and experimentally to pure amino acids and their derivatives. A worm called *Dugesia* reacts positively to such chemicals as lysine and glutamine, negatively to aspartic acid, asparagine, and α-keto-glutaric acid, and gives no observable response to hydroxyproline and glutamic acid. Planarians of different species, when mixed together in the same tank of water, can be separated by species through differences in their chemical-recognition behaviour. These distinctive chemically mediated reactions indicate well-developed sensory function for the planarian nervous system.

Reactions of flatworms to pure chemicals

Little evidence is available about chemical sensitivity among tapeworms and flukes. Tapeworms are said to have only tactile organs, but supporting evidence is almost nil. Adult flukes obviously find their way to specific organs in the bodies of animals they parasitize, but the sensory mechanisms are unknown. The free-swimming stages (miracidia and cercariae) in the life cycle of flukes find their hosts effectively, but there is no general agreement on how this is done. Some workers hold that they swim at random and enter whatever body they encounter; others say that the flukes swim at random but select the host on contact; still others claim that they orient toward the host before contact. Perhaps different species of flukes vary in their behaviour, but the evidence is too sparse to draw general conclusions.

Nematoda. For a phylum with so many commercially and medically important parasites (as well as free-living species), the lack of studies on chemoreception in roundworms (nematoda) is surprising. The integument of these roundworms is supplied with many types of receptors, mostly free nerve endings. These are concentrated anteriorly, particularly on structures around the mouth called papillae. Nematode papillae could be chemoreceptors, but the possibility is supported by no direct evidence. Some roundworms have specialized glandulo-neural structures (amphids at the anterior end of the body and phasmids at the posterior end) that have been claimed to be chemoreceptive, again without critical verifying evidence.

Except for nematodes that parasitize plants, no agreement has been reached on how these animals find their hosts or foods or how they form "social" aggregations, as some free-living species of roundworms do. Parasitic nematodes may attack the roots of plants in response to a chemical attractant in the roots. In some cases the attractant is found to be carbon dioxide that stimulates the worms at a distance, with some other chemical acting on contact. The possibility that control of some agriculturally destructive pests may be achieved by changing the chemical environment in the soil is drawing increased attention to behavioral studies of these nematodes.

Echinodermata. These marine animals (*e.g.*, starfish, sea urchins, sea cucumbers) have also been little studied. They are generally sensitive to chemicals, seemingly most acutely at the tips of their myriad tubular "feet" (podia). Only free nerve endings are present in the integument (skin) of most echinoderm species, but sea cucumbers have sensory pits on their tentacles with more specialized nerve endings. The concentration of primary sensory cells in the integument of many echinoderms is truly striking, upwards of 4,000 per square millimetre (2,600,000 per square inch) being reported for certain starfish. These endings may be multisensitive (to a number of chemicals), or they may be functionally differentiated although structurally they appear to be identical.

The chemoreceptive "feet" of starfish

Reports of studies of chemical reactions among echinoderms are few and spotty. These animals respond positively to natural foods and to some food chemicals (such as glutamic acid) at a distance, and they feed on specific items on contact. They avoid harmful chemicals (*e.g.*, injurious acids and salts). They also form specific aggregations, possibly through chemical responses to their fellows, and are known to spawn synchronously as a result of chemicals released during the process.

Annelida. Annelids (*e.g.*, leeches and earthworms) are sensitive to chemicals all over the body; they are selective in feeding, but no specialized chemoreceptors are yet known for them. Three types of nerve endings in the skin of these animals have been claimed to be chemoreceptive, but without direct evidence: (1) primary sensory cells concentrated at the anterior end, up to 700 per square millimetre (450,000 per square inch) in front of the mouth (on the prostomium) of an earthworm; (2) branching free nerve endings in the skin, possibly mechanoreceptors rather than chemoreceptors; and (3) special concentrations of nerve endings, called integumental sense organs. Some "hairy" marine annelids (polychaets) have a so-called nuchal organ near the head, ranging in complexity from a simple ciliated pit to an elaborate set of folds covering many of the ringlike segments (somites) that form the body. The nuchal organ has been reported as chemoreceptive, but no direct evidence has been produced.

Chemoreception among annelids has been studied mainly by dipping them into or flooding them with various solutions and noting withdrawal or by feeding them natural and man-made foods. The animals respond appropriately, so that thresholds for eliciting responses have been determined. What these mean in the lives of the worms is generally obscure; as usual, low concentrations of many substances are accepted or produce positive responses, whereas high concentrations are rejected or repel. Studies of nerve impulses picked up from receptors in the skin of the body wall have been made with earthworms. The receptors, still unidentified, produce impulses when stimulated with appropriate concentrations of table salt, quinine, and acids, but they fail to respond to ordinary sugar (sucrose). The prostomium, however, does have receptors that are sensitive to sucrose solutions.

Feeding, selection of places on which to settle by some marine annelids, and selection of soil by earthworms have been shown to be chemically mediated. Commensal polychaetes (*e.g.*, *Podarke*) distinguish the organisms with which they live through chemicals coming from their hosts. Synchronous spawning occurs in many anchored (sessile) marine worms, being mediated through the release of signal chemicals. Release of sperms by breeding males of *Platynereis*, a swimming marine polychaete, requires chemical stimuli from the female. Earthworms incorporate an alarm chemical in the mucus given off when they are roughly handled; the effect is to repel other earthworms for as long as several months thereafter.

Mollusca. More information about chemoreception among mollusks (*e.g.*, snails, clams, squids) is available than there is for the groups discussed so far; but these animals comprise a large phylum, and very few species have been studied.

Chemical sensitivity is generally distributed over the mollusk's body, being greatest at the mouth, tentacles, front of the foot, and along the edge of its thin, capelike mantle. The receptors, although not identified with certainty, are thought to be variously branched free nerve endings. Body regions known to be most sensitive to chemicals have high concentrations of these cells. These regions are: (1) tentacles—a variety of projections on various parts of the body; (2) osphradia—ridges or projections near the front of the mantle cavity, best studied in marine gastropods (*e.g.*, snails and slugs); (3) abdominal receptors at the base of the siphons in bivalves (*e.g.*, oysters and mussels); and (4) olfactory pockets behind the eyes in cephalopods (*e.g.*, octopuses and nautiluses). Other organs have been designated as chemoreceptors, but with no critical evidence: (1) so-called subradular organs in the mouths of lower mollusks; (2) a structure called Hancock's organ in some gastropods; and (3) rhinophores (once identified as "olfactory" tentacles) of some gastropods called opisthobranchs. The last, however, are almost certainly established as receptors for water currents rather than as chemoreceptors.

Blinded octopuses

Most of the physiological studies with mollusks have been on reactions to food or to foreign chemicals. Octopuses have been blinded and then trained or conditioned to respond to pure chemicals with specific behaviour patterns. Studies of orientation to or acceptance of feeding stimulants have shown that tentacles and osphradia bear receptors for odorous materials and that receptors near the mouth initiate feeding. Thus separation of contact from distance chemoreception among these animals seems probable; but, until specific receptors are identified through their nerve impulses, the distinction remains conjectural. Although nerve-impulse studies have been made with at least two gastropods (*Aplysia* and *Buccinum*), specific receptors have not been identified thus far. The osphradium has finally been shown to bear chemoreceptors (a matter long debated), and reactions to food extracts and chemicals in natural foods have been studied.

Location of food or prey by many species of mollusks involves what suggests distance chemoreception, generally through the tentacles. Some carnivorous land snails detect and follow (by "tasting") the slime trail left by the prey. Specific "social" aggregations are common among marine bivalves; some of these are brought about by the settling of bivalve larvae near chemically detected members of their group (conspecifics). Chemically regulated synchronous spawning is common among marine mollusks. Land snails and slugs find mating partners by following their slime trails by "tasting" them. Limpets and other snails that live close to the shore emerge to feed when seawater splashes on them at low tide; the sense organs involved differentiate seawater from rain.

Many bivalves and gastropods react strikingly to chemicals from their predators. Herbivorous marine snails, for example, move rapidly away from predators as soon as they touch them. A freshwater snail (*Physa*), when touched by a leech, swings its shell back and forth and then drops to the bottom. These reactions are induced by specific chemicals; the skin of echinoderms, for instance, has yielded such a material, the extract being found to resemble a group of chemicals called saponins.

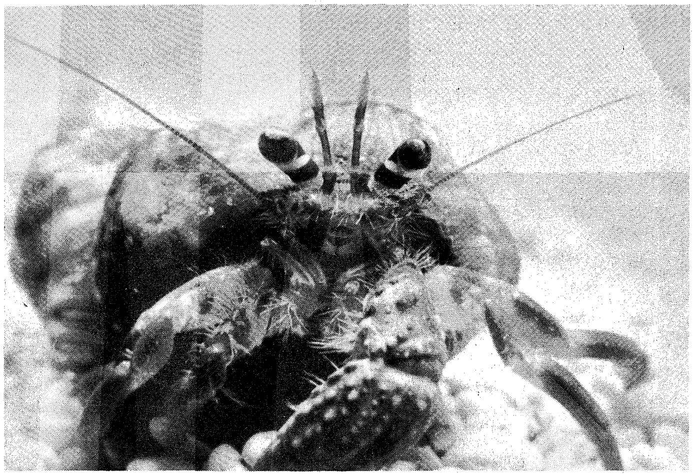
ARTHROPOD CHEMORECEPTORS

In the Arthropoda, which includes more than two-thirds the total number of all individual animals alive, detailed chemoreceptive studies have been reported for less than 10 species of insects and five species of crustaceans; reliable information about other arthropods (*e.g.*, sow bugs and centipedes) is rudimentary. Many of these latter animals have hairs on their outer surface (exoskeleton) that may be chemosensory, since they are similar to those known to be chemoreceptive in insects and crustaceans.

Responses to food and mates, supposedly chemically mediated, have been described for millipedes, centipedes, and a number of arachnids (*e.g.,* spiders). Electrophysiological studies of chemoreceptors have been made with the horseshoe crab (*Limulus*) found on many beaches. The receptors are in spines on the legs and chilaria (flaps behind the mouth) of the animal. Each sense organ has from six to 15 nerve cells that respond or fire when bathed in clam juice or in solutions of amino acids. A tick (*Ornithodoros*), when fed through an artificial membrane, accepts glucose solutions with such substances as reduced glutathione, adenosine triphosphate, and nicotinamide-adenine-dinucleotide; glutamic acid inhibits feeding behaviour in this arachnid. Among some wandering spiders, the male locates the female by the scent of her silken dragline, which serves to identify species and sex. Contact chemoreceptors at the tips of the spider's legs are the sensitive structures. These observations represent a good sample of the scattered work to date with arthropods other than insects and crustaceans.

Chemoreceptors of horseshoe crabs, ticks, and spiders

Crustacea. Crustaceans include such arthropods as crabs, lobsters, shrimps, barnacles, and many other forms. For a number of crustacean species, reactions to food chemicals or other substances have been used to locate the body regions that bear chemoreceptors. The list is impressive. Distance chemoreceptors are borne on the antennae and the smaller antennules, specialized structures (esthetascs) on the tips of the antennules being particularly sensitive (Figure 8). Contact chemoreceptors are borne chiefly on the tips of the walking legs, the mouthparts, antennules, tail flap (telson), walls of the gill chambers, and, in some species, on the general body surface.



Hubert Frings

Figure 8: Hermit crab in shell, showing antennae (long and thin) and antennules (held vertically between eyes) with esthetascs (specific chemoreceptors) along edges near tips.

Locations and structure of chemoreceptors. The sense organs in these regions are various, but only the esthetascs have been shown electrophysiologically to be chemoreceptive. Scattered over the body are so-called funnel canals (or pore organs), which are assumed to mediate avoidance reactions to high concentrations of chemicals. Also widely distributed over the body is a variety of hairlike structures that are similar in appearance to known chemoreceptors of insects. Short blunt projections, resembling certain specialized receptors (basiconic sensilla) of insects, on the body wall of terrestrial isopods (*e.g.,* wood louse or pill bug) are also assumed to be chemoreceptive. The esthetascs at the tips of the antennules are groups of hairlike or spinelike structures. Receptors in these produce nerve impulses when stimulated with a variety of chemicals. Each esthetasc hair receives 100–500 nerve endings from cells aggregated in a ganglion-like structure at its base. The nerve endings have a cilia-like pattern of fibrils, characteristic of the primary chemoreceptors of insects and vertebrates. The outer layer (cuticle) of the esthetascs is very thin, but it has no openings through it, as does the cuticle of the sensory hairs of insects.

Most studies on chemoreception among crustaceans have been made on a few species of crabs and crayfish, with food selection or reactions to chemicals as indicators of reception. Tests before and after removal of parts of the body have led to the discovery of the chemoreceptor locations. There have been a few recent electrophysiological studies with only a very limited number of species.

Responses. In general, crustaceans respond to a wide range of chemicals, negatively at high concentrations and positively at low. In many species, although the body regions that bear chemoreceptors have only one structural type of sensory hair, reactions to different chemicals vary. The antennae of crayfish, for example, have only one distinguishable type of hair, yet the antennae have distance chemoreceptors functionally resembling those of insects and vertebrates, as well as contact chemoreceptors. This has led some to suggest that there is no differentiation between "taste" and "smell" in these animals, merely differences in thresholds. Nevertheless, the behaviour patterns of crayfish stimulated by different classes of chemicals are different. Receptors in the antennules of a shrimp (*Crangon*) respond electrophysiologically to coumarin (usually considered an odour substance) at concentrations of 0.0001–0.00005 percent, to salt (NaCl) at 1.3–7.2 percent, to acetic acid at 0.01 percent, and to quinine chloride at 0.001–0.0005 percent. The observed differences are sufficient to put coumarin in a separate ("smell" or distance) class from the other (contact or "taste") chemicals, as it is for insects and mammals. Thresholds for the other three substances are on the same order as they are for insects and mammals. Thus, although two structurally different receptors have not been distinguished for crustaceans, these animals still show evidence of two types of chemoreception (distance and contact), as in insects and vertebrates. Perhaps the structural similarity of crustacean antennal hairs masks functional differences in their nerve cells.

Questions of the distinction between "taste" and "smell" in crustacea

Behavioral significance of crustacean chemoreception. Chemically modifiable behaviour patterns are wide-spread among crustaceans and have received considerable study. Feeding responses usually occur in two steps: (1) response to chemicals from food at a distance, mediated through receptors on the antennae, antennules, and sometimes the tips of the legs; and (2) acceptance or rejection upon contact with receptors on the antennae, legs, and mouthparts. Barnacles have receptors that mediate feeding responses when stimulated with glutamic acid, proline, or potassium ions. It is believed that these materials initiate ingestion when they are released from prey that is punctured by spines on the entrapping legs of the barnacles. Electrophysiological studies on specialized appendages (dactyls) of the crab (*Cancer*) show that these respond to a variety of amino acids. Among crabs that feed on fish, the receptors respond to trimethylamine oxide and betaine, both chemicals found in fish flesh.

Parasitic and commensal crustaceans respond to chemicals from their hosts. Receptors on the antennules of commensal shrimps initiate nerve impulses when stimulated with fluid discharges (effluents) from their mollusk or echinoderm hosts. Communication by chemicals within any crustacean species is presumably common in the group but has been little studied. Swimming barnacle larvae aggregate specifically, attracted by a chemical given off by settled (fixed) individuals of the same species. This eventually makes reproduction possible among these fixed animals, since their eggs are fertilized internally. Sperms from one barnacle are transferred by a long penis to a neighbouring individual, this being feasible only because the animals aggregate. Sex pheromones have been reported for certain crabs. When ready to moult to sexual maturity, a female crab (*Portunus*) releases a chemical in her urine that attracts the male. In many species of crabs, the male is attracted from a distance by pheromones but uses his contact chemical sense for final identification of the female before mating.

Reactions to environmental chemicals are almost universal in crustaceans. Intertidal barnacles, like intertidal mollusks, respond when splashed with seawater by opening and becoming active, and they react to fresh water by closing tighter. The receptors that mediate this behaviour are along the edges of the mantle. Terrestrial isopods (sow bugs) select places that have specific humidities, the preferences varying with species and other environmental conditions. The receptors have been called osmoreceptors (since they conceivably respond to osmotic pressure), but there is no proof that they are distinct from ordinary chemoreceptors.

Insecta. Among the insects, only the blowfly (*Phormia*), the honeybee (*Apis*), and a few species of caterpillars and moths have been given detailed chemoreceptive study. Otherwise studies are scattered, in detail on only one aspect for some species, in others wide-ranging but without detail. Chemoreception in whole orders of insects has been almost entirely neglected; *e.g.,* among Neuroptera (*e.g.,* ant lions), Trichoptera (caddisflies), Odonata (dragonflies), Mecoptera (scorpionflies), and Plecoptera (stoneflies). For *Phormia* and *Apis,* however, investigative evidence rivals that available for man and rat; and understanding of the mechanisms of taste for *Phormia* is better than that for mammals.

Locations and structure of insect chemoreceptors. There is general agreement as to the parts of the insect body that bear chemoreceptors. Distance chemoreceptors are usual on the antennae and on the palpi of the mouthparts. For most insects, the antennae are probably the major locations of these receptors. In the honeybee, each antenna has about 500,000 receptor cells, most of them probably chemoreceptive, the remainder being mechanoreceptive (for tactile stimuli) and thermoreceptive (for temperature). Contact chemoreceptors are on the following structures: external mouthparts, pharyngeal wall (inner mouth), and ovipositor (egg-laying organ) in both chewing and sucking insects; tarsi (feet) and antennae in sucking species. A form of common chemical sense has been reported for insects but has been poorly studied. The receptors seem to be generally distributed over the animal's body, but they are still unidentified.

Chemoreceptors on insect feet

Regions of the insect body known to bear chemoreceptors have many types of so-called hair sensilla, named on the basis of their shape (Figure 9). The following types of sensilla are known from critical behavioral or electrophysiological studies to be chemoreceptive: (1) trichodea (hairs), distance and contact reception; (2) basiconica (pegs), distance and contact; (3) coeloconica (pegs in pits), distance; and (4) placodea (pore-plates), distance.

The following types of structures are suspected of being chemoreceptive: (1) sensilla ampullacea (flasklike pits), distance; (2) sensory patches in the pharynx, contact; and (3) free nerve endings in hairs and integument, common chemical sense.

The shapes of the sensilla are not fully reliable indicators of function. Trichoid sensilla, particularly, are active not only in both distance and contact chemoreception, but also in thermoreception and mechanoreception. Electrophysiological recording of impulses from specific sensilla should help settle the matter. The designations by shape also are not entirely precise, for many types of insect "hairs" are intermediate between typical long thin types and short blunt pegs, and some have extensive modifications of the walls.

In the central cavity of the hair or peg, chemoreceptive sensilla have terminal strands from neuron cell bodies at the base of the sensillum. The nerve cells are usually few in number, and their terminal strands (dendrites) branch variously to lead eventually to micropores (detectable only by electron microscopy) in the walls of the hair or peg. The taste hairs (labellar hairs) on the end of the extensible proboscis of the blowfly (*Phormia*) have been studied most thoroughly. Each of these has three to five neurons that send their dendrites to the micropores, plus a mechanoreceptive neuron with its dendrite attached to the base of the hair. The discovery of these micropores (formerly the exoskeleton of insects was thought to be imperforate) has necessitated considerable reinterpretation of experimental results.

Insect chemoreceptive processes. In the physiology of chemoreception among insects, many types of studies have been made—unfortunately, however, usually scattered among different species. Behavioral studies of feeding responses and other reactions to chemical substances at a distance and in contact, coupled with experimental removal of body parts and similar manipulations, have produced a large published literature. A few insects have been trained to give special reactions to chemical stimuli, the honeybee having been most extensively conditioned chemoreceptively. Some beetles, wasps, ants, flies, and cockroaches have also been studied in this way. Nerve impulses induced by chemical stimulation of the labellar hairs of *Phormia* have been detected electrophysiologically, representing the first time (1955) that a chemoreceptor of any animal was so studied. Since then, electrophysiological studies have been numerous, but mostly with relatively few species of Diptera (true flies) and Lepidoptera (moths and butterflies).

Among selected examples from the history of research on the functions of insect chemoreceptors, studies before 1950 had shown that the principal loci of distance ("olfactory") chemoreceptors are the antennae and that the end organs (terminal structures) are basiconic sensilla and pore-plates. Determinations of response thresholds, differing with the testing conditions, showed that the classes of chemicals to which insects respond at a distance are about the same as those that elicit responses from vertebrates. (The thresholds for series of chemicals are in the same general order for both groups of animals, although absolute values often differ widely.) Some species of insects are found to have distance chemoreceptors on structures other than the antennae, mainly the palpi of the mouthparts. The exact receptors and their properties were little understood in the 1950s.

Since about 1960, electrophysiological studies have yielded major data about the distance chemoreceptors

Electrical activity of silkworm antennae

of insects. Nerve impulses are recorded from the antennal nerves to produce so-called electroantennograms. The major species studied are silkworm moths, both the commercial silkworm (*Bombyx mori*) and the giant silkworms (Saturniidae). Males of these species find their prospective mates by means of a special scent given off by the females; receptors on the antennae of males are remarkably sensitive to these special compounds. *Bombyx* males have about 40,000 sex-odour receptor cells on each antenna, with endings in various hairs and pegs. These structures are generally tuned to specific odours and so are called "odour specialists." They can be stimulated with odorant concentrations as low as 100 molecules of the given chemical per cubic centimetre of air. Females of the *Bombyx* species have distance chemoreceptors that are not so tuned; instead, the cells respond to a wide variety of chemicals, being called "odour generalists." The generalist type of receptor cell can respond both by increased neural firing (excitation) or by decreasing firing (inhibition).

Among caterpillars that feed on plants, odours are detected by similar sensilla on the short antennae. These structures are generalists, each responding to a variety of compounds. Their responses, however, differ in a number of ways: (1) latency, the time needed for response after a stimulus is presented; (2) rate of increase in frequency of firing; (3) rate of adaptation, such as loss of responsive capacity as stimulation continues; and (4) alternation of increase and decrease in the frequency of neural firing. Although there are only a few receptors present in the antennae of such a caterpillar, distinctive patterns of these four modes of response to different compounds represent a kind of code that the central nervous system of the animal seems to interpret as, at least, acceptable or unacceptable chemical stimulation.

After many years of behavioral studies on contact chemoreceptive processes among insects, electrophysiological methods have dominated the field since 1955. In many cases these continue to be supplemented by corresponding behavioral observations. The blowfly (*Phormia*) has become the "standard" subject, just as the fruit fly (*Drosophila*) has served in genetics. The labellar hairs of *Phormia* are known to be contact chemoreceptors; when its tip is inserted into a capillary tube containing a sapid solution, the hair responds with electrical changes that may be picked up through the solution. Thus the animal's responses to specific chemical substances can be readily monitored. An extensive mass of data has been gathered with this fruitful system.

Besides having a mechanoreceptive cell at its base, the blowfly's labellar hair has dendrites from four or five sensory cells. Each of these makes electrical responses that distinguish the cell as one of at least four types: (1) salt receptor (or cation receptor), once called L fibre because it produces large spikelike patterns of electrical activity on the recording screen; this cell is stimulated by positively charged ions (cations such as Na^+) and by acids and mediates behavioral rejection in water-satiated flies; (2) anion receptor, stimulated by negatively charged ions, and mediating rejection under all circumstances; (3) water receptor, once called W fibre; this structure fires when stimulated by water and mediates its acceptance by the animal; and (4) sugar receptor, once called S fibre because of its small electrical spike; stimulated by sugars, it mediates their acceptance by the fly.

Extension of the proboscis

Thus, rejection or acceptance of sapid solutions largely depends on the blowfly's receptors. A sugar solution causes one set of receptors to fire to bring about extension of the animal's proboscis and to stimulate feeding activity. A solution containing salt or acid stimulates another set of receptors to fire to inhibit extension of the proboscis and of feeding behaviour.

The stimulating thresholds for a great number of chemicals have been determined with the blowfly, and some general rules have been propounded. The stimulative effectiveness of cations and anions is proportional to the effective intensity of the electrical field generated by the given ion. At least for cations, stimulative effectiveness also seems correlated with the speed at which they move in solution (*i.e.,* their ionic mobilities). The data suggest that the receptor is stimulated by penetration or adsorption of the chemical on the surface; so far neither ionic mobility nor electrical field has been shown to be the only factor that affects thresholds. Rejection of alcohols and of other organic compounds by blowflies seems to be mediated by inhibition of the animal's sugar receptors. Stimulative effectiveness increases with carbon-chain length in a given series of chemicals up to about 11 carbon atoms. The effectiveness seems best correlated with the comparative solubility of the substance in water and oil, suggesting that penetration of the receptor surface is involved in stimulation. The effectiveness of sugars shows no obvious relationship to any of their chemical or physical properties but loosely seems to depend on their nutritional utility to the insect. Lactose, one sugar that is not adequate for nourishing flies, for example, does not stimulate the sugar receptor. Most stimulating are fructose, sucrose, and glucose, in that order; this is the order of their sweetness as tasted by man. In spite of the large amount of data available, however, neither the exact mechanisms of stimulation nor the details of their interrelationships has been worked out for these insects.

Among the so-called pseudotracheae ("false air ducts") on the labellar pads at the tip of the proboscis of these flies are short peglike sensilla (the interpseudotracheal papillae). Studied electrophysiologically, the papillae show evidence of bearing four kinds of receptors: (1) a mechanoreceptor; (2) a sugar receptor; (3) a salt receptor having other sensitivity as well; and (4) one with chemosensory function unknown as yet, although some data suggest that it may respond to amino acids. Specifically, the labellar hairs do not respond to amino acids, yet amino acids are ingested by blowflies.

The electrophysiological activity of taste receptors in *Phormia* has been correlated with the feeding behaviour of the animal. Attraction to foods from a distance is olfactory, mediated by receptors on the fly's antennae and palpi. Extension of the proboscis (at rest it is folded into the head capsule) is brought about by stimulation of sugar receptors, usually in tarsal hairs, sometimes in labellar hairs. Extension can be inhibited by appropriate stimulation of other sensory fibres by salts, acids, or repellent organic compounds. Stimulation of the labellar sugar receptors brings about sucking as long as stimulation of the other fibres is not too intense or provided that inhibition by other organic substances is not too great. Feeding behaviour is maintained and its level of activity is determined by stimulation of labellar and interpseudotracheal sugar receptors. The higher the concentration of sugar in solution, the more avid the fly becomes and the longer it feeds. As feeding proceeds, the sugar receptors adapt to stimulation, finally no longer firing above their resting levels, and feeding ceases. After this, chemoreceptors in the blowfly's foregut take over and shut off feeding behaviour until the meal is moved out. How widely this *Phormia* scheme will be found to operate remains to be seen, but, as studied so far, it seems generally to hold for other insects.

Behavioral significance of insect chemoreception. Studies on feeding behaviour among insects are extensive. Some insects are strictly monophagous (eating only one food); at the other extreme there are highly polyphagous insects (that eat almost any organic matter). Most insects, however, fall between these rare extremes, showing restricted food preferences that depend on the presence of specific marker chemicals (feeding stimulants) in acceptable items of diet.

Prey location by mosquitoes

Insects engage in a tremendous variety of mutual and commensal relationships; to do so they must find symbiotic partners. Many cases of chemical orientation to partners are recorded, usually in connection with the important communication signals of insects. Host finding by insects that parasitize other animals is likewise influenced or determined by chemical signals. Mosquitoes, for instance, find suitable hosts (*e.g.,* human picnickers) by sensing lactic acid, carbon dioxide, and moisture on the victim's skin, as well as by detecting his body heat and movement.

Chemical communication is probably universal among insects; it is certainly of major importance for the largest and best known groups. The possible practical use by man of sexual communication chemicals (pheromones) produced by insects (or made synthetically) in the control of these animals has led to extensive studies of materials that induce their sexual behaviour.

Social insects (*e.g.*, termites, bees, wasps, and ants) have been known for some time to use chemicals to scent the nest and to recognize individual members of the community. Advances in chemical analysis have facilitated the isolation and identification of many of these compounds. Some of these undoubtedly affect more than the insect's transient behaviour; the so-called queen substance of honeybees (trans-9-oxy-2-decenoic acid), for instance, suppresses development of ovaries in worker bees, often producing (when the swarm is not too large) a community with only one functional female. Similar chemicals are also used for trail marking and as guidance marks to food sources. In ants and stingless bees, deposits of secretions from the mandibular ("jaw") glands (containing such chemicals as geraniol, citral, various terpenes, and methyl ketones) function as guidance spots in the environment to direct fellows to food sources. The most thoroughly studied pheromones of insects are those used for sexual attraction and activation. Specific sexual attractants have been identified in about 250 species of insects. All but about 60 of these are Lepidoptera (moths and butterflies); most of the others are Coleoptera (beetles and weevils). In about 200 of these species, females attract males, and, in about 50 species, males attract females. Generally the attractant substances are what chemists call substituted hydrocarbons, with chain lengths of between eight and 17 carbon atoms in the molecule. It has been theorized that molecules that will allow sufficient structural variety while still being stimulating to insects should have chains of 10 to 17 carbon atoms and molecular weights of 180 to 300. Most of the active substances studied thus far fall within these limits.

Synthetic chemicals that act like the natural pheromones have been prepared for many insect species; these are mainly acetates with chains of 12–16 carbon atoms. Reactions of insects' olfactory receptors to these materials are remarkably specific. In field tests, male moths distinguished the specific chemicals of their own females when these substances were mixed with 26 other pheromones from different species of moths. In the laboratory, where concentrations may be made much higher than in the field, males may confuse some of the compounds, but not under natural conditions. Small differences in molecular structure or configuration can be highly significant. One molecular mirror image (trans isomer) of the Propylure molecule, a substance that attracts pink bollworm males, is active; the other mirror image (the cis isomer) does not attract, yet it masks the trans form when mixed with it.

Remarkably small concentrations of these pheromones can elicit behavioral responses. What was once thought to be the gypsy moth pheromone (isolated in tiny quantities from an extract of hundreds of thousands of female moths) and its synthetic version (Gyplure) have now been found to be inactive in themselves. The active principle seems to be some still unknown impurity present in even more minuscule amounts in the original extracts.

Use of pheromones in insect control

Insect pheromones are thought to be excellent prospects for pest control because of their attractant properties. Unfortunately, most attract males, and even a few fertilized females can maintain a population. At present, the major use of these materials is in population sampling; for instance, male cotton boll weevils (which emit substances called terpenoids) are used in traps to attract females in making a census of their population.

The use of pheromones in insect control is complicated by the finding that high concentrations repel and low concentrations attract. Thus, if high concentrations are used in insect traps to get wide coverage, the animals may be repelled when they get near. Furthermore, a pheromone used in baiting a trap must compete with the attractant from living members of the species. Many pheromones have multiple effects, depending not only upon their concentrations but on environmental factors as well. The so-called Nassonoff gland pheromone of honeybees, for example, consisting mainly of terpenes, serves the insects for attracting workers and queens, for marking food sources, in marking the hive, in scenting prospective hive locations by scouts, and in gathering swarms in flight. Thus, different behavioral reactions to the same pheromone can occur under different circumstances.

As a possible way out of many difficulties, it has been suggested that pheromones could be used to flood given locations with odour. This could fatigue the chemoreceptors of the insects and prevent them from finding mates; their sexual communication channel would be jammed. So far, the few tests of this idea that have been made in the field have not yielded very promising results. Except for short-term, geographically restricted effects, as among insects that live in warehouses where farm products are stored, pheromones for insect control have yet to fulfill earlier optimistic expectations.

Besides responding to food and communication odours, insects are oriented by a variety of other environmental chemical factors. Humidity responses have been extensively studied, but whether the receptors react to water vapour or are hygroreceptors (responding to lack of water) is much debated, with no general agreement. Places for laying eggs are selected by many insects (*e.g.*, mosquitoes and parasitic wasps) by chemical sampling of the prospective sites. Some plant chemicals and a number of synthetic materials repel various insects. There seems to be no generally occurring repellent for all insects, nor has any special relationship between chemical composition and olfactory repellency been discovered.

Protection of man and other mammals from attack by mosquitoes, fleas, ticks (which are arachnids, not insects), and other bloodsucking arthropods has been sought in chemical repellents. Tens of thousands of organic compounds have been tested as insect repellents, mainly for use against mosquitoes. Besides repelling at adequate levels when put on a part of the body that attracts the pests, the compound should not irritate the skin nor be otherwise harmful and should have a reasonable rate of evaporation. In the face of such criteria, few practical repellents have been found. Among those in common use are such substances as dimethyl phthalate, Indalone, Rutgers-612, benzyl benzoate, and Deet; the last is widely used, since it repels many arthropods—mosquitoes, fleas, and ticks. Repellent substances also have been sought among the many warning and alarm chemicals produced by insects, but most of these prove to be irritating to the skin or nose of mammals.

Alarm signals among ants

Alarm pheromones have been studied most intensively in ants, which produce them with special glands to alert their colonies to invaders or to other dangers. The active materials are generally related to hydrocarbons, often ketones; citral and its relatives are important components. Some of these chemicals are also constituents of social and sexual pheromones. Honeybees produce an alarm scent that contains citral and isoamylacetate, among other materials. Formic acid, produced by specialized glands of ants, is found to excite both ants and bees. All of these materials function to alert members of an insect colony when the community is threatened. Other insects (*e.g.*, some beetles) produce strongly repellent chemicals that serve to ward off predators. These chemicals range from apparently harmless but strongly odorous substances to such toxic materials as hydrocyanic acid gas. Among bombardier beetles the ejected spray is even heated by chemical action to about the boiling point of water.

CHEMORECEPTION IN THE VERTEBRATES

Besides the familiar vertebrates (animals with backbones), the phylum Chordata includes some smaller creatures sometimes called protochordates. Little indeed is known about chemoreception in such protochordates (*e.g.*, the lancelets and tunicates) beyond that they seem to show some selection of food and location and that they respond negatively to a variety of foreign chemicals. A group of what are commonly called lower vertebrates is the cyclostomes, such round-mouthed aquatic forms as lampreys and hagfish. Cyclostomes have a well-developed nasal

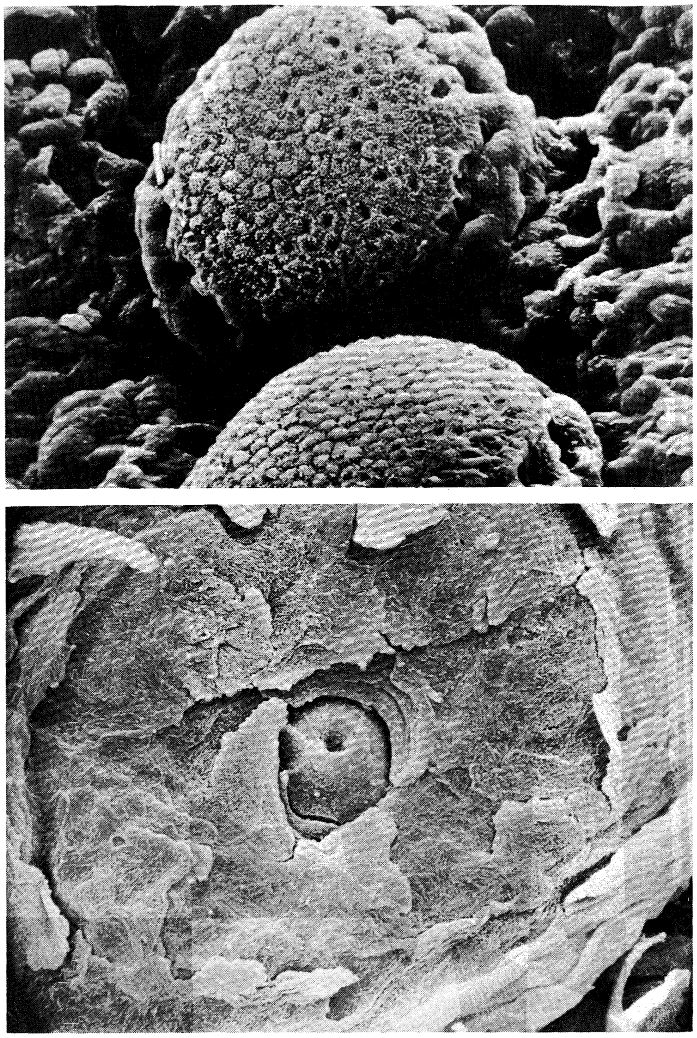

Figure 10: Scanning electron micrographs of (top) two frog fungiform papillae (magnified about 515 ×), and (bottom) taste bud with pore projecting through surface of rat fungiform papilla (magnified about 850 ×).

tract, with a single median (central) nostril; they can locate their prey by smell, but otherwise almost nothing is established about their chemical senses. For this reason, the bulk of attention given here to chordate chemoreception will be confined to the five main divisions of vertebrates: fish, amphibians, reptiles, birds, and mammals.

General vertebrate chemoreception. *Gustatory receptors.* The taste buds of vertebrates are secondary sense organs (*i.e.*, sensilla) derived from epithelial cells (Figure 10). Their structure has been well studied by electron microscopy, but in relatively few species (mostly mammals). Each vertebrate taste bud seems to consist of a number of cells of three or four types, but there is some debate as to their exact classification. One widely held view is that the taste bud has four types of cells: so-called supporting cells, sensory cells (the true receptors), basal cells (supplying replacements for old sensory cells), and another type of unknown function. Attempts have been made to designate developmental stages of these types and to view some of them as stages in the development of others, thus giving rise to at least five classes. The sensory cells are continually replaced, each cell having an average life span (at least for rat, mouse, and rabbit) of about 10 days (Figure 11). Each taste bud is innervated by up to 50 nerve fibres entering from below and branching into 200 or more branches to form a basket-like set of dendrites. Presumably chemical stimuli produce electrical changes in the sensory cells of the taste bud, these activating the afferent neurons nearby to generate nerve impulses.

Taste buds of reptiles, birds, and mammals are confined mainly to the upper surface of the tongue, with a few on the pharyngeal walls. In amphibians (*e.g.,* frogs) they are more numerous on the pharyngeal walls and present also on the cheeks and lips. In fish, taste buds are present also on the fins and in some species on the tail. In all cases, vertebrate taste buds are innervated from cranial nerves, mostly the facial and the glossopharyngeal.

Olfactory receptors. Among vertebrates these are the cells of the olfactory epithelium in the nasal cavities. They are primary receptors, true nerve cells the fibres of which form the olfactory nerve leading to the lobe of the brain that mediates the sense of smell. The structure of the cells of this epithelium, as seen with an ordinary (light-wave) microscope, appears remarkably similar for all vertebrates. Electron microscope studies reveal much more structural detail but have not changed the general interpretations. There are three fundamental cell types in the olfactory membrane: receptor cells, supporting cells, and basal cells; in addition, numerous gland cells furnish a mucous covering for the epithelium. Ramifying (branching) among the cells are very delicate terminal fibres of neurons leading to the brain through the trigeminalnerve. These are thought to be receptors of the common chemical sense, responding chiefly to irritants. The olfactory receptor cells have terminal cilia, which are fused into olfactory rods projecting outward.

Olfactory cell types

Man has about 40,000 sensory cells per square millimetre (26,000,000 per square inch) of olfactory epithelium, while the rabbit has about 120,000 per square millimetre, with an estimated total of 100,000,000 such cells. (Fish average between 45,000 and 95,000 per square millimetre, the eel having a total of about 800,000.) A significant discovery made with the electron microscope is that the olfactory sensory cells seem to be synaptically related. Such an arrangement would permit the cells to interact through mutual excitation and inhibition, thus allowing versatility of response at the receptor level itself.

The olfactory epithelium forms at least one wall of the nasal cavity of vertebrates. In fish, the nasal cavities are mostly paired pits or tubes just in front of the eyes, each with two nostrils, one anterior, the other posterior. In terrestrial vertebrates, the paired nasal cavities have external openings, the nostrils (external nares), and paired or unpaired internal openings (internal nares) into the mouth or pharynx. In all cases, water or air is moved through the nasal cavity and over the olfactory epithelium.

Another olfactory receptor of many vertebrates is the so-

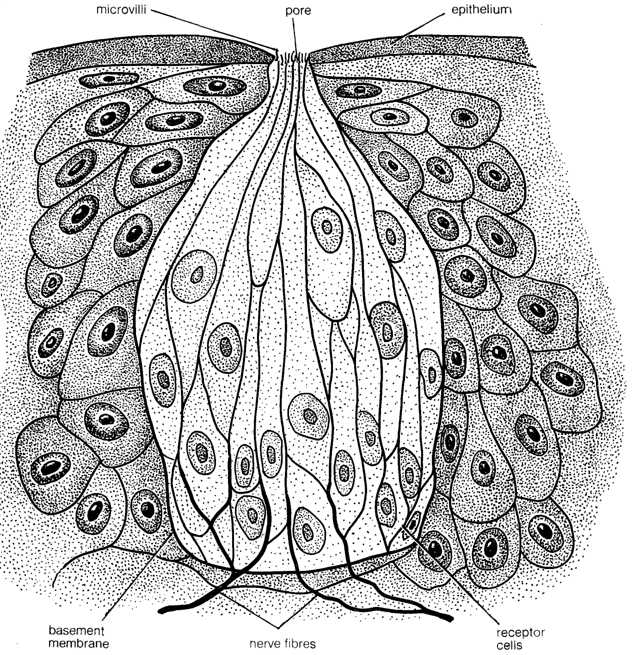

Figure 11: Microscopic section of taste buds of circumvallate papilla.

called Jacobson's organ (vomeronasal organ). This structure is variously developed; absent in fish, birds, and some mammals, it is highly developed in lizards and snakes. Nerve fibres from this organ lead to the accessory olfactory lobe of the brain and so are closely related to the primary olfactory system.

Common chemical receptors. Mucous membranes in vertebrates have receptors that respond to the presence of chemicals rather indiscriminately and, when stimulated, tend to evoke avoidance reactions from the animal. In mammals these common chemical receptors are restricted to the mucous membranes of the nose, mouth, pharynx, eyes, and genital organs. Free nerve endings in the olfactory epithelium of mammals are believed to respond to irritant chemicals.

Free nerve endings

In fish and larval amphibians, free nerve endings all over the animal's body seem to be sensitive to chemicals, their excitation eliciting avoidance reactions. These free nerve endings send their fibres to the central nervous system through spinal nerves. The free nerve endings of the head region enter the brain via the trigeminal nerve. These widely responsive receptors are vitally important in enabling the animals to escape from harmful chemicals in the environment, but relatively few studies have been made on them.

Process of gustation (taste). Among vertebrates other than man, the usual types of behavioral studies (*e.g.,* involving feeding responses) have been made, and training or conditioning procedures also have been used. Gustatory thresholds for detection, acceptance, and rejection have been determined. In more recent years electrophysiological techniques have been most numerous. Human reactions to tasted chemicals can be studied by experiments involving recognition of materials and verbal specification of preference or aversion. Aside from man, the animals most studied are frog, monkey, rabbit, rat, and cat; the investigations have focussed on taste qualities and on the action of sapid substances.

During the 19th century it was widely held that there are four primary taste qualities (salt, sweet, sour, and bitter) and that all other gustatory experiences represent combinations of these. Some investigators have added to these an alkaline and a metallic taste, but others claim that they are not primary qualities. On the assumption that there are four primary taste qualities, chemicals supposedly exemplifying each of the classes (NaCl for salt, sugars for sweet, acids for sour, and alkaloids for bitter) have been applied to the tongues of man and laboratory animals in attempts to find regions of selective sensitivity or (by electrophysiological tests) to locate different types of taste receptors.

Unfortunately taste buds are compound structures, and their neural connections are complex. At any rate, impulses recorded from nerves, or even from single taste buds, fail to give direct evidence about what the individual receptor cells can do. While recordings can be made by inserting fine wires into individual taste buds, the exact cell sampled is not known. It is clear, however, that vertebrate taste receptor cells are not classifiable as sugar, cation, anion, and water receptors as they are among insects. Some vertebrate cells respond to a fairly narrow range of chemicals, but most do not; those cells that respond to salts may also react to acids and sugars, or even water. Certain regions of the tongue tend to be selectively sensitive (*e.g.,* the tip of the human tongue seems highly responsive to sweet chemicals, but not uniquely so). It is no longer expected that, by studying impulses in single gustatory nerves, specific salt, sweet, sour, and bitter receptor cells will be discovered. It seems that patterns of response (rather than specific receptor activation) set up among the sensory cells on the tongue mediate the different taste sensations in man.

As in the case of insects, there is no general agreement on how sapid substances stimulate vertebrate taste receptors. For related series of organic chemicals, stimulative effectiveness is proportional to carbon-chain length up to some maximum and is also related to the comparative solubility of the substance in water and oil. Among inorganic materials, cations generally seem to have stimulative effects that are proportional to their mobilities, but there is great variability in response to the same ions from one vertebrate species to another. Sweet substances are not chemically definable; at least there is no obvious relation of taste with molecular structure. Although many sugars apparently stimulate the same receptors, man and other mammals often can easily distinguish one sugar from the other. Activation or inhibition of receptor cells occurs upon stimulation with different materials. The idea of four primary taste qualities or senses (modalities) has semantic utility, but to date it has not proved useful to investigators as a central dogma in understanding fundamental mechanisms of taste.

Process of olfaction. Studies of smell reception among vertebrates have been similar to those with taste, with electrophysiological methods dominating modern research. The literature on the subject is large, particularly with respect to man.

While attempts have been made to categorize odours in classes that could be considered primary, they have not produced a generally accepted system. The smallest number of primary odour qualities suggested is four, but more than 30 have been offered by some theorists. Attempts to relate odours to chemical structure or to other generalizable physical characteristics of odorous materials have not succeeded. Studies on mechanisms of stimulation of olfactory cells have similarly given rise only to theories, none generally acceptable.

The most active research on human olfaction is concerned with attempts to link odours, such as those of foods or perfumes, with specific chemical structures. Newer analytical techniques, as with insect pheromones, have facilitated the determination of the chemical composition of odorous materials present in the tiny amounts typical of natural products. By these means, extracts from foods can be separated into components with characteristic odours and chemically identified. From the standpoint of olfactory physiology, these studies emphasize the immense capacity of individual olfactory cells to detect a tremendous variety of chemical materials.

From white bread alone, for example, approximately 70 odorants have been identified, including alcohols, organic acids, esters, aldehydes, and ketones. From coffee, 103 separable volatile compounds have been isolated and many chemically identified; it is estimated that at least

(Top) Puffer (*Tetraodon*) with nostrils on "tentacles."
(Bottom) Cod (*Gadus*) with typical form of nostrils (inset shows detail of folds in nasal cavity).

150 substances contributing to the flavour of coffee will be discovered. Since many of these are present in extremely minute quantities, the capabilities of the human olfactory epithelium, usually regarded as having low sensitivity as compared with that of other mammals, seem remarkable. For substances called mercaptans (*e.g.,* in the skunk odorant), only about 40 receptor cells in the human nose need be stimulated by no more than nine molecules each to give a detectable odour sensation.

Skunk odour

Chemoreception in the main vertebrate divisions. *Fish.* Structure, location, and innervation of fish chemoreceptors are like those of terrestrial animals; thus separation into distance and contact chemoreceptive channels is possible. Taste buds are more widely distributed over the body in fish than in terrestrial vertebrates. In teleosts (*e.g.,* herring, trout, perch) they occur not only in the mouth and pharynx but also on the lips and regions nearby, on whisker-like barbels where present, on fins, and (in some fishes) on the tail. These taste buds are all innervated by branches of the facial nerve. The olfactory epithelium in the fish is in nasal cavities through which water passes; the nasal cavities do not, except in lungfishes, open to the mouth. There is no true Jacobson's organ, although some authors believe that structures near the nostrils may represent a rudiment of this organ (Figure 12).

Feeding behaviour among fish, as with all animals, is determined primarily by the chemical senses, smell being used to find food and taste to determine final palatability. Odours from foods excite movement in hungry fish, but true orientation toward food requires a current to indicate direction.

Social and sexual chemical signals are widespread among fish, though they are probably not as important as visual and possibly acoustic signals. In darkness, or for blindfish in light, species odours are important in schooling. Species differentiation may be excellent; a minnow (*Phoxinus*) can be trained to distinguish 14 different species of fish by their odours, even when the odours are offered in up to 15 different combinations. Mouthbreeders, fishes that hold eggs and young in the mouth, are able to distinguish their own offspring from those of others by odour. Some fish chemically mark their nests with mucus. Redfin shiners, fishes that lay their eggs in the nests of green sunfish, find these nests by the sunfish odour.

Some fish have remarkable powers of olfactory orientation to specific geographic locations. Minnows can distinguish the galaxy of odours of aquatic plants in their home streams and return to them when displaced. The most noteworthy of homing fish are salmon and eels, which return to the fresh water (where they began life) after some years in the sea. Each fish returns to the precise stream in which it was hatched. Many experiments have shown that this is possible only because they sense the odour of the natal stream. Apparently a form of learning called imprinting occurs in these baby fish. The hatchlings learn (or are imprinted) to associate the particular odour of a specific stream with home base. Orientation to the mouths of the streams from the sea requires some other talents as well; but, once the fish enters its home river, it unerringly finds its way to the headwaters where it started life.

Among the earliest reports of animal warning odours was that of the so-called *Schreckstoff* (German for "fright substance") given off by agitated fish. Injured fish produce chemicals that alarm other members of their own species, generally causing them to flee. The material is detectable to fish at extremely low concentrations. Some predators have turned this to their advantage; for example, sharks can detect the odour of an injured fish and swim toward it. In the hope that some chemicals besides those naturally occurring could repel sharks from swimmers, considerable effort has been expended to try to find a suitable shark repellent. So far the results have not been promising, but compounds that are remarkably effective in stimulating other fishes have been found; for example, phenacyl bromide repels teleosts at 0.01 part per million, but unfortunately it does not do this to sharks.

Shark repellents

Amphibians. In spite of the widespread use of frogs in physiology laboratories, understanding of chemoreception in amphibians is extremely meagre, particularly as related to their normal life. The gustatory organs are typical taste buds not only on the tongue and walls of the mouth and pharynx but also variously distributed on the lips. The nasal cavities of urodeles (*e.g.,* salamanders, newts) are relatively simple, but those of anurans (toads and frogs) are complex, with three chambers. The olfactory epithelium is of the usual type; in *Triton,* a salamander that lives both in water and air, cells of the olfactory epithelium have long cilia when the animal is an air breather and short cilia when it is a water breather. The Apoda, wormlike amphibians that are blind, have well-developed nasal cavities and olfactory epithelium. The organ of Jacobson in urodeles is a mere grooved channel in the nasal cavity, but in anurans it forms one chamber of the three nasal cavities.

As usual, feeding is chemically mediated, at least in part, although anurans mostly use their eyes for food capture. There have been few studies on chemicals that determine feeding among amphibians. Chemical communication is probably dominant in salamanders, odours of females attracting males in many species. Females of aquatic salamanders are induced to mate by chemicals produced by males. The chemicals are wafted toward the females by tail-wagging on the part of the males. Frogs and toads seem not to use chemical signals for communication, relying instead on auditory and possibly visual signals. As among fish, salamanders displaced from their home stream are able to find their way back by chemical sensing. Tadpoles, like fish, produce a *Schreckstoff* when injured, its discharge causing other tadpoles to scatter.

Reptiles. Chemoreception among reptiles has been very poorly studied. The major physiological work has been with turtles, mostly with objectives that are totally unrelated to the normal lives of the animals. The taste buds of the turtle are restricted to the tongue and the walls of the pharynx; the olfactory epithelium is in the nasal cavity. All reptiles but turtles have well-developed nasal cavities, crocodilians having exceedingly complex cavities and accessory sinuses. Jacobson's organ reaches its acme of development in lizards and snakes, where it opens into the anterior part of the mouth. Nearby, the lacrimal ducts (tear ducts) open, thus irrigating Jacobson's organ and possibly aiding in its function. This organ is absent in crocodilians and indistinct in turtles. While there has been considerable argument about the function of Jacobson's organ, it is now generally believed that it acts as a second olfactory organ in snakes and lizards at least. The forked tongue of some snakes can be inserted into the openings (inside the mouth) of Jacobson's organ, thus bringing chemical particles picked up on the tongue into contact with the olfactory epithelium. All snakes cannot do this, however, and apparently in some species the materials are dissolved off the tongue in the secretion from the lacrimal glands and thus brought to the organ.

Jacobson's organ in reptiles

Feeding behaviour among reptiles is probably determined to a large extent by chemical stimuli, but there have been few verifying studies. Some snakes find their prey by using the sense of smell, as is shown when newborn young of some snake species attack objects scented with extracts from the skin of species upon which they prey. The receptors involved in this case are in Jacobson's organ. Some predatory snakes cannot trail their prey when this organ is destroyed.

Communication in lizards, turtles, and crocodilians seems to be mostly by visual signals, although some tortoises have glands that secrete chemicals, which they distribute in their territories. Male snakes track females by detecting an odour on their skin; the male will not court his prospective mate if his nostrils are plugged. Rattlesnakes react defensively to the odour of king snakes; conversely, the predatory king snakes track rattlesnakes by their odour. Snakes seem to be more reactive to olfactory stimuli than are other reptiles; nevertheless, reasonable generalizations about the role of chemoreception in the lives of reptiles can only be expected to come from much more study than these animals have had to date.

Birds. General opinion among ornithologists is that birds are predominantly auditory and visual creatures; certainly among birds these senses are usually well developed.

This opinion, however, has led to a possibly unwarranted lack of interest in chemical reception among birds. There is growing evidence that chemoreceptors are well developed in at least some birds. The receptors are well-known: taste buds on the tongue and olfactory epithelium in a rather uncomplicated nasal cavity. The olfactory lobe of the brain in many birds (*e.g.,* kiwis, albatrosses) is large, suggesting a high degree of olfactory sensitivity. Birds have no organ of Jacobson.

Early observations on birds in the field led to the belief that their chemical senses were poorly developed, or even totally absent. Later studies, though few and scattered, suggest otherwise, however. Birds taste water before drinking or bathing, for instance, and their thresholds for rejection are similar to those for mammals. Indeed, birds drink water containing some chemicals at concentrations higher than those they tolerate in bathing water. The bathing thresholds may be well below thresholds for gustatory stimulation of mammals. The large olfactory brain areas of many birds certainly indicate that older ideas about their being olfactorily impoverished need reexamination. The few recent studies that have been made show that birds do, indeed, have an olfactory sense. Quail, for instance, can be trained easily to respond to odours and apparently can mark feeding locations by scent from their bodies, much as mammals do. The chemical senses and the place of chemoreception in the lives of birds—as well as reptiles and amphibians—deserve much more study than they have received up to now.

Mammals. Chemoreceptively, mammals are the best studied of vertebrates by far, and man is probably the most studied of all, although experimental techniques that can be used with blowflies (*Phormia*) and rats are inappropriate for humans. The taste buds of mammals are mostly on the upper surface of the tongue, on so-called vallate, foliate, and fungiform papillae. Some taste buds are also on the palate and in the walls of the pharynx. The olfactory epithelium lies dorsally in the nasal cavity, which in most mammals is extensive and complicated. Bony structures (conchae) subdivide the nasal passages, and sinuses extend into the bones of the mammalian skull. Aquatic mammals alone have relatively small olfactory areas. Jacobson's organ is absent in aquatic mammals, bats, and primates (*e.g.,* monkeys and humans). In almost all other mammals the organ is in the nasal septum (central dividing wall), being small but functional. In a few groups of mammals, Jacobson's organ opens into the mouth cavity through special (nasopalatine) ducts.

Mammalian feeding behaviour is dominated by the chemical senses; indeed, mammals generally are activated and oriented primarily by chemical stimuli. Food finding usually involves olfaction, and food testing involves gustation and olfaction together. Flavours of foods seem to determine acceptance or rejection in all mammals. (Flavour refers to the combined experience of taste, smell, texture, and temperature.)

Flavour testing

Flavour testing of foods for human use is an important factor in the economics of commercial food processing. Therefore an extensive literature exists on the techniques and results of flavour testing and on the production of synthetic flavouring materials. The gustatory organs supply rather restricted information to the brain, but the olfactory receptors supply a vast set of information. As an example of the wide array of volatile chemicals in foods, strawberries contain at least 35 chemical constituents contributing to their odour. These vary from time to time and with conditions in the same berry; for example, crushing converts some materials present in the intact fruit to other substances. The human olfactory organ easily detects these subtle changes, and responses in the brain are thereby affected.

It seems clear that the most important communication signals of mammals are chemical. Social aggregation and territoriality are guided by marking scents secreted by a variety of special glands in different places on the animals' bodies (*e.g.,* on the flanks, back, belly, and near the anus). The secretions are wiped onto objects or sprayed over terrain or are deposited by discharge of urine and feces at particular locations. Almost all mammals chemically mark their nesting or resting areas and quickly detect intruders. Members of a flock or herd (*e.g.,* of sheep) identify one another mainly by scent, apparently producing not only the species scent but also an odour distinctive of that flock or herd alone. Man's use of incense and perfumes in social and religious activities is probably rooted in the basic mammalian pattern of odour sharing within a group.

Similarly, chemical sexual signals are general among mammals. When their nostrils are plugged, male rhesus monkeys and males of some herbivores (*e.g.,* cattle) show no interest in females in heat. Among mice, the odour of strange males (from other communities of mice) interferes with the normal development of fertilized eggs in females; yet, signs of sexual arousal (estrus) can be induced in female mice and other rodents by the odour of a strange male. In probably all terrestrial mammals, arousal of the estral state in females is in response to odours produced by the male genital glands. While fastidious people often may say that sexual odours do not exist for man, the widespread use of perfumes (which supply masked sexual odours) attests to the importance to man of chemical channels in sexual communication.

Orientation to chemical cues is also general among mammals. Many mammals find water or home territories, even when far from them, by the sense of smell. As with fish, it is probable that the total odour complex from soil and plants of a region is detected by mammals.

Mammalian alarm odours

Alarm odours are part of the general communication system of most mammals. Many herbivores have special glands that release odours that alarm the herd when the animals are frightened. Similarly the odour of blood is repellent to many mammals. Many animals (*e.g.,* skunks) have warning odours that repel prowling predators. The tendency of mammals to discharge feces or urine when frightened is also adaptive, for these may act as olfactory repellents to enemies.

Man seems to be an unusual mammal in his limited use of the sense of smell. Other land mammals use olfactory function as their primary sensory basis for interacting with the environment. The sensitivity demonstrated for the human nose with respect to flavour discrimination suggests that even man relies much more than he realizes on the array of olfactory stimuli reaching him from the environment as sources of information. (The human senses of smell and taste are discussed further below; see *Human sensory reception.*)

THEORIES OF CHEMORECEPTOR ACTION

Attempts to create theoretical concepts to explain the actions of chemicals on chemoreceptors have generally been directed toward answering one, or both, of two questions:

1. What characteristics of chemical molecules are critical in producing responses by receptor cells?

2. What molecular characteristics elicit the experiences of particular tastes and smells?

There is still no generally accepted answer for either of these. The theoretical constructs developed have been somewhat different for taste and smell.

Taste (contact chemoreception). Many kinds of actions of sapid substances at gustatory receptor cells have been postulated, and some evidence has supported each. Unfortunately, much evidence militates against each. The most widely accepted possible mechanisms for stimulation of gustatory receptors are the following: (1) chemical reactions at the cell surface; (2) adsorption of molecules on the cell surface; (3) penetration of substances into the cell; (4) enzymatic reactions at the cell surface; and (5) protein bonding in the cell membrane.

Not all of the many adherents of theory (1) select the same type of chemical reaction at the receptor-cell surface. A few physicochemical models of the theory have been proposed, but none fits all the data. The adsorptive theory (2) is probably most widely believed now; while a wide spectrum of data fits this well, not all of the evidence is explained. The penetration theory (3) is supported by correlations between the oil–water solubility and stimulative effectiveness of sapid substances, but the mechanism seems to be too slow and too long lasting. The enzymatic theory (4) can be made to explain almost any data, if one just imagines the existence of the right enzymes (yet to be discovered). Nevertheless, the temperature independence of taste stimulation militates strongly against it, for enzymatic reactions are strikingly influenced by temperature. The protein-bonding theory (5) is weakened, as is the penetration theory (3), because these processes would be slow to reverse; otherwise good fits with data can be obtained by postulating the existence of appropriate proteins.

Some correlation between human taste responses and chemical composition has been found for sweet, salty, and sour substances, but the results are much less clear-cut for bitter materials. Most substances do not have one of the four simple tastes, and there are other suggested primary taste qualities, the validity of which has not been settled. Almost all investigators who have studied contact chemoreception in detail have come to doubt the validity of any theory of four primary tastes, at least for mammals. More recent electrophysiological data, although gathered mainly by workers who originally adopted the concept of four primary qualities as their guide, do not support the theory. Individual receptors (except labellar hairs of blowflies) are generally not excited by only one of the four presumed primary categories of sapid compounds. The intergrading of tastes for a large series of chemical compounds and the variety of electrical response patterns of receptors obtained in the laboratory suggest more of a continuum of taste-response patterns in a population of receptor cells than the existence of four specialized receptors for primary gustatory qualities.

Smell (distance chemoreception). Theories of olfactory stimulation are even less satisfactory than are those for taste. The events that have been suggested as occurring at the receptor cell to trigger off an olfactory response include the following: (1) chemical reactions at the cell surface; (2) solution of odorant molecules at the surface, thus altering surface tension; (3) radiant energy from an odorant affecting the cell without actual contact of the chemical molecule with the cell; (4) adsorption of the odorant on the cell surface; (5) effect of molecular internal vibrations (molecular resonance) on some aspect of cellular function; (6) enzymatic reactions; (7) penetration of odorant molecules with disruption of receptor-cell membranes; and (8) effect on an olfactory chemical or pigment within the receptor cell, similar to the effect of light on visual pigments such as visual purple (rhodopsin) within the retina of the eye.

Stages in the olfactory response

As would be expected with this array of olfactory theories (and not all proposed ideas are included), there is even less agreement than in the case of taste. The first, fourth, sixth, and seventh of these theories of smell are similar to their counterparts suggested for taste and have the same strong and weak points. The solution theory (2) seems too slow, particularly in accounting for recovery of olfactory sensitivity after adaptation to an odorant has occurred. There is no good positive evidence for olfactory theories based on radiant energy (3) or on olfactory pigments (8). Neither the molecular-resonance theory (5) nor the penetration theory (7) has even majority acceptance right now, although the idea that adsorption (4) is the critical step in stimulation seems to attract adherents.

Attempts to find and name odour primaries have proved more difficult than in the case of postulated taste primaries. A major stumbling block is that none of the theorized primary odour qualities can be related to specific classes of chemical compounds. The postulated primary odours have received such names as: foul, fruity, ethereal, fragrant, resinous, and burnt. The number varies from as few as four primaries to as many as 32, the most usual number being six or eight.

Some current theories relating olfactory experience to chemical or physical characteristics of odorous materials rely upon some postulated selection of primary odours; others do not. Although the first class of theories is based upon attempts to relate specific odours to particular chemicals, no reasonable correspondence between chemical structure and odour has yet been found. Attempts to correlate solubilities or other physicochemical characteristics with odours have been equally unsuccessful. Because many workers believe that the first step in olfactory excitation is adsorption of odorants on the surface of receptor cells, extensive studies have been made on correlations between odour and adsorptive behaviour of chemical compounds at interfaces between water and lipids (*e.g.,* fats or oils). The correlation is surprisingly good in some cases and poor in others. By changing postulated cell-surface characteristics, good correspondence with experimental data can sometimes be obtained, but the theory then potentially seems to fit any data and therefore is suspect.

Two newer, widely discussed theories are based, at least in part, on molecular shape rather than on chemical structure alone. One theory is based on the assumption that odorant molecules puncture the receptor-cell surface, thus releasing ions, and that the ability to puncture the surface depends not only upon the molecule's chemical properties but also on its shape. The olfactory quality experienced is believed to be the result of differential ability of molecules to puncture the receptor cells, determined by the size and shape of the molecules, and by differential rates of healing of the punctures by the cell. Not enough observational data are available on the fundamental events assumed here to make evaluation possible.

Theory of molecular shape

An alternative theory starts with the postulate that there are only seven primary odours, each of which results from the fitting of molecules of seven specific sizes and shapes into special receptor sockets imagined to exist on the cells. Thus molecules of compounds with a similar odour should have similar size and shape, and proponents of this idea believe that this is so. Others, however, find situations that are inexplicable by this "socket" theory. A most critical objection to this theory is that it is impossible to code the tremendous variety of definable smells with a system of only seven units. This has led some investigators to postulate many more than seven primary odours, separable molecular shapes for all of which have yet to be discovered.

Still another theory (5) of odour qualities starts from observations of high correlations between low-frequency molecular vibrations (resonances) and odours. This theory assumes different primary receptor cells, the number still unknown but probably relatively large. The primaries, in this case, are not postulated ahead of time (a priori). Since the theory depends on experimental evidence for its detailed development, only time will tell how or if the correlations will emerge. It is not assumed that the molecular characteristics being measured (*e.g.,* resonances called Raman spectra) are in themselves the stimulative factors; instead it is theorized that they are accompaniments of molecular energy characteristics that are the actual factors in olfactory stimulation. Thus, the unspecified molecular vibrational characteristics are postulated as acting upon energy-transfer mechanisms in the cell membrane or as determining orientation of odorant molecules on the cell surfaces.

None of these theories of smell at present has wide enough acceptance to be said to be the dominant idea. The general attitude is one of wait and see, while proponents of each gather data. Only further research will decide whether any one of these, or none, fits the observed evidence. Theories of gustatory qualities, starting with widely accepted agreement on primary tastes, and those on olfaction, starting without a generally accepted scheme of primary modalities, have now come to about the same conceptual turning point. (H.W.F.)

Photoreception

Photoreception is the activation of a biological process by means of illumination. Most organisms, including man, respond to visible light; some react to wavelengths of light not seen by man; and still others can react to properties of light not detectable by man, such as polarization (vibration of light waves in a definite pattern). This section is concerned with the sensory processes by which animals detect information carried by light (a detailed discussion of the human eye and its function is to be found below; see *Human vision*).

Light energy is necessary for life on Earth. Green plants require light for photosynthesis, the process by which water and carbon dioxide are transformed into carbohydrates; plants also show adaptive responses (*e.g.*, germination and flowering) to annual changes in daily light periods. Animals depend on plants for food and thus are indirectly dependent upon photosynthesis. In some animals, response to variations in day length is of great importance in the regulation of annual reproductive cycles. (For additional information about the above responses to light, see PHOTOSYNTHESIS and BEHAVIOUR, ANIMAL: *Stereotyped Response* and *Photoperiodism.*)

Light, the name given to the mediator of the sensation of sight in higher animals, including man, and the equivalent of this sensation in lower animals, is the part of the electromagnetic spectrum that is visible to animals; it includes the range of wavelengths from about 300 nanometres (1 nm = 10^{-6} millimetre) in the near ultraviolet to about 700 nanometres in the deep red (300 nanometres is beyond violet and does not evoke sensation in the human eye).

The entire cell of a unicellular animal such as *Amoeba* may be sensitive to light so that the cell moves toward or away from it. Some unicellular animals (*e.g.*, *Euglena*) have developed a light-sensitive receptor, or eyespot—a region with a lower threshold for light stimulation than occurs in the rest of the cell. Some multicellular animals have photoreceptive cells, or eyespots, scattered in various parts of or throughout the body; those in the outer covering of the earthworm (*Lumbricus*) serve in directional orientation, which involves comparison of light intensities at different directions. Most animals have localized photoreceptors of varying complexity—*e.g.*, the ocellus of certain mollusks and arthropods; the compound eyes of arthropods; and the camera eyes of cephalopods and vertebrates.

Evidence indicates that the eyes of certain insects can make use of the information carried by near ultraviolet wavelengths of light as well as that carried by visible wavelengths; both carry information related to the sensation of colour. The eyes of many invertebrates, such as certain arthropods and mollusks, have evolved in such a way that they can detect polarized light; *i.e.*, it evokes a sensation and provides information used for navigation. Visual sensation in higher organisms is primarily a complex response to the intensity and the spatial and temporal distribution of light on the photosensitive retina (the innermost layer of nervous tissue within the eye). Different eyes, different specialized parts of the same eye, and even the same parts of the same eye vary in their responses to illumination. Both the properties of light and those of the eye are thus important determinants of visual sensation. The great differences in the light-analyzing capacities of animals are reflected in the great diversity of gross structural organization involved in photoreception. The fundamental mechanism of photoreception—photochemical activation of a light-receptive pigment and the primary excitation-initiating process—seems to be similar among most animals, however.

This section deals with the optical properties of eyes, including the basic arrangements for image formation and light detection and the morphology of photoreceptors; the photochemistry of light detection; and the physiological functioning of the receptor cells that initiate nervous activity. These initial processes of photoreception provide information for the neural centres of the retina and higher nervous centres. The neural events involving the higher centres lead to visual perception.

THE OPTICAL PROPERTIES OF EYES

The first active step in vision is the absorption of light by a photosensitive substance, a visual pigment. Various devices within the eye assist vision by directing incoming light to this pigment; *i.e.*, they act as light guides by refracting (bending), reflecting (turning back), or guiding light. The arrangement of the optical structures influences the resolving capability and other basic properties of visual sensation.

Camera eyes. *In vertebrates.* The mammalian eye (Figure 13), somewhat like a camera, has a cornea (a transparent, anterior portion) and a lens; it functions as a dioptric system—*i.e.*, a system in which light rays are refracted so as to focus on the retina; the image projected on the retina is inverted. In the retina the light first passes through several layers of nerve cells before impinging on the photoreceptor cells, called rods and cones. The dimensions and refractive powers of all the optical parts of the human eye are known, making it one of the best understood vertebrate eyes (see below *Human vision*).

The influence of environment on vertebrate eyes

The large size of the camera-like vertebrate eye makes it potentially the most efficient of all eyes because it can project a large image on a large surface area containing a high density of receptors. Both vertebrate and invertebrate eyes reflect the influence of the animal's environment. The optical arrangement of the eyes of animals active during the night (*i.e.*, nocturnal) suggests that resolution is sacrificed for light-gathering power (see Figure 14). The opossum lens, for example, is so large that it almost touches the retina—*i.e.*, it has a short focal length, the distance from the centre of the dioptric system to the place at which the image of distant objects is focussed (retina). The short focal length combined with a wide aperture results in a low focal ratio, or f-number

$$\left(\frac{\text{focal length}}{\text{aperture diameter}}\right),$$

and ensures high light-gathering ability. In the eyes of animals active during the day (diurnal), the lens is smaller; as a result, the optical centre is closer to the front of the eye,

From G.L. Walls. *The Vertebrate Eye*, Cranbrook Institute of Science

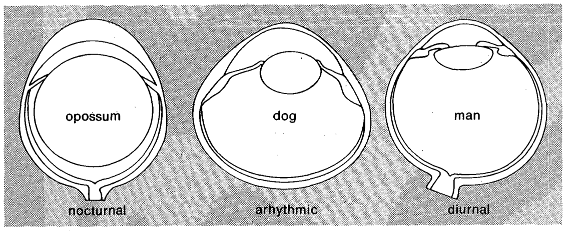

Figure 14: Influence of the environment on the optical arrangements of animal eyes (see text).

and its front surface is flatter. Thus, the focal length of the system is longer, the f-number is higher, and the image on the retina is larger and dimmer than in the nocturnal eye. Assuming that the large image can be detected by the photoreceptors, resolution is improved at the expense of the speed of the lens system.

In order to utilize efficiently a large image, the retinas of diurnal animals have localized areas with many photoreceptors; *i.e.,* a higher receptor density. The receptors in this area, called the area centralis, are usually cones, the receptors of daylight and colour vision. These areas for sharp vision, often circular, are seldom located exactly in the optic axis (an imaginary line drawn through the centre of the cornea and the central point of the eye, see Figure 13). The eyes of most birds have two such areas, the centre of each of which is specialized by a thinning of the retina to include only the receptors. This gives rise to a depression called the fovea, also found in teleost fishes, certain reptiles, and man. When the area centralis contains a yellow pigment, it is called the macula lutea. The macula lutea is found in higher primates (simians) and possibly chameleon lizards. This pigment filters out the shorter wavelengths of light and improves the sharpness of the image by reducing the chromatic aberration (variation of the focal length with different wavelengths of light) that would be caused by the inability of the lens to bring the long and short wavelengths to the same focus.

Accommodation in the eyes of vertebrates

Distant objects are in focus on the retina of the normal human eye. In order for objects closer than about six metres (20 feet) to be in focus, however, an adjustment called accommodation is necessary; otherwise, the image would fall in back of the retina, and the object would appear fuzzy. In mammals, birds, and reptiles other than snakes, the accommodative adjustment consists of sharpening the curvature of the lens so as to shorten its focal length. In snakes, elasmobranchs (*e.g.,* sharks), and amphibians, accommodation is achieved by moving the lens—hence its focal plane—forward. In lampreys and teleost fishes the eye is adjusted for near objects, and accommodation for distant vision is carried out by a backward movement of the lens. Some species have evolved adaptations that make accommodation unnecessary. The retina of the fruit bat (*Pteropus medius*) is in folds, ensuring that some part of it will intercept an image at any location. The ray *Raja batis* and the horse have ramp retinas, in which a continuous and gradual change occurs in the distance between the lens and retina in certain parts of the eye. Specific areas in these animals' eyes are presumably used to view objects at varying distances much as the human eye directs the image for detailed vision onto the fovea.

Because vertebrate species are adapted to almost every aquatic and terrestrial environment, they have evolved equally diverse eyes. In air, for instance, the front surface of the cornea can function effectively for image formation; in underwater eyes, however, the refractive index (the ratio of the speed of light in air to that in a given medium) of water and the cornea are almost identical, and the corneal front surface does not refract light. In these eyes the lens does much of the image formation.

Vertebrates have two types of photosensitive cells, rod cells and cone cells. The rod cells, which are long and fat, contain large amounts of visual pigment; they are the photosensitive cells for vision under conditions of dim illumination (scotopic vision). The cone cells, which are relatively small, mediate daylight vision (photopic vision) and colour sensation in many animals. The photosensitive photoreceptor outer segments of rods and cones are stacks of disks, or lamellae, with the planes of the disks at right angles to the long axis of the rod and cone cells. The retinas of animals active both day and night, as are those of humans, contain both rods (for night vision) and cones. In parts of the human retina the rods and cones are intermingled; elements of the nervous system provide the switching mechanism that permits adjustment for light conditions. The specialized fovea contains only cone cells; in the fovea the switching function is accomplished by eye muscles that change the direction of the field of vision in order to bring the image to the fovea.

The amount of light reaching the photoreceptor cells is controlled to some extent by the pupil, the opening of the eye through which light passes. The iris, the coloured portion of the eye surrounding the pupil, constitutes a diaphragm. Its muscles cause the pupil to change in diameter, decreasing the size of the pupil when light enters and increasing it when little or no light enters. The area of the pupil increases about 15 times in going from one millimetre to four millimetres (0.04–0.16 inch) in diameter, a relatively small increase in comparison with the range of light intensities under which the eye effectively operates. Since the amount of light entering the eye is proportional to the size of the pupil, it can be seen that changes in pupil size modify the amount of light only over a small range. Changes in pupil size are important in the human eye because they allow the lens to be used most effectively for visual acuity. When the whole lens is used, as in dim light when the pupil is large, the image formed by the lens is rather poor, chiefly because of chromatic aberration. The neural image on the retina is already poor, however, because the responses of thousands of rods must be pooled to obtain maximum sensitivity. Use of the whole lens is beneficial because it adds further light without reducing the image quality. When illumination is bright, the pupil is small, and only the aberration-free central part of the lens is used. This high-quality image is used effectively by the cone receptors of the fovea. There, no pooling of receptor responses occurs.

Adaptations of the eyes of nocturnally active animals

Pupils that form a circle when closed cannot greatly change in area; however, a pupil that forms a slit when closed can close almost completely. When nocturnally active animals find themselves in bright sunlight, they need additional protection for their sensitive rod-containing retinas; such animals have evolved pupils that close to form a slit. Many nocturnal vertebrates also show eyeshine (*e.g.,* the glow of a cat's eyes reflecting light at night). Eyeshine, which is caused by a mirror-like reflection from either the retina or choroid (a layer of blood vessels and connective tissue), enhances the sensitivity of the eye. The reflection of the light outward means that it passes the receptors a second time, giving them a chance to absorb light that was not absorbed during the inward passage through the receptors. Some animals thus have smaller rod receptors than they would otherwise need.

In cephalopods. The eyes of the invertebrate cephalopods—octopus, squid, and cuttlefish—are usually cited as examples of convergent evolution because they have independently evolved large camera-like eyes similar to those of vertebrates. The cephalopod eye lies within a cartilaginous cup. It consists of a cornea, lens, iris, and retina with the same basic relations to one another as are found in vertebrate eyes. Iris muscles can enlarge and narrow the pupil. Many details, of course, are different; for example, although the maximum density of photoreceptors in cephalopods is high—about 50,000 per square millimetre (32,000,000 per square inch) in *Loligo* and 100,000 per square millimetre in *Sepia*—the retinal structure otherwise bears little resemblance to that of the vertebrate. The photosensitive cells are of two types and are organized to detect polarized light (see below *Morphological features*). In addition, unlike vertebrate receptors, those of the cephalopod are the first element of the retina to be illuminated (rather than the last, as in vertebrates), and the optic ganglion (a mass of nerve tissue) is separate from the retina (rather than an intimate component, as in vertebrates). Both vertebrate and cephalopod retinas show pigment migration and movement of the receptors in response to adaptation for conditions of light and dark.

The cephalopod cornea does not have any focussing function. Image formation is accomplished entirely by the lens, which is forced forward for viewing nearby objects. The pupil is round in deep-sea cephalopods, such as *Loligo,* and slit-shaped in shallow-water dwellers, such as the octopus. Cephalopod photoreceptors are very long, an adaptation for nocturnal or deep-sea and low-light level conditions. The length allows for the presence of more visual pigment and hence greater absorption of light by each receptor cell.

Eyespots. Eyespots, the most primitive eyes, are found in the protozoan flagellates (unicellular animals with a flagellum, or whiplike structure, used for locomotion), flatworms (Platyhelminthes), and segmented worms (Annelida). An eyespot may be a specialized part of a cell as in protozoans, a single photoreceptor cell, or a small cluster of receptors with few or no accessory optical and neural structures. The entire epithelium (skin) of the annelid earthworm *Lumbricus* contains isolated light-sensitive cells that are eyespots. These photoreceptor cells are rather spherical in shape. A rhabdomere—a structure containing photosensitive pigment—lines a vacuole, or internal cavity, of the photoreceptor cell. The function of the vacuole may be to gather light.

Eyespots in planarians and amphioxus

The flatworm *Planaria* has a more highly developed eyespot. A number of photoreceptor cells are clustered under the epidermis. All of the rhabdomeres, which occur together within a cup-shaped collection of pigment cells, are located on slender filaments some distance from a cell that also gives rise to a nerve fibre.

A third type of eyespot is found in the nerve cord of the cephalochordate amphioxus. Each of a small cluster of photoreceptors, the Hesse cells, has a rhabdomere along the edge that faces a pigmented cell.

Ocelli. The ocellus, which is recognized as a true eye, is similar to a camera in that it usually projects an inverted image onto a light-sensitive layer. The ocellus is distinguished from the compound eye, which has many lenses, and from the more highly developed camera-like eye of the mollusks and vertebrates.

In mollusks. In a simple ocellus, that of *Nautilus,* the photoreceptor cells are bipolar—*i.e.,* the rhabdomere is at one end, the nerve fibre at the other—and arranged in a cup-shaped sheet. There is no lens or cornea, only a pinhole opening.

The more complex ocellus of the slug *Agriolimax reticulatus* is located at the tip of the tentacle (see Figure 15); there is a cornea under the epithelium, a vitreous body (a mass of clear jellylike material), and a lens, as well as a main retina and an accessory retina. The accessory retina is believed to function as an infrared receptor. As the tentacle is withdrawn, the accessory retina is rotated so that it is exposed to incoming radiation. The few photoreceptor cells are surrounded by pigment-containing cells. The ovoid eye is about 0.18 millimetre (0.007 inch) in its longest diameter. Distant objects appear in focus in the photoreceptor cells of *Agriolimax,* and the shape of the eye changes as the state of retraction of the tentacle varies. The change in shape may provide a mechanism for accommodation, although accommodation may not be particularly useful, because indications are that this ocellus does not clearly distinguish form.

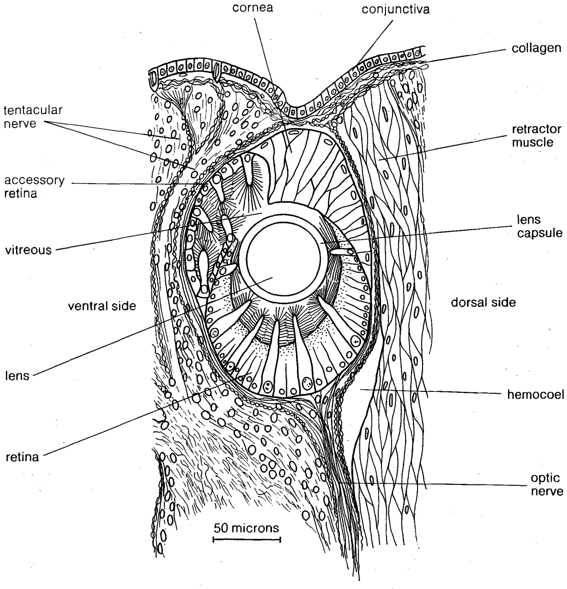

Figure 15: Longitudinal section of the eye of the slug *Agriolimax reticulatus.*

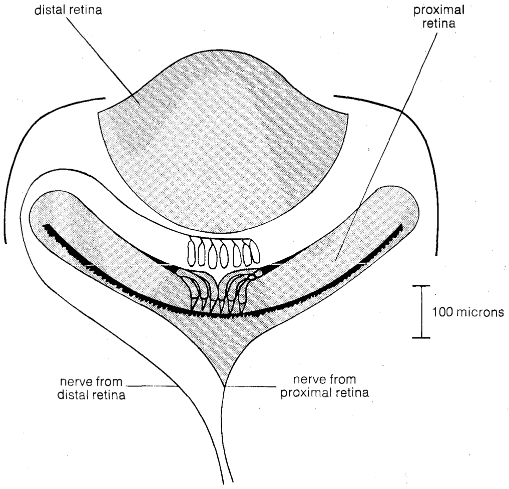

Figure 16: The central region of the eye of the scallop *Pecten.*

From M.F. Land, *Symp. Zool. Soc. London No. 23* (1968); The Zoological Society of London

The molluscan ocelli described above resemble a miniature simple camera, in which an inverted image is projected onto a photosensitive retina. The optics of other ocelli, however, are more sophisticated; for example, the scallop *Pecten* (Figure 16) and related genera have about 100 eyes located along the fringe of the mantle, the lining of the inner surface of the shell. The eyes are one millimetre (0.04 inch) in diameter and have a double retina; one is called a distal retina, the other a proximal retina. The nerve fibres of the distal (*i.e.,* farthest from the body axis) retina respond only to decreases in light intensity; the nerve fibres of the proximal (*i.e.,* closest to the body axis) retina, on the other hand, respond only to increases in light intensity. Because the photoreceptors in the proximal retina are inverted, light passes through all parts of them before reaching the light-sensitive pigment, and the photoreceptors just touch a reflecting structure, the tapetum lucidum. The scallop tapetum contains about 35 layers of thin crystals; the thickness of and the degree of separation between crystals are precise. The crystals and the intervening spaces function as an interference filter. The small reflection from each crystal interface adds to give a large net reflection from the surface of the tapetum. The fact that the photoreceptors just touch the tapetum ensures that they are illuminated on the second pass (after tapetal reflection) by the same light that passed through them the first time. The tapetum in the scallop eye acts as a concave (*i.e.,* depressed toward the centre) mirror, projecting light through the proximal retina and focussing an image of a distant object on the photoreceptors of the distal retina. The combination of tapetum lucidum and inverted photoreceptors in the proximal retina may thus enhance sensitivity without sacrificing resolution. The structural details of the tapetum lucidum have been described not only for the eye of the scallop *Pecten* but also for several arthropod and vertebrate eyes.

The tapetum lucidum

In arthropods. Among arthropods, ocelli are the main organs of sight in arachnids such as spiders and in insect larvae that undergo complete metamorphosis (*i.e.,* a radical physical change during development). Insects that undergo incomplete metamorphosis have three ocelli arranged in a triangle on the dorsal, or top, part of the head; these are subsidiary, however, to the main organs of sight, the compound eyes.

Spiders have two kinds of ocelli, the principal, or antereomedian, eyes and the lateral eyes. The principal eyes of jumping spiders are used when stalking prey and in courtship; the photoreceptors are arranged in four layers in the optic axis (see Figure 17). The two deepest layers cover the entire retina; the two most superficial layers are confined to the retina's central region. The rhabdomeres of the three deepest layers are rod shaped. Those of the most superficial layer are ovoid and oriented in the direction of propagation of light through the eye. Because the receptors are layered, the images of objects at differ-

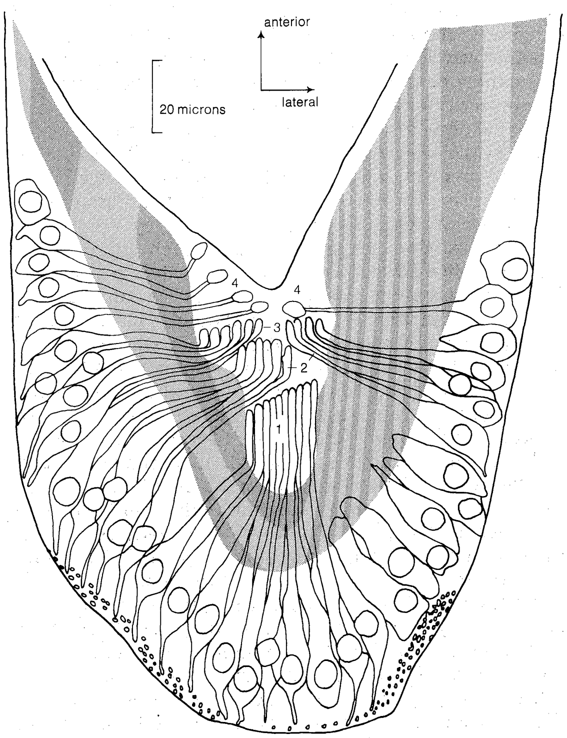

Figure 17: Frontal (horizontal) section close to the centre of the retina of the spider *Metaphiddipus aeneolus,* with the layers of receptor endings numbered 1 to 4. In layers 1, 2, and 3 the presumed receptive part of each receptor is the straight terminal portion; in layer 4 it is the terminal ovoid swelling.

From M.F. Land, *Journal of Experimental Biology,* vol. 51 (1969)

ent distances from the eye appear in different layers; it is possible that this type of retinal system is used for depth perception. It appears more likely, however, that the arrangement is used for colour vision. Images of distant red objects appear in the first retinal layer, blue-green images appear in the second layer, and ultraviolet images in the third layer, because the primitive lens system shows considerable chromatic aberration.

No image for visible light appears in the most superficial ovoid rhabdomeres of the principal eyes of spiders, and it has been postulated that they function to detect polarized light. The principal eyes also have a set of six muscles that produce eye movements when an image falls on the retina. The eye follows the image, which remains centrally fixed.

The lateral ocellus of the caterpillar, which has a group of five or six ocelli on each side of the head, resembles one ommatidium, or unit, of a compound eye. The optical apparatus includes a lens, or cornea; a crystalline cone, which is the principal focussing device; and two layers of photoreceptors (distal and proximal) in the optic axis, each of which is radially arranged like sections of an orange. The rhabdomeres of both cell types are in close apposition over much of their length. Objects at different distances project images at different vertical locations in the rhabdom—*i.e.,* a group of rhabdomeres in physical contact with one another. The proximal and distal rhabdoms form an optically continuous structure, a light guide. The optical information in this structure depends on the light accepted at the distal part of the rhabdom, rather than on the locations in the rhabdom at which images are projected, because the rhabdoms actually touch one another and effectively form one optical structure (see *Optical properties of photoreceptors* below).

Spatial resolution in ocelli and camera eyes

No optical system can form a point image of a distant luminous point, such as a star; because of diffraction (a modification in which a redistribution of energy occurs), the image is instead a small spot, the Airy disk, with a bright centre enclosed in concentric, alternately bright and dim rings. The radius of the first dark ring indicates the size of the diffraction pattern. The smaller the aperture and the longer the wavelength, the bigger the Airy disk and the poorer the resolution.

The degree to which images can be detected is determined both by the size of the Airy disk and the size, separation, and density of packing of photoreceptors. Compared with the eyes of most invertebrates, a relatively large number of photoreceptors occurs in the principal eye of the jumping spider. This suggests that the image is good, that its quality is primarily determined by the size of the lens, and that the mosaic of receptor units makes maximal use of the image quality. By comparison, the theoretical resolution of the human eye is 10 times better than that of the spider. This difference results solely from the difference in the size of the eye. In both the human eye and that of the spider, the focal length is adjusted to transmit the image onto a retina containing about the same density of photoreceptors. Actual resolution, however, is complex and depends on other factors, such as the nature of the target, properties of the illumination, the form of measurement, and neural processing in the eye and brain.

In the lateral ocellus of insect larvae, the size and density of the receptors are probably the limiting factors in resolution. In addition to poor spatial resolution, the light-gathering power of the lateral ocellus is also inferior to that of the spider eye.

Compound eyes. Aggregations of ocelli are found in several lower animals—in polychaete worms, for example. True compound eyes are found only in the arthropods, however. The compound eye of insects is composed of hexagonal or rectangular-shaped, closely packed optical units called ommatidia (small eyes); each ommatidium is virtually a single eye. In different species the size, number, and structure of ommatidia vary. An ommatidium (Figure 18) is composed of a corneal lens, or facet, which consists of a modified extension of the cuticle (the hard outer covering of arthropods) on the surface of the eye; four cells called Semper's cells or cone cells, which form the crystalline cone; and a sensory region called the retinula (small retina). In primitive insects (*e.g.,* the springtail *Lepisma*), in which the transparent cone cells are not specialized, the ommatidia are called acone ommatidia. In the more common eucone ommatidium, which occurs in moths and butterflies, the cone cells have a more complicated structure and contain granules of glycogen, or animal starch; because the granules are packed at various distances from each other, the refractive index varies in different positions in the cell. In certain beetles (*e.g., Lampyris*) and in the horseshoe crab *Limulus,* the crystalline cone is an extension of the cornea.

From *Journal of Cellular and Comparative Physiology* (1965)

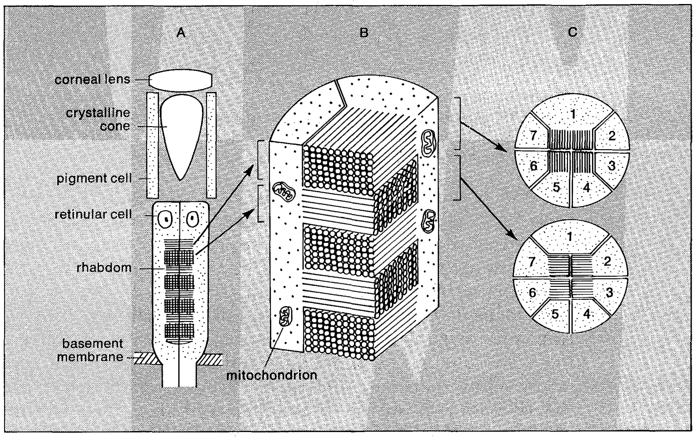

Figure 18: *An ommatidium from the compound eye of the crayfish Procambarus clarkii.*
(A) Longitudinal section through the optic axis with the cone stalk between the crystalline cone and the retinula omitted.
(B) Part of the rhabdom. The direction of the closely parallel microvilli in one layer is perpendicular to that in the next.
(C) Cross sections through the retinula at the levels of two neighbouring layers, rhabdomeres from retinular cells 1, 4, and 5 constituting one layer (upper figure); 2, 3, 6, and 7 constituting the next layer (lower figure); 1, 4, and 5 the third; and so on alternately.

Components of the ommatidium

The sensory part of the ommatidium, the retinula, consists of several radially arranged cells (retinular cells); each has a photoreceptor component, or rhabdomere (see Figure 18). The rhabdomeres of neighbouring retinular cells may be either in contact (forming a rhabdom) or completely separate. The optical isolation of each ommatidium is enhanced by its being surrounded by light-screening, pigment-containing cells. During adaptation to light and dark conditions, migration of pigment in cells around the crystalline cone, the corneal process, the proximal part of the ommatidium, and within the retinular cells has been reported to occur in most types of compound eyes.

The apposition eye. In the compound eyes of diurnal arthropods, each ommatidium is separated from its neighbours by pigmented, or iris, cells under all conditions of illumination. As a result, the rhabdom of each ommatidium receives light only through its own corneal lens; light from the lenses of other ommatidia is blocked by the pigment. This is the basic structure of the apposition eye (Figure 19). There are, however, variations in structure.

From G.A. Mazohkin-Porshnyakov, *Insect Vision* (copyright 1969); Plenum Press

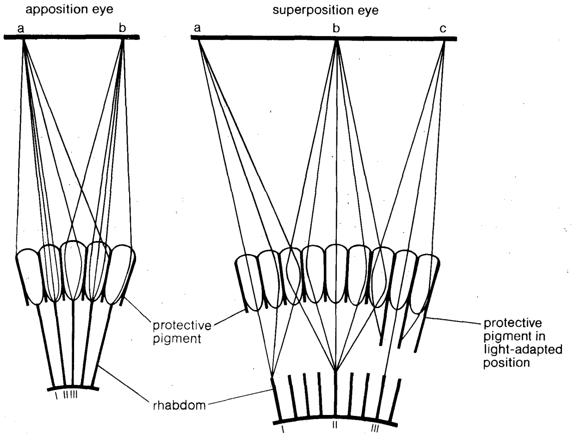

Figure 19: Image formation in apposition and superposition eyes: I, II, III represent different ommatidia; a, b, c represent point objects (see text).

In the honeybee *Apis mellifera,* the cornea is layered, each layer having a different refractive index. It has been shown that the corneal lens projects a small inverted image of a distant object in the crystalline cone some distance short of the rhabdom of an ommatidium. If the image were focussed exactly on the rhabdom, it might effectively transmit image-location information by means of differing responses of the individual retinular cells within an ommatidium. Because the image is focussed in front of the rhabdom, however, individual retinular cells within an ommatidium do not respond to image location. The defocussing also has the effect of broadening the field of view of the ommatidium. As the image moves, it can still be guided into the rhabdom by the crystalline cone, which is considerably wider than the rhabdom.

Specialization of the butterfly eye

It is not possible to generalize from the known optics of the compound eye of the bee to other apposition eyes as, for example, those of the butterfly, which superficially resemble the bee's in having a cylindrical rhabdom. Certain features of the butterfly eye are known, however (see Figure 20). Under the rhabdom of each ommatidium, the tracheole, or respiratory tubule, which supplies air to the ommatidium, has become specialized to form a tapetal filter comparable with that of the *Pecten* eye; it reflects highly saturated colours, usually blue colours in the dorsal ommatidia and more reddish colours in the ventral part of the eye. Each ommatidium thus has its own mirror. (The swallowtails, *Papilio,* are the only butterflies lacking this adaptation.) The light in the rhabdom of an ommatidium is tinted by the coloured light reflected from the mirror, and can be seen only with the aid of an ophthalmoscope—an instrument for viewing the interior of the eye. This filter system probably aids vision by enhancing contrast between objects of certain colours.

Butterflies with a tapetal filter, as well as nocturnal species (with a tapetum of different structure), have a corneal surface structure that acts as an anti-reflector. It consists of minute conical corneal "nipples" that provide a gradual transition between the refractive index of air and that of the cornea, effectively eliminating front-surface reflection for many wavelengths of light. One of the functions of this coating may be to minimize reflection of images from the tapetum lucidum back into the eye.

The rhabdomeres within an ommatidium in the compound eyes of flies (Diptera) have a microvillar structure (*i.e.,* one involving minute hairlike projections; see below *Morphological features*) and are completely separate from one another, in contrast to the apposition eyes above, in which the rhabdomeres are in contact. Each ommatidium contains eight retinular cells and eight rhabdomeres.

From any relatively distant point in space, a small cluster of ommatidia in a fly's eye appears darker than other areas because these ommatidia are the ones that are best aligned to absorb light coming from the direction in which the ommatidia are pointed. This cluster, called the pseudopupil, is often found in insect eyes; it moves, appearing to follow an observer viewing different parts of the compound eye. In the compound eye of the butterfly it is the pseudopupil that lights up with colours when observed and viewed from the same direction as the illumination with the ophthalmoscope. The pseudopupil of flies usually consists of seven ommatidia. In this apposition eye a distant point forms an image on the distal end of the rhabdomere, not within the crystalline cone as in the apposition eye of the bee. From any distant point in space only one rhabdomere in each ommatidium of the pseudopupil is illuminated by a point source; *i.e.,* one rhabdomere in each ommatidium of the pseudopupil is directed toward the same point.

Spatial resolution in the apposition eye

Experimental results suggest that the resolution of the compound eye (*i.e.,* the capability of the eye to distinguish between two separate but adjacent objects) is determined by the divergence angle between the ommatidia. If a compound eye views a pattern of alternating black and white bars in which the angle formed by one bar is the same as that between the ommatidia, the image of one black bar falls on one ommatidium, and the image of the flanking white bars falls on its nearest neighbours. This defines the limit of resolution; if the image of more than one bar falls in an ommatidium, the bars are not resolved.

The image is out of focus at the rhabdom in the bee eye. The angle between fly rhabdomeres is the same as the angle between ommatidia. The fused rhabdom of the bee and the separate rhabdomeres of the fly probably convey

From N. Yagi and N. Koyama, *The Compound Eye of Lepidoptera: Approach from Organic Evolution* (1963); Maruzen Co., Ltd.

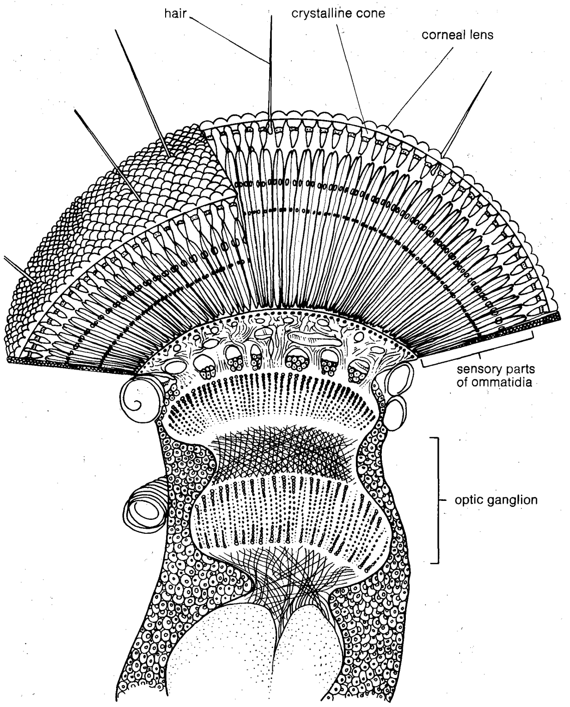

Figure 20: Section through the compound eye and optic lobe of a butterfly.

polarization and colour information rather than spatial information.

The array of corneal lenses on the surface of the eye can be considered as sources of light that interfere deep within the eye to give high-order diffraction images. The structure of the eye suggests that this effect is not detectable by the photoreceptors. Substantial shielding pigment between the ommatidia reduces the intensity of such patterns, which thus should be relatively ineffective in exciting the rhabdom.

The superposition eye. In the compound eyes of nocturnal arthropods, the rhabdoms are deep within the eye, far from the cornea and crystalline cone. In 1891 Sigmund Exner, an Austrian physiologist, reported experiments that showed how these eyes function. He demonstrated that there is pronounced pigment migration within the iris cells. In eyes adapted to darkness, the pigment of these cells migrates upward and into spaces between the crystalline cones of neighbouring ommatidia. In the light-adapted eye, on the other hand, the pigment migrates into the region between the cones and the rhabdom, in effect isolating each ommatidium by surrounding it with a light-absorbing tubular pigmented structure.

The pigment migration has the effect of changing the sensitivity of the eye. When a light-adapted eye is placed in the dark, there is an initial increase in sensitivity of about 10 times with no accompanying pigment movement. In the following 25 minutes in the dark, the sensitivity increases about 100 times, as the pigment gradually withdraws from between the cones.

Important differences between apposition and superposition eyes

Exner found that the corneal process of the firefly *Lampyris,* a structure that resembles the crystalline cone of butterflies and other nocturnal insects, has a higher refractive index at the centre than near the periphery and effectively bends incoming light. When the eye is dark-adapted, light from many facets converges in the rhabdoms of many ommatidia forming a so-called superposition image (Figure 20). This eye differs from the apposition eye in that light from many facets is involved in forming an image in the rhabdom of an ommatidium; in the apposition eye, on the other hand, light from its own corneal lens reaches the rhabdom within a particular ommatidium. The mosaic image of the superposition eye, although less sharply defined than that of the apposition eye, is brighter and thus a valuable adaptation for nocturnal insects. In the light-adapted condition, inward migration of pigment in the iris cells effectively prevents the spread of light to adjacent ommatidia, and the superposition eye acts somewhat like the apposition eye; *i.e.,* only the light from one facet reaches the rhabdom within an ommatidium.

THE PROPERTIES OF PHOTORECEPTORS

The photoreceptor cell absorbs light energy and transforms it into a nervous response. The actual photoreceptor component, or organelle, of the photoreceptor cell contains a coloured substance (visual pigment) that absorbs light and initiates the chain of chemical reactions leading to nervous excitation. The vertebrate photoreceptor cells, the rods and cones, are so called because of the shape of their photoreceptors, which are found in the outer segments of the cells. Invertebrate photoreceptor cells, the photoreceptors of which are the rhabdomeres, show greater diversity of structure than do those of vertebrates.

The function of photoreceptors is dependent on the visual pigment they contain; the identification of photoreceptors ultimately depends, therefore, on correlating the light-absorbing properties of the pigments within them and the physiological response of the receptor cells. Such evidence exists for a number of invertebrates and vertebrates; the identity of some vertebrate and many invertebrate photoreceptors, however, has been inferred from their location, colour, and structure after comparison with known photoreceptors.

When viewed with the light microscope, the outer segments of vertebrate receptors and the rhabdomeres of invertebrates can be recognized by their shape, location, and high refractive index. In the electron microscope, all photoreceptors are seen to consist of a dense collection of membranes. The outer segments of vertebrate photoreceptors are lamellate (layered). Invertebrate rhabdomeres usually consist of microvilli (minute projections of the receptor cell membrane) and resemble a tiny honeycomb in three dimensions. In certain invertebrates, however, the rhabdomeres are lamellate, resembling those of vertebrates. Some features of photoreceptors from various animal groups are discussed below.

Morphological features. *Invertebrate photoreceptors.* The photoreceptor of the jellyfish *Polyorchis penicillatus* (Figure 21) is a modified cilium, or hairlike structure, as are the photoreceptors of many higher animals. Cilia are found in the cells of most animals; their motion is used either to move the animal or to move materials within or outside the body. As seen in the electron microscope, a cilium characteristically consists of nine double, peripherally arranged filaments (very fine threadlike structures) and a central pair of filaments in a so-called 9 + 2 pattern. A cilium arises from a cell structure known as a centriole, near which is often found a second centriole; ciliary rootlets extend from the centrioles to deep within the cell. In sensory cells a cilium often develops into a sensory organelle. Sensory cilia invariably lack the central pair of filaments, having what is called a 9 + 0 pattern. The sensory cilium of *Polyorchis* contains numerous coarse microvilli, which constitute the sensory portion; centrioles and a ciliary rootlet are also present. Near the base of the photoreceptors are frequently found large numbers of cell components called mitochondria. Mitochondria manufacture the compound adenosine triphosphate, which seems necessary for the photoreception process.

Photoreceptors in lower invertebrates

The microvilli found in the primitive photoreceptor of *Polyorchis* are atypical in two respects: first, it is unusual for the microvilli of rhabdomeres to be derived from cilia; second, the microvilli of the rhabdomere, which are usually packed together very densely, are, in the jellyfish, mingled with the microvilli of the pigment-containing cells that envelop the rhabdomere. Migration of pigment into or out of the pigment-cell microvilli provides a mechanism for regulating the amount of light absorbed by the receptor. The identification of photoreceptor cells in the jellyfish has been based on anatomical and behavioral evidence. The cells are located in ocelli, the removal of which renders the jellyfish incapable of responding to illumination.

Although the ctenophorans (comb jellies) usually have been assumed to lack both a response to light and photoreceptor cells, recent evidence has raised some doubt about such a conclusion. Electron microscopic examination of *Pleurobrachia pileus* has revealed a radial arrangement of four groups of lamellate bodies; the lamellae are composed of membranes of about 12 sensory cilia (*i.e.,* 9 + 0 type). The sensory cilia, instead of developing microvilli as in *Polyorchis,* become individual platelets. These lamellate structures, which are located in infolded regions of the presumed photoreceptor cell, resemble similar lamellate structures in certain molluscan and vertebrate photoreceptors; it is presumed by some investigators, therefore, that the lamellate structures of *Pleurobrachia* may be photoreceptors.

The planarian flatworm *Dendrocoelum lacteum* (phylum Platyhelminthes) has photoreceptor cells with well-developed rhabdomeres (see Figure 22). The cytoplasm of the receptor cell, which has a tubular extension, contains many mitochondria; the surface membrane, which forms the tightly packed microvilli that constitute the photoreceptor organelle, is presumed to be the site of the visual pigment. No evidence has been found that either this photoreceptor or those of other flatworms are derived from cilia.

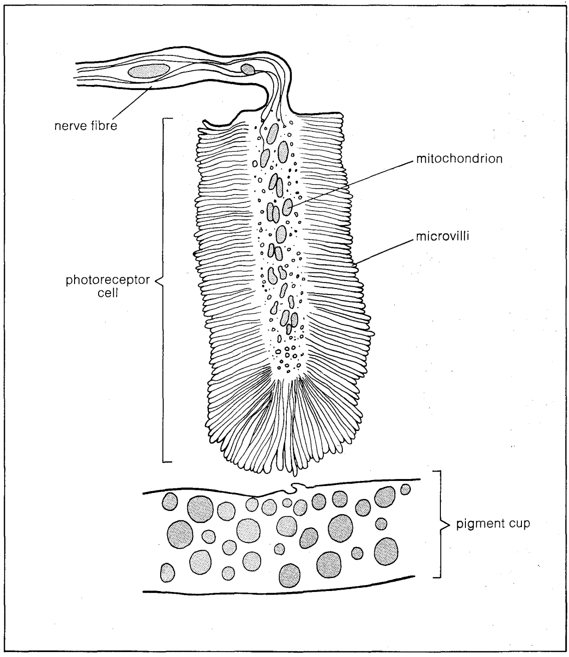

Figure 22: The photoreceptor cell in the flatworm *Dendrocoelum lacteum.*

The nemertine worms (phylum Nemertea) have photoreceptor cells that resemble those of planarians when viewed with the light microscope. The photoreceptor cells on the eye of *Lineus ruber* resemble those of planarians in the electron microscope in that both have a rhabdomere consisting of microvilli. An important difference exists, however: the photoreceptors of *L. ruber* possess a filament that resembles a ciliary rootlet, even though no evidence exists that the rhabdomere is derived from cilia; in fact, cilia have not been observed in this cell. The function of the filament is not yet known.

Photoreceptors in the eye of the rotifer *Asplanchna brightwelli* (phylum Aschelminthes) are lamellate. Thin lamellae, arranged as leaves of a cabbage, apparently are folds of the receptor membrane. There is no evidence that the receptor is derived from cilia.

The photoreceptor cells in the eyes of the arrowworm *Sagitta scrippsae* (phylum Chaetognatha) have rhabdomeres consisting of structures of ciliary derivation that are called microtubules. The microtubules arise from a cone-shaped body filled with granules and cordlike structures. The cone-shaped body is derived from a sensory cilium. The microtubules comprising the rhabdomere are 50 nanometres in diameter and 20 long.

Photoreceptors of annelid worms

The segmented worms (Annelida) are the first invertebrate animal group in which the photoreceptors of a considerable number of species have been investigated. Studies indicate that annelids generally have rhabdomeres consisting of microvilli and are not of ciliary origin; however, at least one exception (*Branchiomma*) to this pattern has been observed.

The photoreceptor cell of the earthworm *Lumbricus terrestris* is an example of a rhabdomere comprised of microvilli; as mentioned previously, the microvilli of the membrane of the rhabdomere border on a vacuole within the receptor cell rather than on its outer surface. A number of sensory cilia are mixed with the microvilli and extend from the cell cytoplasm into the vacuole. The microvilli are not derived from cilia, and their function is as yet unknown. Although rhabdomeres consisting of microvilli have been found in several other annelids, no evidence of cilia has been reported. In the polychaete worm *Nereis vexillosa,* however, the microvillar rhabdomere arises from a tubular extension of the cell containing a centriole and a small fibre (fibril) with the structure of a ciliary rootlet; no direct evidence has been found thus far to link these ciliary vestiges to the rhabdomere.

The photoreceptor of the polychaete *Branchiomma vesiculosum* is a well-documented example of an annelid photoreceptor derived from cilia. The photoreceptor cell has a large invaginated (inpocketed) cavity filled with about 450 flattened lamellar sacs, which are the expanded flattened membranes of cilia having the 9 + 0 configuration. A collection of mitochondria and the nucleus of the receptor cell are displaced from the light path.

The Onychophora represent a transitional group that combines features of both the annelids and the arthropods. The photoreceptor cells of several species of onychophorans have been studied with the electron microscope. The photoreceptor cell of *Peripatus* closely resembles that of some annelids. The rhabdomere, which consists of microvilli, has a sensory cilium near its base. In studies of the *Peripatus* eye during development, no connection has been found between the sensory cilium and the developing microvilli. The function of the sensory cilium in this and in other photoreceptors in which no clear developmental relationship exists between the two is obscure.

Arthropods have few cilia, although they do occur in a few organs and provide the developmental basis for one type of arthropod ear, the chordotonal organ. Cilia have not been found in association with arthropod photoreceptors, however. The photoreceptor cells of all arthropods studied thus far are generally similar. Part of the cell surface forms densely packed microvilli, which is the photoreceptor containing the visual pigment.

The presumed photoreceptor in echinoderms is a collection of loosely packed microvilli extending from each receptor cell into the central cavity of the ocellus. In some species, each receptor cell has at least one cilium with the 9 + 0 pattern; this pattern is presumed to exist in other species. No relationship exists between the cilia and the microvilli; thus, the same condition prevails as in certain mollusks, annelids, and *Peripatus.* The echinoderms studied thus far appear to have a rhabdomere composed of microvilli and in close association with a sensory cilium.

Photoreceptor cells in mollusks and cephalopods

The mollusks (*e.g.,* scallops, clams, squid) have two morphologically distinct types of photoreceptor cells. One contains microvilli; of these, some photoreceptors have rudimentary cilia and fibrils such as those of certain annelids. Most mollusks appear to have this type of photoreceptor. The other type contains cilia; about 100 cilia on one surface of the cell develop into flattened sacs that are either packed tightly, like slices of bread, or curl on one another, like cabbage leaves. The ciliary type of rhabdomere is found in *Onchidium verruculatum* and in *Cardium edule.* The eyes of the bivalves *Pecten, Chlamys, Spondylus,* and *Amussium* contain double retinas, each with one of the types of photoreceptor. Evidence indicates that both types are photoreceptors and that they have different functions. The distal retina, with a ciliary photoreceptor, responds to a decrease in illumination; the proximal retina, with a microvillar photoreceptor, responds to increasing illumination.

The cephalopod retina has long cylindrical photoreceptor cells with rhabdomeres consisting of microvilli. In some cells the long axes of the microvilli are horizontal. The other type has vertical microvilli. The axes of both types of microvilli are parallel to a plane that is tangent to the retinal surface. This orthogonal arrangement of the microvilli in different cells—*i.e.,* in which they are perpendicularly disposed to one another—forms the physical basis for polarized light detection in the cephalopods.

Vertebrate photoreceptors. The photoreceptor of such primitive chordates as the urochordate ascidian tadpole is a modified cilium with the $9 + 0$ pattern; the cilium has developed into numerous lamellae. The cephalochordate *Branchiostoma californiense* may have both microvillar and ciliary photoreceptors. The Hesse cells, shown experimentally to be photoreceptor cells, have typical microvillar rhabdomeres with no cilia. Two other types of cells that may have a photoreceptor function are the dorsal ependymal cells (*i.e.,* special cells lining the cavities of the brain) and cells of the infundibulum, a ventral portion of the brain. Both cells have appendages containing cilia that form lamellae.

Other vertebrates have the two types of photoreceptor cells mentioned before: rods and cones. The rods are the photoreceptors for vision under conditions of dim illumination; the cones mediate daylight vision and colour sensation in many animals. The photoreceptors in both the rods and cones are composed of stacks of disks derived from cilia; the lamellae are stacked at right angles to the long axis of the cell and constitute the outer segments of rod and cone cells.

Most of the lamellae of the outer segment of the rod consist of free-floating disks within the limiting membrane of the outer segment (see Figure 23). The free-floating disks are formed at the base of the outer segment by a process of continuous infolding of the membrane of the outer segment. The process of new disk generation proceeds continuously during the life of the animal, and the entire outer segment of the rod is replaced in about one week. As new disks are being formed at the base of the rod, disks at the other end of the outer segment are being broken off and ingested by pigment cells; the rod length thus remains constant. As infolded regions of the membrane at the base of the rod move outward, they are pinched off to form free-floating disks. The outer segments of the cones, sometimes conical, or cone-shaped, and shorter than the outer segments of the rods, do not have free-floating disks. The process of infolding stops just after formation of the outer segments of the cones; infoldings occur along the entire length of the cones (see Figure 23). Because the membrane of the outer segments of the cones is not formed continuously during life, membrane components are continuously replaced. It has been shown that renewal takes place continuously along the entire surface of the membrane in cones. In rods, on the other hand, the renewal occurs only at the base, as new disks form.

Structural differences between rods and cones

The terms rod and cone are misleading, because these receptors cannot always be identified by shape; considerable variation exists between species. There are, nevertheless, a number of morphological differences between the rods and cones. The outer segments of the rods of many species are deeply incised—*i.e.,* lengthwise clefts in the disks give the outer segment a scalloped appearance in cross section. Both the rods and cones contain dense aggregations of mitochondria in a section of the inner segment called the ellipsoid (see Figure 24). In the same region the cones of many species have an oil droplet, sometimes coloured, that filters the light before it reaches the receptor. An important difference between the photoreceptors of vertebrates and those of most invertebrates is that the latter give rise to nerve fibres that synapse either with cells in the central nervous system or with cells in a nerve ganglion within the eye; the vertebrate receptors, on the other hand, end in a region called a foot piece, into which nerve cells of the retina send synaptic projections.

Embryology and evolution of photoreceptors. There are two types of vertebrate eyes. The more familiar is the highly developed lateral eye. The other is the primitive median, or pineal, eye (in the top of the head). Only cyclostomes, reptiles, and amphibians have a median eye. It is best developed in lizards, in which the cornea is translucent and the number of receptors is small. The photoreceptor cells of the pineal eye are homologous (*i.e.,* structurally or developmentally related) with those of the lateral eye. They are, in fact, cones, the outer segments showing the characteristic infoldings along their entire length. In the median eye, the ends of the outer segments face the lens and light; in the lateral eye the retina is inverted, so that the ends of the outer segments face away from the light and toward the back of the eye.

The vertebrate retina is literally a part of the brain. The photoreceptor cells are derived from cells that line the neural tube, a hollow, dorsal structure that appears early in the embryo. The median eye develops from an outpocketing of the neural tube, and the cilia that develop into outer segments face the lens.

Invertebrates lack a neural tube; their photoreceptor cells develop from embryonic epithelial cells that send out axons—threadlike extensions—that grow into the central nervous system. Often the epithelial cells contain cilia, and the photoreceptors develop from the cilia. The ciliary photoreceptors of invertebrates do not appear to be homologous with those of vertebrates. As mentioned above, it is of particular interest that photoreceptors of diverse structure and in many different phyla develop either from cilia or in close association with them. Still unknown is the developmental and functional role of the sensory cilia that are frequently found in association with photoreceptors of apparently nonciliary origin.

Optical properties of photoreceptors. *Rhabdomeres and outer segments as light guides.* The densely packed membranous structures of photoreceptors have a higher refractive index than the surrounding substances. The refractive index of the rhabdomere of the blowfly (*Calliphora*), for example, is 1.349, and that for the surrounding substance is 1.336; any light reflected from the inside surface of the rhabdomere is called dense to rare reflection. When the angle at which the light strikes the inside surface (angle of incidence) is such that the change of the angle of the light when entering the photoreceptor (*i.e.,* the angle of refraction) is 90°, all of the light is reflected back into the rhabdomere. The angle of incidence at which total internal reflection occurs is called the critical angle. The rhabdomere and outer segment trap the light entering them at angles equal to or greater than the critical angle and propagate it, essentially without loss of energy. The rhabdomere and outer segment thus act as an optical wave guide, or light pipe (see OPTICS).

Although all light entering the photoreceptor organelle—*i.e.,* all light incident at angles equal to or less than the critical angle—is propagated by successive internal reflection, only certain angles of reflection occur; these are determined by various physical characteristics of the organelle. As a result, the light within the photoreceptor light guides is propagated in modes, or patterns, of energy. This is important for the photoreceptive function of the rhabdomere and outer segment because the amount of information the organelle can carry is related to the number of modes propagated. The thinnest photoreceptor organelles, such as those of certain fly rhabdomeres with a diameter of 0.5 nanometre, can, for example, support only one mode, called the lowest order mode. The amount of energy propagated in the rhabdomere in this mode depends on the wavelength of light, so that the shorter wavelengths are best propagated. Thus reddish light is not made available to the rhabdomere's visual pigment as readily as bluish light; the light guide properties of the organelle, therefore, can influence the physiological response of the photoreceptor. The light guide also profoundly affects the amount of image information transmitted because the greater the number of modes, the more image information. This last consideration is of particular importance for fused rhabdoms, in which image information apparently is not transmitted (although the question is not yet entirely settled). These light guide properties are of importance for still another reason. A small amount of the modal energy propagated by a light guide is actually outside the structure. Thus when, as described in the next section, pigment granules come near the photoreceptor organelle, they control the amount of light in the organelle by absorbing the energy propagating outside, so that it can no longer be transmitted by the photoreceptor. Such pigment granules may exert an even more profound effect by raising the refractive index outside the organelle, thus destroying its guiding properties and causing the light to spread into adjoining structures where it is absorbed, but not by visual pigment; absorption thus does not result in sensation.

Migration of pigment granules

Photomechanical light and dark adaptation. A mechanism that may partly control the amount of light within the photoreceptor under widely different illumination conditions involves the migration of photoprotective pigment granules either within the receptor or within neighbouring cells so as to envelop the photoreceptor; it has been observed in both vertebrates and invertebrates. Pigment migration in response to illumination takes place in the retinas of most vertebrates except mammals. The most pronounced effects are found in fishes, frogs, and toads; they also occur in reptiles and in diurnal and nocturnal birds.

From Dr. Samuel R. Detwiller, *Vertebrate Photoreceptors* (1943); Macmillan & Co.

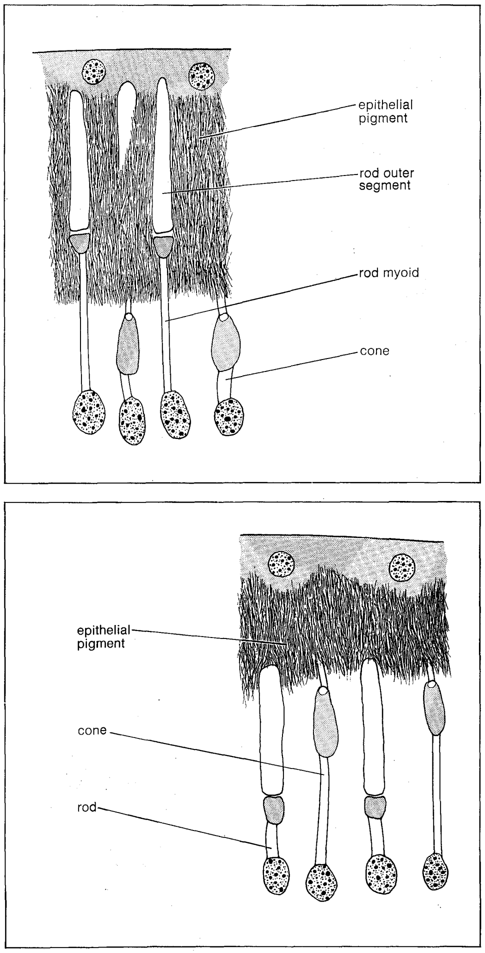

Figure 25: *Adaptation of retina.*
(Top) Theoretical light-adapted retina, showing migrated epithelial pigment, elongated rods, and contracted cones. (Bottom) Theoretical dark-adapted retina, showing contracted pigment, elongated cones, and contracted rods.

Pigment migration is combined with photomechanical movements of the photoreceptor cells of many lower vertebrates (Figure 25). In darkness the pigment granules of the pigment epithelium are withdrawn, as shown in the figure. The rod myoids (contractile elements) are contracted in darkness so that the rod outer segments are withdrawn from the pigment and exposed fully to the available light. On the other hand, the cone myoids are extended, so that their outer segments are within the pigment, which functions effectively to reduce the amount of light in the outer segment, as explained in the previous section. The cone outer segments are enveloped by pigment, presumably to help suppress responses from the daylight receptors under conditions of dim illumination. Under the influence of light the rod myoids extend within several minutes, and the pigment envelops the rod myoids to help suppress the diurnal activity of the rod system (pigment surrounds only the rod myoids, not the outer segments [see Figure 25, top]). At the same time the myoids of the cones contract to withdraw the cone outer segments from the pigment. As mentioned above, neither photomechanical nor pigment movements occur in mammalian eyes; switching between rod and cone systems is accomplished neurally.

The envelopment of rhabdomeres by pigment migration is widespread in invertebrates. An example of this phenomenon occurs in the ommatidium of the amphipod *Gammarus ornatus,* in which the rhabdomeres of five radially arranged receptor cells form a star-shaped rhabdom. Extensions of the receptor cells are directed toward the cornea next to the lenslike crystalline cone and away from the cornea to cell bodies beneath a so-called basement membrane. In the dark-adapted condition the pigment is located around the cone and in the cell body. The rhabdom functions as a light guide within which is the visual pigment, which absorbs light. In the light-adapted condition, the pigment migrates from the receptor cell body to surround the rhabdom completely. Similar cell pigment migrations occur within the receptors of many invertebrates. In the compound eye of the horseshoe crab *Limulus,* the rhabdom is also star-shaped in cross section, but the rays of the star are much longer than are those of *Gammarus.* In the eye of *Limulus* the pigment migrates radially within the receptor cell, completely enveloping the rays in a matter of minutes in bright light and requiring about one hour to withdraw entirely from the rhabdom area in darkness.

The rhabdom of the migratory locust (*Schistocerca*) shows an interesting variation. In the light-adapted retina, mitochondria migrate and become tightly packed around the rhabdom. This may be a device for providing energy for the rapidly metabolizing light-activated photoreceptor. There is physiological evidence, however, that, in the light-adapted condition, the mitochondria, which have a high refractive index, increase the critical angle by coming close to the rhabdom. They thereby cause loss of light from the rhabdom and a decrease in the "field of view" of the rhabdom. When the eye is dark-adapted, the space around the rhabdom is replaced by fluid-filled spaces, with a low refractive index; they return the rhabdom to an efficient light guide mode of operation.

Birefringence and dichroism. The physical properties of certain crystals, glass, liquid, and gas, are the same regardless of the direction of the light propagated through them; for example, the speed and thus the refractive index of light are the same regardless of its direction of propagation. Such a medium is said to be isotropic. In other crystals, the atoms are arranged so the refractive index varies with the direction of propagation of light; such crystals are said to be anisotropic. If a medium has a crystalline arrangement that retards light in a particular direction, it is birefringent. In such an arrangement an entering ray of light is divided into two rays that are polarized in planes at right angles to one another.

When birefringence can be made to disappear by immersing a substance in a liquid with an appropriate refractive index, the birefringence is caused by an orderly arrangement of isotropic particles submicroscopic in size, such as the limiting membranes surrounding cells. Such birefringence is called form birefringence to distinguish it from the intrinsic molecular crystalline birefringence described above. Very small rods, lying parallel to each other, cause positive birefringence; parallel platelets cause negative birefringence. Studies have shown that rods in frogs have a negative form birefringence caused by the platelets and a positive intrinsic birefringence. These phenomena are thought to result from the ordered arrangement of a lipid (fat) layer two molecules thick in the platelet membranes.

Birefringence in the rods of frogs

Variation in the colour of light absorbed dependent on the direction of polarization of the light is termed dichroism. This property is a sensitive indicator of the orientation of molecules in a structure; dichroism in photoreceptors, for example, results from the ordered arrangement of the visual pigment molecules. The visual pigment of outer segments is dichroic, as are the outer segments. Dichroism of the outer segment can be demonstrated only by measuring the absorption of polarized light shone through the side of the outer segment. Light that propagates in the usual direction, that is down the long axis of the outer segment, does not show different absorption properties that depend on the direction of polarization. The fact that there is not dichroism for light propagating along the long axis, but there is for light propagating perpendicular to the long axis, indicates that the visual pigment molecules are oriented at random but with the long axes in the plane of the disks.

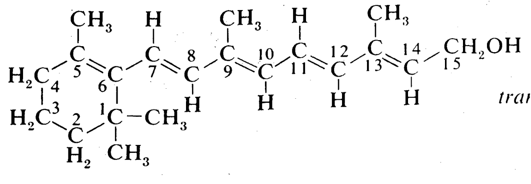
Rhabdoms consisting of microvilli can detect the plane of polarization of polarized light. Invertebrates with such rhabdoms use polarization properties of the blue sky opposite the Sun for navigation. In animals with the ability, the rhabdomeres comprising a rhabdom show orthogonal orientation. It has been shown that the microvilli are dichroic and that the dichroism is caused by the visual pigment. The orientation of the microvilli provides the mechanism for sensation of polarized light. Vertebrates cannot detect polarized light because of the random orientation of visual molecules within the plane of the platelets.

Stiles-Crawford effect. In the Stiles–Crawford effect, first observed in humans, the luminous efficiency of light has been shown to be greater when entering the centre than when entering the edge of the pupil. This effect may be considered an optical property of the cone receptor cells. The energy acceptance, or radiation, pattern of photoreceptors is a consequence of the optical wave guide properties resulting from the small size of the receptors. The Stiles–Crawford effect is not observed with dim illumination (rod vision), probably because the acceptance angle of the rods is wider, and it essentially fills the pupil.

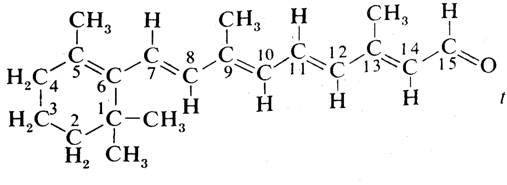
Visual pigments. As light propagates through the photoreceptor, the visual pigment absorbs photons (light particles). The absorption of one photon by a visual pigment molecule can initiate events that lead to nervous excitation. The photoreceptors in the eyes of both vertebrates and invertebrates consist of tightly packed membranes (lamellae), the function of which is to support the visual pigment and other molecules necessary for excitation. The photoreceptor membrane is a lipid layer two molecules thick, with protein either between the layers, coated over the layers, or both. The outer segment of the frog rod is 40 percent lipid and 60 percent protein; more than 80 percent of the protein is visual pigment.

Components. Visual pigment has two components: the light-absorbing chromophore (a chemical group that produces colour) and the protein moiety (opsin) to which it is chemically attached. The structure of the naturally occurring chromophore, retinal, is thought to be the same in all animals. Before it has been exposed to illumination, the chromophore is 11-*cis*-retinal, an alternate structure of vitamin A aldehyde. Upon exposure to light each

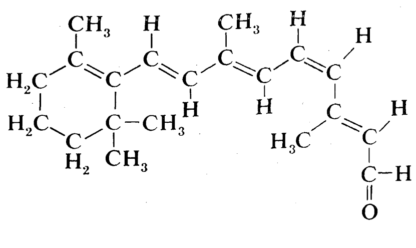
Characteristics of retinal



trans-retinol



trans-retinal



11-*cis*-retinal

chromophore molecule absorbs one photon of light. The absorption of a photon changes 11-*cis*-retinal to *trans*-retinal. (See structural formulas.) The resulting change in the shape of the molecule causes the separation of retinal from its protein component and gives rise to a number of coloured intermediates. In the dark, 11-*cis*-retinal combines spontaneously with the protein component to regenerate the visual pigment.

Hundreds of visual pigments have been identified and characterized by the wavelength of light that is best absorbed by them (absorption maximum, or λ max); the wavelength maxima range from 432 nanometres for the green rod of the frog to 625 nanometres for the red-absorbing cone of the goldfish. The reason for such a great range when the chromophore is the same in all visual pigments lies in part in properties of the chromophore; much of the variation, however, resides in the protein component. Variation in protein structure among different animals gives rise to different absorption maxima.

There are two forms of vitamin A: retinol A_1 and retinol A_2. The structure of A_1 differs only slightly from that of A_2. The effect of this slight structural difference is to increase the wavelength for maximum absorption by as much as 20 to 60 nanometres, depending on the pigment involved. The pigments with the shortest λ max are A_1 pigments; those with the longest are A_2. There is a broad area of overlap within the two groups, however. In general, marine fishes, land vertebrates, arthropods, and mollusks have A_1 pigments; freshwater fishes have A_2 pigments.

The protein components, or opsins, of visual pigments have not yet been fully characterized. The visual pigment of rods, a combination of retinal and opsin, is called rhodopsin, or visual purple. Estimates for the molecular weights of the opsins found in rods centre around 40,000. Squid opsin, however, has a molecular weight of about 70,000. Analyses of the visual pigments from the rods of squid and vertebrates suggest that the protein components are quite different. The nature of cone pigment proteins is thus far virtually unknown.

Important to an understanding of the photochemical reaction is the nature of the attachment of the chromophore to the opsin. Although controversy still exists on this point, it is clear that the visual pigment is part of the photoreceptor membrane and is very closely attached to its lipid and protein.

The role of visual pigments in vision. The sensitivity of the dark-adapted human eye can be measured as a function of wavelength of the stimulating light falling on that part of the retina in which the density of rods is greatest. When such a curve is compared with a curve of the absorption spectrum (the entire range of wavelengths of light absorbed) of human rhodopsin in the outer segments of the rods, the two curves correspond exactly. This is strong evidence that rhodopsin initiates the visual process for light absorbed in the outer segments.

The problem of cone pigments is an important one. More than 100 years have passed since it was concluded after a comparative study of retinas that the rods of vertebrate retinas mediate vision in dim light and the cones mediate daylight and colour vision. Recently, a method called microspectrophotometry has been developed for the study of cone pigments and other visual pigments. By projecting a minute beam of light onto a single photoreceptor, the absorption spectra of a variety of vertebrate and invertebrate photoreceptors have been measured. The absorption spectra of single human and other primate cones have thus been characterized. There are three types: a blue absorbing cone, a green absorbing one, and a yellow absorbing one. Originally suggested in 1802, these three cone types, now positively identified, can quantitatively explain human colour sensation.

Absorption spectra of photoreceptors

Such methods have been helpful in identifying receptors and their visual pigments in animals other than man; for example, in the retina of the frog *Rana pipiens,* a green rod and a red rod have been identified. A double cone with principal and accessory pigments and a single cone have also been characterized. Microspectrophotometry has been used to obtain evidence of visual pigments in rhabdomeres of the fly *Calliphora.*

PHYSIOLOGICAL RESPONSE OF PHOTORECEPTORS

The initial molecular events of photoreception can be summarized: after the absorption of a photon of light, 11-*cis*-retinal is converted into *trans*-retinal; the process disrupts the binding of retinal to opsin and results in the sequential formation of a number of coloured photoproducts.

The final physiological effects of photoreception have also been well defined. Excitation of visual pigments results in a change in certain properties (*i.e.,* permeability and potential) of the limiting membrane of the photoreceptor cell. Because the initial and final molecular events of photoreception are now understood, there is considerable hope that the entire chain of molecular events between the absorption of light by the visual pigment and the changes in potential of the cell membrane can eventually be reconstructed. This challenging problem has stimulated research concerned with the nature of the photoreceptor membrane and the chemistry of the photoproducts.

The internal environment of cells is generally different from that outside. The main cation (positively charged atom) inside cells is usually potassium; the main cation outside is sodium. In the resting, or unexcited, state, the cell membrane of most excitable cells (such as receptor, nerve, and muscle cells) is impermeable to sodium ions but permeable to potassium ions. A separation of charges occurs on either side of the membrane because the positively charged potassium ions diffuse outside of the cell, leaving a surplus of nondiffusing negatively charged atoms (anions) inside the cell. The result is a difference in potential across the cell membrane; this difference is proportional to the logarithm of the ratio of the concentration of potassium ions outside to that inside the cell. Photoreceptor cells are negative by some 30 to 60 millivolts (1 mV = 0.001 volt) inside relative to the outside, the exact value depending on the specific cell. This negative potential difference is termed the resting potential.

Definition of receptor potential

Receptor potential. The absorption of a single photon by the visual pigment in a photoreceptor may result in a physiological response of the receptor cell. Such a response of the cell can be measured as the receptor potential—that is, a change in the potential of the cell membrane caused by a change in the permeability of some part of the membrane to certain ions. The permeability change is in turn related to the absorption of light by the chromophore through a chain of molecular events as yet unknown. The receptor potentials of the eyes of animals from a number of phyla have been investigated. In certain photoreceptors the receptor potential is positive in sign, or depolarizing; in others it is negative, or hyperpolarizing.

Depolarizing receptor potentials. The depolarizing receptor potential, a change in potential response to illumination that is positive in sign, is characteristic of photoreceptor cells in many invertebrate phyla. One of the best known photoreceptors is the retinular cell in the compound eye and in the ventral eye of the horseshoe crab *Limulus,* an arthropod. The membrane potential of this cell is easily measured by means of a very small electrode (a device that can be placed inside a cell to measure the potential across the cell membrane). When the electrode penetrates the cell in the absence of light, the potential falls to some negative value, perhaps −40 millivolts, which is the resting potential. Even in complete darkness, however, variation in the resting potential occurs in the form of slow fluctuations. Although these spontaneously and randomly occurring fluctuations presumably seldom result in a physiological visual response, they are miniature receptor potentials. Each is accompanied by a decrease in the resistance of the membrane (*i.e.,* it becomes a better conductor) and an increase in the permeability of the membrane to sodium ions. When the receptor is illuminated with dim light, the slow potential fluctuations increase in frequency, and, with brighter light, they become briefer and higher in frequency, finally fusing to form a more or less steady depolarizing receptor potential. Thus, a short time after the cell is exposed to light, the membrane becomes depolarized; when the light is removed, the receptor potential decays, and the resting potential is restored. The extent of the receptor potential increases with increasingly stronger illumination; it has a linear relationship to the logarithm

Relationship between receptor potential and illumination of the intensity of illumination. Whatever properties are responsible for this transformation are responsible for the photoreceptor's enormous dynamic range: despite the fact that the receptor potential can change at most on the order of 100 millivolts, the receptor can respond over a range of more than 10 orders of magnitude, a range of intensities of over 100,000,000,000.

In all species with this depolarizing receptor potential, the fact that the resistance of the photoreceptor cell membrane decreases during the receptor potential suggests that it becomes more permeable to some ion or ions during this time. Evidence as to the nature of the permeability change suggests that it is principally an increase in permeability to sodium ions that causes the receptor potential. There is additional evidence for this conclusion (see *Photoreception* in *Bibliography*).

The depolarizing receptor potential is characteristic of the arthropod photoreceptor consisting of microvilli and the receptor cell. Species from most of the orders of Arthropoda have now been investigated, and exceptions have not been reported. Usually, the photoreceptor cell gives rise only to a receptor potential. The receptor potential is conducted passively a short distance to higher order nerve cells via a nerve fibre. The higher order nerve cells convert the receptor potential to propagated action potentials (nerve impulses) for transmission of the information over longer distances.

The proximal sense cell of the double retina of *Pecten* is similar to the above in that illumination gives rise to a depolarizing receptor potential and a decrease in resistance. The morphology of the proximal sense cell is also similar to that of the arthropod photoreceptors in that it has coarse microvilli. But the proximal sense cell of *Pecten* has a long nerve fibre that carries nerve impulses. The depolarizing receptor potential activates the mechanism that initiates an action potential, and steady depolarization of the axon gives rise to a series of nerve impulses; the stronger the intensity of illumination, the greater the extent of the receptor potential and the higher the frequency of nerve impulses. Nerve activity of this nature is rarely found in arthropod photoreceptor cells.

In addition to the arthropods and *Pecten,* a proximal sense cell in the leech (*Hirudo*), an annelid, has the depolarizing type of receptor potential.

The off response

Hyperpolarizing receptor potential with decrease in resistance. As noted above, the proximal sense cells of the *Pecten* eye have a depolarizing receptor potential, and the nerve responds to illumination with a series of nerve impulses. The distal sense cells, which also have nerve fibres, respond to a decrease in illumination with nerve impulses. This is called an off response. Recent studies indicate that the receptor potential of the distal sense cell is a hyperpolarizing potential, a potential change that is negative in sign. When the cell is depolarized, the extent of the receptor potential increases; when the cell is sufficiently hyperpolarized, the receptor potential reverses polarity and becomes depolarizing. The receptor potential of the distal sense cell is accompanied by a decrease in resistance. The hyperpolarizing potential is believed to be caused by an increase in permeability to potassium and perhaps to other ions.

The photoreceptor of the *Pecten* distal sense cell is a ciliary derivative. A primitive chordate, the tunicate *Salpa,* which has a microvillar photoreceptor, has the same type of hyperpolarizing photoreceptor potential. There thus does not seem to be any association of physiological potential types with structurally or embryologically similar photoreceptors.

Hyperpolarizing receptor potential with increase in resistance. The rod and cone photoreceptors of vertebrate eyes have a third type of receptor potential. In the dark, sodium ions flow steadily into the outer segment; light decreases this dark current—*i.e.,* the cell becomes hyperpolarized, and its resistance increases. If the cell is sufficiently hyperpolarized under experimental conditions, depolarization occurs; the receptor potential thus is reversed, as would be expected if the permeability change involves principally sodium ions.

Interpretation of the physiological response. As a nerve cell is depolarized, it discharges nerve impulses; as it becomes hyperpolarized, the membrane potential returns to the resting potential. The fact that certain photoreceptor cells are hyperpolarized by illumination is thus confusing and raises the possibility that light is inhibiting the receptors. In the generation and transmission of information about illumination, however, the sign of the response may actually be unimportant. It has been known for some time that there are several types of optic nerve fibres in vertebrate eyes; some discharge impulses during illumination, others discharge either only at the onset and cessation of illumination or merely at the cessation. In other words, information about the cessation of illumination is at least equal in importance to information about its onset and duration. Such observations of optic nerve activity prove that the hyperpolarizing response of the receptor, the only response of the receptor, is translated into a code that includes the discharge of nerve impulses both during and after illumination. Thus, the hyperpolarizing response of the receptor, although it may be important in emphasizing the off response, does not result in the loss of information about excitation. Because the hyperpolarizing response is definitely used to produce excitation at a later stage, it is misleading to consider it an inhibitory response. The same is true in reverse for the depolarizing response.

The way in which initial photoreception is processed by the retina and higher centres to cause visual perception is beyond the scope of this article. It may be mentioned, however, that the initial information used in this processing is the direct result of the physical and chemical properties of the photoreceptor. (W.H.M.)

Sound reception

Sound waves are a particular kind of mechanical activity consisting of vibrations in a gas, liquid, or solid medium. If an animal possessing an auditory mechanism comes in suitable contact with a medium vibrating at a frequency and intensity within its range of aural (hearing) sensitivity, it may hear the sound. For land animals, the usual vibrating medium is the air; for fishes and other aquatic creatures, it commonly is the water. Yet, under suitable conditions, all hearing animals can perceive sound waves transmitted by media other than the one in which they live; thus, humans can hear noise while underwater. (For a detailed discussion of human sound reception, see below *Human hearing*; additional information is contained in the article SOUND.)

In the course of evolution, animals have developed a variety of sense organs that respond to mechanical stimuli. There are at least 10 of these mechanoreceptors in vertebrates and perhaps as many in advanced invertebrates. Not all of these structures respond to sound, however, for among them are the simple touch endings of the skin and the motion receptors that serve (mediate) bodily equilibrium (see above *Mechanoreception*). Although the different ways of registering mechanical changes in the environment or within the body represent various structural specializations, it is not feasible to identify any one of them simply in terms of its structure; many different mechanisms, cells, or organs may perform similar functions. Ears, for example, take many forms in the lower animals and often have little resemblance to these organs in man and other higher vertebrates. Yet the service that they perform in sound reception is similar enough that they may be called ears.

Although there is no fossil record of the origin and development of auditory structures, in animals with ears the evolutionary process in every instance appears to have been a conversion to an auditory function of structures that previously mediated a simpler form of mechanoreception. Indeed, any mechanoreceptor, even though best adapted to respond to some other form of mechanical stimulation, will respond to vibrations within some region of the sound frequency range if the vibrations have a sufficiently high level of intensity.

Attempts to define hearing

Many attempts have been made to define hearing, often with indifferent success. The task is difficult, and in certain respects the lines of distinction are arbitrary. The ear cannot be identified by any standard structure, nor can it be identified in terms of the stimulus as simply a receiver of sound vibrations. As noted above, mechanical receptor organs will respond to sound vibrations within some region of the frequency range if a sufficiently high level of intensity is provided. Moreover, the ear cannot be characterized in terms of the physical principles by which it operates because these principles vary among the ears of different animal species.

A definition of hearing, therefore, must be sought in terms of the ear's specialization of function and the relative effectiveness with which it performs this function. Thus, hearing may be characterized as the reception of sound vibrations by an organ, the ear, that has developed for this particular purpose and that has reception of sound as its primary function. This definition excludes the reception of sound vibrations by touch (tactual) endings in the skin, for example, because these structures respond most readily to direct pressure. Before such receptors will respond to sound waves, the vibrational intensity of the sound must be relatively great. Also excluded are the hair sensilla, of which arthropods have many types, whenever it can be shown that these organs respond with greater sensitivity to another stimulus (most often a simple direct deflection of the central hair).

Principles of sound reception

Theoretically, several aspects of vibration might serve in its detection by an ear. These characteristics include the amplitude (extent) of the motion of particles (*e.g.*, molecules) in a medium, the velocity and acceleration of the motion, the pressure exerted upon an obstacle in the path of the sound waves, and temperature changes occasioned by the vibrations. All of these manifestations have been utilized in attempts to design microphones for the detection and measurement of sound, but only two (pressure and velocity effects) have proved to be of any practical value. Thus, those devices that employ these two effects are known as pressure and velocity microphones.

It seems more than coincidence that these same two aspects of sound, pressure and velocity, are the only stimulus characteristics on which the evolution of ears appears to have been based. Moreover, just as the pressure microphone is the most practical type designed by man, among ears the pressure type is the most widespread and the most highly developed. Ears that distinguish changes in velocity have appeared only in a few lower animals—as an elaborated hair organ in some insects and perhaps spiders and in two special forms among fishes. All other ears are pressure receptors that have taken two lines of evolutionary development, one in most of the insects and another in vertebrates above fishes.

Types of animals that have ears. Considering the usefulness of the sense of hearing to such highly organized animals as man, it may seem surprising that this sense is so limited in its appearance and development among animals. It is found only in two major groups of animals: arthropods (*e.g.*, insects and crabs) and vertebrates (*e.g.*, amphibians, birds, and mammals). The condition that probably limited the development of hearing in other species was the lack of sufficient advancement and flexibility of the nervous system.

Biological value of ears

In those animals with auditory structures, hearing serves purposes of great biological value: in its more primitive forms, it is used to sense danger and enemies, to detect prey, and to identify prospective mates; at a more complex level, hearing is involved in communication within social groups and in emotional expressions of various kinds. The cry of an infant mouse that has strayed from the nest elicits a response by the mother to retrieve it. The singing of a male thrush asserts a claim to its territory, attracts a female to the area, and warns off other males. Among higher mammals (*e.g.*, monkeys and apes) vocalizations show even greater variety and express a range of meanings that may be interpreted in human terms as expressions of such concepts as danger, aggression, love, and the availability of food. In man, the elaborations of auditory communication can be even more symbolically complex, extending to speech and music (see below *Human hearing*; see also SPEECH). The significant features in complicated sounds that people perceive and differentiate correspond to the physical dimensions of frequency (the number of waves, cycles, or vibrations per second), intensity, phase, complexity of wave form, and temporal pattern. The variety of distinguishable acoustic forms is enormous.

Among the most highly refined applications of the auditory sense are those found in such animals as bats and dolphins. These creatures are able to discern objects around them by a process called echolocation; the animal sends out a cry and, by the nature of the echo, is informed of the presence of obstacles or potential prey. For these animals, the sense of hearing provides a service in the dark that closely approaches the reliability of vision in the perception of objects and spatial relations.

ORGANS OF SOUND RECEPTION IN INVERTEBRATES

It has long been believed that at least some insects can hear. Chief attention has been given to those that make distinctive sounds (*e.g.*, katydids, crickets, and cicadas) because it was naturally assumed that these insects produce signals for communication purposes. Organs suitable for hearing have been found in insects at various locations on the thorax and abdomen and, in one group (mosquitoes), on the head.

Among the many orders of insects, hearing is known to exist in only a few: Orthoptera (crickets, grasshoppers, katydids), Homoptera (cicadas), Heteroptera (bugs), Lepidoptera (butterflies and moths), and Diptera (flies). In the Orthoptera, ears are present, and the ability to perceive sounds has been well established. The ears of katydids and crickets are found on the first walking legs; those of grasshoppers are on the first segment of the abdomen. Cicadas are noted for the intensity of sound produced by some species and for the elaborate development of the ears, which are located on the first segment of the abdomen. The waterboatman, a heteropteran, is a small aquatic insect with an ear on the first segment of the thorax. Moths have simple ears that are located in certain species on the posterior part of the thorax and in others on the first segment of the abdomen. Among the Diptera, only mosquitoes are known to possess ears; they are located on the head as a part of the antennae.

Location of insect ears

All the insects just mentioned have a pair of organs for which there is good evidence of auditory function. Other structures of simpler form that often have been considered to be sound receptors occur widely within these insect groups as well as in others. There is strong evidence that some kind of hearing exists in two other insect orders: the Coleoptera (beetles) and the Hymenoptera (ants, bees, and wasps). In these orders, however, receptive organs have not yet been positively identified.

Types of insect auditory structures. Four structures found in insects have been considered as possibly serving an auditory function: hair sensilla, antennae, cercal organs, and tympanal organs.

Hair sensilla. Many specialized structures on the bodies of insects seem to have a sensory function. Among these are hair sensilla, each of which consists of a hair with a base portion containing a nerve supply. Because the hairs have been seen to vibrate in response to tones of certain frequencies, it has been suggested that they are sound receptors. It seems more likely, however, that the sensilla primarily mediate the sense of touch and that their response to sound waves is only incidental to that function.

Antennae and antennal organs. Many sensory functions have been attributed to the antennae of insects, and it is believed that they serve both as tactual and as smell receptors (see above *Chemoreception*). In some species, the development of elaborate antennal plumes and brushlike terminations has led to the suggestion that they also serve for hearing. This suggestion is supported by positive evidence only in the case of the mosquito, especially the male, in which the base of the antenna is an expanded sac containing a large number of sensory units known as scolophores. These structures, found in many places in the bodies of insects, commonly occur across joints or body segments, where they probably serve as mechanoreceptors for movement. When the scolophores are associated with any structure that is set in motion by sound, however, the arrangement is that of a sound receptor.

Structure of the scolophore

The basic structure of the scolophore is shown in Figure 26. Four cells (base cell, ganglion cell, sheath cell, and terminal cell), together with an extracellular body called a cap, constitute a chain. Extending outward from the ganglion cell is the cilium, a hairlike projection that, because of its position, acts as a trigger in response to any relative motion between the two ends of the chain. The sheath cell with its scolopale provides support and protection for the delicate cilium. Two types of enclosing cells (fibrous cells and cells of Schwann) surround the ganglion and sheath cells. The ganglion cell has both a sensory and a neural function; it sends forth its own fibre (axon) that connects to the central nervous system.

In the mosquito ear (Figure 26) the scolophores are connected to the antenna and are stimulated by vibrations of the antennal shaft. Because the shaft vibrates in response to the oscillating air particles, this ear is of the velocity type. It is supposed that stimulation is greatest when the antenna is pointed toward the sound source, thereby enabling the insect to determine the direction of sounds. The male mosquito, sensitive only to the vibration frequencies of the hum made by the wings of the female in his own species, flies in the direction of the sound and finds the female for mating. For the male yellow fever mosquito, the most effective (*i.e.,* apparently best heard) frequency has been found to be 384 hertz, or cycles per second, which is in the middle of the frequency range of the hum of females of this species. The antennae of insects other than the mosquito and its relatives probably do not serve a true auditory function.

Cercal organs. The cercal organ, which is found at the posterior end of the abdomen in such insects as cockroaches and crickets, consists of a thick brush of several hundred fine hairs. When an electrode is placed on the nerve trunk of the organ, which has a rich nerve supply, a discharge of impulses can be detected when the brush is exposed to sound. Sensitivity extends over a fairly wide range of vibration frequencies, from below 100 to perhaps as high as 3,000 hertz. As observed in the cockroach, the responses to sound waves up to 400 hertz have the same frequency as that of the stimulus. Although the cercal organ is reported to be extremely sensitive, precise measurements remain to be carried out. It is possible, nevertheless, that this structure, which is another example of a velocity type of sound receptor, is primarily auditory in function.

Tympanal organs. The tympanal organ of insects consists of a group of scolophores associated with a thin, horny (chitinous) membrane at the surface of the body, one on each side. Usually the scolophores are attached at one end by a spinous process to the tympanic membrane (eardrum); the other ends rest on an immobile part of the body structure. When the membrane moves back and forth in response to the alternating pressures of sound waves, the nerve fibre from the ganglion cell of the scolophore transmits impulses to the central nervous system. Because the tympanic membrane is activated by the pressure of sound waves, this is a pressure type of ear.

Simple tympanal organs, such as those found in moths, contain only two or four elements, or scolophores. In cicadas, on the other hand, these organs are highly developed; they include a sensory body (a number of scolophores in a capsule) that may contain as many as 1,500 elements. Shown in Figure 26 is the structure of the tympanal organ in the 17-year cicada (*Magicicada septendecim*).

With 80 to 100 scolophores, the grasshopper ear, which has been studied more thoroughly than any other insect ear, is structurally between that of moths and cicadas. Ordinarily, the tympanic membrane is hidden beneath the base of the insect's wing cover. A bundle of auditory nerve fibres runs from one side of the sensory body, which lies on the inner surface of the membrane (Figure 26), and joins other nerve fibres of the region to form a large nerve extending to a ganglion (nerve centre) in the thorax.

Evidence of hearing and communication in insects. *Behavioral observations.* That the insect ear serves an auditory purpose has been proved by a large number of experimental observations, particularly those that have dealt most extensively with katydids and crickets. Males of these groups produce sounds by stridulation, which usually involves rubbing the covers of the wings together in a particular way. One wing has a serrated surface (a "file") that runs along an enlarged vein; the other wing has a sharp edge over which the file is scraped. The scraping causes the wing surfaces to vibrate; the natural resonances of the vibrations and the particular rhythm and repetition rate of the scraping movements determine the nature of the song, which varies with each species. Most females

Stridulation

are silent, but those of a few species have a poorly developed stridulatory apparatus, and weak sounds have been reported. Both males and females have tympanal organs for sound reception.

The observation that the males of many insect species produce repeated stridulatory sounds during the mating season led to the inference that the primary purpose of these noises was to attract a female. That this is indeed the case was first established by the extensive observations of the Yugoslavian entomologist Ivan Regen, who worked over the period 1902–30 mostly with a few species of katydids and crickets. In one of his earliest experiments, Regen proved (1913–14) that a male katydid of the species *Thamnotrizon apterus* responds to the sound of another male by chirping. The first male responds in turn to the second male's chirp, and the two insects then set up an alternating pattern of chirping. Although this pattern had been observed earlier, Regen was the first to prove by a series of experiments that it depends upon the sense of hearing. After removing the forelegs, on which the tympanal organs are located, of certain males, he found that even though these insects continued to stridulate, they did so only in individual rhythms that were not affected by the sounds of other males. Any alternation of chirping between deafened males, or between a deafened and a normal male, occurred only rarely, for brief times, and by chance.

A long series of check experiments by Regen showed that other stimuli, such as light, odours, and surface vibrations, did not affect the chirping behaviour. In these experiments the insects were placed in separate rooms, and their sounds were transmitted by telephone.

Chirping and mating behaviour

Further experiments carried out by Regen on field crickets (*Liogryllus campestris*) demonstrated the reactions of females to chirping males. In the most elaborate of these experiments, 1,600 sexually receptive females were released around the periphery of a large enclosed area in the middle of which had been placed a cage containing one or more chirping males. Precise data concerning the frequency with which the females moved toward the cage were obtained by surrounding the cage site with an array of traps in which the females were caught as they moved inward. The results were statistically significant. Normal females (those with intact tympanal organs) moved toward the cage and eventually reached it. The removal of one foreleg and its tympanal organ, however, caused difficulty; the movements were more random and the approaches fewer, although some females did succeed in reaching the cage. When both tympanal organs were removed or if the male failed to chirp, the performance of the females was reduced to chance. They also failed to exhibit the seeking performances if the male's stridulatory organ was modified, as by removing the file, so that little or no sound was produced.

In 1926 Regen returned to his study of the alternating chirping pattern of katydids and succeeded in having males react to an artificial sound, one that Regen himself produced. He also found that the alternation could be demonstrated with a suitably active male by using a variety of sounds—whistles, percussion noises, and sounds made with his mouth. It was never altogether clear, however, what changes Regen had made in his signals that finally brought success; probably the secret lay in the particular rhythm and timing of the signals. At any rate, this method made possible a study of the general nature of the auditory sensitivity of these insects and the range of sound frequencies to which they responded. It was shown that katydids are most sensitive to the very high frequencies, those that are beyond the limit of the human ear. The instruments available to Regen at the time, however, did not permit a precise measurement of intensity thresholds. (A threshold is the lowest point at which a particular stimulus will cause a response in an organism.)

Although the work of Regen and others established the basic character of sound reception in insects and its role in communication and mating, other details had to await the introduction of electrophysiological methods in this field as well as the development of electronic methods for the precise production, control, and measurement of sound stimuli.

Electrophysiological observations. When making electrophysiological observations of an auditory mechanism, an electrode (one terminal, generally a fine wire, in an electric circuit) is placed on a nerve or some other sensory structure in the mechanism. Sounds, presented at different frequencies and intensities, produce neural or sensory changes, which are actually electrical discharges or changes in electrical potential of extremely small magnitude. The impulses are picked up by the electrode and transmitted to an instrument with which they can be amplified, observed, and recorded. In both behavioral and electrophysiological observations, the auditory sensitivity of an animal to sounds of different frequencies can be illustrated by a curve.

The electrophysiological method was first used in research on the insect ear in 1933, with observations mainly on two katydid and one cricket species. The tympanal organ of these insects is located on one of the segments of the foreleg; its nerve goes to a ganglion in the thorax. When an electrode is placed on this nerve, its threshold sensitivity and overall frequency range can be determined by varying the intensity and frequency of the sounds applied to the tympanic membrane. It has been found that the tympanal organ of these insects responds poorly to low tones (those of low frequency) but improves rapidly as the frequency increases to a maximum sensitivity around 3,000 to 5,000 hertz. For higher frequencies the sensitivity declines, until a limit is reached at 30,000 hertz. It is likely that the insect's identification of its own species by means of song is primarily in terms of intensity and time patterns, with the rapid changes of intensity playing a prominent part. The possibility of frequency also entering into the pattern, however, cannot be ruled out.

A further question concerns the perception of the direction of a sound source. Clearly, if a female is to seek out and find a chirping male, the effectiveness of her performance depends upon an ability to localize the sound. Experiments indicate that the magnitude of electric responses from the tympanal nerve in katydids varies in a systematic manner when a given sound is presented at different angles while the distance is held constant. The insects continue to exhibit this directional pattern even after one of the tympanal organs has been removed. As was mentioned earlier, Regen found that female crickets deprived of one tympanal organ were still able to locate a chirping male, though less effectively than when both organs were intact.

Evidence of hearing and communication in spiders. Whether spiders have a sense of hearing has long been debated. Early anecdotal observations concerning this matter have now been reinforced with both behavioral and electrophysiological evidence showing without doubt that spiders are sensitive to mechanical vibrations and also to aerial sounds. Whether this sensitivity should be regarded as hearing is considered later in this section, after a review of the anatomical and behavioral evidence.

Lyriform organs

Anatomical evidence. The bodies of spiders contain many slitlike openings, called lyriform organs, that have been considered as sensory in nature. Most of these organs probably have a kinesthetic function and thus provide information on local movements of body parts. There is one type of lyriform organ, however, that differs from the others in its location and in certain structural details. It is found on the metatarsal (next to last) segment of each of the eight legs, close to the joint that this segment makes with the tarsus (the last segment, or foot), and consists of a number of slits—about 10 in the common house spider—that partially encircle the leg. Each slit contains a fluid chamber the inner wall of which is pierced by a tubule through which a thin filament runs to one of the two side walls (lamellae) that enclose the slit. This filament is evidently the termination of a ganglion cell that lies deeper in the leg. It has been suggested that an alternating compression of the lamellae stimulates the terminal filament.

The responsiveness of the common house spider to aerial sounds and mechanical vibrations includes a wide range, from below 20 to as high as 45,000 hertz. Within this range the sensitivity, as measured by electrical potentials, varies widely for aerial sounds; in some experiments narrow regions of frequency have been found in which no responses could be obtained at the highest intensities available. These variations of sensitivity are ascribed to mechanical resonances in the lyriform structure.

The tarsus evidently plays an important part in responses to sounds. Removal of portions of the tarsus reduces the responses about in proportion to the amount removed; immobilization of the tarsus greatly impairs the sensitivity. It appears, therefore, that the tarsus serves as a sensing element that transmits vibrations to the lyriform organ, which thus is a velocity type of ear.

Behavioral evidence. It has been reported that spiders react in characteristic ways to a buzzing insect caught in their web. The spider apparently locates the insect at once, runs to it, and attacks it. An inactive object, however, such as a small pebble enmeshed in the web, produces a different response: the spider manipulates the strands of the web, locates the object, and cuts away the filaments surrounding it so that the object drops to the ground. The reactions of a house spider to a mechanical vibrator applied to a point on the web have been observed. Such a stimulus elicits a response similar to that of an active insect if the vibratory frequency is between 400 and 700 hertz. For frequencies above 1,000 hertz, however, the spider reacts either by running to a secluded corner of the web or, if the intensity is too great, by abandoning the web altogether. From this and similar evidence it has been concluded that the spider has the ability of pitch (tone) discrimination between low and high ranges and perhaps can distinguish between tones of the lower range.

Spiders also react to aerial tones from an artificial source, such as a loudspeaker. These stimuli elicit an orientation response, in which the spider faces the source and reaches out with the two front legs. Thus, in view of the high level of sensitivity to both aerial and mechanical stimuli, the reception of sounds in the spider can probably be regarded as true hearing, and the lyriform organ as a form of ear. It is evidently a velocity type of ear, for there is no tympanic surface to respond to sound pressures, and the small leg segments seem to respond to the oscillatory motions of the air particles.

SOUND RECEPTION IN VERTEBRATES—AUDITORY MECHANISMS OF FISHES AND AMPHIBIANS

The labyrinth

The ear of vertebrates appears to have followed more than one line of evolutionary development, but always from the same basic type of mechanoreceptor, the labyrinth. All vertebrates have two labyrinths that lie deep in the side of the head, adjacent to the brain. They contain a number of sensory endings the primary functions of which are to regulate muscle tonus (a state of partial muscular contraction) and to determine the position and movements of the head and body.

Generalized sketches of vertebrate labyrinths are shown in Figure 27, with the usual locations of the sensory endings indicated for the different vertebrate classes. Two main divisions of these endings are distinguished: a superior division, which includes the three semicircular canals, the organs associated with the sense of balance, and the utricle, a small sac into which the semicircular canals open; and an inferior division, which includes the saccule (also a small sac) and its derivatives. Arising at or near the connection between the utricle and the saccule is the endolymphatic duct, which ends in an endolymphatic sac; this structure probably regulates fluid pressures in the labyrinth and aids in the disposal of waste materials.

The superior division of the labyrinth (Figure 27) is remarkably constant in form throughout the vertebrates except in the cyclostomes (*e.g.*, hagfishes and lampreys), in which the canals and endings are reduced in number. The utricle contains a macular ending, the macula utriculi, and each semicircular canal ends in a crista. In all vertebrate classes except the placental mammals and a few other scattered species, a papilla neglecta is present. It is usually located on the floor of the utricle or near the junction of the utricle and the saccule.

The inferior division of the labyrinth always contains a saccule with its macula, the macula sacculi, but the derivatives of the saccule vary greatly in the different vertebrate classes. In teleosts (bony fishes), amphibians, reptiles, and birds there is a lagena (a curved, flask-shaped structure), with its macula, the macula lagenae. Only the amphibians have a papilla amphibiorum, which is located near the junction of the utricle and the saccule. In some amphibians and in all reptiles, birds, and mammals, there is a papilla basilaris, which is usually called a cochlea in the higher forms, in which it is highly detailed. The elaborate sensory structure of higher types of ears, containing hair cells and supporting elements, is called the organ of Corti.

The macular endings consist of plates of ciliated cells (cells with short, hairlike projections) along with accessory cells, all surmounted by an otolith (a calcareous mass containing numerous particles of calcium carbonate embedded in a gelatinous matrix) or, in teleosts, by one large mass of calcium carbonate. The crista endings contain moundlike groups of sensory cells with supporting cells; the sensory cells have elongated cilia that are embedded in a gelatinous body, the cupula, which forms a sort of valve across an expanded portion of each semicircular canal. The papillae contain plates or ribbons of ciliated cells in a structural framework that lies on a movable membrane, except in amphibians, in which the papillae are on a solid base. These ciliated cells are not surmounted by an otolithic mass or a cupula, but some of the cilia are attached either directly or indirectly to a tectorial membrane (a membrane with one edge fixed to a stationary base, thus anchoring the cilia) or to an inertia body (a mass lying over the ciliated cells and restraining the movements of the cilia).

Functions of labyrinthine endings

The endings have different functions: the macular organs serve primarily as gravity receptors and detectors of sudden movements; the crista organs serve for the perception

of rotational acceleration; and the papillae serve for hearing. As structural relations suggest, the auditory endings are derived either from the other labyrinthine receptors or from the primitive labyrinthine epithelium.

Hearing in fishes. The cyclostomes and the elasmobranchs (*e.g.,* sharks and rays) possess a labyrinth with maculae and cristae but have no auditory papillae. There are, nevertheless, two possible ways by which some of these cartilaginous fishes, especially the sharks, react to sounds in the water: by means of the macular organs and by means of the lateral-line apparatus. (For details on these mechanisms, see above *Mechanoreception: reception of external mechanical stimuli.*) It is in the bony fishes (teleosts) that a true ear whose function is hearing first appears among the vertebrates. This ear, which occurs in a number of forms, has varying degrees of effectiveness as a sound receiver; some fishes hear well, others poorly. The differences arise, at least in part, from the accessory mechanisms that aid in the utilization of sound energy.

The basic auditory mechanisms in teleosts. In most fishes, especially in many marine forms, the auditory mechanism is relatively simple, consisting of macular endings that evidently have been diverted from their primitive functions as detectors of gravity and motion. The important change is not in the structure of the end organ but in its innervation—the nerve supply has connections that transmit auditory information. It is thought that in most teleosts the change to an auditory function has occurred in the saccular macula, and probably the lagenar macula as well, and that the utricular macula continues as a receptor for gravity and motion.

Inertia principle in the teleost ear

The simple macular ending of the teleost ear is stimulated by sound through the operation of an inertia principle. Sound waves pass readily through the water and into the body of the fish, causing most of the tissues to vibrate in a uniform manner. The macular otolith, however, represents a discontinuity; because its density is greater than that of the other tissues, it exhibits an inertia effect (resistance to movement). Its motions not only lag behind those of the surrounding tissues but are probably of lesser amplitude as well. Accordingly, a sound creates a relative motion between the otoliths and the other tissues. More specifically, there is relative motion between the bodies of the hair cells, which rest on a tissue base, and the cilia of these cells, the tips of which are in contact with the otolith. This method of stimulating the auditory hair cells is inefficient, however, because of the relatively small difference in density between the body tissues and the otoliths.

Air sacs

Special stimulation mechanisms. In certain groups of teleosts the efficiency of hair-cell stimulation has been increased by a discontinuity that is nearly 1,000 times greater than the one between tissue and otolith; this is the discontinuity between the otolith and a gas bubble. Although there are varying anatomical methods of achieving it, the simplest arrangement, which is found in clupeids, mormyrids, labyrinthine fishes, and a few others, consists of a gas-filled sac that lies against one wall of the labyrinth. In clupeids (*e.g.,* herring), a group in which the utricular macula rather than the saccular or lagenar maculae has an auditory function, long anterior extensions of the swim bladder form air sacs, one adjacent to each utricular macula. In the mormyrids, which include the elephant-nosed fish, a similar condition exists in early life; during adult development, however, the connections with the swim bladder disappear, leaving the air sacs connected with the saccular and lagenar endings. The gas content of these sacs is then maintained by special glands that extract gas from the blood. Air sacs arise in various other ways.

One large group of fishes, referred to as the Ostariophysi (*e.g.,* catfishes, minnows, and carps), has no air sac adjacent to the labyrinth, but a possibly equivalent condition is achieved through a mechanical connection between the swim bladder and fluid chambers adjacent to the labyrinth. A chain of three or four small bones, known as the Weberian ossicles, extends from the anterior wall of a part of the swim bladder to a fluid-filled chamber called the atrium, which in turn connects by fluid passages with the two labyrinths in the region of the saccule-lagena complex (Figure 28). In this arrangement the discontinuity is between the air of the swim bladder and the chain of ossicles in contact with it; the relative motion arising from sound stimulation is communicated through the ossicular (bony) chain and the fluid channels to the macular endings.

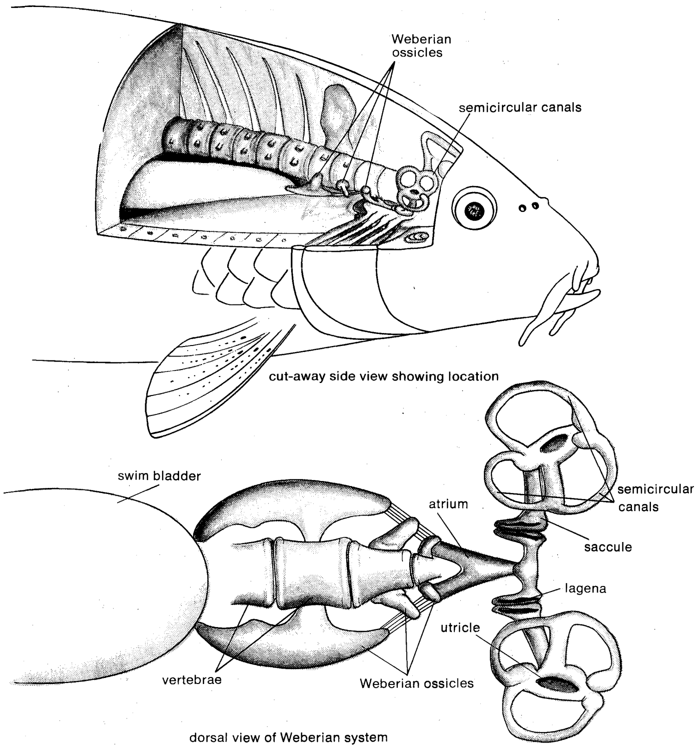

Figure 28: The Weberian ossicles and labyrinths of an ostariophysan fish.
Adapted from *Copeia* (1943) and (bottom) *Nature* (1938)

Regardless of the mechanism employed, however, the ear of all teleost fishes is basically a macular organ. Because it is stimulated by sound that is transmitted to tissues adjacent to the sensory cells and that acts differentially on these cells, this ear is of the velocity type.

Auditory sensitivity of fishes. Although only limited experimental data are available, it appears certain that, in general, fishes with the accessory mechanisms described above have greater sensitivity and a higher frequency range than do those lacking such mechanisms; while upper frequency limits are about 1,000 hertz for many fishes, they are about 3,000 hertz for the Ostariophysi and other specialized types.

Auditory response in goldfish

Many experiments have dealt with the problem of auditory sensitivity in fishes, but the species most extensively tested has been the goldfish, a variety of carp belonging to the Ostariophysi. In one well-controlled investigation, the sound intensities required to inhibit respiratory movements, after conditioning with electric shock, were studied. The greatest sensitivity was found to be around 350 hertz; above 1,000 hertz sensitivity declined rapidly.

In view of the simple anatomical character of the ear, the question of whether fishes can distinguish between tones of different frequencies is of special interest. Two studies dealing with this problem have shown that the frequency change just detectable is about four cycles for a tone of 50 hertz and increases regularly, slowly at first, then more rapidly as the frequency is raised.

Hearing in amphibians. There are three orders of living amphibians: the Apoda, which are legless, wormlike types such as caecilians; the Urodela, which are tailed forms such as mudpuppies, newts, and salamanders; and the Anura, which are tailless forms including frogs and toads. Although members of all three orders have ears, the structures vary greatly in the different groups, and little is known about them except in such advanced types as frogs.

The auditory mechanism in frogs. Although the frog has no external ear (structures on the outside that direct sound vibrations inward), the middle-ear mechanism is well developed. On each side of the head, flush with the surface, a disk of cartilage covered with skin serves as an eardrum. From the inner surface of this disk, a rod of cartilage and bone, called the columella, extends through an air-filled cavity to the inner ear. The columella ends in an expansion, the stapes, which makes contact with the fluids of the inner-ear (otic) capsule through an opening, the oval window. A second opening in the otic capsule, the round window, is covered by a thin, flexible membrane; it is bounded externally by a fluid-filled space that can expand into the air-filled cavity of the middle ear. When the alternating pressures of sound waves cause the eardrum to vibrate, the vibrations are transmitted along the columella and through the oval window to the inner ear, where they are relayed to the round window in a path across the otic capsule by movements of the inner-ear fluids. Along this path are two auditory endings, the amphibian and basilar papillae, the sensory hair cells of which are stimulated by the fluid movements. These movements are transmitted to the ciliary tufts of the sensory cells by a tectorial membrane, which is suspended from the hair cells in such a way that it can be moved by the oscillations of the inner-ear fluids.

Papillae

As sense organs for hearing, the papillae, which appear for the first time in amphibians, have cells like those in lower vertebrates that serve the same purpose. There are two types of papillae: the amphibian papilla, which is found in all amphibians, and the basilar papilla, which is found in some amphibians. Because they are located in different places in the inner ear, the papillae probably represent two distinct evolutionary developments. Moreover, they operate on a mechanical principle found in no other animal group: a tectorial membrane, moving in response to sound vibrations that have been transmitted to it by the inner-ear fluids, stimulates the sensory hair cells directly through connections to the cilia of these cells. In all higher types of ears, on the other hand, the sensory cells themselves are set in motion by the sound vibrations, while the tips of the ciliary tufts are restrained in one of several ways.

Auditory sensitivity of amphibians. Although it is presumed that all amphibians possess hearing of some kind, the evidence is sparse; only salamanders other than anurans have been studied experimentally. Salamanders trained to come for food at the sound of a tone responded only at low frequencies, up to 244 hertz in one specimen and to 218 hertz in three others.

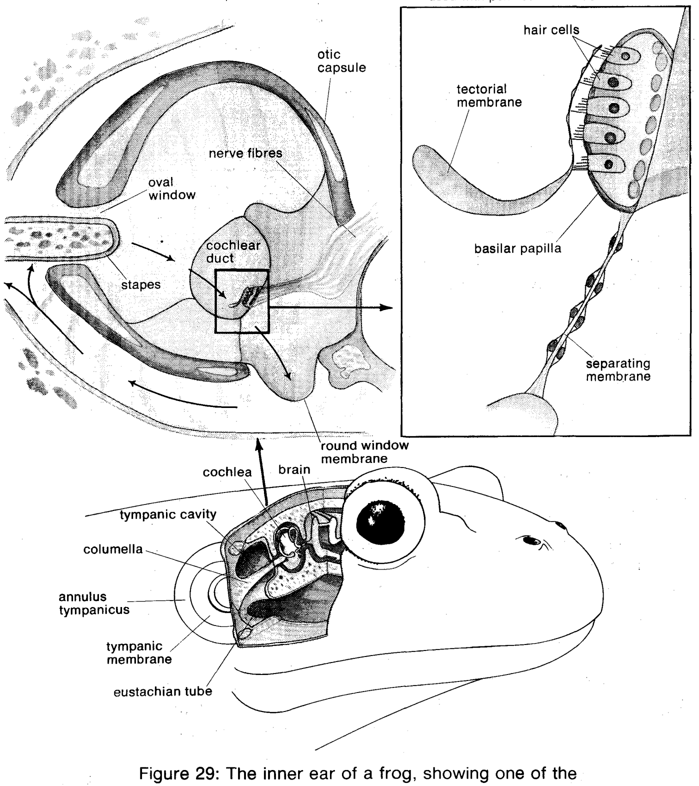

Figure 29: The inner ear of a frog, showing one of the papillae. The arrows indicate the path along which sound vibrations are transmitted by movements of the inner-ear fluids. At the right is an enlarged view of the separating membrane and the basilar papilla.

Frogs, which are of special interest because they first live in the water as tadpoles and then undergo a metamorphosis that equips them for life on land, have been studied more extensively. Considerable modifications of the middle-ear mechanism occur during metamorphosis. Presumably, the tadpole larva has an aquatic ear that is later transformed into an aerial type.

Croaking

Interest in the hearing of adult frogs has been stimulated by their active and often loud croaking during the breeding season. Evidently, their vocalizations assist in the location and selection of mates. The first experimental study of auditory sensitivity in frogs, carried out in 1905, showed that leg movements in response to strong tactual stimuli may be enhanced or even inhibited by sounds.

Somewhat later, following some unsuccessful attempts to train frogs to make behavioral responses to acoustic stimuli, two other methods were employed to determine the sensitivity and range of their hearing. One of these was the recording of changes in the electrical potentials of the inner ear and auditory nerve; the other was the observation of changes in the potentials of the skin (electrodermal responses) to acoustic stimuli. As a result of these investigations, inner-ear potentials and electrodermal responses in the bullfrog have been recorded over a range from 100 to 3,500 hertz. In the treefrog, these same responses have been found in a range that extended from 50 to 3,000 hertz, with the greatest sensitivity from 600 to 800 hertz, and again at 2,000 hertz.

The recording of impulses from single fibres in the auditory nerve of bullfrogs and the green frog indicates that two types of auditory nerve fibres are present. This has led to the suggestion that they represent the different characteristics of the amphibian and basilar papillae. It is believed that the amphibian papilla is more sensitive to low tones and that the basilar papilla is more sensitive to high tones.

AUDITORY STRUCTURES OF REPTILES

The living reptiles belong to four orders: the Squamata (lizards, snakes, and amphisbaenians), the Rhynchocephalia (one rare species, the tuatara of New Zealand), the Chelonia (turtles), and the Crocodylia (crocodiles and alligators). The reptile ear has many different forms, especially within the suborder Sauria (lizards), and variations occur in all elements of its structure—the external ear is often absent or may consist of an auditory meatus (passage) of varying length; the middle ear shows several forms in the different groups; and the inner ear varies in the degree of development of the auditory papilla and also in the ways by which the sensory cells are stimulated by sound.

Lizards. *Auditory structure.* There are about 20 families of lizards, ranging from the chameleon, a divergent type, to the gecko, certain species of which have the most highly developed ears found in the group. The chameleons, of those species studied thus far, have only a few sensory hair cells (40 to 50) in the auditory papilla. The geckos, on the other hand, have several hundred hair cells, and the *Gekko gecko* has about 1,600, the largest known number of hair cells in any saurian. Other lizard species fall between these two extremes in inner-ear development, with the iguanids, the most common lizards in the Western Hemisphere, having from 60 to 200 hair cells, according to the species.

Middle ear of lizards

What may be regarded as the standard type of middle-ear structure in the lizards consists of a tympanic membrane and a two-element ossicular chain that extends from the inner surface of this membrane to the oval window of the otic capsule. As shown in Figure 30, the ossicular chain is made up of two parts: the osseous (bony) columella, whose expanded innermost end (the stapes) fills the oval window, and the extracolumella, a cartilaginous extension that usually spreads out in two to four processes that are embedded in the fibrous layer of the tympanic membrane. Geckos have a single middle-ear muscle attached to the lateral part of the extracolumella; evidently, contractions

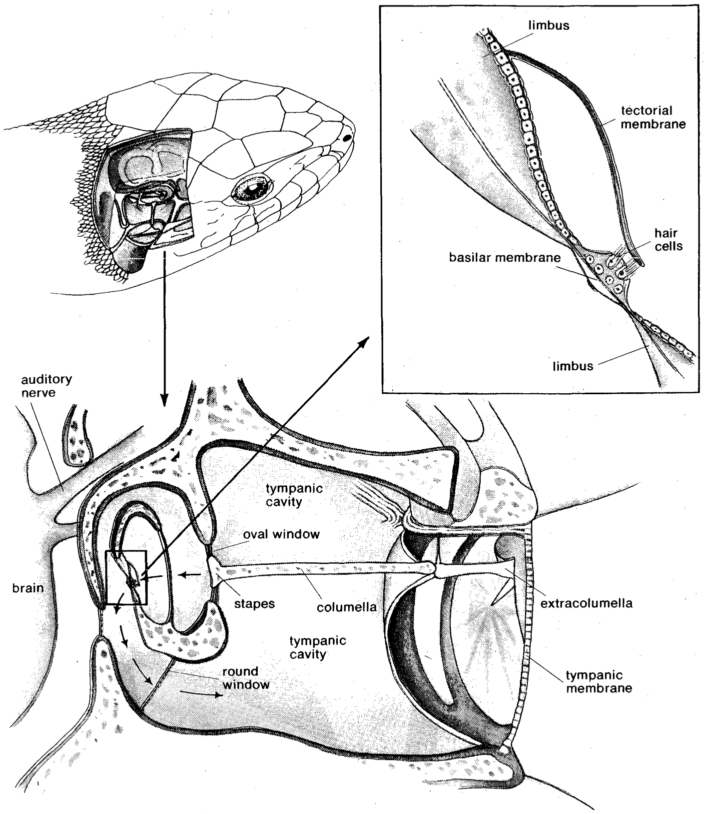

Figure 30: The auditory structures in the right lizard ear as seen from behind and from the left (see text).
From *Journal of Auditory Research* (1965)

of this muscle stiffen the extracolumella, thereby dampening the ossicular motions and protecting the ear against excessively intense sounds.

The auditory part (cochlea) of the inner ear (Figure 30) consists of a basilar membrane lying in an opening in the limbus, which is a plate of connective tissue. The form of the basilar membrane, which is unlike the structure of the same name in amphibians and is clearly of different origin, varies from a simple oval in iguanids to a long, tapered ribbon in gekkonids. In many species the middle portion of the basilar membrane is greatly thickened, especially in some regions of the cochlea. Over this thickening, which is called the fundus, lies the auditory papilla proper—*i.e.,* that part of the cochlea in which the sensory hair cells are held in a framework of supporting tissues and cells. The hair cells usually occur in regular transverse rows, with the number of cells in a row varying along the cochlea. They have a tuft of cilia, the so-called sensory hairs, of graduated lengths, the longest of which are usually attached either directly or indirectly to a tectorial membrane. This membrane arises from a region of the limbus that is usually elevated, often strikingly so, and runs as a thin web or sheet to the region of the hair cells. Only rarely does the free edge of the tectorial membrane connect directly with the cilia of the hair cells; usually there are intermediate connecting structures that take a variety of forms, from simple fibres to relatively massive plates.

Modes of auditory stimulation

The function of the tectorial membrane and its connections to the ciliary tuft of a hair cell is to immobilize the tuft when the body of the hair cell moves in unison with the basilar membrane on which it rests. This produces a relative motion between the ciliary tuft and the body of the cell and stimulates the cell. All auditory stimulation depends ultimately upon this relative motion, and the means just described for achieving it can be regarded as the most fundmental process by which sounds are perceived. Although it is employed in the great majority of ears, it is not the only mode of stimulation. Another mode is that in the ears of fishes, in which an otolith lies upon the ciliary tufts and, by its inertia, reduces and alters the motion of the tuft relative to the cell body. Still another method is the one in the frog papilla, in which the tectorial membrane is moved by the cochlear fluids while the body of the sensory cell remains at rest.

In some lizards the inertia principle has a form different from that found in fishes. In the former, a body called a sallet lies upon the ciliary tufts of a group of hair cells and, by its inertia (or by an equivalent means), restrains the movement of the cilia when the cell body is made to move. The result is a relative motion and a stimulation of the hair cells, like the more common restraint by a tectorial membrane.

The ears of two lizard families show only the inertial restraint method of stimulation; in several other families this method functions in some regions of the cochlea for certain hair cells. Hair-cell stimulation by two or more different arrangements within the same cochlea, however, is the rule rather than the exception because of its many advantages. Although the tectorial-restraint method provides great sensitivity for individual cells, the sallet system also attains good sensitivity, but in another way: by causing many cells—those in common contact with a given sallet—to work in parallel, thus producing a spatial summation. The sallet system has the advantage of being more resistant to damage by overstimulation from intense sounds. In such lizards as the geckos, for example, in which the hair cells are divided nearly equally between tectorial and sallet systems, an exposure to excessive sound has been observed to break all the tectorial connections to the hair cells while leaving the sallet connections intact. But even though the most sensitive hair cells are inoperative, the animal can respond to sounds, although with lesser acuity.

Hearing abilities of lizards. The lizards are the lowest vertebrates to have a well-developed spatial differentiation of the cochlea in which different regions respond to different frequencies of tone. The problem of tonal discrimination has been somewhat solved in frogs, in which the differential responses to tones by the two papillae may provide some information concerning the pitch of sounds. The mechanism in frogs, however, is a poor one, as it can give only crude and uncertain cues at best.

Tonal discrimination

In some lizards, such as iguanids and agamids, a minimum of structural variation occurs along the cochlea; in others (*e.g.,* geckos, which have very extensive differentiation along their extended basilar membranes) the differentiation is almost as great as that in higher vertebrates, including man. Most geckos are nocturnal in habit and use vocalizations to maintain individual territories and probably to find mates.

Although it has been possible to train two species of lizards (*Lacerta agilis* and *Lacerta vivipara*) to make feeding movements in response to a variety of sounds, including tones between 69 and 8,200 hertz, most attempts to train lizards to respond reliably to tonal stimuli have failed. The one useful method thus far developed to study the sensitivity of these animals to sounds involves recording electrical responses in the ear and in the auditory nervous system. Although such observations have provided information about peripheral response to sounds, they do not reveal anything about other processes in the nervous and behavioral systems.

Electrical responses in the cochlea of many lizard ears show considerable variations: in absolute sensitivity, in the tonal regions in which responsiveness is best, and in the extent of the frequency range. It has been concluded that most lizards have good auditory sensitivity over a range from 100 to 4,000 hertz and relatively poor hearing for lower and higher tones. This auditory range is not very different from that of man, although somewhat more restricted than that of most mammals.

Snakes. Without much doubt, snakes developed from some types of early lizards but lost their legs when they adopted habits of burrowing in the ground. Although some snakes burrow, others have taken up different habits: many species live on the surface of the ground, several are largely aquatic, and some live in trees. All, however, show drastic ear modifications that reflect their early history as burrowers; for example, there is no external ear—*i.e.,* no opening at the surface of the head for the entrance of

Auditory modifications of snakes

sound. This fact, together with a seeming indifference to airborne sounds, has led to the supposition that snakes are deaf or that they can perceive only such vibrations as reach them through the ground on which they crawl.

This supposition is incorrect; snakes are sensitive to some airborne sound waves and are able to receive them through a mechanism that serves as a substitute for the tympanic membrane. This mechanism consists of a thin plate of bone (the quadrate bone) that was once a part of the skull but that has become largely detached and is held loosely in place by ligaments. It lies beneath the surface of the face, covered by skin and muscle, and acts as a receiving surface for sound pressures. The columella, attached to the inner surface of the quadrate bone, conducts the received vibrations to its expanded inner end, which lies in the oval window of the cochlea. If the columella is severed, the sensitivity of the ear is significantly reduced.

Although the sensitivity of the snake ear varies with the species, it is appreciably sensitive only to tones in the low-frequency range, usually those in the region of 100 to 700 hertz. For this low range the large mass of the conducting mechanism and the presence of tissues lying over the quadrate bone are not of any great consequence. Moreover, while the sensitivity of most snakes to the middle of the low-tone range is below that of most other types of ears, it is not seriously so. In a few snakes, however, the sensitivity is about as keen as in the majority of lizards with conventional types of ear openings and middle-ear mechanisms.

That the ears of the snake receive some aerial sound waves instead of depending exclusively on vibrations transferred from the ground has been proved by recording the potentials in the cochlea of one ear while rotating the animal in front of a sound-wave source so that the ear being studied was sometimes facing the source and sometimes directed away from it. The recorded potentials were significantly greater when the ear was facing the source. There would have been no difference in the responses if the sound first set up vibrations in the ground and these were then transmitted to the body. This observation also shows that the ears of the snake can determine the direction of a sound in terms of its relative intensity in the two ears. Although snakes can perceive vibrations from the ground that are present at a sufficient intensity, this ability is not peculiar to them; all ears respond to vibrations transmitted to the head.

Amphisbaenians. The amphisbaenians form a little-known group of reptiles. Because they are burrowers and live almost entirely underground, they are seldom seen. The one species in the United States, *Rhineura floridana,* is found in some parts of Florida; a number of species occur in other regions of the world, especially in South America and Africa.

The animals construct a maze of underground tunnels, which they patrol in search of such food as grubs and worms. Although small eyes below the body surface can receive light through a transparent scale, amphisbaenians evidently make little use of vision. There is reason to believe, however, that they use hearing to locate their prey.

Auditory structures in the face of amphisbaenians

Amphisbaenians, like snakes, have no surface indication of an ear; a receptive mechanism below the surface and different from that in snakes conveys vibrations to the inner ear. In the oval window, which occupies the entire lateral surface of the otic capsule, is a stapes. The head of the stapes in most species is directed laterally and forward; it is united by a joint with a rod of cartilage (the extracolumella) that extends forward along the face, in the line of the lower jaw. The extracolumella lies below the surface, where it makes close contact with and finally enters a dense layer of the skin. When the facial region is exposed to sounds, the vibrations are transmitted through the dense layer of the skin to the extracolumellar rod and then through it to the stapes, finally reaching the fluid of the inner ear. That this is the route of sound conduction has been proved by cutting the extracolumella at different places and observing the reduction of recorded responses in the ear.

The auditory mechanism of amphisbaenians varies somewhat according to species but is substantially as described above. The sensitivity, which also varies with species, is surprisingly high in some species, considering the unusual nature of the mechanism involved. Studies similar to those described for snakes have proved that this ear receives aerial sounds and that it can determine the direction from which the sound originated. As expected, this ear also responds to mechanical vibrations communicated directly to the skull.

Turtles. It is sometimes supposed that the turtle's ear is a degenerate organ, largely or even completely unresponsive to sound. Although the turtle's ear is unusual in some respects, and can be regarded as specialized in its manner of receiving and utilizing sounds, it is not a degenerate organ. There is good evidence that turtles are sensitive to low-frequency airborne waves and that some species have excellent acuity in this range.

A plate of cartilage on each side of the head serves as a tympanic membrane. Leading inward from the middle of this plate is a two-element ossicular chain consisting of a peripheral extracolumella and a medial columella the expanded end (the stapes) of which lies in the oval window of the otic capsule. Within the otic capsule are the usual labyrinthine endings, including an auditory papilla. As shown in Figure 31, the auditory papilla lies in a path between the oval window and an opening (the round window) in the posterior wall of the otic capsule. Unlike the round window in most ears, that in turtles has no membranous covering for transmitting pressure changes to the air-filled cavity of the middle ear. Instead, the opening leads to a fluid-filled chamber, the pericapsular recess, that extends laterally and anteriorly to enclose the external

From *Proceedings of the National Academy of Sciences* (1956)

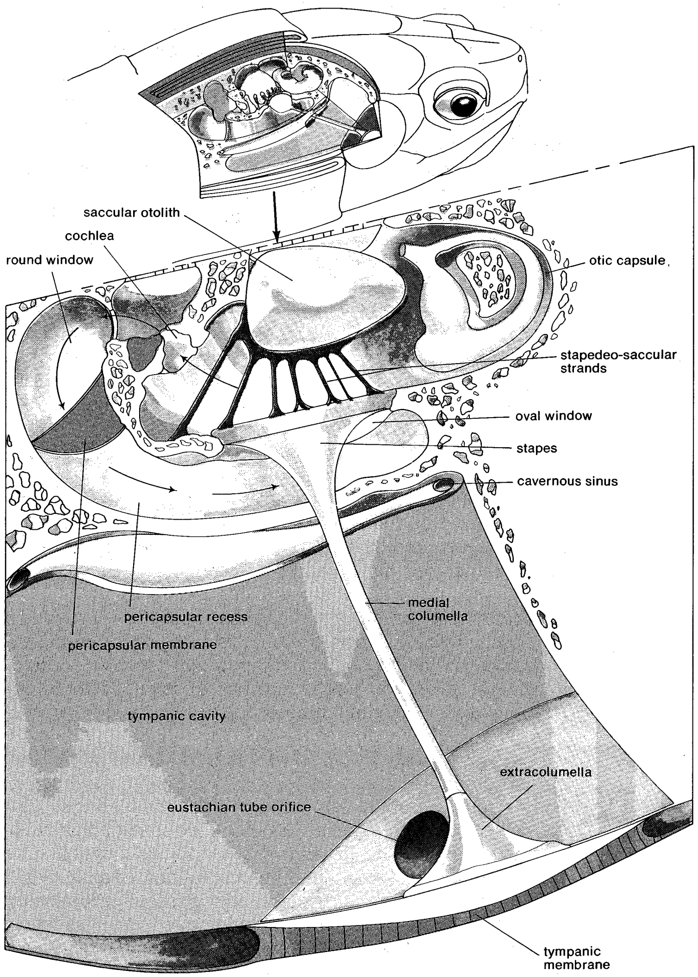

Figure 31: *Structure of the turtle ear.*
(Top) View of the head, showing the location of the otic capsule; (bottom) detail of the otic capsule. Arrows indicate the path along which vibrations are transmitted by movements of the cochlear fluids.

portion of the stapedial expansion of the columella. A pericapsular membrane separates the perilymph (fluid) of the otic capsule from the fluid of the recess. When the stapes is moved inward by the columella at one phase of a sound vibration, the fluid of the otic capsule is displaced, causing a pressure change that, after passing through the sac containing the auditory endings, continues in a circuitous course to the external surface of the stapes. This circuit is indicated by the arrows in Figure 31. When the columella moves outward, the fluid circuit reverses itself. Hence the result of a continuous sound wave is a surging back and forth of the fluids in the otic capsule and the pericapsular recess at the same frequency as that of the sound.

The special mechanical arrangement in the turtle ear is fully effective within the low-frequency range. Indeed, the relatively large mass of tissue and fluid involved in the response to sounds is in part responsible for the efficiency of the ear at low frequencies and also for the rapid loss of sensitivity as frequency increases.

This type of cochlear response to sounds is not peculiar to turtles; it is also found in snakes, through a structural arrangement of similar form. Although it also occurs in amphisbaenids, the fluid path in these animals is entirely different: it proceeds through the perilymphatic recess into the brain cavity and then by an anterior passage across the head to the lateral surface of the stapes.

Certain experiments involving the turtle's sensitivity to sounds have used training methods (conditioned responses); only a few have met with success. It has been found that turtles of the species *Pseudemys scripta,* trained to withdraw their head, respond to sound over the low-frequency range, with the greatest sensitivity in the region of 200 to 640 hertz. This result is in close agreement with electrophysiological observations in which it has been found that impulses could be obtained from the auditory nerve of *Chrysemys picta* for tones between 100 and 1,200 hertz, with highest sensitivity for tones below 500 hertz. Similar results have been obtained by additional observations of this kind with several other species of turtles, some of which are very sensitive to a narrow band of frequencies in the low-tone range. Evidently, the type of receptor mechanism in the turtle can achieve great sensitivity through mechanical resonance at a particular region of the low-frequency scale.

Low-frequency sensitivity in turtles

Evidence has also been obtained that these responses are to aerial waves and not to vibrations set up in the ground. The sensitivity to surface vibrations was considerably poorer than that to aerial sounds. In addition, cutting the columella seriously impaired the responses to aerial sounds but hardly affected responses to mechanical vibrations applied to the turtle's shell.

Crocodiles. The order Crocodylia includes four groups of closely related forms: crocodiles, alligators, caimans, and gavials. The crocodile ear, although clearly reptilian in general structure, has a number of peculiar features. Leading to a tympanic membrane on each side of the head is a shallow external passage the outside opening of which is protected by an earlid that is closed when the animal enters the water and dives. Beyond the tympanic membrane is a middle-ear cavity, with the one on the right connected to the one on the left by an air passage that runs across the head above the brain. A sound presented to one ear, therefore, reaches the other ear about equally well. A columellar system connects the tympanic membrane to the oval window of the otic capsule, as in other reptiles. The inner ear is highly developed and bears many similarities to the cochlea of birds, described in the next section. Elongated and slightly curved, the cochlea contains about 11,000 sensory hair cells, about seven times as many as found in that of the most advanced lizard (*Gekko gecko*).

In comparison to some lizards, the cochlea of *Caiman crocodilus,* which has been most extensively studied, exhibits only a moderate degree of structural differentiation. Yet in this cochlea fibre bundles that extend from the root portion of the tectorial membrane separate into fine fibres that form individual connections with the ciliary tuft of each hair cell. This arrangement is not a common one, though present in certain lizards, such as the chameleons, and also in some degree in birds. It probably provides a high level of specificity in the stimulation process or as much specificity as the overall mechanical pattern permits.

The hearing of crocodilians has not been studied very extensively. It has been noted that the breathing rate in a crocodile accelerates in response to loud sounds, such as the firing of a gun, and it has been observed that specimens of the Mississippi River alligator produce vocalizations of roaring or hissing when low-frequency sounds are made by blowing a horn or by plucking a metal rod. Studies of the electrical potentials in the ear of *Caiman crocodilus* show that it is sensitive to frequencies ranging from 20 to 15,000 hertz.

HEARING IN BIRDS

The avian auditory structure. Ears of birds show considerable uniformity in general structure and are similar in many respects to those of reptiles. The outer ear consists of a short external passage, or meatus, ordinarily hidden under the feathers at the side of the head. Most birds have a muscle in the skin around the meatus that can partially or completely close the opening.

The tympanic membrane of birds

The tympanic membrane bulges outward as in most lizards. In the songbirds, however, it consists of two separate membranes, with the outer one apparently serving to protect the inner one from injury. From the inner surface of the tympanic membrane an ossicular chain transmits vibrations of the cochlea. As in lizards, the chain consists of an osseous inner element, the columella, and a cartilaginous extracolumella that extends the columella peripherally and connects with the tympanic membrane.

The cochlea of birds is similar to that of crocodiles, consisting of a short, slightly curved bony tube within which lies the basilar membrane with its sensory structures. The length of the basilar membrane varies between 2.5 and 4.5 millimetres (0.1 and 0.2 inch) in most birds, but in the owls it may reach 10 millimetres (0.4 inch) or more. At the end of the cochlea is another ending with a different function, the lagena and its macula.

Auditory sensitivity in birds. Using the conditioned-response method to study auditory sensitivity in a small songbird, the bullfinch, responses over a frequency range from 100 to 12,800 hertz have been observed. The electrophysiological method was first applied to the study of hearing in birds in 1936. In this study impulses from the cochlea of pigeons were recorded for tones usually up to 10,000 hertz and occasionally as high as 11,500 hertz. Although this method has been used since 1936, few detailed and quantitative results have been obtained; nevertheless, one striking characteristic revealed by these studies has been the high degree of sensitivity in the low and middle range and the very rapid decrease in the high tones.

Uses of hearing in birds. Like other animals, birds use hearing to warn them of enemies and other kinds of danger. To a degree hardly equalled in lower species, they also use hearing in social relations and communication. Many male birds sing to hold their territories and to attract mates. Some birds also use vocalizations to identify their mates or group members. During the breeding period of the emperor penguin, for example, the male leaves his mate for a journey taking many days in order to obtain food. Upon returning to the general area where his mate has remained with a pack of hundreds of birds, the male is able to locate and to recognize his partner by an interchange of calls.

There is good reason to believe that certain birds, including the swiftlets (*Collocalia*) of Asia and Australia, the oilbirds (*Steatornis*) of tropical America, and possibly a few others, are able to use echolocation when flying in the dark caves that they inhabit. Moreover, it is well established that many owls locate and catch their prey by auditory cues. On a dark night, an owl perched in a tree can hear the rustling sounds made by a mouse in the grass and leaves on the ground below; by accurately localizing this signal, he can make his strike and capture the prey without any visual aid.

HEARING IN MAMMALS

Auditory structure of mammals. In the mammals the ear reaches its highest level of development, with well-differentiated divisions of outer ear, middle ear, and inner ear. Except in some of the sea mammals, in which certain modifications and degenerations have taken place, these structures carry out their functions in a remarkably regular manner.

The pinna

The outer ear consists of pinna (or auricle) located behind the ear opening and partially enclosing it and an auditory meatus that leads inward. The pinna varies greatly in size relative to the size of the animal, being large enough in many species to serve a useful purpose in the collection and reflection of sounds. Many mammals can move the pinna back and forth to regulate in some degree the entrance of sounds to the auditory meatus, which transmits the sounds inward to the tympanic membranes. In some mammals, such as many of the marine types, the external opening can be closed to keep out water when the animal dives, and in certain species of bats the tube itself contains a valve that can be closed to protect the ear against undesirable sounds.

The middle ear of mammals consists of a tympanic membrane, an ossicular chain of three elements, and two tympanic muscles. The tympanic membrane bulges inward, unlike the usually outward-bulging membrane of reptiles and birds. The elements in the ossicular chain are the malleus (hammer), incus (anvil), and stapes (stirrup), so named because of the resemblance of the bones to these objects. The malleus is attached to and partly embedded in the fibrous layer of the inner surface of the tympanic membrane. It connects to the incus, which connects in turn to the stapes, the footplate of which lies in the oval window of the cochlea.

One tympanic muscle extends from an attachment to the skull to an insertion on the malleus. Another muscle has its insertion on the neck of the stapes. By their contractions, both muscles add friction and stiffness to the ossicular chain, thereby reducing its mobility and protecting the inner ear from excessive sounds. The contraction of the muscles is a reflex action and occurs in both ears at the same time in response to loud sounds.

The coiled cochlea

The inner ear is called the cochlea because in man this structure is a complex tube coiled into about 2.5 turns, thus bearing some resemblance to a snail's shell, from which the term is derived. The name cochlea has now been extended to include the auditory portion of the labyrinth in all animals, even when the structure is not coiled, as in reptiles, birds, and egg-laying mammals. In the mammals in which it is coiled, the number of turns in the cochlea varies with species from a little less than two to as many as four. The guinea pig and its relatives have the largest number of cochlear turns. Extending along the inside of this coiled passage is the basilar membrane, bearing on its surface the sensory structure known as the organ of Corti, which contains the hair cells.

In mammals a uniform system is employed in the stimulation of the hair cells by sounds. A relatively thick tectorial membrane, anchored securely on one edge to the supporting structure (the limbus), lies with its free portion over the hair cells and with the cilia of these cells firmly attached to the lower surface of this portion. When vibratory movements of the basilar membrane cause the bodies of the hair cells to move, the tips of the cilia are restrained by their attachments to the tectorial membrane. Hence the relative motion between the bodies and cilia of the hair cells stimulates them.

The sizes, shapes, and spatial relations of many otic structures vary in the different mammalian species, but it is thought that the same basic principles of operation are involved. This uniformity contrasts with their situation in reptiles, in which different systems are present both in different species and sometimes within one ear.

Auditory sensitivity among mammals

A number of features are of particular significance in determining the sensitivity and frequency range, which vary with species. Because large masses involve great resistances when moved at high frequencies, the size and mass of the moving parts determine to some degree the variations of sensitivity with frequency and the frequency limits within which the ear operates. The ossicular chain is a mechanical lever, and its lever ratio and the difference in area between the tympanic membrane and the stapedial footplate determine the efficiency of sound transmission from air to the cochlear fluid. The mechanical characteristics of the cochlea and the degree of variation of these characteristics along its extent determine the frequency range of hearing and the degree to which different tones can produce different response patterns. Finally, the numbers and distribution of hair cells along the basilar membrane and the density and specificity of innervation of these cells determine the delicacy and precision with which their periodic activity and spatial patterns are registered by the central areas of the auditory nervous system.

These anatomical features have been studied in detail in a few animals: among the mammals, mainly in cats, guinea pigs, and to a lesser degree in man. The functional aspects, as shown in responses to sounds and to discriminations among different sounds, have been considered principally in man and to a much more limited extent in other mammals. (The characteristics of human hearing are treated at length below; see *Human hearing.*) Some of the auditory characteristics of mammals below man are described in the sections that follow.

Hearing in subhuman mammals. *Primates.* The hearing of other species in the division of mammals to which man belongs has always been of special interest. A number of species have been studied, including monkeys, marmosets, and chimpanzees among the primates considered as the most advanced, the anthropoids; and tree shrews, lemurs, and lorises among the more primitive.

By using a variety of training methods with chimpanzees, monkeys, and marmosets, behavioral thresholds have been recorded in response to sounds of different intensities and frequencies. When compared with each other and with man, it has been found that the hearing sensitivity of these animals and man is remarkably similar over a range of frequencies from 100 to 5,000 hertz, after which the sensitivity begins to differ. The differences observed at the higher frequencies, however, may be partly attributed to variations in experimental procedures. Thus, the results for the chimpanzee stop at 8,192 hertz because this was the highest tone used in the tests. Other observations have shown that chimpanzees can hear tones up to about 33,000 hertz and that young human subjects often hear tones as high as 24,000 hertz. It is also evident that monkeys and marmosets of the species studied can hear still higher tones.

Common laboratory animals. Certain mammals have long been favourite subjects for various kinds of biological studies in the laboratory, largely because of their convenient size, hardiness under caged conditions, and gentle temperament. Familiar among these are cats, dogs, guinea pigs, rats, mice, rabbits, and, more recently, hamsters, chinchillas, and gerbils. Auditory sensitivity functions have been obtained in these animals by a variety of behavioral and electrophysiological methods.

When measured behaviorally by conditioned responses and then plotted on a curve, the auditory threshold sensitivity of cats, guinea pigs, and chinchillas is much the same—a progressive improvement in sensitivity as the frequency is raised until the middle tones (about 500 to 5,000 hertz) are reached, at which point sensitivity tends to remain the same, and then shows a rapid loss in the upper frequencies. There are differences, however, in the maximum sensitivity attained in the middle region, with the guinea pig the least sensitive and the cat the most sensitive of the three species.

Differences between behavioral and electrophysiological observations

Sensory responses in the cochlea of mammals have been measured electrophysiologically by placing an electrode on the round window membrane. Unlike behavioral curves, however, the curves obtained by plotting the sound required to produce an arbitrary amount of electrical potential of the cochlea do not represent auditory thresholds. Instead, their usefulness is largely in their shapes, which indicate in a relative way the regions of good and poor sensitivity. In addition, these curves represent the performance of the peripheral portion of the auditory mechanism up to the point at which the sound stimulus activates the sensory hair cells in which the potentials are generated. Hence, unlike the curves obtained by behavioral responses, those obtained by cochlear potential methods do not indicate the performance of the central auditory nervous system (the nerve connections between the ear and brain and those parts of the brain in which neural impulses from the ear are processed to produce behavioral responses).

In the simpler animals, the two types of curves are much alike, judging from the very limited evidence available. In mammals, however, the behavioral curves differ from the cochlear potential curves in three ways. In the behavioral curves there is (1) an exaggerated gain in sensitivity to tones of low frequency, (2) a greater sensitivity to the medium-high tones, and (3) a more rapid loss of sensitivity to the extreme-high tones and a lower frequency of the upper limit. These differences are believed to arise mainly through the elaborate neural processing that takes place in the more highly developed mammalian nervous system, a processing that improves the sensitivitity to high-frequency tones but reaches a limit of effectiveness and finally fails above some frequency limit. With these conditions in mind, the electrophysiological curves can be used to predict reasonably well an animal's behavioral responses to sound waves.

Large mammals. Because most of the mammals in which hearing has been studied by laboratory methods are small, much less is known about the auditory capabilities of large ones, even of such domesticated animals as horses and cows; nevertheless, it is usually assumed that the auditory capabilities of these animals are much like those of humans. At least they hear sounds in man's vocal range because they seem to respond to verbal signals. Elephants, for example, trained as working animals, are said to obey as many as 30 different commands. A number of wild animals of medium and large size—raccoons, opossums, and several members of the cat and dog families—have been studied electrophysiologically by the cochlear-response method. Their sensitivity curves are fairly similar in form and in the upper limits attained.

Marine mammals. Of special interest are the sea mammals, which have been derived from early land species and which have undergone certain changes in order to adapt themselves to at least a partially aquatic existence. In the course of adapting to marine conditions, however, some sea mammals, such as seals and sea lions, seem to have made only limited alterations in their ear structures. In addition to being able to close the meatus when diving, their pinnas have been greatly reduced or essentially lost, a feature of streamlining for rapid progress through the water.

Adaptations for aquatic hearing

There are three possible ways that the hearing of marine mammals might be adapted to an aquatic environment: (1) unchanged aerial hearing, with no aquatic adaptation; (2) conversion to an aquatic type of hearing with loss of good hearing for aerial sounds; and (3) development of some kind of double system, with at least serviceable reception of both aerial and aquatic vibrations. In a study of hearing in the common seal, in which responses to aerial and aquatic stimuli were compared, it was found that this animal has a greater sensitivity to aquatic sounds, especially in the upper frequencies, which extended to the remarkably high frequency of 160,000 hertz. Yet, although the seal has made an adjustment for hearing in water, it has not sacrificed the quality of its aerial hearing, which remains at an excellent level, especially for one frequency around 2,000 hertz and another around 12,000 hertz. These differences in auditory senstivity suggest that the mechanisms in this animal for aerial and aquatic hearing are somehow different, but no complete explanation of the adaptations has yet been found.

Whales, on the other hand, have converted their ears to a truly aquatic form, apparently with some sacrifice of aerial reception. The study of their ears and hearing has been carried out in only a few species of the toothed whales, which produce sounds and use their ears in the process of echolocation (see next section).

The ear of whales has undergone extensive changes. The pinna is absent and the external ear opening has been reduced to such a minute size, almost a pinhole in some species, that it no longer serves as a path for the entrance of sound. The eardrum, although present in a modified form, seems to serve no useful purpose; it is connected to the malleus only by a ligament, and this connection can be cut without an ensuing loss of sound reception. The usual three ossicles of the middle ear are present, with the footplate of the stapes resting in the oval window. These ossicles are much more massive than the ordinary mammalian ossicles.

It appears that the whale ear has been converted to a true aquatic type, functioning according to principles similar to those found in the ears of fishes, as described earlier. Sound vibrations in the water readily pass through the tissues of the head and reach the deep-lying middle- and inner-ear structures. Probably the ossicles represent an inertial mass in somewhat the same way that the otolithic body does in fishes. Because of their inertia, the ossicles tend to move with smaller amplitudes and in different phase relations when the tissues of the head, including parts of the cochlea, are set in vibration. This difference in relative motion produces an alternating displacement of the cochlear fluid, which is in contact with the footplate of the stapes and which can be set in motion because of the presence of a pocket of gas in the region of the round window. The performance of the whale ear has been measured in an exact manner throughout the frequency range in one species, the bottle-nosed dolphin (*Tursiops truncatus*). By a conditioned-response method, it has been found that this animal possesses excellent auditory sensitivity that extends well into the high frequencies.

Echolocation in bats. Bats are divided into the large bats and the small bats. With one or two exceptions, the large bats live on fruits and find their way visually. The small bats feed mostly on insects, catching them on the wing by a process known as echolocation. As was mentioned earlier, echolocation is a process in which an animal produces sounds and listens for the echoes reflected from surfaces and objects in the environment. From the information contained in these echoes, the animal is able to perceive the objects and their spatial relations.

How echolocation works

Bats produce sounds with the larynx, an organ in the throat that has undergone certain adaptations that make it unusually effective in producing intense, high-frequency sounds. The character of the sounds varies with the species and also with the particular activity. On striking a small object such as a flying insect, the emitted sounds are reflected with only a small fraction of their original energy; the sound is further weakened before reaching the ears of the bat when it must travel some distance through the air.

Although the frequency of bat cries varies with species, their cries usually occur in a range between 80,000 and 30,000 hertz. In most species, such as *Myotis lucifugus* and *Eptesicus fuscus,* the cry is a frequency-modulated pulse of sound; it begins at a high frequency, say, of 70,000 hertz, and in about 0.2 second declines in frequency to about 33,000 hertz. The starting frequency may vary, even in successive cries; a second pulse might begin at 60,000 and end at 30,000 hertz. The greatest energy in the cry is usually in the middle of this frequency range, perhaps around 50,000 hertz in the species mentioned above.

The use of such high frequencies is an essential feature of the bat's sonar system. In order to determine the nature of objects by reflected sounds, it is necessary that the wavelengths of the sound be small in relation to the dimensions of the objects—indeed, as small as possible if fine details are to be represented.

An important problem of echolocation is how the bat is able to detect reflected sounds, often in the presence of disturbing noises, and to obtain the information necessary for tracking and catching an insect as well as discriminating between this object and others in the environment. This problem involves considering first the structure of the auditory mechanism in bats and then the nature of their hearing.

The external ear of bats is usually well developed. In most species the pinna is large relative to the size of the head, and in those species called the whispering bats, because they make such faint sounds, this structure is huge. With its large surface, the pinna acts as an efficient collector and resonator of high-frequency sounds. It is also freely movable and can be rotated and inclined in various ways. The meatus leads inward to the eardrum and, as already mentioned, contains a valve that can be closed to reduce the entrance of sounds. The middle ear of bats is of the usual mammalian pattern—a three-part ossicular chain—but its structure is impressive in the extraordinary delicacy of the moving parts. The two tympanic muscles, however, are relatively large.

The cochlea of bats also shows the general mammalian form, but there are variations that may be significant for the special functions that are performed by this ear. The basilar membrane is not particularly well developed; it is short in comparison with that of most mammals, and its structural variation from basal to apical ends is only moderate in extent. Whereas most basilar membranes are rather strongly tapered in width, being narrow at the basal end of the cochlea and several times broader near the apical end, in the bat there is only a slight taper, between twofold and threefold. Another curious feature in the cochlea of bats is the presence of local thickenings of the basilar membrane that may add to the stiffness of the cochlear structure.

The auditory portion of the nervous system has undergone extraordinary development in bats. The regions concerned with hearing are relatively enormous, which is in accord with the great predominance of hearing over the other senses in this animal.

Auditory sensitivity of bats

The hearing of bats has been studied by both electrophysiological and behavioral methods. In the species *Myotis lucifugus,* electrophysiological measurements of cochlear potentials indicate that response is poor in the low frequencies but improves fairly steadily until the range of 2,000 to 5,000 hertz is reached, at which it tends to level off. Beyond 15,000 hertz there are many irregularities but, in general, the sensitivity declines at a rapid rate. The results of similar studies on a specimen of *Eptesicus fuscus* are much the same as those for *Myotis,* though the observations were not extended into the lowest frequencies. The most sensitive range for this species is around 4,000 to 15,000 hertz, after which there is a fairly rapid decline in the upper frequencies.

The behavioral threshold curve for *Eptesicus* has a markedly different form. There is a rapid improvement in sensitivity from 2,500 to 10,000 hertz, but the greatest sensitivity is in two peak areas, from 10,000 to 30,000 hertz and from 50,000 to 70,000 hertz, with a separation by a moderate reduction around 40,000 hertz.

There are other peculiarities of the behavioral sensitivity of *Eptesicus* to sound stimuli that are of particular interest. The rapid loss of sensitivity to tones around 40,000 hertz may be caused by a failure of neural processing for these tones. The slope of the low-frequency end of the curve is unexpectedly steep, and this appears in a region where the cochlear response is passing through its maximum. Nothing like this has been observed in other animals; it seems to be a peculiarity of the bat.

When the cochlear responses of bats are compared with similar responses in other small mammals—as, for example, the rat—there is a general similarity in the results. The rat, however, has better sensitivity as measured by this method, reaching a level of especially good acuity in the range from 20,000 to 60,000 hertz, the range in which the bat sensitivity falls off rapidly. As mentioned previously, it must be kept in mind that the sensitivity indicated by the cochlear potentials is mediated in the peripheral mechanism, before involvement of the central auditory nervous system. When the behavioral response is considered, however, the contribution made by the bat's central auditory nervous system can be appreciated: the region of greatest auditory sensitivity, extending from 10,000 to 70,000 hertz, is the same region as the frequency of the echolocation cries and the one in which bats have the greatest need of acute hearing.

The failure of these bats to exhibit a behavioral response to tones below a frequency of 10,000 hertz can perhaps be explained also in relation to their peculiar use of hearing. This is a region of frequency that has little or no value for echolocation. More than that, it often contains noises of various kinds that, if heard, might be detrimental to this essential function. It has often been observed that bats are not easily disturbed by extraneous sounds of low frequencies, even extraordinarily intense ones. This peculiarity of hearing in bats may account for their resistance to masking sounds. The slight degree of structural differentiation found in the cochlea of bats may represent another aspect of the limitation of their hearing to that part of the sound spectrum most useful in echolocation. Therefore, it appears that the ear of the bat, which is a rather ordinary type of mammalian structure so far as level of auditory sensitivity and degree of tonal differentiation are concerned, has been developed for a particular purpose—namely, the reception of high-frequency sounds within a limited range.

Echolocation in other mammals. Among the mammals possessing echolocation are the toothed whales. These animals probably produce sounds in the water in two ways: with the larynx and with the complex system of passages connected to the blowhole, which is a nostril in the top of the head. Although many different types of sounds are possible, during echolocation they consist mainly of a rapid series of clicks. These clicks contain many components, but the principal energy is in the high frequencies, from perhaps 50,000 to as much as 200,000 hertz. The use of such high frequencies by these animals is a requirement for effective echolocation in water. Because the velocity of sound is greater in water than in air, the wavelengths are longer; therefore, in order for echolocation to attain the same effectiveness of object discrimination as that achieved by the bat with aerial sounds, an aquatic animal has to use frequencies at least five times as high.

High-frequency clicks of toothed whales

Whales have good vision when submerged, and apparently their eyes remain fairly serviceable when their heads are out of water. Dolphins can be trained to strike targets or leap over obstacles held several feet above the surface of the water. For many tasks, however, they use echolocation very effectively, such as when catching fish at night or when visibility is poor in murky water. Dolphins have been trained to make fine discriminations of objects when their vision has been completely excluded by blindfolding. Echolocation of some form and degree of effectiveness is suspected in still other animals, such as shrews and sea lions, but the evidence is meagre thus far. (E.G.W.)

HUMAN SENSORY RECEPTION

Ancient philosophers called the human senses "the windows of the soul," and Aristotle enumerated at least five senses—sight, hearing, smell, taste, and touch—and his influence has been so enduring that many people still speak of the five senses as if there were no others. Yet, the human skin alone is now regarded as participating in (mediating) a number of different modalities or senses (*e.g.,* hot, cold, pressure, and pain). The modern sensory catalogue also includes a kinesthetic sense (sense organs in muscles, tendons, and joints) and a sense of balance or equilibrium (so-called vestibular organs of the inner ear stimulated by gravity and acceleration). In addition, there are receptors within the circulatory system that are sensitive to carbon dioxide gas in the blood or to changes in blood pressure; and there are receptors in the digestive tract that appear to mediate such experiences as hunger and thirst.

Not all receptors give rise to direct sensory awareness; circulatory (cardiovascular) receptors function largely in reflexes that adjust blood pressure or heart rate without the person being conscious of them. Though perceptible as hunger pangs, feelings of hunger are not exclusively mediated by the gastric (stomach) receptors. Some brain cells may also participate as "hunger" receptors. This is especially true of cells in the lower parts of the brain (such as the hypothalamus) where some cells have been found to be sensitive to changes in blood chemistry (water and other products of digestion) and even to changes in temperature within the brain itself.

General considerations of sensation

BASIC FEATURES OF SENSORY STRUCTURES

Classification by stimuli

One way to classify sensory structures is by the stimuli to which they normally respond; thus, there are photoreceptors (for light), mechanoreceptors (for distortion or bending), thermoreceptors (for heat), chemoreceptors (*e.g.,* for chemical odours), and nociceptors (for painful stimuli). This classification is useful because it makes clear that various sense organs can share common features in the way they convert (transduce) stimulus energy into nerve impulses. Thus, auditory cells and vestibular (balance) receptors in the ear and some receptors in the skin all respond similarly to mechanical displacement (distortion). Because many of the same principles apply to other animals, their receptors can be studied as models of the human senses. In addition, many animals are endowed with specialized receptors that permit them to detect stimuli that man cannot sense. A snake (the pit viper) boasts a receptor of exquisite sensitivity to "invisible" infrared light; some insects have receptors for ultraviolet light and for pheromones (chemical sex attractants and aphrodisiacs unique to their own species) thereby also exceeding human sensory capabilities.

Regardless of their specific anatomical form, all sense organs share basic features. (1) They contain receptor cells which are specifically sensitive to one class of stimulus energies, usually within a restricted range of intensity. Such selectivity means that each receptor can be said to have its own "adequate" or proper or normal stimulus, as, for example, light is the adequate stimulus for visual experience. Nevertheless, other energies ("inadequate" stimuli) can also activate the receptor if they are sufficiently intense. Thus, one may "see" pressure when, for example, the thumb is placed on a closed eye and one experiences a bright spot (phosphene) seen in the visual field at a position opposite the touched place. (2) The sensitive mechanism for each modality is often localized in the body at a receiving membrane or surface (such as the retina of the eye) where transducer neurons (sense cells) are to be found. Often the sensory organ incorporates accessory structures to guide the stimulating energy to the receptor cells; thus, the normally transparent cornea and lens within the eye focus light on the retinal sensory neurons. In some cases, blindness can be cured by surgically removing a lens that has grown opaque from cataract in order to permit light once again to reach the retina. Additional postoperative optical correction in the form of a contact lens or eyeglasses is necessary to compensate for the missing lens. Retinal nerve cells themselves are more or less shielded from nonvisual sources of energy by the surrounding structure of the eye; but mild electrical currents delivered to most sense organs, including the eye, can produce sensory experiences appropriate to the specific organ.

The generalized electrical nature of neural function largely accounts for the effectiveness of such currents in evoking a full range of different sensations. (3) The primary transducers or sensory cells in any receptor structure normally connect (synapse) with secondary, ingoing (afferent) nerve cells that carry the nerve impulse along. In some receptors, such as the skin, the individual primary cells possess threadlike structures (axons) that may be yards long, winding from just beneath the skin surface through subcutaneous tissues until they reach the spinal cord. Here each axon from the skin terminates and synapses with the next (second-order) neuron in the chain. By contrast, each primary receptor cell in the eye has a very short axon that is contained entirely in the retina, making synaptic contact with a network of several types of second-order (internuncial) cells, which, in turn, make synaptic contact with third-order neurons called bipolar cells, all still in the retina. The bipolar-cell axons extend afferently beyond the retina, leaving the eyeball to form the optic nerve, which enters the brain to make further synaptic connections. If this visual system is considered as a whole, the retina may be said to be an extended part of the brain on which light can directly fall. (4) From such afferent nerves, still higher order neurons make increasingly complex connections with anatomically separate pathways of the brainstem and deeper parts of the brain (*e.g.,* the thalamus) that eventually end in specific receiving areas in the cerebral cortex (the convoluted outer shell of the brain). Different sensory receiving areas are localized in particular regions of the cortex; *e.g.,* occipital lobes in back for vision, temporal lobes on the sides for hearing, and parietal lobes toward the top of the brain for tactual function.

Sensory parts of the brain

APPROACHES TO THE STUDY OF SENSING

The science of the human senses is truly interdisciplinary. Philosophers, physicians, anatomists, physical scientists, physiologists, psychologists, and others have all joined in studying sensory activities. Some of their earliest work was anatomical, an approach that continues to be fruitful. Physical scientists, particularly physicists and chemists, made especially important contributions to an understanding of the nature of stimulus energies (*e.g.,* acoustic, photic, thermal, mechanical, chemical); in the process, they also carried out many fundamental measurements of human sensory function. Hermann L.F. von Helmholtz, a 19th century German scientist who was a physicist, physiologist, and psychologist, studied the way in which sound waves and light are received (sensed or detected) and also how they are interpreted (perceived) by people.

Modern studies of sensation have been enhanced by contemporary devices permitting the precise production and control of sensory stimuli. With other kinds of instruments, physiologists have been able to probe the electrical signals generated by sensory cells and afferent nerve fibres to provide a biophysical analysis of sensory mechanisms. Psychophysics embraces the study of the inner (private, subjective) aspects of sensation in terms of outer (public, objective) stimulus energies. One of the oldest and most classical approaches to the study of sensation, psychophysics includes the study of people's reports of their sensations when they are stimulated: of their ability, for example, to match tones of equal loudness, to detect stimulus differences, and to estimate sensory magnitude or intensity under conditions of controlled stimulation. Psychophysical research continues as an active enterprise particularly among modern psychologists.

An old philosophical notion that "mind" is but a clean slate or tablet (*tabula rasa*) until written on by impressions from the senses no longer seems fully tenable; human infants, for example, show inborn (innate) ways of sensing or perceiving at birth. In its modern form, the problem of learned versus innate factors in sensory experience is studied in terms of the extent to which the genetically determined structure and function of sense organs and brain depend upon stimulation and experience for their proper maturation. Poverty of stimulation (sensory deprivation) in an infant's early life increasingly is being documented as detrimental to the full flowering of mature perceptual and intellectual functions. Since this sort of evidence may indeed lend some support to the notion of the *tabula rasa,* modern investigators give credence both to nativistic (based on heredity) and empiricistic (based on learning) interpretations of human sensory function (see also LEARNING AND COGNITION).

Emotional aspects of sensation

A distinction between the discriminatory (epicritic) and emotional (protopathic) features of sensations was made by Sir Henry Head (1861–1940), a British neurologist, who noted, for example, that after a sensory nerve from the skin had been cut, the first sensations to recover as the nerve healed appeared to be diffuse, poorly localized, and extremely unpleasant. He theorized that this initial lack of sharp discrimination associated with unpleasant experience reflected the properties of a primitive protopathic (emotional) neural system which regenerated first. He held that this system subserves pain and the extremes of temperature and pressure sensation usually associated with an affective (emotional) tone. Because recovery of fine tactual discrimination, sensitivity to lightly graded stimuli, and the ability to localize points touched on the skin returned later, Head posited the existence of another discriminatory system. While later research has not confirmed his theory, the sequence of changes in the recovery following nerve injury is most typical.

Chemical-visceral sensations particularly have hedonic (pleasure–pain) properties. Most people tend to refer to odours and tastes as pleasant or unpleasant; thus, the chemical senses are closely tied to motivation, to preferences, or to aversions. Although reflex licking or sucking is stimulated by tactual stimulation of lips and mouth, newborn infants tend to suck longer and harder when the stimulus has clear hedonic value; *e.g.,* avidly turning their lips toward a nipple to get a sweet taste. (See also EMOTION AND MOTIVATION.) Apparently, one's sweet tooth is largely nativistic, in that it requires little prior learning. The craving for salt (especially heightened under conditions of salt deprivation) likewise appears to be widespread throughout the animal kingdom without prior learning. The role of taste and smell as innate factors in behaviour may not be quite so influential in man as in other animals. Man's food habits and preferences are strongly overladen with custom and tradition; that is, they are learned in large measure.

In the modern era, the language of communication engineering has been found to be useful in describing human senses. Thus, each sensory modality may be described as a channel that receives stimulus information (input), that processes and stores the information, and that retrieves it as needed for the effective behaviour (output) of the individual. In addition, modern engineering has provided devices (*e.g.,* radio, television, radar, the electron microscope) that serve to extend the range and power of man's senses; in the last analysis, however, all such devices convert (transduce) their information back to a form of stimulus energy that is directly perceptible to the unaided senses. Thus a television set is a transducer that converts imperceptible electromagnetic waves into visual and auditory signals. For some special purposes, people may employ alternative sensory channels, as when blind people use Braille or other tactual input as substitutes for the missing visual channels. While the chemical senses have little function in symbolic communication among people, the use of perfumes in romantic signalling is a notable exception. In general, however, the human chemical senses are more directly involved in physiological survival; *e.g.,* warning that a putrid fish is dangerous to eat. One's physical well-being also rests heavily on his proprioceptors (for sensing his own bodily position) and on his sense of balance. These structures, monitoring (feeding back information on) his bodily orientation in space, provide crucial sensory feedback for guiding one's movements (see also PERCEPTION).

Survey of some of the human senses

CUTANEOUS (SKIN) SENSES

It was observed above that studies of cutaneous (skin) sensitivity yield evidence that man's senses number more than five. There is evidence for two pressure senses (for light and for deep stimulation), for two kinds of temperature sensitivity (warm and cold), and for a pain sense. In the 1880s, experimental findings that the human skin is punctate (selectively sensitive at different points) gave clear indication of a dissociation among functions once lumped together as the sense of touch. Mapping the skin with a fine bristle or with a narrow-tipped (warm or cold) cylinder showed that there were different spots of maximum sensitivity to pressure, warm, and cold. When stimulated between the spots on the skin, people reported no such sensations. Pain spots also can be located with a finely pointed needle, but the punctate character is less striking since pain seems to be widespread when stimulus intensity is increased. The number of spots is greatest for pain, next for touch, then for cold, and least for warm. Efforts to identify specific receptor cells for each of these sensitive points have been the subject of much debate and still pose a problem that is not completely settled.

Mapping sensitive spots of skin

Nerve function. Microscopic examination of the skin reveals a variety of nerve terminals; there are free nerve endings (which are most common), so-called Ruffini endings, and encapsulated endings, such as the pacinian corpuscle, Meissner's corpuscle, or Krause end bulb, all named for investigators who discovered them (Figure 32). At one time it was thought that each of these specialized structures mediated one of the cutaneous modalities, but efforts to extirpate (surgically remove) the nerve endings under the spots have yielded only questionable data. Further, the cornea of the eye shows only free nerve endings; yet pain, pressure, and some temperature sensations can be elicited by stimulating the corneal surface.

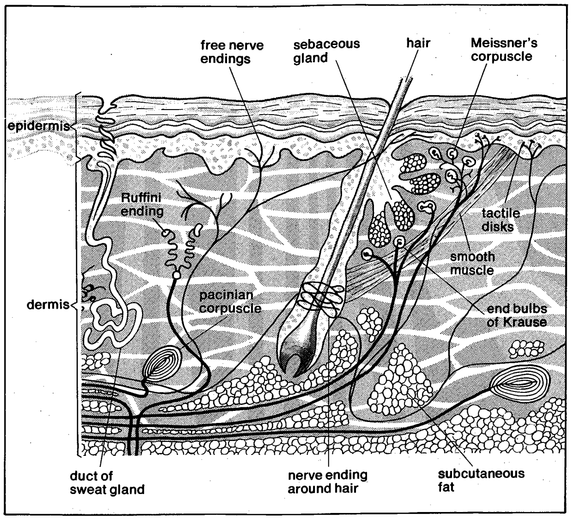

Figure 32: Microscopic view of human skin.
From E. Gardner, *Fundamentals of Neurology,* 5th ed. (1968); W.B. Saunders Company, Philadelphia

Electrical recordings from the cutaneous nerves of laboratory animals suggest a much wider variety of receptors than are encompassed by the reports people give of their sensations. Some nerve endings seem to respond only to one type of stimulus (*e.g.,* to pressure stimuli of very light weight or to slight temperature changes); others exhibit a broad range of sensitivity. There are some receptors that show combined sensitivity to both temperature and pressure. In some cases only special types of mechanical stimulation (such as rubbing) may be effective. Furthermore, there is an extensive overlap in the areas of skin (receptor fields) for the individual nerve fibres examined, suggesting that there is a neural integration of overlapping afferent inputs of skin nerves. A model of the sensory system that envisages only a single nerve fibre serving one tactual spot is clearly contradicted.

On the other hand, some tactual receptors (*e.g.,* Pacinian corpuscles) respond only to mechanical deformation. This corpuscle is an onion-shaped structure of non-neural (connective) tissue built up around the nerve ending; indeed, the distinctive corpuscle, if anything, reduces the mechanical sensitivity of the nerve terminal itself. If the onion-like capsule is entirely removed, mechanical sensitivity not only remains but is somewhat greater than when the capsule is present.

Variations in sensory nerve fibres

In addition to the differences in the sensory end structures of the skin, the afferent nerve fibres (axons) from them also show diversity. The nerve fibres range in size from large myelinated (sheathed) axons of 10 to 15 microns diameter down to extremely small unmyelinated fibres measuring only tenths of microns across. Fatter axons tend to conduct nerve impulses more rapidly than do small fibres; when axons of different diameters form a single bundle (a nerve), they constitute a so-called mixed nerve. Thus, electrical records from a mixed nerve show what are labelled A (fast), B (medium), and C (slow) components that reflect the typical speeds at which axons of different diameters conduct. Although such specialized capsules as Pacinian corpuscles tend to be associated with larger diameter axons, and temperature-sensitive endings tend to be associated with medium-size fibres, a unique relation of each of the skin modalities with one of the A, B, or C fibre groups cannot be supported. All of the cutaneous senses seem to be associated with some fibres of all diameters; furthermore, the C fibres (once thought to be restricted to the pain function) display quite specific sensitivities to nonpainful stimuli applied to the skin.

A major neural pathway for tactual impulses runs along the back (in the dorsal columns) of the spinal cord. Afferent fibres enter the cord from the cutaneous nerves and ascend without synaptic break in one (the ipsilateral) dorsal column. This is a very rapidly conducting pathway shared by fibres that mediate sensations of deep pressure and also kinesthesis. Other tactual, temperature, and pain information crosses the spinal cord close to the level of entry of the sensory fibres and ascends to the brain in contralateral pathways of the cord (the lateral and ventral spinothalamic tracts).

Each of the nerves distributed along the spinal cord contains a sensory bundle that serves a well-defined strip of skin (a dermatome) about 2.5 centimetres (one inch) or more wide on the body surface. Successive spinal nerves overlap, so that each place on the skin represents two and sometimes three dermatomes; this yields a segmented pattern of strips over the body from head to toe. All dermatomes feed into a single relay centre (the sensory thalamus) deep within the brain, where a precise three-dimensional layout of tactual sensitivity at the body surface can be found. The neurons in this part of the thalamus (the ventral posterolateral nucleus) are specific to particular skin senses (such as pressure) and form small and precise receptor fields. There is a second more diffuse thalamic system (in the posterior thalamic nuclei) where the receptor fields are large, perhaps bilateral, on the left and right sides, perhaps including one whole side of the body. The receptor fields here or the types of stimuli to which they respond are not clearly delineated.

The dissociation of cutaneous senses is dramatically demonstrated in the course of some diseases; for example, in a disorder called syringomyelia, degeneration of the central canal of the spinal cord leads to loss of pain and temperature sensitivity. Nevertheless, the sufferer still can experience pressure. In some instances there may be a complete absence of pain sensitivity with disastrous consequences for the welfare of the afflicted person. Such individuals are bruised and cut and even lose parts of the body because they are unable to sense the dangerous (painful) characteristics of stimuli. Among people born with total absence of the pain sense, there may not be demonstrable anatomic abnormality. Still other instances of dissociation of pain versus pressure occur in surgical procedures (such as tractotomy) in which spinal tracts or parts of the nerves leading into the brainstem are selectively cut. Such operations are designed specifically to relieve pain without unduly diminishing pressure sensitivity.

Pathways from the specific (ventral posterolateral) thalamus end (or project) in a narrow band of brain cortex (the posterior rolandic cortical sensory area in man) where there is a point-for-point representation of the body surface on the cortical surface. The cortical projection of the more diffuse (posterior) thalamic system is less well charted. There thus appears to be a dissociation between those tactual structures that are highly specific and those that are more generalized.

Tactual psychophysics. The mixture of sensitivities within a given patch of skin provides a ready basis for the concept of adequate stimulation. Sometimes, for example, a cold spot responds to a very warm stimulus, and the person experiences what is called paradoxical cold. The sensation of heat from a hot stimulus presumably arises from the adequate stimulation of warmth receptors combined with the inadequate or inappropriate (albeit effective) stimulation of cold and pain receptors.

Paradoxical cold

Human ability to barely detect pressure (*i.e.,* the human pressure threshold) generally appears when a tension of about 0.85 grams per square millimetre (equivalent to about 1.2 pounds per square inch) of skin surface is applied on the back of the hand. Thus a force of 85 milligrams applied to a stimulus hair (or bristle) of 0.1 square millimetre is just about enough to elicit the experience of pressure. The energy of impact at pressure threshold is very much greater than that required for hearing or seeing, the skin requiring on the order of 100,000,000 times more energy than the ear and 10,000,000,000 times more energy than the eye. Differential pressure discrimination (the ability to detect just noticeable differences in intensity) requires changes of roughly 14 percent at maximum sensitivity.

Adaptation to pressure is well known; one's awareness of a steadily applied bristle fades and ultimately disappears. As a result people are rarely aware of the steady pressure of their clothing unless movement brings about a change in stimulation. Most dramatic and perhaps best known among tactual experiences is adaptation to thermal stimulation. Continued presentation of a warm or cold stimulus leads to reduction or disappearance of the initial sensation and an increase in threshold values. Total obliteration of thermal sensation through adaptation occurs in the range from about 16° to 42° C (61° to 108° F). If one hand is placed in a bowl of hot (40° C [104° F]) water and adapted to that, and at the same time the other hand is adapted to cold (20° C [68° F]) water, then when both hands are simultaneously placed in lukewarm (30° C [86° F]) water, the previously cooled hand feels warm and the other hand feels cold. This effect was once interpreted as evidence for a single temperature sense, but careful study shows that there are indeed two kinds of temperature receptors, both of which show adaptation. Cold receptors are characterized by an electrical discharge on sudden cooling, normally showing no response to sudden warming; similarly appropriate electrical responses are made by warmth receptors. Both receptors show steady discharges selectively depending on temperature; maximum discharge typically occurs between 38° to 43° C (100° to 109° F) for individual warmth cells and between 15° and 34° C (59° and 93° F) for cold receptors. These temperature receptors show no electrical response to weak mechanical stimulation in either laboratory animals or human subjects.

Pain

Pain is least understood among all the human senses. The pattern of stimulation is more crucial in pain than in any other sense. A single brief electric shock to the skin or to an exposed nerve may not elicit the experience of pain; yet it tends to become painful upon repetitive stimulation. Cutaneous pain is often sensed more sharply than is pain associated with deep tissues of the body (*e.g.,* viscera). Certain areas of the body are relatively analgesic (free of pain); for example, the mucous lining of the cheek into which one can bite shallowly without discomfort. The organs of the abdominal cavity are usually insensitive to cutting or burning, but traction or stretching of hollow viscera is painful (as when the stomach is distended by gas). Pain displays sensory adaptation, although the process appears to be more complex than it is for other sensory modalities. Thus, the intensities of headaches, toothaches, and pains from injury often show cyclic fluctuations, possibly from such factors as changes in blood circulation or in degree of inflammation. The visceral pains, those of dental origin, or of diseased tissues can be reduced by analgesic drugs, which tend to be less effective on cutaneous pain. Pain has a strong emotional context. In certain cases, after frontal lobotomies (a type of brain surgery) have been performed, a person may report that he still feels the pain of a pin prick or other irritation but that he does not find it as disturbing or emotionally disruptive as he did before the lobotomy. Many phenomena indicate the powerful role of the brain and spinal cord in sensing potentially painful sensory input. Indeed, according to one theory, a so-called gate control system in the spinal cord modulates (increases or decreases) sensory input from the skin to determine whether the input is perceived as painful. This theoretical formulation also may account for moment-to-moment fluctuations in the intensity of perceived pain despite the absence of any stimulus change. Such brain-mediated factors as emotional tension or past psychological experience are held to influence pain perception by acting upon this spinal gate control system.

Itching

Itching seems to bear the same relation to pain as tickle does to pressure. The experience usually lasts long enough to demand attention and (like tickle) normally leads to a response such as rubbing or scratching the affected area. A number of skin disorders are accompanied by itching, presumably from a fairly low level of irritation in the affected area (which also may be produced in undiseased skin). While a single shock by a low-intensity electrical spark normally produces no sensation, a repetitive pattern of such shocks may induce an itch not unlike that produced by an insect bite. Itching also may occur as an aftereffect of the sharp pricking sensation produced by single strong shocks, presumably because the nerves continue to produce a patterned afterdischarge following the cessation of the stimulus. Nonpainful tactile pattern stimulation is exemplified by vibration. Different frequencies of vibration are readily discriminated and a tactual communication system employing vibrations on the skin has been devised, particularly for people who cannot see or hear. Further research will probably reveal other ways of utilizing the fine discriminatory capacities of the cutaneous senses as substitutes for other sensory avenues of communication.

KINESTHETIC (MOTION) SENSE

It is a common experience that, with the eyes closed, one is aware of the positions of his legs and arms and can perceive the active or passive movement of a limb and its direction. The term kinesthesis (literally "feeling of motion") has been coined for this sensibility.

Nerve function. Four types of sensory structures are widely distributed in muscles, tendons, and joints (Figure 33): (1) the neuromuscular spindle consists of small, fine muscle fibres around which sensory fibre endings are wrapped; (2) the Golgi tendon organ consists of sensory nerve fibres that terminate in a rich branching encapsulated within the tendon; (3) joint receptors (as in the knee) consist of "spray-type" endings (Ruffini) and Golgi-type and Pacinian corpuscles within the joints; and (4) free nerve endings. All these receptors combine to provide information on active contraction, passive stretch of muscle fibres, and tension whether produced actively or passively. In passive stretch both the muscle-spindle receptors and the tendon receptors send trains of impulses over their sensory (afferent) nerves; in active contraction the spindles show a silent period of neural activity when tension on the parallel fibres is unloaded, while the tendon receptors discharge just as when stretch is passive.

From E. Gardner, *Fundamentals of Neurology*, 5th ed. (1968); W.B. Saunders Company, Philadelphia

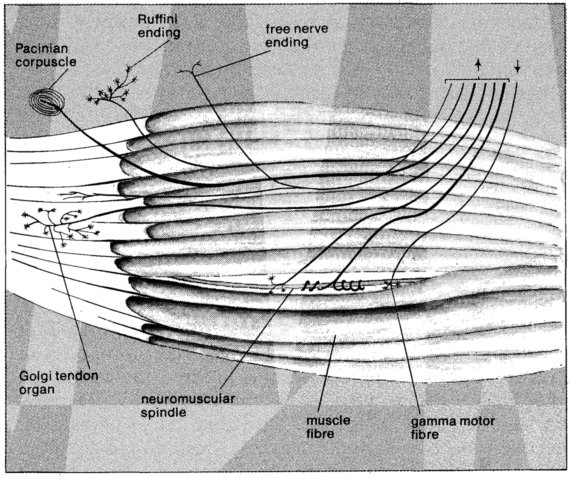

Figure 33: Sensory structures of muscle, tendon, and joint. Arrows indicate direction of conduction. (Motor nerves and motor nerve endings on contractile muscle fibres not shown.)

The muscle spindle is contractile in response to its own small-diameter, so-called gamma motor (efferent) fibre. The receptors and the gamma fibres of the muscle spindle form a neuromuscular loop that serves to insure that tension on the spindle is maintained within its efficient operating limits. The excitability of the muscle spindle also can be influenced through other neural pathways that control the general level of excitability of the central nervous system (brain and spinal cord). Activity of the descending reticular formation (a network of cells in the brainstem) may enhance the contraction of the spindle and hence influence its neural discharges.

The knee jerk

Muscle and tendon receptors combine to play an intimate and crucial role in the regulation of reflex and voluntary movement. Much of this control is automatic (involuntary) and not directly perceptible except in the aftereffects of movement or change of position. The knee jerk that follows a tap just below the kneecap of a freely hanging leg is one such involuntary reflex. Sensory (afferent) impulses from stretching the receptors (*e.g.*, in the muscles) relay to the spinal cord and activate a path to the motor (efferent) nerves leading back to the same muscle. The knee jerk is a purely spinal reflex response (the brain is not required) which is tested usually to determine nerve damage or other interference with the spinal-cord motor mechanisms. Besides producing loss of knee jerk, a disease such as syphilis may lead to locomotor ataxia (a clumsy and stumbling gait) when the germ (called a spirochete) attacks the sensory nerves of the cord's dorsal column. The result is that the sufferer has difficulty sensing the position of his limbs. Another general function of the muscle receptors is the maintenance of muscle tone (or tonus: partial contraction) to permit rapid response (fast reaction time) to stimulation. In normal conditions the muscle has tone and is ready to go; but, when it is without motor stimulation (deafferented), the muscle is flaccid, showing little tone. One's upright posture depends on the tonus of opposing (extensor and flexor) muscles in response to the effects of gravity.

The exact contribution of the muscle receptors to sensation is not entirely understood. It seems clear, however, that they are not essential to the sensation of bodily position. It has been suggested that the appreciation of passive movement of the limbs probably comes largely from the joints, since, after anesthetizing the overlying skin and muscles (*e.g.*, with cocaine), sensibility to the limb movement seems little affected. Evidence also shows that very few of the impulses arising from the muscle receptors themselves reach the cerebral cortex; instead, they ascend in the spinal pathways to another part of the brain (the cerebellum) where they interact in the automatic control of bodily movement. Impulses arising from the joint receptors, on the other hand, have been recorded in both the thalamus and brain cortex, the degree of angular displacement of a joint being reflected systematically in these structures by the frequency of nerve impulses. Symptoms of some diseases also emphasize the importance of joint sensitivity. When bone disease, for example, destroys only the joint receptors the person's ability to appreciate posture and movement is lost.

Cerebellar disorders

The feedback system. The feedback system leading to muscle tonus is a most delicately balanced mechanism. The gamma loop feeds back information that serves to maintain the muscle tonus and postural adjustments appropriate to the efficient performance of different voluntary actions. The afferent input from the muscle spindles via the spinal cord to the brain's cerebellum traverses an extensive circuit involving interactions of excitatory and inhibitory processes, the end result of which helps insure smooth and finely coordinated movements. Disease or other neurological damage in the cerebellum is characterized by distortions of movement and posture. Some sufferers of cerebellar disorders display crude, overactive motor activity (ballistic movement) that overshoots the mark in attempted voluntary coordination. Other victims of cerebellar disease display what resembles a drunken gait, jerkily stumbling and swaying along. By relying on other sensory cues (*e.g.*, visual and tactual), some people are able to compensate for awkward and uncoordinated movements associated with cerebellar damage.

VESTIBULAR SENSE (EQUILIBRIUM)

Function of the inner ear. The human inner ear contains parts (the nonauditory labyrinth or vestibular organ) that are sensitive to acceleration in space, rotation, and orientation in the gravitational field. Rotation is signalled by way of the semicircular canals, three bony tubes in each ear that lie embedded in the skull roughly at right angles to each other. These canals are filled with fluid (endolymph); in the ampulla of each canal are receptor cells with fine hairs that project up into the fluid to be displaced as the endolymph lags behind when rotation begins. When rotation is maintained at a steady velocity, the fluid catches up, and stimulation of the hair cells no longer occurs until rotation suddenly stops, again circulating the endolymph. Whenever the hair cells are thus stimulated, one normally experiences a sensation of rotation in space. During rotation one exhibits reflex nystagmus (back-and-forth movement) of the eyes. Slow displacement of the eye occurs against the direction of rotation and serves to maintain the gaze at a fixed point in space; this is followed by a quick return to the initial eye position in the direction of the rotation. Stimulation of the hair cells in the absence of actual rotation tends to produce an apparent swimming of the visual field, often associated with dizziness and nausea; compensatory postural adjustments commonly follow.

Two sacs or enlargements of the vestibule (the saccule and utricle) react to steady (static) pressures; *e.g.,* those of gravitational forces. Hair cells within these structures are covered by a gelatinous cap in which are embedded small granular particles of calcium carbonate (otoliths) that weigh against the hairs. When iron particles are implanted in the same structures of a fish, they may be displaced by externally applied magnets. In this way the fish can be made to assume inverted or other unusual positions in the water. In man, unusual stimulation of the vestibular receptors and semicircular canals also can give rise to sensory distortions in visual and motor activity. The resulting discord between one's visual and motor responses and the external space (as aboard ship in a heaving sea) often leads to nausea and disorientation (*e.g.,* seasickness). In space flight these sensory systems usually are not stimulated except as the weightless astronaut affects them by his own movements. Such abnormal gravitational and acceleratory forces apparently contribute to the nausea or disequilibrium sometimes reported by people in outer space. Training before space flight reduces the likelihood and severity of these symptoms.

Seasickness

Factors affecting equilibrium. In some diseases (*e.g.,* ear infections), irritation of vestibular nerve endings occurs, and the sufferer may be subject to falling as well as to spells of disorientation and vertigo (dizzy confusion). Similar symptoms may be induced by flushing hot and cold water into the outer opening of the ear, since the temperature changes produce currents in the endolymph of the semicircular canals. This caloric (temperature) effect is used in clinical tests for vestibular functions and in physiological experiments. Externally applied electrical currents may also stimulate the nerve endings of the vestibule. When current is applied to the right mastoid bone (just behind the ear), nystagmus to the right tends to occur, associated with a reflex right movement of the head; movement tends to the left for the opposite mastoid. In man, destruction of the labyrinth in only one ear causes vertigo and other vestibular symptoms, such as nystagmus, inaccurate pointing, and tendency to fall. (The vestibular functions of the ear are described in detail below; see *Human hearing*, with special attention to the section *Ear diseases and hearing disorders: the inner ear.*)

TASTE (GUSTATORY) SENSE

The sensory structures for taste in man are the taste buds, clusters of cells contained in goblet-shaped structures (papillae) that open by a small pore to the mouth cavity. A single bud contains about 50 to 75 slender cells, all arranged in a bananalike cluster pointed toward the gustatory pore (see also *Chemoreception* above). These are the taste receptor cells, which differentiate from the surrounding epithelium, grow to mature form, and then die out to be replaced by new cells in a turnover period as short as seven to 10 days. The various types of cells in the taste bud appear to be different stages in this turnover process. Slender nerve fibres entwine among and make contact usually with many cells. In man and other mammals, taste buds are located primarily in fungiform (mushroom-shaped), foliate, and circumvallate (walled-around) papillae of the tongue or in adjacent structures of the palate and throat. Many gustatory receptors in small papillae on the soft palate and back roof of the mouth in human adults are particularly sensitive to sour and bitter, whereas the tongue receptors are relatively more sensitive to sweet and salt. Some loss of taste sensitivity suffered among wearers of false teeth may be traceable to mechanical interference of the denture with taste receptors on the roof of the mouth.

Locations of taste buds

Nerve supply. There is no single sensory nerve for taste in vertebrates. In man, the anterior (front) two-thirds of the tongue is supplied by one nerve (the lingual nerve), the back of the tongue by another (the glossopharyngeal nerve), and the throat and larynx by certain branches of a third (the vagus nerve), all of which subserve touch, temperature, and pain sensitivity in the tongue as well as taste. The gustatory fibres of the anterior tongue leave the lingual nerve to form a slender nerve (the chorda tympani) that traverses the eardrum on the way to the brain stem. When the chorda tympani at one ear is cut or damaged (by injury to the eardrum), taste buds begin to disappear and gustatory sensitivity is lost on the anterior two-thirds of the tongue on the same side. Impulses have been recorded from the human chorda tympani, and good correlations have been found between the reports people give of their sensations of taste and of the occurrence of the afferent nerve discharge. The taste fibres from all the sensory nerves from the mouth come together in the brainstem (medulla oblongata). Here and at all levels of the brain, gustatory fibres run in distinct and separate pathways, lying close to the pathways for other modalities from the tongue and mouth cavity. From the brain's medulla, the gustatory fibres ascend by a pathway to a small cluster of cells in the thalamus and thence to a taste-receiving area in the anterior cerebral cortex.

Physiological basis of taste. No simple relation has been found between chemical composition of stimuli and the quality of gustatory experience except in the case of acids. The taste qualities of inorganic salts (such as potassium bromide, a sedative) are complex; epsom salt (magnesium sulfate) commonly is sensed as bitter, while table salt (sodium chloride) is typical of sodium salts, which usually yield the familiar saline taste. Experiences of sweet and bitter are elicited by many different classes of chemical compound.

Theorists of taste sensitivity classically posited only four basic or primary types of human taste receptors, one for each gustatory quality: salty, sour, bitter, and sweet. Yet, recordings of sensory impulses in the taste nerves of laboratory animals show that many individual nerve fibres from the tongue are of mixed sensitivity, responding to more than one of the basic taste stimuli, such as acid plus salt or acid plus salt plus sugar. Other individual nerve fibres respond to stimuli of only one basic gustatory quality. Most numerous, however, are taste fibres subserving two basic taste sensitivities; those subserving one or three qualities are about equal in number and next most frequent; fibres that respond to all four primary stimuli are least common. Mixed sensitivity may be only partly attributed to multiple branches of taste nerve endings. In man, experiences of sugars, synthetic sweeteners, weak salt solutions, and the taste of some unpleasant medicines are blocked by a drug (gymnemic acid) obtained from *Gymnema* bushes native to India. Among some laboratory animals, gymnemic acid blocks only the nerve response to sugar, even if the fibre mediates other taste qualities. Such a multiresponsive fibre still can transmit taste impulses (*e.g.,* for salt or sour), so that blockage by the drug can be attributed to chemically specific sites or cells in the taste bud.

Types of taste receptors

In some species of animals (*e.g.,* the cat), specific taste receptors appear to be activated by water; these so-called water receptors are inhibited by weak saline solutions. Water taste might be considered a fifth gustatory quality in addition to the basic four.

The qualities of taste. *Sour.* The hydrogen ions of acids (*e.g.,* hydrochloric acid, HCl) are largely responsible for the sour taste; but, although a stimulus grows more sour as its hydrogen ion (H^+) concentration increases, this factor alone does not determine sourness. Weak organic acids (*e.g.,* the acetic acid in vinegar) taste more sour than would be predicted from their hydrogen ion concentration alone; apparently the rest of the acid molecule affects the efficiency with which hydrogen ions stimulate.

Salt. Although the salty taste is often associated with water-soluble salts, most such compounds (except sodium chloride) have complex tastes such as bitter-salt or sour-salt. Salts of low molecular weight are predominantly salty, while those of higher molecular weight tend to be bitter. The salts of heavy metals such as mercury have a metallic taste, although some of the salts of lead (especially lead acetate) and beryllium are sweet. Both parts of the molecule (*e.g.,* lead and acetate) contribute to taste quality and to stimulating efficiency. In man the following series for degree of saltiness, in decreasing order, is found: ammonium (most salty), potassium, calcium, sodium, lithium, and magnesium salts (least salty). The order appears to vary for other animals.

Sweet. Except for some salts of lead or beryllium, the sweet taste is associated largely with organic compounds (such as alcohols, glycols, sugars, and sugar derivatives). Human sensitivity to synthetic sweeteners (*e.g.,* saccharin) is especially remarkable; the taste of saccharin can be detected in a dilution 700 times weaker than that required for cane sugar. The stereochemical (spatial) arrangement of atoms within a molecule may affect its taste; thus, slight changes within a sweet molecule will make it bitter or tasteless (Figure 34). Several theorists have proposed that the common feature for all of the sweet stimuli is the presence in the molecule of a so-called proton acceptor, such as the OH (hydroxyl) components of carbohydrates (*e.g.,* sugars) and many other sweet-tasting compounds. It has also been theorized that such molecules will not taste sweet unless they are of appropriate size.

From R.W. Moncrieff, *Chemical Senses* (1944); Leonard Hill Books

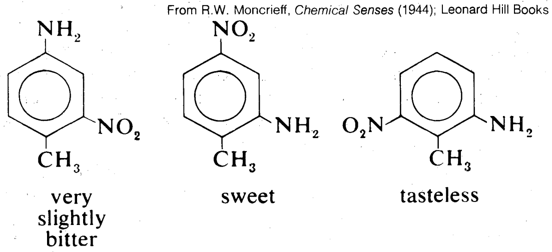

Figure 34: Effects of molecular arrangement on taste sensation (see text).

Bitter. The experience of a bitter taste is elicited by many classes of chemical compounds and often is found in association with sweet and other gustatory qualities. Among the best known bitter substances are such alkaloids (often toxic) as quinine, caffeine, and strychnine. Most of these substances have extremely low taste thresholds and are detectable in very weak concentrations. The size of such molecules is theoretically held to account for whether or not they will taste bitter. An increase in molecular weight of inorganic salts or an increase in length of chains of carbon atoms in organic molecules tends to be associated with increased bitterness.

Taste blindness

A substantial minority of people exhibit specific taste blindness, an inability to detect as bitter such chemicals as PTC (phenylthiocarbamide). Taste blindness for PTC and other carbamides appears to be hereditary (as a recessive trait), occurring least frequently among American Indians and Africans, in about a third of Europeans, and in roughly 40 percent of the people in Western India. Evidence for such taste blindness among other animals has been observed only in anthropoid apes; apparently it appeared at a relatively late stage of evolution. Taste blindness for carbamides is not correlated with insensitivity to other bitter stimuli, the reasons for this being poorly understood.

Factors affecting taste sensitivity. Fluids of extreme temperature, especially those that are cold, may produce temporary taste insensitivity. People generally seem to taste most acutely when the stimulus is at or slightly below body temperature. When the tongue and mouth are first adapted to the temperature of a taste solution, sugar sensitivity increases with temperature rise, salt and quinine sensitivity decrease, and acid sensitivity is relatively unchanged. Gustatory adaptation (partial or complete disappearance of taste sensitivity) may occur if a solution is held in the mouth for a period of time. The effect of one adapting stimulus on the person's sensitivity for another one (cross adaptation) is especially common with substances that are chemically similar and that elicit the same taste quality. Adaptation to sodium chloride will reduce one's ability to sense the saltiness of a variety of the inorganic salts but will leave undiminished or even enhance such qualities as bitterness, sweetness, or sourness that were part of the taste of the salt before adaptation. Likewise, adaptation by one acid may reduce sensitivity to the sourness of other acids.

Contrast effects

Adaptation studies often are complicated by so-called contrast effects; for example, people say that distilled water tastes sweet following their exposure to a weak acid. Water may take on other taste qualities as well; following one's adaptation to a sour-bitter chemical (urea), water may taste salty. Adaptation tends to diminish or enhance the effect of a subsequent stimulus depending on whether the two stimuli normally elicit the same or a contrasting taste. Thus the adapted sweetness of water and all normally sweet-tasting substances are enhanced after one has tasted acid (sour). The bitterness of tea and coffee or the sourness of lemon are masked or suppressed by sugar or saccharin.

The human gustatory difference threshold (for a just noticeable difference in intensity) is approximately a 20 percent change in concentration. For very weak taste stimuli, however, the threshold sensitivity is poorer.

Food choice. One's ability to taste is intimately concerned in his eating habits or in his rejection of noxious substances. One of the earliest reflex responses of the infant, that of sucking, can be controlled by gustatory stimuli. Sweet solutions are sucked more readily than is plain water; bitter, salty, or sour stimuli tend to stop the sucking reflex.

Among insects, a very specific feeding reaction (proboscis extension) is so automatic that it is widely used as an index of taste stimulation. If a common housefly is held relatively immobile in wax, different parts of the mouth, legs, and body readily may be stimulated by a drop of solution. Sugar solution will make the fly extend its proboscis when a drop is applied to the legs or mouth parts. A fly that has been starved will show a positive response to a weak sugar solution that ordinarily would not affect one that is satiated. Addition of salt or acid to the sugar solution inhibits this response.

Many animals provide clear examples of beneficially selective feeding behaviour. Laboratory rats, when given unhampered choice of carbohydrates, proteins, vitamins, and minerals (each in a separate container), show consistent patterns of self-selection that may be modified by physiological stresses and strains. A rat made salt-deficient by removal of its adrenal glands, for example, will increase its intake of sodium chloride sufficiently to maintain health and growth; normally, such gland removal is fatal in the absence of salt-replacement therapy. Histories of similar effects have been reported in human beings, one dramatic case being that of a child with adrenal disorder who kept himself alive by satisfying an intense salt craving.

Among human adults, past experience shows a strong influence on eating habits, sometimes to the point that physiological well-being suffers. Food habits and other factors play a significant role in eating behaviour.

Poisonous substances often are unpalatable, but not invariably. Lead acetate, sometimes called sugar of lead, once was used as a sweetening agent with disastrous results before its potentially fatal effects were appreciated. Many palatable substances, including some synthetic sweeteners, are toxic; taste alone is not a reliable guide to safety. A rat poison, alpha-naphthylthiourea (ANTU), was developed in a relatively insoluble and therefore tasteless form; soluble forms of ANTU had all been rejected by the animals. Taste aversions also may be readily established by conditioning, even for substances that have been normally preferred. In one study, a rat tasted saccharin solution three hours before being exposed to enough radiation to become sick. When the animal recovered, it was found to have a strong aversion to the taste of saccharin. Other aversions selectively can be produced by injecting the individual with a nauseating drug following specific taste experience. An unusual finding is that long delays of up to several hours in the time between the presentation of the taste stimulus and the induction of illness do not prevent the conditioning. In most other studies, only brief intervals (perhaps up to minutes in duration) have been found to result in successful conditioning. Bait shyness developed by wild rats that survive poisoning strongly suggests conditioned taste aversion. Positive preferences also are subject to conditioning, as when the tastes of drugs or vitamins become associated with the feelings of well-being they generate.

SMELL (OLFACTORY) SENSE

Olfactory receptors

In mammals the olfactory receptors are located high in the nasal cavity. The yellow-pigmented olfactory membrane in humans covers about 2.5 square centimetres (0.4 square inch) on each side of the inner nose. The olfactory sense receptor is a long thin cell ending in several delicate hairs (cilia) that project into and through the mucus that normally covers the nasal epithelium or lining (Figure 35). Electron microscope photographs show from six to 12 olfactory cilia per cell. The end of each receptor narrows to a fine nerve fibre, which, along with many others, enters the olfactory bulb of the brain through a fine channel in the bony roof of the nasal cavity. The olfactory membrane of a young rabbit contains about 100,000,000 ciliated receptor cells that provide as much area as total skin surface of the animal.

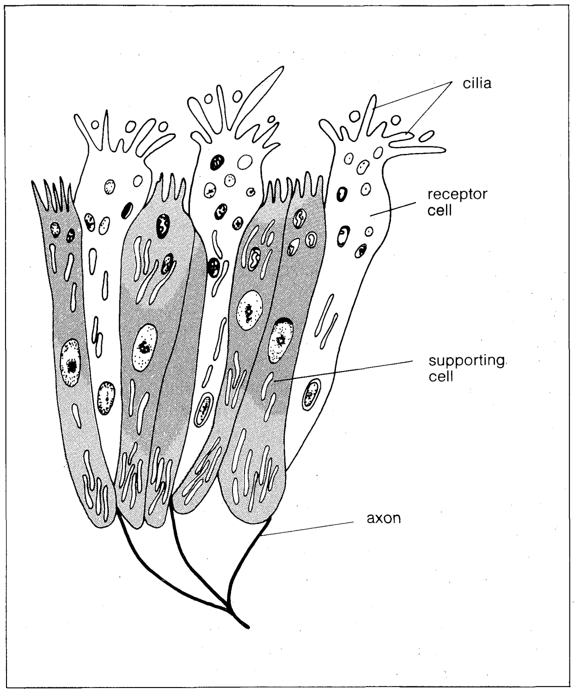

Figure 35: Olfactory lining of the nose.

Pain endings of the trigeminal nerve fibres are widely distributed throughout the human nasal cavity, including the olfactory region. Relatively mild odorants, such as orange oil, as well as the more obvious irritants, such as ammonia, stimulate such free nerve endings as well as the olfactory receptors.

Odorous molecules may be carried to the olfactory region by slight eddies in the air during quiet breathing, but vigorous sniffing brings a surge into the olfactory region. Odour sensitivity may be impaired by blocking the nasal passages mechanically, as when membranes are congested by infection.

It is generally agreed that the antennae of insects are their principal olfactory sites, but specific mouth parts may also bear endings for smell. The nonliving outer covering (cuticle) of such structures has been shown to be pierced by many ultramicroscopic holes through which odorous molecules enter, presumably to dissolve the fluid underneath. In vertebrates (such as man), olfactory stimulation occurs only after the odour molecule is dissolved in the mucus that covers the olfactory membrane. In spite of the wide biological gap between them, odour sensitivity of man and that of insect display certain similarities of mechanism.

Olfactory bulbs

In vertebrates the olfactory nerve fibres enter either of two specialized structures (olfactory bulbs), stemlike projections under the front part of the brain, to end in a microscopic series of intricate basket-like clusters called glomeruli. Each glomerulus receives impulses from about 26,000 receptors and sends them on through other cells, eventually to reach higher olfactory centres at the base of the brain. There are also fibres that cross over from one olfactory bulb to the other. When the olfactory bulbs are removed by surgery, the individual's ability to discriminate odours is lost; details of higher brain centres for smell are still unclear.

Olfactory qualities. The vocabulary of odour is rich with the names of substances that elicit a great variety of olfactory qualities. One of the best known published psychological attempts at classification was in 1916 on the basis of tests of more than 400 different scents on human observers. On the basis of the apparent similarities of perceived odour quality or confusions in naming, it was concluded that there were six main odour qualities: fruity, flowery, resinous, spicy, foul, and burned.

Electrical activity can be detected readily with fine insulated wires inserted into the olfactory bulb. Those portions of the bulb toward the anterior or oral (mouth) region in the rabbit are found to be more sensitive to water-soluble substances, whereas the more posterior or aboral (away from the mouth) parts of the olfactory bulb are more sensitive to fat-soluble substances. In addition, when very fine electrodes are used, individual cells (so-called mitral cells) are found to be sensitive to different groups of chemicals. Evidence for the existence of only a few primary receptors, however, does not emerge from such studies; a variety of different combinations of sensitivity has been found. Similarly, recordings from the primary receptor nerve fibres reveal different patterns of sensitivity. Electrical recording of this type also shows that olfactory sensitivity can be enhanced by a painful stimulus, such as a pinch on the foot of an experimental animal. This appears to be a reflex that serves to enhance the detection of dangerous stimuli in the environment. Different parts of the olfactory neural pathways seem to be selectively tuned to discriminate different classes of olfactory information. Thus, the third- and fourth-order olfactory neurons found beyond the olfactory bulb of the rat seem particularly concerned with distinguishing the odour of sexually receptive females. These neurons appear to be especially important in the preference the male rat shows for the smell of urine from a female in heat.

Characteristics that impart odour

Odorous substances. To be odorous, a substance must be sufficiently volatile for its molecules to be given off and carried into the nostrils by air currents. The solubility of the substance also seems to play a role; chemicals that are soluble in water or fat tend to be strong odorants, although many of them are inodorous. No unique chemical or physical property that can be said to elicit the experience of odour has yet been defined.

Only seven of the chemical elements are odorous: fluorine, chlorine, bromine, iodine, oxygen (as ozone), phosphorus, and arsenic. Most odorous substances are organic (carbon-containing) compounds in which both the arrangement of atoms within the molecule as well as the particular chemical groups that comprise the molecule influence odour. Stereoisomers (*i.e.,* different spatial arrangements of the same molecular components) may have different odours. On the other hand, a series of different molecules that derive from benzene all have a similar odour. It is of historic interest that the first benzene derivatives studied by chemists were found in pleasant-smelling substances from plants (such as oil of wintergreen or oil of anise), and so the entire class of these compounds was labelled aromatic. Subsequently, other so-called aromatic compounds were identified that have less attractive odours.

The scent of flowers and roots (such as ginger) depends upon the presence of minute quantities of highly odorous essential oils. Although the major odour constitutents can be identified by chemical analysis, some botanical essences are so complex that their odours can be duplicated only by adding them in small amounts to synthetic formulations.

Odour sensitivity. In spite of the relative inaccessibility of the human olfactory receptor cells, odour stimuli can be detected at extremely low concentrations. Olfaction is said to be 10,000 times more sensitive than taste. A human threshold value for such a well-known odorant as ethyl mercaptan (found in rotten meat) has been cited in the range of 1/400,000,000th of a milligram per litre of air. A just-noticeable difference in odour intensity may be apparent when there is a 20 percent increase in odorant strength, but at low concentrations as much as 100 percent increase in concentration may be required. Temperature influences the strength of an odour by affecting the volatility and hence the emission of odorous particles from the source; humidity also affects odour for the same reasons. Hunting dogs can follow a spoor (odour trail) most easily when high humidity retards evaporation and dissipation of the odour. Perfumes contain chemicals called fixatives, added to retard evaporation of the more volatile constituents. The temporary anosmia (absence of sense of smell) following colds in the nose may be complete or partial; in the latter case, only the odours of certain substances are affected. Paranosmia (change in perceived odour quality) also may occur during respiratory infections. Changes in sensitivity are reported to occur in women during the menstrual cycle, particularly in regard to certain odorants (steroids) related to sex hormones. Olfactory sensitivity also is said to become more acute during hunger.

Factors affecting odour sensitivity

Human adaptation to odours is so striking that the stench of a slaughterhouse or chemical laboratory ceases to be a nuisance after a few minutes have passed. Olfactory adaptation, as measured by a rise in threshold, is especially pronounced for stronger odours. Cross adaptation (between different odours) may take place; thus, eucalyptus oil may be difficult to detect after one becomes adapted to the smell of camphor.

Adaptation long was regarded solely as the result of changes in the olfactory receptor; however, electrical recordings show that the receptor cells in the nose seem to adapt only partially. Rhythmic discharges continue in the olfactory bulb long after the experimenter ceases to detect the odour that is stimulating the experimental animal. Apparently, some olfactory adaptation may occur in the brain as well as in the sense organ.

Odour blending and flavour. The ancient art of perfumery and the modern science of odour control depend on mixing and blending. Two different odours presented together may be readily identifiable. The more they resemble each other, the greater will be the tendency to blend; yet trained workers usually can discriminate the components of a successfully blended perfume. The substantially greater intensity of one odour may mask another. Masking, however, is less effective than chemical conversion or physical collection (removal) as a basis for odour control. Some odorants also may be removed by passing air through activated charcoal.

Flavours and the sense of smell

The distinctive flavours of food are known largely through the sense of smell. Flavour is the composite of experiences from many senses, but the aroma of roast beef and the delicate bouquet of wine are mainly olfactory in origin. Flavour technology has assumed a well-entrenched place in the food industry; it is common practice for manufacturers to use flavour panels of several trained members to judge the flavour of new food products. Using psychophysical methods with adequate statistical control, such panels are very reliable and can detect qualities so subtle that they defy the methods of physics and chemistry.

In using large, untrained consumer panels, the emphasis is on acceptability, often an emotional reaction to the product. Such untrained judgments are unstable and may vary among individuals because of idiosyncrasy or differences in experience. For example, the strong cheese odour so palatable to the gourmet can produce revulsion in the uninitiated.

Effects on behaviour. Recognition of friend or foe by social insects may depend upon olfactory cues: certain ants attack their own kind furiously if deprived of the sense of smell by amputation of their antennae; bees entering a strange hive are put to death because the scent of a foreign hive clings to them. Bees also have a specialized organ on the end of the abdomen that deposits a scent on a newly discovered food source to guide other foraging workers. The scents of flowers attest to the evolutionary importance of odour; those flowers that attract insects most efficiently are the likeliest to be pollinated and to reproduce their kind.

The effect of odours on the sexual behaviour of invertebrates is most striking; a female moth, for example, was observed to attract more than 100 males during relatively brief observation periods of about six hours. The physiological basis for the attraction can be traced to specific odour attractants (pheromones), molecules produced by the scent glands of the female. Pheromones also function in defense and as alarms of impending danger. The specific sex attractant of the female silk moth (*Bombyx*) has been identified and synthesized. It has been found that the antennae of the male silk moth contain olfactory receptors specifically sensitive to the female pheromone but that the females have no receptors to detect their own attractiveness.

Mammals in the wild state appear to utilize their odour glands for sexual attraction. Laboratory rats show a preference for the branch of a maze that has been scented with the odour of a sexually receptive female. It is likely that some rudiments of these effects operate in man. The most sexually provocative perfumes have a high proportion of musk or musklike odour. Genuine musk is derived from the sexual glands of the musk deer and is chemically related to human sex hormones; odour sensitivity in humans varies with the menstrual cycle.

Among laboratory animals the secretion of reproductive hormones can be markedly influenced by odour stimulation. This seems to be an innate physiological process rather than the result of learning. A most dramatic effect (pregnancy block) is observed when the odour of a strange male is presented to a recently mated female. The normal hormonal changes following copulation are blocked under these conditions, and the fertilized egg fails to survive. A related study of the periodicity and length of menstrual cycle in women exposed to the normal odours of men suggests there may be similar effects among people. Human behaviour, molded and shaped by custom and culture though it is, has many of its roots in his basic sensual appetites. (C.Pf.)

HUMAN VISION: STRUCTURE AND FUNCTION OF THE EYE

Anatomy of the visual apparatus

STRUCTURES AUXILIARY TO THE EYE

The orbit. The eye is protected from mechanical injury by being enclosed in a socket, or orbit, which is made up of portions of several of the bones of the skull to form a four-sided pyramid the apex of which points back into the head. Thus, the floor of the orbit is made up of parts of the maxilla, zygomatic, and palatine bones, while the roof is made up of the orbital plate of the frontal bone and, behind this, by the lesser wing of the sphenoid. The optic foramen, the opening through which the optic nerve runs back into the brain and the large ophthalmic artery enters the orbit, is at the nasal side of the apex; the superior orbital fissure is a larger hole through which pass large veins and nerves. These nerves may carry nonvisual sensory messages—*e.g.*, pain—or they may be motor nerves controlling the muscles of the eye. There are other fissures and canals transmitting nerves and blood vessels. The eyeball and its functional muscles are surrounded by a layer of orbital fat that acts much like a cushion, permitting a smooth rotation of the eyeball about a virtually fixed point, the centre of rotation. The protrusion of the eyeballs—proptosis—in exophthalmic goitre is caused by the collection of fluid in the orbital fatty tissue.

The eyelids. It is vitally important that the front surface of the eyeball, the cornea, remain moist. This is achieved by the eyelids, which during waking hours sweep

The layers in the lids

the secretions of the lacrimal apparatus and other glands over the surface at regular intervals and which during sleep cover the eyes and prevent evaporation. The lids have the additional function of preventing injuries from foreign bodies, through the operation of the blink reflex. The lids are essentially folds of flesh covering the front of the orbit and, when the eye is open, leaving an almond-shaped aperture. The points of the almond are called canthi; that nearest the nose is the inner canthus, and the other is the outer canthus (Figure 36). The lid may be divided into four layers: (1) the skin, containing glands that open onto the surface of the lid margin, and the eyelashes; (2) a muscular layer containing principally the orbicularis oculi muscle, responsible for lid closure; (3) a fibrous layer that gives the lid its mechanical stability, its principal portions being the tarsal plates, one in each lid, which border directly upon the opening between the lids, called the palpebral aperture; and (4) the innermost layer of the lid, a portion of the conjunctiva. The conjunctiva is a mucous membrane that serves to attach the eyeball to the orbit and lids but permits a considerable degree of rotation of the eyeball in the orbit.

From P. Kronfeld, *The Eye*, vol. 1 (1962); Academic Press

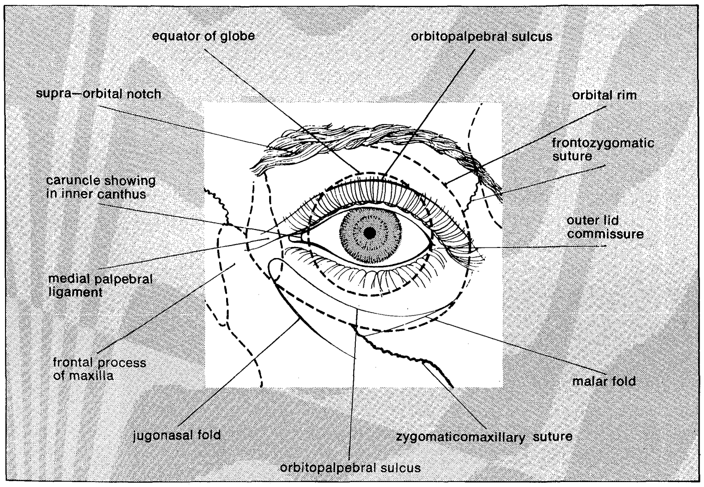

Figure 36: Frontal view of the eye and its related structures (see text).

The conjunctiva. The conjunctiva lines the lids and then bends back over the surface of the eyeball, constituting an outer covering to the forward part of this and terminating at the transparent region of the eye, the cornea. The portion that lines the lids is called the palpebral portion of the conjunctiva; the portion covering the white of the eyeball is called the bulbar conjunctiva. Between the bulbar and the palpebral conjunctiva there are two loose, redundant portions forming recesses that project back toward the equator of the globe. These recesses are called the upper and lower fornices, or conjunctival sacs; it is the looseness of the conjunctiva at these points that makes movements of lids and eyeball possible. (The ophthalmologist finds the lower conjunctival sac a useful cavity in which to place drops containing drugs. He accomplishes this by merely pulling the outer lid away from the globe. The drops are retained in the cavity long enough to act directly on the cornea and to diffuse through this into the internal structures of the eye.)

The fibrous layer. The fibrous layer, which gives the lid its mechanical stability, is made up of the thick, and relatively rigid, tarsal plates, bordering directly on the palpebral aperture, and the much thinner palpebral fascia, or sheet of connective tissue; the two together are called the septum orbitale. When the lids are closed, the whole opening of the orbit is covered by this septum. Two ligaments, the medial and lateral palpebral ligaments, attached to the orbit and to the septum orbitale, stabilize the position of the lids in relation to the globe. The medial ligament, by far the stronger, is well illustrated in Figure 36.

Horner's muscle and the muscle of Riolan

The muscles. Closure of the lids is achieved by contraction of the orbicularis muscle, a single oval sheet of muscle extending from the regions of the forehead and face and surrounding the orbit into the lids. It is divided into orbital and palpebral portions, and it is essentially the palpebral portion, within the lid, that causes lid closure. The palpebral portion passes across the lids from a ligament called the medial palpebral ligament and from the neighbouring bone of the orbit in a series of half ellipses that meet outside the outer corner of the eye, the lateral canthus, to form a band of fibres called the lateral palpebral raphe. Additional parts of the orbicularis have been given separate names—namely, Horner's muscle and the muscle of Riolan; they come into close relation with the lacrimal apparatus and assist in drainage of the tears. The muscle of Riolan, lying close to the lid margins, doubtless contributes to keeping the lids in close apposition, an important feature for maintaining the junction watertight. The orbital portion of the orbicularis is not normally concerned with blinking, which may be carried out entirely by the palpebral portion; however, it is concerned with closing the eyes tightly. The skin of the forehead, temple, and cheek is then drawn toward the medial (nose) side of the orbit, and the radiating furrows, formed by this action of the orbital portion, eventually lead to the so-called crow's feet of elderly persons. It must be appreciated that the two portions can be activated independently; thus, the orbital portion may contract, causing a furrowing of the brows that reduces the amount of light entering from above, while the palpebral portion remains relaxed and allows the eyes to remain open.

Opening of the eye is not just the result of passive relaxation of the orbicularis muscle but also is the effect of the contraction of the levator palpebrae superioris muscle of the upper lid. This muscle takes origin with the extraocular muscles at the apex of the orbit (the back of the eye socket) as a narrow tendon and runs forward into the upper lid as a broad tendon, the levator aponeurosis, which is attached to the forward surface of the tarsus and the skin covering the upper lid. Contraction of the muscle causes elevation of the upper eyelid. The nervous connections of this muscle are closely related to those of the extraocular muscle required to elevate the eye, so that when the eye looks upward the upper eyelid tends to move up in unison.

The orbicularis and levator are striped muscles under voluntary control. The lids contain, in addition, unstriped (involuntary) muscle fibres that are activated by the sympathetic division of the autonomic system and tend to widen the palpebral fissure (the eye opening) by elevation of the upper, and depression of the lower, lid.

In addition to the muscles already described, other facial muscles often cooperate in the act of lid closure or opening. Thus, the corrugator supercilii muscles pull the eyebrows toward the bridge of the nose, making a projecting "roof" over the medial angle of the eye and producing characteristic furrows in the forehead; the roof is used primarily to protect the eye from the glare of the sun. The pyramidalis, or procerus, muscles occupy the bridge of the nose; they arise from the lower portion of the nasal bones and are attached to the skin of the lower part of the forehead on either side of the midline; they pull the skin into transverse furrows. In lid opening, the frontalis

By permission from Eugene Wolff, *Anatomy of the Eye and Orbit*. London: H.K. Lewis & Co.

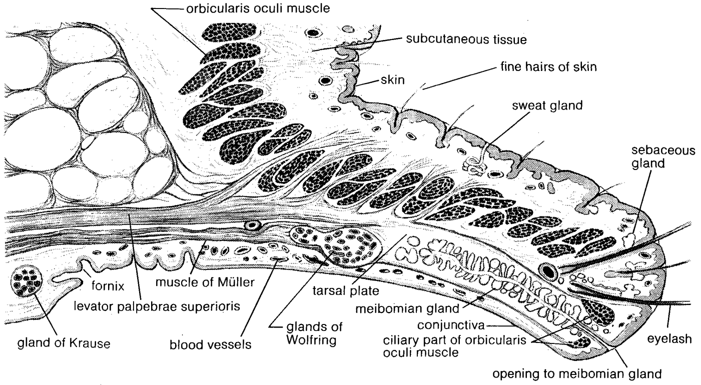

Figure 37: Vertical section through upper lid (see text).

muscle, arising high on the forehead, midway between the coronal suture, a seam across the top of the skull, and the orbital margin, is attached to the skin of the eyebrows. Contraction therefore causes the eyebrows to rise and opposes the action of the orbital portion of the orbicularis; the muscle is especially used when one gazes upward. It is also brought into action when vision is rendered difficult either by distance or the absence of sufficient light.

The skin. The outermost layer of the lid is the skin, with features not greatly different from skin on the rest of the body, with the possible exception of large pigment cells, which, although found elsewhere, are much more numerous in the skin of the lids. The cells may wander, and it is these movements of the pigment cells that determine the changes in coloration seen in some people with alterations in health. The skin has sweat glands and hairs. As the junction between skin and conjunctiva is approached, the hairs change their character to become eyelashes (Figure 37).

Tear glands

The glandular apparatus. The eye is kept moist by secretions of the lacrimal glands (tear glands). These almond-shaped glands under the upper lids extend inward from the outer corner of each eye. Each gland has two portions. One portion is in a shallow depression in the part of the eye socket formed by the frontal bone. The other portion projects into the back part of the upper lid. The ducts from each gland, three to 12 in number, open into the superior conjunctival fornix, or sac. From the fornix, the tears flow down across the eye and into the puncta lacrimalia, small openings at the margin of each eyelid near its inner corner. The puncta are openings into the lacrimal ducts; these carry the tears into the lacrimal sacs, the dilated upper ends of the nasolacrimal ducts, which carry the tears into the nose.

The evaporation of the tears as they flow across the eye is largely prevented by the secretion of oily and mucous material by other glands. Thus, the meibomian, or tarsal glands, consist of a row of elongated glands extending through the tarsal plates; they secrete an oil that emerges onto the surface of the lid margin and acts as a barrier for the tear fluid, which accumulates in the grooves between the eyeball and the lid barriers.

Extraocular muscles. Six muscles outside the eye govern its movements. These muscles are the four rectus muscles—the inferior, medial, lateral, and superior recti—and the superior and inferior oblique muscles. The rectus muscles arise from a fibrous ring that encircles the optic nerve at the optic foramen, the opening through which the nerve passes, and are attached to the sclera, the opaque portion of the eyeball, in front of the equator, or widest part, of the eye. The superior oblique muscle arises near the rim of the optic foramen and somewhat nearer the nose than the origin of the rectus medialis. It ends in a rounded tendon that passes through a fibrous ring, the trochlea, that is attached to the frontal bone. The trochlea acts as a pulley. The tendon is attached to the sclera back of the equator of the eye (Figure 38).

The inferior oblique muscle originates from the floor of the orbit, passes under the eyeball like a sling, and is attached to the sclera between the attachments of the superior and lateral rectus muscles. The rectus muscles direct the gaze upward and downward and from side to side. The inferior oblique muscle tends to direct the eye upward, and the superior oblique to depress the eye; because of the obliqueness of the pull, each causes the eye to roll, and in an opposite direction.

The oblique muscles are strictly antagonistic to each other, but they work with the vertical rectus muscles in so far as the superior rectus and inferior oblique both tend to elevate the gaze and the inferior rectus and superior oblique both tend to depress the gaze. The superior and inferior recti do not produce a pure action of elevation or depression because their plane of action is not exactly vertical; in consequence, as with the obliques, they cause some degree of rolling, but by no means so great as that caused by the obliques; the direction of rolling caused by the rectus muscle is opposite to that of its synergistic oblique; the superior rectus causes the eye to roll inward, and the inferior oblique outward.

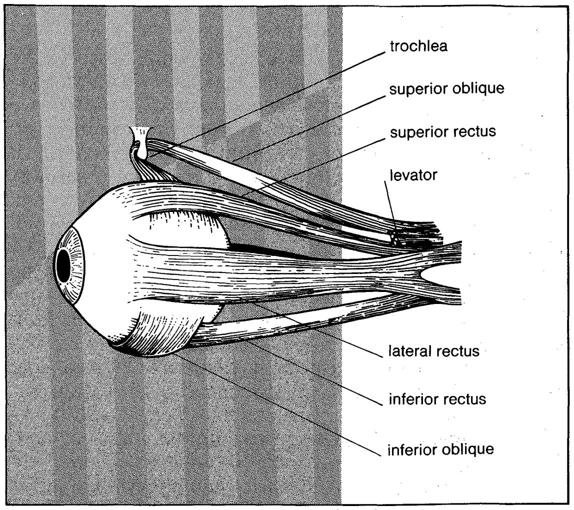

Figure 38: The extraocular muscles.

THE EYE

Visible parts of the eye

General description. The eyeball is not a simple sphere but can be viewed as the result of fusing a small portion of a small, strongly curved sphere with a large portion of a large, not so strongly curved sphere (Figure 39). The small piece, occupying about one-sixth of the whole, has a radius of eight millimetres (0.3 inch); it is transparent and is called the cornea; the remainder, the scleral segment, is opaque and has a radius of 12 millimetres (0.5 inch). The ring where the two areas join is called the limbus. Thus, on looking directly into the eye from in front one sees the white sclera surrounding the cornea; because the latter is transparent one sees, instead of the cornea, a ring of tissue lying within the eye, the iris. The iris is the structure that determines the colour of the eye. The centre of this ring is called the pupil. It appears dark because the light passing into the eye is not reflected back to any great extent. By use of an ophthalmoscope, an instrument that permits the observer to illuminate the interior of the eyeball while observing through the pupil, the appearance of the interior lining of the globe can be made out; this is called the fundus; it is characterized by the large blood vessels that suppy blood to the retina; these are especially distinct as they cross over the pallid optic disk, or papilla, the region where the optic nerve fibres leave the globe.

From H. Davson, M.D., *Physiology of the Eye*

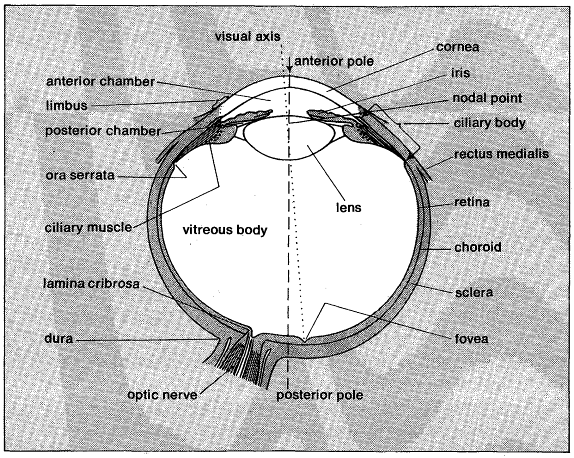

Figure 39: Horizontal section of the eye.

The dimensions of the eye are reasonably constant, varying among individuals by only a millimetre or two; the sagittal (vertical) diameter is about 24 millimetres (about one inch) and is usually less than the transverse diameter. At birth the sagittal diameter is about 16 to 17 millimetres (about 0.65 inch); it increases rapidly to about 22.5 to 23 millimetres (about 0.89 inch) by the age of three years; between three and 13 the globe attains its full size. The weight is about 7.5 grams (.25 ounce), and its volume 6.5 millilitres (0.4 cubic inch).

The eye is made up of three coats, which enclose the optically clear aqueous humour, lens, and vitreous body (Figure 39). The outermost coat consists of the cornea and the sclera; the middle coat contains the main blood supply to the eye and consists, from the back forward, of the choroid, the ciliary body, and the iris. The innermost layer is the retina, lying on the choroid and receiving most of its nourishment from the vessels within the choroid, the remainder of its nourishment being derived from the retinal vessels that lie on its surface and are visible in the ophthalmoscope. The ciliary body and iris have a very thin covering, the ciliary epithelium and posterior epithelium of the iris, which is continuous with the retina.

Within the cavities formed by this triple-layered coat there are the crystalline lens, suspended by fine transparent fibres—the suspensory ligament or zonule of Zinn—from the ciliary body; the aqueous humour, a clear fluid filling the spaces between the cornea and the lens and iris; and the vitreous body, a clear jelly filling the much larger cavity enclosed by the sclera, the ciliary body, and the lens. The anterior chamber of the eye is defined as the space between the cornea and the forward surfaces of the iris and lens, while the posterior chamber is the much smaller space between the rear surface of the iris and the ciliary body, zonule, and lens; the two chambers both contain aqueous humour and are in connection through the pupil.

Outer and middle tunics of the globe. *The outermost coat.* The outermost coat is made up of the cornea and the sclera. The cornea is the transparent window of the eye. It contains five distinguishable layers; the epithelium, or outer covering; Bowman's membrane; the stroma, or supporting structure; Descemet's membrane; and the endothelium, or inner lining. Up to 90 percent of the thickness of the cornea is made up of the stroma. The epithelium, which is a continuation of the epithelium of the conjunctiva, is itself made up of about six layers of cells. The superficial layer is continuously being shed, and the layers are renewed by multiplication of the cells in the innermost, or basal, layer.

The layers of the cornea

The stroma appears as a set of lamellae, or plates, running parallel with the surface and superimposed on each other like the leaves of a book; between the lamellae lie the corneal corpuscles, cells that synthesize new collagen (connective tissue protein) essential for the repair and maintenance of this layer. The lamellae are made up of microscopically visible fibres that run parallel to form sheets; in successive lamellae the fibres make a large angle with each other. The lamellae in man are about 1.5 to 2.5 microns (one micron = 0.001 millimetre) thick, so that there are about 200 lamellae in the human cornea. The fibrous basis of the stroma is collagen.

Immediately above the stroma, adjacent to the epithelium, is Bowman's membrane, about eight to 14 microns thick; in the electron microscope it is evident that it is really stroma, but with the collagen fibrils not arranged in the orderly fashion seen in the rest of the stroma.

Beneath the stroma are Descemet's membrane and the endothelium. The former is about five to 10 microns thick and is made up of a different type of collagen from that in the stroma; it is secreted by the cells of the endothelium, which is a single layer of flattened cells. There is apparently no continuous renewal of these cells as with the epithelium, so that damage to this layer is a more serious matter.

The sclera is essentially the continuation backward of the cornea, the collagen fibres of the cornea being, in effect, continuous with those of the sclera. The sclera is pierced by numerous nerves and blood vessels; the largest of these holes is that formed by the optic nerve, the posterior scleral foramen. The outer two-thirds of the sclera in this region continue backward along the nerve to blend with its covering, or dural sheath—in fact, the sclera may be regarded as a continuation of the dura mater, the outer covering of the brain. The inner third of the sclera, combined with some choroidal tissue, stretches across the opening, and the sheet thus formed is perforated to permit the passage of fasciculi (bundles of fibres) of the optic nerve. This region is called the lamina cribrosa (Figure 39). The blood vessels of the sclera are largely confined to a superficial layer of tissue, and these, along with the conjunctival vessels, are responsible for the bright redness of the inflamed eye. As with the cornea, the innermost layer is a single layer of endothelial cells; above this is the lamina fusca, characterized by large numbers of pigment cells.

The most obvious difference between the opaque sclera and the transparent cornea is the irregularity in the sizes and arrangement of the collagen fibrils in the sclera by contrast with the almost uniform thickness and strictly parallel array in the cornea; in addition, the cornea has a much higher percentage of mucopolysaccharide (a carbohydrate that has among its repeating units a nitrogenous sugar, hexosamine) as embedding material for the collagen fibrils. It has been shown that the regular arrangement of the fibrils is, in fact, the essential factor leading to the transparency of the cornea.

Differences between sclera and cornea

When the cornea is damaged—*e.g.,* by a virus infection—the collagen laid down in the repair processes is not regularly arranged, with the result that an opaque patch called a leukoma, may occur.

When an eye is removed, or a man dies, the cornea soon loses its transparency, becoming hazy; this is due to the taking in of fluid from the aqueous humour, the cornea becoming thicker as it becomes hazier. The cornea can be made to reassume its transparency by maintaining it in a warm, well-aerated chamber, at about 31° C (88° F, its normal temperature); associated with this return of transparency is a loss of fluid.

Modern studies have shown that, under normal conditions, the cornea tends to take in fluid, mainly from the aqueous humour and from the small blood vessels at the limbus, but this is counteracted by a pump that expels the fluid as fast as it enters. This pumping action depends on an adequate supply of energy, and any situation that prejudices this supply causes the cornea to swell—the pump fails, or works so slowly that it cannot keep pace with the leak. Death is one cause of the failure of the pump, but this is primarily because of the loss of temperature; place the dead eye in a warm chamber and the reserves of metabolic energy it contains in the form of sugar and glycogen are adequate to keep the cornea transparent for 24 hours or more. When it is required to store corneas for grafting, as in an eye bank, it is best to remove the cornea from the globe to prevent it from absorbing fluid from the aqueous humour. The structure responsible for the pumping action is almost certainly the endothelium, so that damage to this lining can lead to a loss of transparency with swelling.

The cornea is exquisitely sensitive to pain. This is mediated by sensory nerve fibres, called ciliary nerves, that run just underneath the endothelium; they belong to the ophthalmic branch of the fifth cranial nerve, the large sensory nerve of the head. The ciliary nerves leave the globe through holes in the sclera, not in company with the optic nerve, which is concerned exclusively with responses of the retina to light.

The uvea. The middle coat of the eye is called the uvea (from the Latin for "grape") because the eye looks like a reddish-blue grape when the outer coat has been dissected away. The posterior part of the uvea, the choroid, is essentially a layer of blood vessels and connective tissue sandwiched between the sclera and the retina. The forward portion of the uvea, the ciliary body and iris, is more complex, containing as it does the ciliary muscle and the sphincter and dilator of the pupil.

Ciliary body and iris

The blood supply to the human eye is twofold, consisting of the retinal and uveal circulations, both of which derive from branches of the ophthalmic artery. The two systems of blood vessels differ in that the retinal vessels, which supply nutrition to the innermost layers of the retina, derive from a branch of the ophthalmic artery, called the central artery of the retina, that enters the eye with the optic nerve, while the uveal circulation, which supplies the middle and outer layers of the retina as well as the uvea, is derived from branches of the ophthalmic artery that penetrate the globe independently of the optic nerve.

The ciliary body is the forward continuation of the choroid. It is a muscular ring, triangular in horizontal section, beginning at the region called the ora serrata and ending, in front, as the root of the iris (Figure 40). The surface is thrown into folds, called ciliary processes, the whole being covered by the ciliary epithelium, which is a double layer of cells; the layer next to the vitreous body (see below), called the inner layer, is transparent, while the outer layer, which is continuous with the pigment epithelium of the retina, is heavily pigmented. These two layers are to be regarded embryologically as the forward continuation of the retina, which terminates at the ora serrata. Their function is to secrete the aqueous humour.

From P. Kronfeld, *The Eye*, vol. 1 (1962); Academic Press

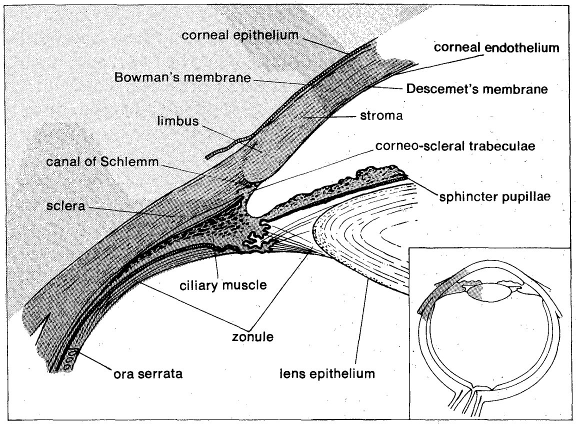

Figure 40: The anteronasal portion of a horizontal (meridional) section through a right eye. Shaded area of inset locates magnified portion. (See text.)

The ciliary muscle is an unstriped, involuntary, muscle concerned with alterations in the adjustments of focus—accommodation—of the optical system; the fibres run both across the muscle ring and circularly, and the effect of their contraction is to cause the whole body to move forward and to become fatter, so that the suspensory ligament that holds the lens in place is loosened.

The most forward portion of the uvea is the iris. This is the only portion that is visible to superficial inspection, appearing as a perforated disc, the central perforation, or pupil, varying in size according to the surrounding illumination and other factors. A prominent feature is the collarette at the inner edge, representing the place of attachment of the embryonic pupillary membrane that, in embryonic life, covers the pupil. As with the ciliary body, with which it is anatomically continuous, the iris consists of several layers: namely, an anterior layer of endothelium, the stroma; and the posterior iris epithelium. The stroma contains the blood vessels and the sphincter and dilator muscles; in addition, the stroma contains pigment cells that determine the colour of the eye. Posteriorly, the stroma is covered by a double layer of epithelium, the continuation forward of the ciliary epithelium; here, however, both layers are heavily pigmented and serve to prevent light from passing through the iris tissue, confining the optical pathway to the pupil. The pink iris of the albino is the result of the absence of pigment in these layers. The cells of the anterior layer of the iris epithelium have projections that become the fibres of the dilator muscle; these projections run radially, so that when they contract they pull the iris into folds and widen the pupil; by contrast, the fibres of the sphincter pupillae muscle run in a circle around the pupil, so that when they contract the pupil becomes smaller.

Usually, a baby belonging to the white races is born with blue eyes because of the absence of pigment cells in the stroma; the light reflected back from the posterior epithelium, which is blue because of scattering and selective absorption, passes through the stroma to the eye of the observer. As time goes on, pigment is deposited, and the colour changes; if much pigment is laid down the eye becomes brown or black, if little, it remains blue or gray.

The inner tunic of the globe. The inner tunic of the rear portion of the globe, as far forward as the ciliary body, is the retina, including its epithelia or coverings. These epithelia continue forward to line the remainder of the globe.

The pigment epithelium

The epithelia. Separating the choroid (the middle tunic of the globe) from the retina proper is a layer of pigmented cells, the pigment epithelium of the retina; this acts as a restraining barrier to the indiscriminate diffusion of material from the blood in the choroid to the retina. The retina ends at the ora serrata, where the ciliary body begins (Figure 39). The pigment epithelium continues forward as a pigmented layer of cells covering the ciliary body; farther forward still, the epithelium covers the posterior surface of the iris and provides the cells that constitute the dilator muscle of this diaphragm. Next to the pigment epithelium of the retina is the neuroepithelium, or rods and cones (see below). Their continuation forward is represented by a second layer of epithelial cells covering the ciliary body, so that by the ciliary epithelium is meant the two layers of cells that are the embryological equivalent of the retinal pigment epithelium and the receptor layer (rods and cones) of the retina. This unpigmented layer of the ciliary epithelium is continued forward over the back of the iris, where it acquires pigment and is called the posterior iris epithelium.

The retina. The retina is the part of the eye that receives the light and converts it into chemical energy. The chemical energy activates nerves that conduct the messages out of the eye into the higher regions of the brain. The retina is a complex nervous structure, being, in essence, an outgrowth of the forebrain.

Ten layers of cells in the retina can be seen microscopically. In general, there are four main layers: (1) Next to the choroid is the pigment epithelium, already mentioned. (2) Beneath the epithelium is the layer of rods and cones, the light-sensitive cells. The changes induced in the rods and cones by light are transmitted to (3) a layer of neurons (nerve cells) called the bipolar cells, which are analogous to the sensory neurons that carry messages from the touch and heat receptors of the skin and transmit them to the cells of the spinal cord or the medulla (the part of the brain that is a continuation of the spinal cord). These bipolar cells connect with (4) the innermost layer of neurons, the ganglion cells; and the transmitted messages are carried out of the eye along their projections, or axons, which constitute the optic nerve fibres. Thus, the optic nerve is really a central tract, rather than a nerve, connecting two regions of the nervous system, namely, the layer of bipolar cells, and the cells of the lateral geniculate body, the latter being a visual relay station in the diencephalon (the rear portion of the forebrain).

The arrangement of the retinal cells in an orderly manner gives rise to the outer nuclear layer (layer 4 in Figure 41), containing the nuclei of the rods and cones; the inner nuclear layer (layer 6), containing the nuclei and perikarya (main cell bodies outside the nucleus) of the bipolar cells, and the ganglion cell layer (layer 8), containing the corresponding structures of the ganglion cells. The plexiform layers are regions in which the neurons make their interconnections. Thus, the outer plexiform layer (layer 5) contains the rod and cone projections terminating as the rod spherule and cone pedicle; these make connections with the dendritic processes of the bipolar cells, so that changes produced by light in the rods and cones are transmitted by way of these connections to the bipolar cells. (The dendritic process of a nerve cell is the projection that receives nerve impulses to the cell; the axon is the projection that carries impulses from the cell.) In the inner plexiform layer (layer 7) are the axons of the bipolar cells and the dendritic processes of the ganglion and amacrine cells (see below). The association is such as to allow messages in the bipolar cells to be transmitted to the ganglion cells, the messages then passing out along the axons of the ganglion cells as optic nerve messages.

The rods and cones

The photosensitive cells are, in the human and in most vertebrate retinas, of two kinds, called rods and cones, the rods being usually much thinner than the cones but both being built up on the same plan. The light-sensitive pigment is contained in the outer segment (layer 2), which rests on the pigment epithelium (layer 1). Through the other end, called the synaptic body, effects of light are

transmitted to the bipolar and horizontal cells. When examined in the electron microscope, the outer segments of the rods and cones are seen to be composed of stacks of disks, apparently made by the infolding of the limiting membrane surrounding the outer segment; the visual pigment, located on the surfaces of these disks, is thus spread over a very wide area, and this contributes to the efficiency with which light is absorbed by the visual cell.

The arrangement of the retina makes it necessary for light to pass through the layers not sensitive to light first before it reaches the light-sensitive rods and cones. The optical disadvantages of this arrangement are largely overcome by the development of the fovea centralis, a localized region of the retina, close to the optic axis of the eye, where the inner layers of the retina are absent. The result is a depression, the foveal pit, where light has an almost unrestricted passage to the light-sensitive cells. It is essentially this region of the retina that is employed for accurate vision, the eyes being directed toward the objects of regard so that their images fall in this restricted region. If the object of interest is large, so as to subtend a large angle, then the eye must move rapidly from region to region so as to bring their images successively onto the fovea; this is typically seen during reading. In the central region of the fovea there are cones exclusively; toward its edges, rods also occur, and as successive zones are reached the proportion of rods increases while the absolute density of packing of the receptors tends to decrease. Thus, the central fovea is characterized by an exclusive population of very densely packed cones; here, also, the cones are very thin and in form very similar to rods. The region surrounding the fovea is called the parafovea; it stretches about 1,250 microns from the centre of the fovea, and it is here that the highest density of rods occurs. Surrounding the parafovea, in turn, is the perifovea, its outermost edge being 2,750 microns from the centre of the fovea; here the density of cones is still further diminished, the number being only 12 per hundred microns compared with 50 per hundred microns in the most central region of the fovea. In the whole human retina there are said to be about 7,000,000 cones and from 75,000,000 to 150,000,000 rods.

Retinal organization

The fovea is sometimes referred to as the macula lutea ("yellow spot"); actually this term defines a rather vague area, characterized by the presence of a yellow pigment in the nervous layers, stretching over the whole central retina; *i.e.,* the fovea, parafovea, and perifovea.

The blind spot in the retina corresponds to the optic papilla, the region on the nasal side of the retina through which the optic nerve fibres pass out of the eye.

Although the rods and cones may be said to form a mosaic, the retina is not organized in a simple mosaic fashion in the sense that each rod or cone is connected to a single bipolar cell that itself is connected to a single ganglion cell. There are only about 1,000,000 optic nerve fibres, while there are at least 150,000,000 receptors, so that there must be considerable convergence of receptors on the optic pathway. This means that there will be considerable mixing of messages. Furthermore, the retina contains additional nerve cells besides the bipolar and ganglion cells; these, the horizontal and amacrine cells, operate in the horizontal direction, allowing one area of the retina to influence the activity of another. In this way, for example, the messages from one part of the retina may be suppressed by a visual stimulus falling on another, an important element in the total of messages sent to the higher regions of the brain. Finally, it has been argued that some messages may be running the opposite way; they are called centrifugal and would allow one layer of the retina to affect another, or higher regions of the brain to control the responses of the retinal neurons. In primates the existence of these centrifugal fibres has been finally disproved, but in such lower vertebrates as the pigeon, their existence is quite certain.

The pathway of the retinal messages through the brain is described later in this article; it is sufficient to state here that most of the optic nerve fibres in primates carry their messages to the lateral geniculate body, a relay station specifically concerned with vision. Some of the fibres separate from the main stream and run to a midbrain centre called the pretectal nucleus, which is a relay centre for pupillary responses to light.

Secretion and course of aqueous humour

The transparent media. Within the cavities enclosed by the three layers of the globe described above there are the aqueous humour in the anterior and posterior chambers; the crystalline lens behind the iris; and the vitreous body, which fills the large cavity behind the lens and iris (Figure 39).

The aqueous humour. The aqueous humour is a clear colourless fluid with a chemical composition rather similar to that of blood plasma (the blood exclusive of its cells) but lacking the high protein content of the latter. Its main function is to keep the globe reasonably firm. It is secreted continuously by the ciliary body into the posterior chamber, and flows as a gentle stream through the pupil into the anterior chamber, from which it is drained by way of a channel at the limbus; that is, the juncture of the cornea and the sclera. This channel, the canal of Schlemm, encircles the cornea and connects by small connector channels to the blood vessels buried in the sclera and forming the intrascleral plexus or network. From this plexus the blood, containing the aqueous humour, passes into more superficial vessels; it finally leaves the eye in the anterior ciliary veins. The relation of the canal of Schlemm to the aqueous humour is clear from Figure 40. The wall of the canal that faces the aqueous humour is very delicate and allows the fluid to percolate through by virtue of the relatively high pressure of the fluid within the eye. Obstruction of this exit, for example, if the iris is pushed forward to cover the wall of the canal, causes a sharp rise in the pressure within the eye, a condition that is known as glaucoma. Often the obstruction is not obvious, but is caused perhaps by a hardening of the tissue just adjacent to the wall of the canal—the trabecular meshwork (Figure 40), in which case the rise of pressure is more gradual and insidious. Ultimately the abnormal pressure damages the retina and causes a variable degree of blindness. The normal intraocular pressure is about 15 millimetres (0.6 inch) of mercury above atmospheric pressure, so that if the anterior chamber is punctured by a hypodermic needle the aqueous humour flows out readily. Its function in maintaining the eye reasonably hard is seen by the collapse and wrinkling of the cornea when the fluid is allowed to escape. An additional function of the fluid is to provide nutrition for the crystalline lens and also for the cornea, both of which are devoid of blood vessels; the steady renewal and drainage serve to bring into the eye various nutrient substances, including glucose and amino acids, and to remove waste products of metabolism.

The vitreous body. The vitreous body is a jelly. It is remarkable for the small amount of solid matter required to give it this semisolid structure; the solid material is made up of a form of collagen, vitrosin, and a mucopolysaccharide, hyaluronic acid. Thus, its composition is rather similar to that of the cornea, but the proportion of water is much greater, about 98 percent or more, compared with about 75 percent for the cornea. The jelly is probably secreted by certain cells of the retina. In general, the vitreous body is devoid of cells, in contrast with the lens, which is packed tight with cells. Embedded in the surface of the vitreous body, however, there is a population of specialized cells, the hyalocytes of Balazs, which may contribute to the breakdown and renewal of the hyaluronic acid. The vitreous body serves to keep the underlying retina pressed against the choroid.

The crystalline lens. The lens is a transparent body, flatter on its anterior than on its posterior surface, and suspended within the eye by the zonular fibres of Zinn attached to its equator; its anterior surface is bathed by aqueous humour, and its posterior surface by the vitreous body. The lens is a mass of tightly packed transparent fibrous cells, the lens fibres, enclosed in an elastic collagenous capsule. The lens fibres are arranged in sheets that form successive layers; the fibres run from pole to pole of the lens, the middle of a given fibre being in the equatorial region. On meridional (horizontal) section, the fibres are cut longitudinally to give an onion-scale appearance, whereas a section at right-angles to this—an equatorial section—would cut all the fibres across, and the result would be to give a honeycomb appearance. The epithelium, covering the anterior surface of the lens under the capsule, serves as the origin of the lens fibres, both during embryonic and fetal development and during infant and adult life, the lens continuing to grow by the laying down of new fibres throughout life.

The visual process

THE WORK OF THE AUXILIARY STRUCTURES

The protective mechanisms. The first line of protection of the eyes is provided by the lids, which prevent access of foreign bodies and assist in the lubrication of the corneal surface. Lid closure and opening are accomplished by the orbicularis oculi and levator palpebri muscles; the orbicularis oculi operates on both lids, bringing their margins into close apposition in the act of lid closure. Opening results from relaxation of the orbicularis muscle and contraction of the levator palpebri of the upper lid; the smooth muscle of the upper lid, Müller's muscle, or the superior palpebral muscle, also assists in widening the lid aperture. The lower lid does not possess a muscle corresponding to the levator of the upper lid, and the only muscle available for causing an active lowering of the lid, required during the depression of the gaze, is the inferior palpebral muscle, which is analogous to the muscle of Müller of the upper lid (called the superior palpebral muscle). This inferior palpebral muscle is so directly fused with the sheaths of the ocular muscles that it provides cooperative action, opening of the lid on downward gaze being mediated, in effect, mainly by the inferior rectus.

Blinking

Innervation. The seventh cranial nerve—the facial nerve—supplies the motor fibres for the orbicularis muscle. The levator is innervated by the third cranial nerve—the oculomotor nerve—that also innervates some of the extraocular muscles concerned with rotation of the eyeball, including the superior rectus. The smooth muscle of the eyelids and orbit is activated by the sympathetic division of the autonomic system. The secretion of adrenaline during such states of excitement as fear would also presumably cause contraction of the smooth muscle, but it seems unlikely that this would lead to the protrusion of the eyes traditionally associated with extreme fear. It is possible that the widening of the lid aperture occurring in this excited state, and dilation of the pupil, create the illusion of eye protrusion.

Blinking is normally an involuntary act, but may be carried out voluntarily. The more vigorous "full closure" of the lids involves the orbital portion of the orbicularis muscle and may be accompanied by contraction of the facial muscles that have been described as accessory muscles of blinking: namely, the corrugator supercilii, which on contraction pulls the eyebrows toward the bridge of the nose; and the procerus or pyramidalis, which pulls the skin of the forehead into horizontal folds, acting as a protection when the eyes are exposed to bright light. The more vigorous full closure may be evoked as a reflex response.

Voluntary full closure of lids

Blink reflexes. Reflex blinking may be caused by practically any peripheral stimulus, but the two functionally significant reflexes are (1) that resulting from stimulation of the endings of the fifth cranial nerve in the cornea, lid, or conjunctiva—the sensory blink reflex, or corneal reflex—and (2) that caused by bright light—the optical blink reflex. The corneal reflex is rapid (0.1 second reflex time) and is the last to disappear in deepening anesthesia, impulses being relayed from the nucleus of the fifth nerve to the seventh cranial nerve, which transmits the motor impulses. The reflex is said to be under the control of a medullary centre. The optical reflex is slower; in man, the nervous pathway includes the visual cortex (the outer substance of the brain; the visual centre is located in the occipital—rear—lobe). The reflex is absent in children of less than nine months.

Normal rhythm. In the waking hours the eyes blink fairly regularly at intervals of two to 10 seconds, the actual rate being a characteristic of the individual. The function of this is to spread the lacrimal secretions over the cornea. It might be thought that each blink would be reflexly determined by a corneal stimulus—drying and irritation—but extensive studies indicate that this view is wrong; the normal blinking rate is apparently determined by the activity of a "blinking centre" in the globus pallidus of the caudate nucleus, a mass of nerve cells between the base and the outer substance of the brain. This is not to deny that the blink rate is modified by external stimuli.

There is a strong association between blinking and the action of the extraocular muscles. Eye movement is generally accompanied by a blink, and it is thought that this aids the eyes in changing their fixation point.

Secretion of tears. The exposed surface of the globe (eyeball) is kept moist by the tears secreted by the lacrimal apparatus, together with the mucous and oily secretions of the other secretory organs and cells of the lids and conjunctiva; these have been described earlier. The secretion produces what has been called the precorneal film, which consists of an inner layer of mucus, a middle layer of lacrimal secretion, and an outer oily film that reduces the rate of evaporation of the underlying watery layer. The normal daily (24-hour) rate of secretion has been estimated at about 0.75 to 1.1 grams (0.03–0.04 ounce avoirdupois); secretion tends to decrease with age. Chemical analysis of the tears reveals a typical body fluid with a salt concentration similar to that of blood plasma. An interesting component is lysozyme, an enzyme that has bactericidal action by virtue of its power of dissolving away the outer coats of many bacteria.

Tear reflexes

Tears are secreted reflexly in response to a variety of stimuli—*e.g.*, irritative stimuli to the cornea, conjunctiva, nasal mucosa; hot or peppery stimuli applied to the mouth and tongue; or bright lights. In addition, tear flow occurs in association with vomiting, coughing, and yawning. The secretion associated with emotional upset is called psychical weeping. Severing of the sensory root of the trigeminal (fifth cranial) nerve prevents all reflex weeping, leaving psychical weeping unaffected; similarly, the application of cocaine to the surface of the eye, which paralyzes the sensory nerve endings, inhibits reflex weeping, even when the eye is exposed to potent tear gases. The afferent (sensory) pathway in the reflex is thus by way of the fifth cranial, or the trigeminal nerve. The motor innervation is by way of the autonomic (involuntary) division; the parasympathetic supply derived from the facial nerve (the seventh cranial nerve) seems to have the dominant motor influence. Thus, drugs that mimic the parasympathetic, such as acetylcholine, provoke secretion, and secretion may be blocked by such typical anticholinergic drugs as atropine. Innervation of the lacrimal gland is not always complete at birth, so that the newborn infant is generally said to cry without weeping. Because absence of reflex tearing fails to produce any serious drying of the cornea, and surgical destruction of the main lacrimal gland is often without serious consequences, it seems likely that the subsidiary secretion from the accessory lacrimal glands is adequate to keep the cornea moist. The reflex secretion that produces abundant tears may be regarded as an emergency response.

A drainage mechanism for tears is necessary only during copious secretion. The mechanism, described as the lacrimal pump, consists of alternately negative and positive pressure in the lacrimal sac caused by the contraction of the orbicularis muscle during blinking.

Movements of the eyes. Because only a small portion of the retina, the fovea, is actually employed for distinct vision, it is vitally important that the motor apparatus governing the direction of gaze be extremely precise in its operation, and rapid. Thus, the gaze must shift swiftly and accurately during the process of reading. Again, if the gaze must remain fixed on a single small object—*e.g.,* a golf ball—the eyes must keep adjusting their gaze to compensate for the continuous small movements of the head and to maintain the image exactly on the fovea. The extraocular muscles that carry out these movements are under voluntary control; thus, the direction of regard can be changed deliberately. Most of the actual movements of the eyes are carried out without awareness, however, in response to movements of the objects in the environment, or in response to movements of the head or the rest of the body, and so on. In examining the mechanisms of the eye movements, then, one must resolve them into a number of reflex responses to changes in the environment or the individual, remembering, of course, that there is an overriding voluntary control.

Centring images on the fovea

The axes of the eye. It is worthwhile at this point to define certain axes of the eyes employed during different types of study. The optic axis of the eye is a line drawn through the centre of the cornea and the nodal (central) point of the eye; it actually does not intersect with the retina at the centre of the fovea as might be expected, but toward the nose from this, so that there is an angle of about five degrees between (1) the visual axis—the line joining the point fixated (the point toward which the gaze is directed) and the nodal point—and (2) the optic axis.

Actions of muscles. The general modes of action of the six extraocular muscles have been described in connection with their anatomy: rotation of the eye toward the nose is carried out by the medial rectus; outward movement is by the lateral rectus. Upward movements are carried out by the combined actions of the superior rectus and the inferior oblique muscles, and downward movements by the inferior rectus and the superior oblique. Intermediate directions of gaze are achieved by combined actions of several muscles. When the two eyes act together, as they normally do, and change their direction of gaze to the left, for example, the left eye rotates away from the nose by means of its lateral rectus, while the right eye turns toward the nose by means of its medial rectus. These muscles may be considered as a linked pair; that is, when they are activated by the central nervous system this occurs conjointly and virtually automatically. This linking of the muscles of the two eyes is an important physiological feature and has still more important pathological interest in the analysis of squint, when the two eyes fail to be directed at the same point.

Binocular movements. The binocular movements (the movements of the two eyes) fall into two classes, the conjugate movements, when both eyes move in the same direction, as in a change in the direction of gaze, and disjunctive movements, when the eyes move in opposite directions. Thus, during convergence onto a near object both eyes move toward the nose; the movement is horizontal, but disjunctive, by contrast with the conjugate movement when both eyes move, say, to the right. The disjunctive movement of convergence can be carried out voluntarily, but the act is usually brought about reflexly in response to the changed optical situation—*i.e.,* the nearness of the object of gaze. A seesaw movement of the eyes, whereby one eye looks upward and the other downward, is possible, but not voluntarily; to achieve this a prism is placed in front on one eye so that the object seen through it appears displaced upward or downward; the other eye sees the object where it is. The result of such an arrangement is that, unless the eye with the prism in front makes an upward or downward movement, independent of the other, the images will not fall on corresponding parts of the retinas in the two eyes. Such a noncorrespondence of the retinal images causes double vision; to avoid this, there is an adjustment in the alignment of the eyes so that a seesaw movement is actually executed. In a similar way, the eyes may be made to undergo torsion, or rolling. A conjugate torsion, in which both eyes rotate about their anteroposterior (fore-and-aft) axes in the same sense, occurs naturally; for example, when the head tips toward one shoulder the eyes tend to roll in the opposite direction, with the result that the image of the visual field on the retina tends to remain vertical in spite of the rotation of the head.

Conjugate and disjunctive movements

Nervous control. The nerves controlling the actions of the muscles are the third, fourth, and sixth cranial nerves, with their bodies (nuclei) in the brainstem; the third, or oculomotor nerve, controls the superior and inferior recti, the medial rectus, and inferior oblique; the fourth cranial nerve, the trochlear nerve, controls the superior oblique; and the sixth, the abducens nerve, controls the lateral rectus. The nuclei of these nerves are closely associated; especially, there are connections between the nuclei of the sixth cranial nerve, controlling the lateral rectus, and the nucleus of the third, controlling the medial rectus; it is through this close relationship that the linking of the lateral rectus of one eye and the medial rectus of the other, indicated above, is achieved. Another type of linking is concerned with reciprocal inhibition; that is, when there are two antagonistic muscles, such as the medial and the lateral rectus, contraction of one is accompanied by a simultaneous inhibition of the other. Muscles show a continuous slight activity even when at rest; this keeps them taut; this action, called tonic activity, is brought about by discharges in the motor nerve to the muscle. Hence, when the agonist muscle contracts its antagonist must be inhibited.

Reflex pathways. In examining any reflex movement one must look for the sensory input—*i.e.,* the way in which messages in sensory nerves bring about discharges in the motor nerves to the muscles; this study involves the connections of the motor nerves or nuclei with other centres of the brain.

When a subject is looking straight ahead and a bright light appears in the periphery of his field of vision, his eyes automatically turn to fix on the light; this is called the fixation reflex. The sensory pathway in the reflex arc leads as far as the cerebral cortex because removal of the occipital cortex (the outer brain substance at the back of the head) abolishes reflex eye movements in response to light stimuli. If the occipital cortex is stimulated electrically, movements of the eyes may be induced, and in fact one may draw a pattern of the visual field on the occipital cortex corresponding with the directions in which the gaze is turned when given points on the cortex are stimulated. This pattern corresponds with the pattern obtained by recording the visual responses to light stimuli from different parts of the visual field.

Fixation reflex

The remainder of the pathway—*i.e.,* from the occipital cortex to the motor neurons in the brainstem—has long been considered to involve the superior colliculi as relay stations, and they certainly have such a role in lower animals; but in human beings a pathway from the cortex to the eye-muscle nuclei independent of the superior colliculi of the midbrain is now generally assumed.

Continual movements of the eyes occur even when an effort is made to maintain steady fixation of an object. Some of these movements may be regarded as manifestations of the fixation reflex; thus, the eyes tend to drift off their target, and, because of this, the fixation reflex comes into play, bringing the eyes back on target.

Nystagmus

Experimentally, the fixation reflex can be studied by observation of the regular to-and-fro movements of the eyes as they follow a rotating drum striped in black and white. (Such movements of the eyes directed at a moving object are called optokinetic nystagmus; nystagmus itself is the involuntary movement of the eye back and forth, up and down, or in a rotatory or a mixed fashion.) While the eyes watch the moving drum, they involuntarily make a slow movement as a result of fixing their gaze on a particular stripe. At a certain point, fixation is broken off, and the eyes spring back to fix on a new stripe. Thus, the nystagmus consists of a slow movement with angular velocity equal to that of the rotation of the drum, then a fast saccade, or jump from one point of fixation to another, in the opposite direction; the process is repeated indefinitely.

Another type of nystagmus reveals the play of another set of reflexes. These are mediated by the semicircular canals—*i.e.,* the organs of balance or the vestibular apparatus. Such a reflex may be evoked by rotating the subject in a chair at a steady speed; the eyes move slowly in the opposite direction to that of rotation and, at the end of their excursion, jump back with a fast saccade in the direction of rotation. If rotation suddenly ceases, the eyes go into a nystagmus in the opposite direction, the postrotatory nystagmus.

During rotation, certain semicircular canals are being stimulated, and the important point is that any acceleration of the head that stimulates these canals will cause reflex movements of the eyes; thus, acceleration of the head to the right causes a movement of the eyes to the left, the function of the reflex being to enable the eyes to maintain steady fixation of an object despite movements of the head. The reflex occurs even when the eyes are shut, and, when the eyes are open, it obviously cooperates with the fixation reflex in maintaining steady fixation. In many lower animals this connection between organs of balance and eyes is very rigid; thus, one may move the tail of a fish, and its eyes will move reflexly. In man, not only do the semicircular canals function in close relation to the eye muscles but so also do the gravity organ—the utricle—and the stretch receptors in the muscles of the neck. Thus, when the head is turned upward, there is a reflex tendency for the eyes to move downward, even if the eyes are shut. The actual movement is probably initiated by the reflex from the semicircular canals, which respond to acceleration, but the maintenance of the position is brought about by a reflex through the stretch of the neck muscles and also through the pull of gravity on the utricle, or otolith organ, in the inner ear.

Voluntary centre. The eyes are under voluntary control, and it is thought that the cortical area subserving voluntary eye movements is in the frontal cortex. Stimulation of this in primates causes movements of the eyes that are well coordinated, and a movement induced by this region prevails over one induced by stimulation of the occipital cortex. The existence of a separate centre in man is revealed by certain neurological disorders in which the subject is unable to fixate voluntarily but can do so reflexly; *i.e.,* he can follow a moving light.

The nature of eye movements. So far, the relation of the movements of the eyes to the requirements of the visual apparatus and their control have been touched upon. To examine the character of the movements in some detail requires rapid, accurate measurement of the movements that the eyes undergo. Modern studies of this subject employ a contact lens fitting on to the globe; on the lens is a small plane mirror, and a parallel bundle of rays is reflected off this mirror onto a moving film.

By the use of refined methods of measuring the position of the eyes at any moment, it becomes immediately evident that the eyes are never stationary for more than a fraction of a second; the movements are of three types: (1) irregular movements of high frequency (30–70 per second) and small excursions of about 20 seconds of arc; (2) flicks, or saccades, of several minutes of arc occurring at regular intervals of about one second; and between these saccades there occur (3) slow irregular drifts extending up to six minutes of arc. The saccades are corrective, serving to bring the fixation axis on the point of regard after this has drifted away from it too far, and thus are a manifestation of the fixation reflex.

The significance of these small movements during fixation was revealed by studies on the stabilized retinal image: by a suitable optical device the image of an object could be held stationary on the retina in spite of the movements of the eye. It was found that under these conditions the image would disappear within a few seconds. Thus, the movements of the eye are apparently necessary to allow the contours of the image to fall on a new set of rods and cones at repeated intervals; if this does not occur, the retina adapts to their stimulus and ceases to send messages to the central nervous system. The small flicks mentioned above are essentially the same as the larger movement made when the two eyes fixate (fix on) a light when it suddenly appears in the peripheral field; this is given the general name of the saccade, to distinguish it from the slower movements occurring during convergence and smooth following. The dynamics of the saccade have been studied in some detail by several workers. There is a reaction time of about 120 to 180 milliseconds, after which both eyes move simultaneously; there is a definite overshoot and, with an excursion of 20°, the operation is completed in about 90 milliseconds. The maximum velocity increases with the extent of the movement, being 300° per second for 10° and 500° per second for 30°. A remarkable feature is the apparent absence of significant inertia in the eyeball, so that movement is halted, not by any checking action of antagonistic muscles but simply by cessation of contraction of the agonists; thus, the movement is not ballistic. Once under way, the saccade is determined in amount, so that the subject cannot voluntarily alter its direction and extent. The control mechanism for the saccadic type of movement can be described as a sampled data system, *i.e.,* the brain makes discontinuous samples of the position of the eyes in relation to the target and corrects the error, in contrast to a continuous feedback system that takes account of the error all the time.

The saccade, disjunctive movements, and tracking

The movements of the eyes when they converge onto a near object are in remarkable contrast to the saccade; the angular velocity is only about 25° per second, compared with values as high as 500° per second in the saccade. The great difference in speed suggested to two investigators that the two movements are executed by different muscle fibres. In fact, the extraocular muscles do contain two types of muscle fibre with characteristically different nerve supplies, and some recent studies tend to support this view of a dual mechanism.

If a moving light suddenly appears in the field of view, and if its rate of movement is less than about 30° per second, the response of the eyes is remarkably efficient; a saccade brings the eyes on target, and they follow the motion at almost exactly the same angular velocity as that of the target; inaccuracies in following lead to corrective saccades. When the rate of movement of the target is greater than about 30° per second, these corrective saccades become more obvious because now smooth following is not possible; the eyes make constant-velocity movements, but the velocity rarely matches that of the moving target, so that there must be frequent corrective saccades. Studies have shown that the following movements are highly integrated and must involve a continuous feedback system whereby errors are used to modify the performance. Thus, the systems for control of saccades and tracking movements are fundamentally different.

Vision suppression during a saccade. If one looks into a mirror and fixates one of one's eyes and then fixates the other, one does not see the eyes moving; and it has been argued that, during an eye movement, vision is suppressed; if vision were not suppressed, moreover, it seems likely that the images of the external world would appear smeared during a movement. Experimental studies have shown that there is, indeed, a suppression of vision during a saccade.

THE WORK OF THE OPTICAL LENS SYSTEM

Refraction by cornea and lens. The optical system of the eye is such as to produce a reduced inverted image of the visual field on the retina; the system behaves as a convex lens but is, in fact, much more complex, refraction taking place not at two surfaces, as in a lens, but at four separate surfaces—at the anterior and the posterior surfaces of the cornea and of the crystalline lens. Each of these surfaces is approximately spherical, and at each optical interface—*e.g.,* between air and the anterior surface of the cornea—the bending of a ray of light is toward the axis, so that, in effect, there are four surfaces tending to make rays of light converge on each other. If the rays of light falling on the cornea are parallel—*i.e.,* if they come from a distant point—the net effect of this series of refractions at the four surfaces is to bring these rays to a point focus of the optical system, which in the normal, or emmetropic, eye corresponds with the retina. The greatest change of direction, or bending of the rays, occurs where the difference of refractive index is greatest, and this is when light passes from air into the cornea, the refractive index of the corneal substance being 1.3376; the refractive indices of the cornea and aqueous humour are not greatly different, that of the aqueous humour being 1.336 (as is that of the vitreous); thus, the bending, as the rays meet the concave posterior surface of the cornea and emerge into a medium of slightly less refractive index, is small. The lens has a greater refractive index than that of its surrounding aqueous humour and vitreous body, 1.386 to 1.406, so that its two surfaces contribute to convergence, the posterior surface normally more than the anterior surface because of its greater curvature (smaller radius).

Four refractive surfaces

Normal sightedness and near- and farsightedness. In contrast to the focussing of the normal (emmetropic) eye, in which the image of the visual field is focussed on the retina, the image may be focussed in front of the retina (nearsightedness, or myopia), or behind the retina (farsightedness or hyperopia). In myopia the vision of distant objects is not distinct because the image of a distant point falls within the vitreous and the rays spread out to form a blur circle on the retina instead of a point. In this condition the eye is said to have too great dioptric (refractive) power for its length. When the focus falls behind the retina, the image of the distant point is again a circle on the retina; and the farsighted eye is said to have too little dioptric power. The important point to appreciate is that emmetropia, or normal sight, requires that the focal power of the dioptric system be matched to the axial length of the eye; it certainly is remarkable that emmetropia is indeed the most common condition when it is appreciated that just one millimetre of error in the matching of axial length with focal length would cause a person to require a spectacle correction. In general, however, the effects of variations in dimensions tend to compensate each other. Thus, for example, an unusually large eye might, at first thought, be expected to be myopic, but a large eye tends to be associated with a large radius of curvature of the cornea, and this would reduce the power—*i.e.,* increase the focal length—and so an unusually large eye is not necessarily a myopic one.

Accommodation. *Effects of accommodation.* The image of an object brought close to the eye would be formed behind the retina if there were no change in the focal length of the eye. This change to bring the image of an object upon the retina is called accommodation. The point nearer than which accommodation is no longer effective is called the near point of accommodation. In very young people, the near point of accommodation is quite close to the eye, namely about seven centimetres (about three inches) in front at 10 years old; at 40 years the distance has increased to about 16 centimetres (about 6 inches), and at 60 years it is 100 centimetres or one metre (39 inches). Thus, a 60-year-old would not be able to read a book held at the convenient distance of about 40 centimetres (16 inches), and the extra power required would have to be provided by convex lenses in front of the eye, an arrangement called the presbyopic correction.

The near point of accommodation

Mechanism of accommodation. It is essentially an increase in curvature of the anterior surface of the lens that is responsible for the increase in power involved in the process of accommodation. A clue to the way in which this change in shape takes place is given by the observation that a lens that has been taken out of the eye is much rounder and fatter than one within the eye; thus, its attachments by the zonular fibres to the ciliary muscle within the eye preserve the unaccommodated or flattened state of the lens; and modern investigations leave little doubt that it is the pull of the zonular fibres on the elastic capsule of the lens that holds the anterior surface relatively flat. When these zonular fibres are loosened, the elastic tension in the capsule comes into play and remolds the lens, making it smaller and thicker. Thus, the physiological problem is to find what loosens the zonular fibres during accommodation. The ciliary muscle has been described earlier, and it has been shown that the effect of contracting its fibres is, in general, to pull the whole ciliary body forward and to move the anterior region toward the axis of the eye by virtue of the sphincter action of the circular fibres. Both of these actions will slacken the zonular fibres and therefore allow the change in shape. As to why it is the anterior surface that changes most is not absolutely clear, but it is probably a characteristic of the capsule rather than of the underlying lens tissue. Defective accommodation in presbyopia is not due to a failure of the ciliary muscle but rather to a hardening of the substance of the lens with age to the point that readjustments of its shape become ever more difficult.

Nerve action. Accommodation is an involuntary reflex act, and the ciliary muscle belongs to the smooth involuntary class. Appropriate to this, the innervation is through the autonomic system, the parasympathetic nerve cells belonging to the oculomotor nerve (the third cranial nerve) occupying a special region of the nucleus in the midbrain called the Edinger-Westphal nucleus; the fibres have a relay point in the ciliary ganglion in the eye socket, and the postganglionic fibres enter the eye as the short ciliary nerves. The stimulus for accommodation is the nearness of the object, but the manner in which this nearness is translated into a stimulus is not clear. Thus, the fact that the image is blurred is not sufficient to induce accommodation; the eye has some power of discriminating whether the blurredness is due to an object being too far away or too close, so that something more than mere blurredness is required.

The pupil. The amount of light entering the eye is restricted by the aperture in the iris, the pupil.

When a person is in a dark room his pupil is large, perhaps eight millimetres (0.3 inch) in diameter, or more. When the room is lighted there is an immediate constriction of the pupil, the light reflex; this is bilateral, so that even if only one eye is exposed to the light both pupils contract to nearly the same extent. After a time the pupils expand even though the bright light is maintained, but the expansion is not large. The final state is determined by the actual degree of illumination; if this is high, then the final state may be a diameter of only about three to four millimetres (about 0.15 inch); if it is not so high, then the initial constriction may be nearly the same, but the final state may be with a pupil of four to five millimetres (about 0.18 inch). During this steady condition, the pupils do not remain at exactly constant size; there is a characteristic oscillation in size that, if exaggerated, is called hippus.

The light and near reflexes

A pupillary constriction will also occur when a person looks at a near object—the near reflex. Thus, accommodation and pupillary constriction occur together reflexly and are excited by the same stimulus. The function of the pupil is clearly that of controlling the amount of light entering the eye, and hence the light reflex. The constriction occurring during near vision suggests other functions, too; thus, the aberrations of the eye (failure of some refracted rays to focus on the retina) are decreased by reducing the aperture of its optical system. In the dark, aberrations are of negligible significance, so that a person is concerned only with allowing as much light into the eye as possible; in bright light high visual acuity is usually required, and this means reducing the aberrations. The depth of focus of the optical system is increased when the aperture is reduced, and the near reflex is probably concerned with increasing depth of focus under these conditions.

Dilation of the pupil occurs as a result of strong psychical stimuli and also when any sensory nerve is stimulated; dilation thus occurs in extreme fear and in pain.

Neuromuscular mechanisms. The muscles of the iris have been described earlier. It is clear from their general features that constriction of the pupil is brought about by shortening of the circular ring of fibres—the sphincter; dilation is brought about by shortening of the radially oriented fibres. The sphincter is innervated by parasympathetic fibres of the oculomotor nerve, with their cell bodies in the Edinger-Westphal nucleus, as are the nerve cells controlling accommodation; thus, the close association between the accommodation and pupillary reflexes is reflected in a close anatomical contiguity of their motor nerve cells.

The sensory pathway in the light reflex involves the rods and cones, bipolar cells, and ganglion cells. As indicated earlier, a relay centre for pupillary responses to light is the pretectal nucleus in the midbrain. There is a partial crossing-over of the fibres of the pretectal nerve cells so that some may run to the motor nerve cells in the Edinger-Westphal nucleus of both sides of the brain, and it is by this means that illumination of one eye affects the other. The Edinger-Westphal motor neurons have a relay point in the ciliary ganglion, a group of nerve cells in the eye socket, so that its electrical stimulation causes both accommodation and pupillary constriction; similarly, application of a drug, such as pilocarpine, to the cornea will cause a constriction of the pupil and also a spasm of accommodation; atropine, by paralyzing the nerve supply, causes dilation of the pupil and paralysis of accommodation (cycloplegia).

Dilator response

The dilator muscle of the iris is activated by sympathetic nerve fibres. Stimulation of the sympathetic nerve in the neck causes a powerful dilation of the iris; again, the influx of adrenalin into the blood from the adrenal glands during extreme excitement results in pupillary dilation.

Many involuntary muscles receive a double innervation, being activated by one type of nerve supply and inhibited by the other; modern experimentation indicates that the iris muscles are no exception, so that the sphincter has an inhibitory sympathetic nerve supply, while the dilator has a parasympathetic (cholinergic) inhibitor. Thus, a drug like pilocarpine not only activates the constrictor muscle but actively inhibits the dilator. A similar double innervation has been described for the ciliary muscle. In general, any change in pupillary size results from a reciprocal innervation of dilator and constrictor; thus, activation of the constrictor is associated with inhibition of the dilator and vice versa.

The near response. In general, as has been indicated, pupillary constriction and accommodation occur together, in response to the same stimulus; a third element in this near response is, of course, the convergence (turning in) of the eyes, mediated by voluntary muscles, the medial recti. Experimentally, it is often possible to separate these activities, in the sense that one may cause convergence without accommodation by placing appropriate prisms in front of the eyes; or one may cause accommodation without convergence by placing diverging lenses in front of the eyes. There are many experiments that show that accommodation and convergence are neurologically linked to some extent, however.

THE WORK OF THE RETINA

Some basic facts of vision. So far, attention has been directed to what are essentially the preliminaries to vision; it is now time to examine some of the elementary facts of vision and to relate them to the structure of the retina and, later, to chemically identifiable events.

Measurement of the threshold. An important means of measuring a sensation is to determine the threshold stimulus—*i.e.,* the minimum energy required to evoke the sensation. In the case of vision, this would be the minimum number of quanta of light entering the eye in unit time. If it is found that the threshold has altered because of a change of some sort, then this change can be said to have altered the subject's sensitivity to light, and a numerical value can be assigned to the sensitivity by use of the reciprocal of the threshold energy. Practically, a subject may be placed in the dark in front of a white screen, and the screen may be illuminated by flashes of light; for any given intensity of illumination of the screen, it is not difficult to calculate the flow of light energy entering the eye. One may begin with a low intensity of flash and increase this successively until the subject reports that he can see the flash. In fact, at this threshold level, he will not see every flash presented, even though the intensity of the light is kept constant; for this reason, a certain frequency of seeing—*e.g.,* four times out of six—must be selected as the arbitrary point at which to fix the threshold.

Decline in visual threshold

When measurements of this sort are carried out, it is found that the threshold falls progressively as the subject is maintained in the dark room. This is not due to dilation of the pupil because the same phenomenon occurs if the subject is made to look through an artificial pupil of fixed diameter. The eye, after about 30 minutes in the dark, may become about 10,000 times more sensitive to light. Vision under these conditions is, moreover, characteristically different from what it is under ordinary daylight conditions. Thus, in order to obtain best vision, the eye must look away from the screen so that the image of the screen does not fall on the fovea; if the screen is continuously illuminated at around this threshold level it will be found to disappear if its image is brought onto the fovea, and it will become immediately visible on looking away. The same phenomenon may be demonstrated on a moonless night if the gaze is fixed on a dim star; it disappears on fixation and reappears on looking away. This feature of vision under these near-threshold or scotopic conditions suggests that the cones are effectively blind to weak light stimuli, since they are the only receptors in the fovea.

Duplicity theory of vision

This is the basis of the duplicity theory of vision, which postulates that when the light stimulus is weak and the eye has been dark-adapted, it is the rods that are utilized because, under these conditions, their threshold is much lower than that of the cones. When the subject first enters the dark, the rods are the less sensitive type of receptor, and the threshold stimulus is the light energy required to stimulate the cones; during the first five or more minutes the threshold of the cones decreases; *i.e.,* they become more sensitive. The rods then increase their sensitivity to the point that they are the more sensitive, and it is they that now determine the sensitivity of the whole eye, the threshold stimuli obtained after 10 minutes in the dark, for example, being too weak to activate the cones.

Scotopic sensitivity curve. When different wavelengths of light are employed for measuring the threshold, it is found, for example, that the eye is much more sensitive to blue-green light than to orange. The interesting feature of this kind of study is that the subject reports only that the light is light; he distinguishes no colour. If the intensity of a given wavelength of light is increased step by step above the threshold, a point comes when the subject states that it is coloured, and the difference between the threshold for light appreciation and this, the chromatic threshold, is called the photochromatic interval. This suggests that the rods give only achromatic, or colourless, vision, and that it is the cones that permit wavelength discrimination. The photochromatic interval for long wavelengths (red light) is about zero, which means that the intensity required to reach the sensation of light is the same as that to reach the sensation of colour. This is because the rods are so insensitive to red light; if the dark-adaptation curve is plotted for a red stimulus it is found that it follows the cone path, like that for foveal vision at all wavelengths.

Loss of dark adaptation. If, when the subject has become completely dark-adapted, one eye is held shut and the other exposed to a bright light for a little while, it is found that, whereas the dark-adapted eye retains its high sensitivity, that of the light-exposed eye has decreased greatly; it requires another period of dark adaptation for the two eyes to become equally sensitive.

These simple experiments pose several problems, the answers to which throw a great deal of light on the whole mechanism of vision. Why, for example, does it require time for both rods and cones to reach their maximum sensitivity in the dark? Again, why is visual acuity so low under scotopic conditions compared with that in daylight, although sensitivity to light is so high? Finally, why do the rods not serve to discriminate different wavelengths?

Bleaching of rhodopsin. It may be assumed that a receptor is sensitive to light because it contains a substance that absorbs light and converts this vibrational type of energy into some other form that is eventually transmuted into electrical changes, and that these may be transmitted from the receptor to the bipolar cell with which it is immediately connected. When the retina of a dark-adapted animal is removed and submitted to extraction procedures, a pigment, originally called visual purple but now called rhodopsin, may be obtained. If the eye is exposed to a bright light for some time before extraction, little or no rhodopsin is obtained. When retinas from animals that had been progressively dark-adapted were studied, a gradual increase in the amount of rhodopsin that could be extracted was observed. Thus, rhodopsin, on absorption of light energy, is changed to some other compound, but new rhodopsin is formed, or rhodopsin is regenerated, during dark adaptation. The obvious inference is that rhodopsin is the visual pigment of the rods, and that when it is exposed to relatively intense lights it becomes useless for vision. When the eye is allowed to remain in the dark the rhodopsin regenerates and thus becomes available for vision. There is now conclusive proof that rhodopsin is, indeed, the visual pigment for the rods; it is obtained from retinas that have only rods and no cones—*e.g.,* the retinas of the rat or guinea pig, and it is not obtained from the pure cone retina of the chicken.

Rhodopsin as the photopigment

When the absorption spectrum is measured, it is found that its maximum absorption occurs at the point of maximum sensitivity of the dark-adapted eye. Similar measurements may be carried out on animals, but the threshold sensitivity must be determined by some objective means—*e.g.,* the response of the pupil, or, better still, the electrical changes occurring in the retina in response to light stimuli. Thus, the electroretinogram (ERG) is the record of changes in potential between an electrode placed on the surface of the cornea and an electrode placed on another part of the body, caused by illumination of the eye.

The high sensitivity of the rods by comparison with the cones may be a reflection of the greater concentration in them of pigment that would permit them to catch light more efficiently, or it may depend on other factors—*e.g.,* the efficiency of transformation of the light energy into electrical energy. The pigments responsible for cone vision are not easily extracted or identified, and the problem will be considered in the material on colour vision. An important factor, so far as sensitivity is concerned, is the actual organization of the receptors and neurons in the retina.

Synaptic organization of the retina. The basic structure of the retina has been indicated earlier. As in other parts of the nervous system, the messages initiated in one element are transmitted, or relayed, to others. The regions of transmission from one cell to another are areas of intimate contact known as synapses. An impulse conveyed from one cell to another travels from the first cell body along a projection called an axon, to a synapse, where the impulse is received by a projection, called a dendrite, of the second cell. The impulse is then conveyed to the second cell body, to be transmitted further, along the second cell's axon.

It will be recalled that the functioning cells of the retina are the receptor cells—the rods and cones; the ganglion cells, the axons of which form the optic nerve; and cells that act in a variety of ways as intermediaries between the receptors and the ganglion cells. These intermediaries are named bipolar cells, horizontal cells, and amacrine cells.

Plexiform layers. As was indicated earlier, the synapses occur in definite layers, the outer and inner plexiform layers. In the outer plexiform layer the bipolar cells make their contacts, by way of their dendrites, with the rods and cones, specifically the spherules of the rods and the pedicles of the cones. In this layer, too, the projections from horizontal cells make contacts with rods, cones, and bipolar cells, giving rise to a horizontal transmission and thereby allowing activity in one part of the retina to influence the behaviour of a neighbouring part. In the inner plexiform layer, the axons of the bipolar cells make connection with the dendrites of ganglion cells, once again at special synaptic regions. (The dendrites of a nerve cell carry impulses to the nerve cell; its axon, away from the cell.) Here, too, a horizontal interconnection between bipolar cells is brought about, in this case by way of the axons and dendrites of amacrine cells.

Inner plexiform layer

The bipolar cells are of two main types: namely, those that apparently make connection with only one receptor—a cone—and those that connect to several receptors. The type of bipolar cell that connects to a single cone is called the midget bipolar. The other type of bipolar cell is called diffuse; varieties of these include the rod bipolar, the dendritic projections of which spread over an area wide enough to allow contacts with as many as 50 rods; and the flat cone bipolar, which collects messages from up to seven cones.

Ganglion cells are of two main types: namely, the midget ganglion cell, which apparently makes a unique connection with a midget bipolar cell, which in turn is directly connected to a single cone; and a diffuse type, which collects messages from groups of bipolar cells.

Convergence of the messages. The presence of diffuse bipolar and ganglion cells collecting messages from groups of receptors and bipolar cells, and, what may be even more important, the presence of lateral connections of groups of receptors and bipolar cells through the horizontal and amacrine cells, means that messages from receptors over a rather large area of the retina may converge on a single ganglion cell. This convergence means that the effects of light falling on the receptive field may be cumulative, so that a weak light stimulus spread over about 1,000 rods is just as effective as a stronger stimulus spread over 100 or less; in other words, a large receptive field will have a lower threshold than a small one; and this is, in fact, the basis for the high sensitivity of the area immediately outside the fovea, where there is a high density of rods that converge on single bipolar cells. Thus, if it is postulated that the cones do not converge to anything like the same extent as the rods, the greater sensitivity of the latter may be explained; and the anatomical evidence favours this postulate.

It has been indicated above that the regeneration of visual pigment is a cause of the increased sensitivity of the rods that occurs during dark adaptation. This, apparently, is only part of the story. An important additional factor is the change in functional organization of the retina during adaptation. When the eye is light-adapted, functional convergence is small, and sensitivity of rods and cones is low; as dark adaptation proceeds, convergence of rods increases. The anatomical connections do not change, but the power of the bipolar cells and ganglion cells to collect impulses is increased, perhaps by the removal of an inhibition that prevents this during high illumination of the retina.

Absolute threshold and minimum stimulus for vision. As was indicated earlier, the threshold is best indicated in terms of frequency of seeing since, because of fluctuations in the threshold, there is no definite luminance of a test screen at which it is always seen by the observer, and there is no luminance just below this at which it is never seen. Experiments, in which 60 percent was arbitrarily taken as the frequency of seeing and in which the image of a patch of light covered an area of retina containing about 20,000,000 rods, led to the calculation that the mean threshold stimulus represents 2,500 quanta of light that is actually absorbed per square centimetre of retina. This calculation leads to two important conclusions: namely, that at the threshold only one rod out of thousands comes into operation, and that during the application of a short stimulus the chances are that no rod receives more than a single quantum.

A quantum, defined as the product of Planck's constant (6.63×10^{-27} erg-second) times the frequency of light, is the minimum amount of light energy that can be employed. A rod excited by a single quantum cannot excite a bipolar cell without the simultaneous assistance of one or more other rods. Experiments carried out in the 1940s indicated that a stimulus of about 11 quanta is required; thus it may require 11 excited rods, each receiving one quantum of light, to produce the sensation of light.

Uncertainty principle

Quantum fluctuations. With such small amounts of energy as those involved in the threshold stimulus, the uncertainty principle becomes important; according to this, there is no certainty that a given flash will have the expected number of quanta in it, but only a probability. Thus, one may speak of a certain average number of quanta and the actual number in any given flash, and one may compute on statistical grounds the shape of curve that is obtained by plotting frequency with which a flash contains, say, four quanta or more against the average number in the flash. One may also plot the frequency with which a flash is seen against the average number of quanta in the flash, and this frequency-of-seeing curve turns out to be similar to the frequency-of-containing-quanta curve when the number of quanta chosen is five to seven, depending on the observer. This congruence strongly suggests that the fluctuations in response to a flash of the same average intensity are caused by fluctuations in the energy content of the stimulus, and not by fluctuations in the sensitivity of the retina.

Spatial summation. In spatial summation two stimuli falling on nearby areas of the retina add their effects so that either alone may be inadequate to evoke the sensation of light, but, when presented simultaneously, they may do so. Thus, the threshold luminance of a test patch required to be just visible depends, within limits, on its size, a larger patch requiring a lower luminance, and vice versa. Within a small range of limiting area, namely that subtending about 10 to 15 minutes of arc, the relationship called Ricco's law holds; *i.e.,* threshold intensity multiplied by the area equals a constant. This means that over this area, which embraces several hundreds of rods, light falling on the individual rods summates, or accumulates, its effects completely so that 100 quanta falling on a single rod are as effective as one quantum falling simultaneously on 100 rods. The basis for this summation is clearly the convergence of receptors on ganglion cells, the chemical effects of the quanta of light falling on individual rods being converted into electrical changes that converge on a single bipolar cell through its branching dendritic processes. Again, the electrical effects induced in the bipolar cells may summate at the dendritic processes of a ganglion cell so that the receptive field of a ganglion cell may embrace many thousands of rods.

Temporal summation. In temporal summation, two stimuli, each being too weak to excite, cause a sensation of light if presented in rapid succession on the same spot of the retina; thus, over a certain range of times, up to 0.1 second, the Bunsen-Roscoe law holds: namely, that the intensity of light multiplied by the time of exposure equals a constant. Thus it was found that within this time interval (up to 0.1 second), the total number of quanta required to excite vision was 130, irrespective of the manner in which these were supplied. Beyond this time, summation was still evident, but it was not perfect, so that if the duration was increased to one second the total number of quanta required was 220. Temporal summation is consistent with quantum theory; it has been shown that fluctuations in the number of quanta actually in a light flash are responsible for the variable responsiveness of the eye; increasing the duration of a light stimulus increases the probability that it will contain a given number of quanta, and that it will excite.

Inhibition. In the central nervous system generally, the relay of impulses from one nerve cell or neuron to excite another is only one aspect of neuronal interaction. Just as important, if not more so, is the inhibition of one neuron by the discharge in another. So it is in the retina. Subjectively, the inhibitory activity is reflected in many of the phenomena associated with adaptation to light or its reverse. Thus, the decrease in sensitivity of the retina to light during exposure to light is only partially accounted for by bleaching of visual pigment, be it the pigment in rod or cone; an important factor is the onset of inhibitory processes that reduce the convergence of receptors on ganglion cells. Some of the rapidly occurring changes in sensitivity described as alpha adaptation are doubtless purely neural in origin.

Many so-called inductive phenomena indicate inhibitory processes; thus, the phenomenon of simultaneous contrast, whereby a patch of light appears much darker if surrounded by a bright background than by a black, is due to the inhibitory effect of the surrounding retina on the central region, induced by the bright surrounding. Many colour-contrast phenomena are similarly caused; thus, if a blue light is projected onto a large white screen, the white screen rapidly appears yellow; the blue stimulus falling on the central retina causes inhibition of blue sensitivity in the periphery; hence, the white background will appear to be missing its blue light—white minus blue is a mixture of red and green—*i.e.,* yellow. Particularly interesting from this viewpoint are the phenomena of metacontrast; by this is meant the inductive effect of a primary light stimulus on the sensitivity of the eye to a previously presented light stimulus on an adjoining area of retina. It is a combination of temporal and spatial induction. The effect is produced by illuminating the two halves of a circular patch consecutively for a brief duration. If the left half only, for example, is illuminated for 10 milliseconds it produces a definite sensation of brightness. If, now, both halves are illuminated for the same period, but the right half from 20 to 50 milliseconds later, the left half of the field appears much darker than before and, near the centre, may be completely extinguished. The left field has thus been inhibited by the succeeding, nearby, stimulus. The right field, moreover, appears darker than when illuminated alone—it has been inhibited by the earlier stimulus (paracontrast).

Meta- and paracontrast

Flicker. Another visual phenomenon that brings out the importance of inhibition is the sensation evoked when a visual stimulus is repeated rapidly; for example, one may view a screen that is illuminated by a source of light the rays from which may be intercepted at regular intervals by rotating a sector of a circular screen in front of it. If the sector rotates slowly, a sensation of black followed by white is aroused; as the speed increases the sensation becomes one of flicker—*i.e.,* rapid fluctuations in brightness; finally, at a certain speed, called the critical fusion frequency, the sensation becomes continuous and the subject is unaware of the alterations in the illumination of the screen.

At high levels of luminance, when cone vision is employed, the fusion frequency is high, increasing with increasing luminance in a logarithmic fashion—the Ferry-Porter law—so that at high levels it may require 60 flashes per second to reach a continuous sensation. Under conditions of night, or scotopic, vision, the frequencies may be as low as four per second. The difference between rod and cone vision in this respect probably resides in the power of the eye to inhibit activity in cones rapidly, so that the sensation evoked by a single flash is cut off immediately, and this leaves the eye ready to respond to the next stimulus. By contrast, the response in the rod lasts so much longer that, when a new stimulus falls even a quarter of a second later, the difference in the state of the rods is insufficient to evoke a change in intensity of sensation; it merely prolongs it. One interesting feature of an intermittent stimulus is that the intensity of the sensation of brightness, when fusion is achieved, is dependent on the relative periods of light and darkness in the cycle, and this gives one a method of grading the effective luminance of a screen; one may keep the intensity of the illuminating source constant and merely vary the period of blackness in a cycle of black and white. The effective luminance will be the average luminance during a cycle; this is known as the Talbot-Plateau law.

Visual acuity. As has been stated, the ability to perceive detail is restricted in the dark-adapted retina when the illumination is such as to excite only the scotopic type of vision; this is in spite of the high sensitivity of the retina to light under the same conditions. The power of distinguishing detail is essentially the power to resolve two stimuli separated in space, so that, if a grating of black lines on a white background is moved farther and farther away from an observer, a point is reached when he will be unable to distinguish this stimulus pattern from a uniformly gray sheet of paper. The angle subtended at the eye by the spacing between the lines at the point where they are just resolvable is called the resolving power of the eye; the reciprocal of this angle, in minutes of arc, is called the visual acuity. Thus, a visual acuity of unity indicates a power of resolving detail subtending one minute of arc at the eye; a visual acuity of two indicates a resolution of one-half minute, or 30 seconds of arc. The visual acuity depends strongly on the illumination of the test target, and this is true of both daylight (photopic) and night (scotopic) vision; thus, with a brightly illuminated target, with the surroundings equally brightly illuminated (the ideal condition), the visual acuity may be as high as two. When the illumination is reduced, the acuity falls so that, under ordinary conditions of daylight viewing, visual acuity is not much better than unity. Under scotopic conditions, the visual acuity may be only 0.04 so that lines would have to subtend about 25 minutes at the eye to be resolvable; this corresponds to a thickness of 4.4 centimetres (1.7 inches) at a distance of six metres (20 feet).

Resolving power and visual acuity

Measurement. In the laboratory, visual acuity is measured by the Landolt C, which is a circle with a break in it. The subject is asked to state where the break is when the figure is rotated to successive random positions. The size of the *C*, and thus of its break, is reduced until the subject makes more than an arbitrarily chosen percentage of mistakes. The angle subtended at the eye by the break in the *C* at this limit is taken as the resolving power of the eye. The testing of the eyes by the ophthalmologist or optometrist is essentially a determination of visual acuity; here the subject is presented with the Snellen chart, rows of letters whose details subtend progressively smaller angles at the eye. The row in which, say, five out of six letters are seen correctly is chosen as that which measures the visual acuity. If the details subtended one minute of arc, the visual acuity would be unity. The notation employed is somewhat obscure; a visual acuity of unity would be expressed as 6/6; an acuity of a half as 6/12, and so on; here the numerator is the viewing distance in metres from the chart and the denominator the distance at which details on the letters of the limiting row subtend one minute of arc at the eye.

The Snellen chart

Anatomical basis; the retinal mosaic. From an anatomical point of view one may expect the limit to resolving power to be imposed by the "grain" of the retinal mosaic in the same way that the size of the grains in a photographic emulsion imposes a limit to the accuracy with which detail may be photographed. Two white lines on a black ground, for example, could not be appreciated as distinct if their images fell on the same or adjacent sets of receptors. If a set of receptors intervened between the stimulated ones, there would be a basis for discrimination because the message sent to the central nervous system could be that two rows of receptors, separated by an unstimulated row, were sending messages to their bipolar cells. Thus, the limit to resolution, on this basis, should be the diameter of a foveal cone, or rather the angle subtended by this at the nodal point of the eye; this is about 30 seconds of arc and, in fact, corresponds with the best visual acuity attainable. If this grain of the retinal mosaic is to be the basis of resolution, however, one must postulate, in addition, a nervous mechanism that will transmit accurately the events taking place in the individual receptors, in this case the foveal cones; *i.e.*, there must be a one-to-one relationship between cones, bipolar cells, ganglion cells, and lateral geniculate cells so that what is called the local sign of the impulses from a given foveal cone may be obtained. It must be appreciated that restriction on convergence (or its reverse, spread) of messages may be achieved by inhibition; the anatomical connections may be there, but they may be made functionally inoperative by inhibition exerted by other neurons; thus, the horizontal and amacrine cells might well exert a restraining influence on certain junctions, thereby reducing the spread, or convergence, of messages, and it seems likely that the improvement in foveal visual acuity from one to two, brought about by increased luminance of the target and its surroundings, is achieved by an increase in inhibition that tends to make transmission one-to-one in the fovea.

It must be appreciated that true one-to-one connections in the retina do not exist; a cone, although making an exclusive type of synapse with a midget bipolar, may also make a less exclusive contact with a flat bipolar cell; furthermore, midget bipolars and cones are connected laterally by amacrine and horizontal cells so that it is most unlikely that a given optic nerve fibre carries messages from only a single cone. The one-to-one relationship may in fact exist under certain conditions, but that is because pathways from other receptors have been blocked or occluded by inhibitory processes that keep the line clear for a given cone.

Scotopic acuity

The low visual acuity obtained in night, or rod, vision is now understandable. It has been pointed out that a high sensitivity to light is achieved by the convergence of rods on the higher neurons to allow spatial summation, and it is this convergence that interferes with the resolution of detail. If hundreds of rods converge on a single bipolar cell and if many bipolar cells converge on a single ganglion cell, it is understandable that the unit responsible for resolution may be very large and thus that the visual acuity is very small.

The retinal image. It has been implied, in the comments on visual acuity, that the limiting factor is one of an anatomical arrangement of receptors and of their neural organization. A very important feature, however, must be the accuracy of the formation of an image of external objects by the optical system of the eye. It may be calculated, for example, that the image of a grating produces lines 0.5 micron wide on the retina, but this is on the basis of ideal geometrical optics; in fact, the optics of the eye are not perfect, while diffraction of light by its passage through the pupil further spoils the image. As a result of these defects, the image of a black and white grating on the retina is not sharp, the black lines being not completely black but gray because of spread of light from the white lines. (When the optical system of the eye is defective, moreover, as in nearsightedness, the imagery is worse, but this can be corrected by the use of appropriate lenses.) Physiologically, the eye effectively improves the retinal image by enhancing contrasts; thus, the image of a fine black line on a white background formed on the retina is not a sharply defined black line but a relatively wide band of varying degrees of grayness; yet to the observer the line appears sharply defined, and this is because of lateral inhibition, the receptors that receive most light tending to inhibit those that receive less; the result is a physiological "sharpening of the image," so that the eye often behaves as though the image were perfect. This applies to chromatic aberration, too, which should cause black and white objects to appear fringed with colour, yet, because of suppression of the chromatic responses, one is not aware of the coloured fringes that do in effect surround the images of objects in the external world.

The pupil

The iris behaves as a diaphragm, modifying the amount of light entering the eye; probably of greater significance than control of the light entering the eye is the influence on aberrations of the optical system; the smaller the pupil the less serious, in general, are the aberrations. The smaller the pupil, however, the more serious become the effects of diffraction, so that a balance must be struck. Experimentally, it is found that at high luminances with pupils below three millimetres (0.12 inch) in diameter the visual acuity is not improved by further reduction of the diameter; increasing the pupil size beyond this reduces acuity, presumably because of the greater optical aberrations. It is interesting that when a subject is placed in a room that is darkened steadily, the size of the pupil increases, and the size attained for any given level of luminance is, in fact, optimal for visual acuity at this particular luminance. The reason that visual acuity increases with the larger pupils is that the extra light admitted into the eye compensates for the increased aberrations. When the gaze is fixed intently on an object for a long time, peripheral images that tend to disappear reappear immediately when the eyes are moved. This effect is called the Troxler phenomenon. To study it reproducibly it is necessary to use an optical device that ensures that the image of any object upon which the gaze is fixed will remain on the same part of the retina however the eyes move. Two investigators found, when they did this, that the stabilized retinal image tended to fade within a few seconds. It may be assumed that in normal vision the normal involuntary movements—the microsaccades and drifts mentioned earlier—keep the retinal image in sufficient movement to prevent the fading, which is essentially an example of sensory adaptation, the tendency for any receptive system to cease responding to a maintained stimulus.

Electrophysiology of the retina. *Neurological basis.* Subjective studies on human beings can traverse only a certain distance in the interpretation of visual phenomena; beyond this the standard electrophysiological techniques, which have been successful in unravelling the mechanisms of the central nervous system, must be applied to the eye; this, as repeatedly emphasized, is an outgrowth of the brain.

Receptive fields

Records from single optic nerve fibres of the frog and from the ganglion cell of the mammalian retina indicated three types of response. In the frog there were fibres that gave a discharge when a light was switched on the "on-fibres." Another group, the "off-fibres," remained inactive during illumination of the retina but gave a powerful discharge when the light was switched off. A third group, the "on-off fibres," gave discharges at "on" and "off" but were inactive during the period of illumination. The responses in the mammal were similar, but more complex than in the frog. The mammalian retina shows a background of activity in the dark, so that on- and off-effects are manifest as accentuations or diminutions of this normal discharge. In general, on-elements gave an increased discharge when the light was switched on, and an inhibition of the background discharge when the light was switched off. An off-element showed inhibition of the background discharge during illumination and a powerful discharge at off; this off-discharge is thus a release of inhibition and reveals unmistakably the inhibitory character of the response to illumination that takes place in some ganglion cells. Each ganglion cell or optic nerve fibre tested had a receptive field; and the area of frog's retina from which a single fibre could be activated varied with the intensity of the light stimulus. The largest field was obtained with the strongest stimulus, so that, in order that a light stimulus, falling at some distance away from the centre of the field, might affect this particular fibre it had to be much more intense than a light stimulus falling on the centre of the field. This means that some synaptic pathways are more favoured than others.

The mammalian receptive field is more complex, the more peripheral part of the field giving the opposite type of response to that given by the centre. Thus, if, at the centre of the field, the response was "on" (an on-centre field) the response to a stimulus farther away in the same fibre was at "off," and in an intermediate zone it was often mixed to give an on-off element. In order to characterize an element, therefore, it must be called on-centre or off-centre, with the meaning thereby that at the centre of its receptive field its response was at "on" or at "off," respectively, while in the periphery it was opposite. By studying the effects of small spot stimuli on centre and periphery separately and together, one investigator demonstrated a mutual inhibition between the two. A striking feature was the effect of adaptation; after dark adaptation the surrounding area of opposite activity became ineffective. In this sense, therefore, the receptive field shrinks, but, as it is a reduction in inhibitory activity between centre and periphery, it means, in fact, that the effective field can actually increase during dark adaptation—*i.e.,* the regions over which summation can occur—and this is exactly what is found in psychophysical experiments on dark adaptation.

Inhibitory effect of periphery receptors

Anatomical basis. The receptive field is essentially a measure of the number of receptors—rods or cones or a mixture of these—that make nervous connections with a single ganglion cell. The organization of centre and periphery implies that the receptors in the periphery of an on-centre cell tend to inhibit it, while those in the centre of the field tend to excite it, so that the effects of a uniform illumination covering the whole field tend to cancel out. This has an important physiological value, as it means, in effect, that the brain is not bombarded with an enormous number of unnecessary messages, as would be the case were every ganglion cell to send discharges along its optic nerve fibre as long as it was illuminated. Instead, the cell tends to respond to change—*i.e.,* the movement of a light or dark spot over the receptive field—and to give an especially prominent response, often when the spot passes from the periphery to the centre, or vice versa. Thus, the centre-periphery organization favours the detection of movement; in a similar way it favours the detection of contours because these give rise to differences in the illumination of the parts of the receptive fields. The anatomical basis of the arrangement presumably is given by the organization of the bipolar and amacrine cells in relation to the dendrites of the ganglion cell; it is interesting that the actual diameter of the centre of the receptive field of a ganglion cell is frequently equal to the area over which its dendrites spread; the periphery exerts its effects presumably by means of amacrine cells that are capable of connecting with bipolars over a wide area. These amacrine cells could exert an inhibitory action on the bipolar cells connected to the receptors of the central zone of the field, preventing them from responding to these receptors; in this case, the ganglion cell related to these bipolars would be of an on-centre and off-periphery type.

Direction-sensitive ganglion cells. When examining the receptive fields of rabbit ganglion cells, investigators found some that gave a maximal response when a moving spot of light passed in a certain "preferred" direction, while they gave no response at all when the spot passed in the opposite direction; in fact, the spontaneous activity of the cell was usually inhibited by this movement in the "null" direction. It may be assumed that the receptors connected with this type of ganglion cell are organized in a linear fashion, so that the stimulation of one receptor causes inhibition of a receptor adjacent to it. This inhibition would prevent the excitatory effect of light on the adjacent receptor from having a response when the movement was in the null direction, but would arrive too late at the adjacent receptor if the light was moving in the preferred direction.

The electroretinogram. If an electrode is placed on the cornea and another, indifferent electrode, placed, for example, in the mouth, illumination of the retina is followed by a succession of electrical changes; the record of these is the electroretinogram or ERG. Modern analysis has shown that the electrode on the cornea picks up changes in potential occurring successively at different levels of the retina, so that it is now possible to recognize, for example, the electrical changes occurring in the rods and cones—the receptor potentials—those occurring in the horizontal cells, and so on. In general, the electrical changes caused by the different types of cell tend to overlap in time, so that the record in the electroretinogram is only a faint and attenuated index to the actual changes; nevertheless, it has, in the past, been a most valuable tool for the analysis of retinal mechanisms. Thus, the most prominent wave—called the *b*-wave—is closely associated with discharge in the optic nerve, so that in animals, or man, the height of the *b*-wave can be used as an objective measure of the response to light. Hence, the sensitivity of the dark-adapted frog's retina to different wavelengths, as indicated by the heights of the *b*-waves, can be plotted against wavelength to give a typical scotopic sensitivity curve with a maximum at 5000 angstroms (one angstrom = 1×10^{-4} micron) corresponding to the maximum for absorption of rhodopsin.

Flicker. Electrophysiology has been used as a tool for the examination of the basic mechanism of flicker and fusion. The classical studies based on the electroretinogram indicated that the important feature that determines fusion in the cone-dominated retina is the inhibition of the retina caused by each successive light flash, inhibition being indicated by the *a*-wave of the electroretinogram. In the rod-dominated retina—*e.g.,* in man under scotopic conditions— the *a*-wave is not prominent, and fusion depends simply on the tendency for the excitatory response to a flash to persist, the inhibitory effects of a succeeding stimulus being small. More modern methods of analysis, in which the discharges in single ganglion cells in response to repeated flashes are measured, have defined fairly precisely the nature of fusion, which, so far as the retinal message is concerned, is a condition in which the record from the ganglion cell becomes identical with the record observed in the ganglion cell during spontaneous discharge during constant illumination.

The nature of fusion

Visual acuity. Although the resolving power of the retina depends, in the last analysis, on the size and density of packing of the receptors in the retina, it is the neural organization of the receptors that determines whether the brain will be able to make use of this theoretical resolving power. It is therefore of interest to examine the responses of retinal ganglion cells to gratings, either projected as stationary images on to the receptive field or moved slowly across it. One group of investigators showed that ganglion cells of the cat differed in sensitivity to a given grating when the sensitivity was measured by the degree of contrast between the black and white lines of the grating necessary to evoke a measurable response in the ganglion cell. When the lines were made very fine (*i.e.,* the "grating-frequency" was high), a point was reached at which the ganglion cell failed to respond, however great the contrast; this measured the resolving power of the particular cell being investigated. The interesting feature of this work is that individual ganglion cells had a special sensitivity to particular grating-frequencies, as if the ganglion cells were "tuned" to particular frequencies, the frequencies being measured by the number of black and white lines in a given area of retina. When the same technique was applied to human subjects, the electrical changes recorded from the scalp being taken as a measure of the response, the same results were obtained.

Colour vision. The spectrum, obtained by refracting light through a prism, shows a number of characteristic regions of colour—red, orange, yellow, green, blue, indigo, and violet. These regions represent large numbers of individual wavelengths; thus, the red extends roughly from 7600 angstrom units to 6500; the yellow from 6300 to 5600; green from 5400 to 5000; blue from 5000 to 4200; and violet from 4200 to 4000. Thus, the limits of the visual spectrum are commonly given as 7600 to 4000 angstroms. In fact, however, the retina is sensitive to ultraviolet light to 3500 angstroms, the failure of the short wavelengths to stimulate vision being due to absorption by the ocular media. Again, if the infrared radiation is strong enough, wavelengths as long as 10,000–10,500 angstroms evoke a sensation of light.

Hue discriminations

Within the bands of the spectrum, subtle distinctions in hue may be appreciated. The power of the eye to discriminate light on the basis of its wavelength can be measured by projecting onto the two halves of a screen lights of different wavelengths. When the difference is very small—*e.g.,* five angstroms—no difference can be appreciated. As the difference is increased, a point is reached when the two halves of the screen appear differently coloured. The hue discrimination (hue is the quality of colour that is determined by wavelength) measured in this way varies with the region of the spectrum examined; thus, in the blue-green and yellow it is as low as 10 angstroms, but in the deep red and violet it may be 100 angstroms or more. Thus, the eye can discriminate several hundreds of different spectral bands, but the capacity is limited. If it is appreciated that there are a large number of nonspectral colours that may be made up by mixing the spectral wavelengths, and by diluting these with white light, the number of different colours that may be distinguished is high indeed.

Spectral sensitivity curve. At extremely low intensities of stimuli, when only rods are stimulated, the retina shows a variable sensitivity to light according to its wavelength, being most sensitive at about 5000 angstroms, the absorption maximum of the rod visual pigment, rhodopsin. In the light-adapted retina one may plot a similar type of curve, obtained by measuring the relative amounts of light energy of different wavelengths required to produce the same sensation of brightness; now the different stimuli appear coloured, but the subject is asked to ignore the colours and match them on the basis of their luminosity (brightness). This is carried out with a special instrument called the flicker-photometer. There is a characteristic shift in the maximum sensitivity from 5000 angstroms for scotopic (night) vision to 5550 angstroms for photopic (day) vision, the so-called Purkinje shift. It has been suggested that the cones have a pigment that shows a maximum of absorption at 5550 angstroms, but the phenomena of colour vision demand that there be three types of cone, with three separate pigments having maximum absorption in the red, green, and blue, so that it is more probable that the photopic luminosity curve is a reflection of the summated behaviour of the three types of cone rather than of one.

The Purkinje shift has an interesting psychophysical correlate; it may be observed, as evening draws on, that the luminosities of different colours of flowers in a garden change; the reds become much darker or black, while the blues become much brighter. What is happening is that, in this range of luminosities, called mesopic, both rods and cones are responding, and, as the rod responses become more pronounced—*i.e.,* as darkness increases—the rod luminosity scale prevails over that of the cones.

It may be assumed that the sensation of luminosity under any given condition is determined by certain ganglion cells that make connections to all three types of cone and also to rods; at extremely low levels of illumination their responses are determined by the activity aroused in the rods. As the luminance is increased, the ganglion cell is activated by both rods and cones, and so its luminosity curve is governed by both rod and cone activity. Finally, at extremely high luminances, when the rods are "saturated" and ceasing to respond, the luminosity curve is, in effect, compounded of the responses of all three types of cone.

Colour mixing. The fundamental principle of colour mixing was discovered by Isaac Newton when he found that white light separates spatially into its different component colours on passing through a prism. When the same light is passed through another prism, so that the individual bands of the spectrum are superimposed on each other, the sensation becomes one of white light. Thus, the retina, when white light falls on it, is really being exposed to all the wavelengths that make up the spectrum. Because these wavelengths fall simultaneously on the same receptors, the evoked sensation is one of white. If the wavelengths are spread out spatially, they evoke separate sensations, such as red or yellow, according to which receptors receive which bands of wavelengths. In fact, the sensation of white may be evoked by employing much fewer wavelengths than those in the spectrum: namely, by mixing three primary hues—red, green, and blue.

Three primary hues

Furthermore, any colour, be it a spectral hue or not, may be matched by a mixture of these three primaries, red, green, and blue, if their relative intensities are varied. Many of the colours of the spectrum can be matched by mixtures of only two of the primary colours, red and green; thus the sensations of red, orange, yellow, and green may be obtained by adding more and more green light to a red one.

To one accustomed to mixing pigments, and to mixing a blue pigment, for example, with yellow to obtain green, the statement that red plus green can give yellow or orange, or that blue plus yellow can give white, may sound strange. The mixing of pigments is essentially a subtractive process, however, as opposed to the additive process of throwing differently coloured lights on a white screen. Thus, a blue pigment is blue because it reflects mainly blue (and some green) light and absorbs red and yellow; and a yellow pigment reflects mainly yellow and some green and absorbs blue and red. When blue and yellow pigments are mixed, and white light falls on the mixture, all bands of colour are absorbed except for the green colour band.

Colour defectiveness. The colour-defective subject is one whose wavelength discrimination apparatus is not as good as that of the majority of people, so that he sees many colours as identical that normal people would see as different. About one percent of males are dichromats; they can mix all the colours of the spectrum, as they see them, with only two primaries instead of three. Thus, the protanope (red blind) requires only blue and green to make his matches; since, for the normal (trichromatic) subject the various reds, oranges, yellows, and many greens are the result of mixing red and green, the protanope matches all these with a green. In other words, he is unable to distinguish all these hues from each other on the basis of their colour; if he distinguishes them, it is because of their different luminosity (brightness). The protanope matches white with a mixture of blue and green and is, in fact, unable to distinguish between white and bluish-green. The deuteranope (green blind) matches all colours with a mixture of red and blue; thus, his white is a mixture of red and blue that appears purple to a person with normal vision. The deuteranope also is unable to discriminate reds, oranges, yellows, and many greens, so that both types of dichromat are classed as red-green-blind. For the protanope, however, the spectrum is more limited because he is unable to appreciate red. The tritanope (blue blind) is rare, constituting only one in 13,000 to 65,000 of the population; because he is blue blind, his colour discrimination is best in the region of red to green, where that of the protanope and deuteranope is worse.

Responses of uniform population of receptors. The scotopic (night) visual system, mediated by rods, is unable to discriminate between different wavelengths; thus, a threshold stimulus of light with a wavelength of 4800 angstroms gives a sensation of light that is indistinguishable from that evoked by a wavelength of 5300 angstroms. If the intensities are increased, however, the lights evoke sensations of blue and green, respectively. Rods are unable to mediate wavelength, or colour, discrimination while the cones can because the rods form a homogeneous population, all containing the same photopigment, rhodopsin. Thus, the response of a nerve cell connected with a rod or group of rods will vary with the wavelength of light, and probably in the manner indicated by Figure 42, in which the response, measured in frequency of discharge in the bipolar or ganglion cell, is plotted against the wavelength of the stimulating light. The curve is essentially similar to the absorption spectrum of rhodopsin when the same amount of energy is in each stimulus; thus, blue-green of 5000 angstroms has the most powerful effect because it is absorbed most efficiently, while violet and red have the smallest effects. In this sense, the rods behave as wavelength discriminators, but it is to be noted that there are pairs of wavelengths on each side of the peak to which the same response is obtained; thus, a blue of 4800 angstroms and a yellow of 6000 angstroms give the same discharge. Moreover, if the intensity of the stimulus is varied, a new curve is obtained (as in the dotted line of Figure 42), and now the same response is obtained with a high intensity of violet at 4000 angstroms as with blue at the lower intensity. In general, it is easy to show that, by varying the intensity of the stimulus of a single wavelength, all types of response may be obtained, so that the brain would never receive a message indicating, in a unique fashion, that the retina was stimulated with, say, green light of 5300 angstroms; the same message could be given by blue light of 4800 angstroms, red light of 6500 angstroms, and so on.

From H. Davson, M.D., *Physiology of the Eye*

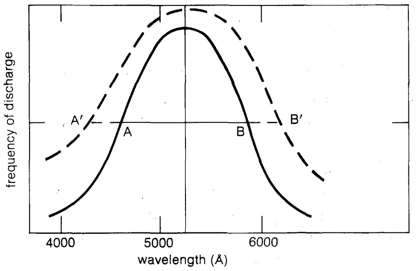

Figure 42: Theoretical wavelength response curve for a single receptor of *Limulus* retina. The maximum response will occur at 5200 Å, the absorptional maximum of the retinal pigment. With wavelengths of light corresponding to the points A and B, the responses will be identical, so that no discrimination between these two wavelengths is possible. When the intensity of the light is changed and a new curve is obtained (the dotted line), the responses at A′ and B′ are also identical.

Why rods fail to discriminate between colours

Ideally, colour discrimination would require a large number of receptors specifically sensitive to small bands of the spectrum, but the number would have to be extremely large because the capacity for hue discrimination is extremely great, as has been indicated. In fact, however, the phenomena of colour mixing suggest that the number of receptors may be limited.

Young-Helmholtz theory. It was the phenomena of colour mixing that led Thomas Young in 1802 to postulate that there are three receptors, each one especially sensitive to one part of the spectrum; these receptors were thought to convey messages to the brain, and, depending on how strongly they were stimulated by the coloured light, the combined message would be interpreted as that due to the actual colour. The theory was developed by Hermann Ludwig Ferdinand von Helmholtz, and is called the Young-Helmholtz trichromatic theory. As expressed in modern terms, it is postulated that there are three types of cone in the retina, characterized by the presence of one of three different pigments, one absorbing preferentially in the red part of the spectrum, another in the green, and another in the blue. A coloured stimulus—*e.g.,* a yellow light—would stimulate the red and green receptors, but would have little effect on the blue; the combined sensation would be that of yellow, which would be matched by stimulating the eye with red and green lights in correct proportions of relative intensity. A given coloured stimulus would, in general, evoke responses in all three receptors, and it would be the pattern of these responses—*e.g.,* blue strongly, green less strongly, and red weakest—that would determine the quality of the sensation. The intensity of the sensation would be determined by the average frequencies of discharge in the receptors. Thus, increasing the intensity of the stimulus would clearly change the responses in all the receptors, but if they maintained the same pattern, the sensation of hue might remain unaltered and only that of intensity would change; the observer would say that the light was brighter but still bluish green. Thus, with several receptors, the possibility is reduced of confusion between stimuli of different intensity but the same wavelength composition; the system is not perfect because the laws of colour mixing show the eye is incapable of certain types of discrimination, as, for example, between yellow and a mixture of red and green, but as a means of discriminating subtle changes in the environment the eye is a very satisfactory instrument.

The direct proof that the eye does contain three types of cone has been secured, but only relatively recently. This was done by examining the light emerging from the eye after reflection off the retina; in the dark-adapted eye the light emerging was deficient in blue light because this had been preferentially absorbed by the rhodopsin. In the light-adapted eye, when only cone pigments are absorbing light, the emerging light can be shown to be deficient in red and green light because of the absorption by pigments called erythrolabe and chlorolabe. Again, the light passing through individual cones of the excised human retina can be examined by a microscope device, and it was shown by such examination that cones were of three different kinds according to their preference for red, green, and blue lights.

The nervous messages. If the three types of cones respond differently to light stimuli, one may expect to find evidence for this difference in type of response by examining the electrophysiological changes taking place in the retina; ideally, one should like to place a microelectrode in or on a cone, then in or on its associated bipolar cell, and so on up the visual pathway. In the earliest studies, the optic nerve fibres of the frog were examined—*i.e.,* the axons of ganglion cells. The light-adapted retina was stimulated with wavelengths of light stretching across the

Dominator impulse

spectrum, and the responses in arbitrarily selected single fibres were examined. The responses to stimuli of the same energy but different wavelengths were plotted as frequency of discharge against wavelength, and the fibres fell into several categories, some giving what the investigator called a dominator response, the fibre responding to all wavelengths and giving a maximum response in the yellow-green at 5600 angstroms. Other fibres gave responses only over limited ranges of wavelengths, and their wavelengths of maximum response tended to be clustered in the red, green, and blue regions. The investigator called these modulators, and considered that the message in the dominator indicated to the brain the intensity of the stimulus—*i.e.,* it determined the sensation of brightness—while the modulators indicated the spectral composition of the stimulus, the combined messages in all the modulators resulting in a specific colour sensation. In the dark-adapted retina, when only rods were being stimulated, the response was of the dominator type, but this time the maximum response occurred with a wavelength of 5000 angstroms, the absorption maximum of rhodopsin.

A more careful examination of the responses in single fibres, especially in the fish, which has good colour vision, showed that things were not quite as simple as the original investigator had thought because, as has been seen, the response of a ganglion cell, when light falls on its receptive field in the retina, is not just a discharge of action potentials that ceases when the light is switched off. This type of response is rare; the most usual ganglion cell or optic nerve fibre has a receptive field organized in a concentric manner, so that a spot of light falling in the central part of the field produces a discharge, while a ring of light falling on the surrounding area has the opposite effect, giving an off-response—*i.e.,* giving a discharge only when the light is switched off. Such a ganglion cell would be called an on-centre-off-periphery unit; others behaved in the opposite way, being off-centre-on-periphery.

When these units are examined with coloured lights, and when care is taken to stimulate the centres and surrounding areas separately, an interesting feature emerges; the centre and surrounding areas usually have opposite or opponent responses. Thus, some may be found giving an on-response to red in the centre of the field and an off-response to green in the surrounding area, so that simultaneous stimulation of centre with red and surrounding area with green gives no response, the inhibitory effect of the off-type of response cancelling the excitatory effect of the on-type. With many other units the effects were more complex, the centre giving an on-response to red and an off-response to green, while the surrounding area gave an off-response to red and an on-response to green, and vice versa. This opponent organization probably subserves several functions. First, it enables the retina to emphasize differences of colour in adjacent parts of the field, especially when the boundary between them moves, as indeed it is continually doing in normal vision because of the small involuntary movements of the eyes. Second, it is useful in "keeping the retina quiet"; there are about one million optic nerve fibres, and if all these were discharging at once the problem of sorting out their messages, and making meaning of them, would be enormous; by this "opponence," diffuse white light falling on many of these chromatic units would have no effect because the inhibitory surrounding area cancelled the excitatory centre, or vice versa. When the light became coloured, however, the previously inactive units could come into activity.

S-potentials

These responses show that by the time the effect of light has passed out of the eye in the optic nerve the message is well colour-coded. Thus all the evidence points to the correctness of the Young-Helmholtz hypothesis with respect to the three-colour basis. The three types of receptor, responding to different regions of the spectrum in specific manners, transmit their effects to bipolar and horizontal cells. The latter neurons have been studied from the point of view of their colour-coding. The potentials recorded from them were called *S*-potentials; these were of two types, which classified them as responding to colour (*C*-units) and luminosity (*L*-units).

The *C*-type of cell gave an opponent type of response, in the sense that the electrical sign varied with the wavelength band, red and green having opponent effects on some cells, and blue and yellow on others. These responses reflect the connections of the horizontal cells to groups of different cones, the blue-yellow type, for example, having connections with blue and red and green cones, while the red-green would have connections only with red and green cones.

Lateral geniculate cells. As indicated above, the cells at the next stage, the ganglion cells, give a fairly precisely coded set of messages indicating the chromatic (colour) quality and the luminosity (brightness) of the stimulus, organized in such a way, however, as to facilitate the discrimination of contrast. At higher stages—*e.g.,* in the cells of the lateral geniculate body—this emphasis on opponence, or contrast, is maintained and extended; thus, several types of cell have been described that differ in accordance with the organization of their receptive fields from the colour aspect; some were very similar to ganglion cells, while others differed in certain respects. Some showed no opponence between colours when centre and periphery were compared, so that if a red light on the periphery caused inhibition, green and blue light would also do so. Others had no centre-periphery organization, the receptive field consisting of only a central spot; different colours had different effects on this spot; and so on.

In the cerebral cortex there is the same type of opponence with many units, but because cortical cells require stimuli of definite shape and often are not activated by simple spot stimuli, early studies carried out before these requirements were known probably failed to elucidate the true chromatic requirements of these high-order neurons. In general, the responses are what might be predicted on the basis of connections made to lateral geniculate neurons having the chromatic responses already known. Thus the final awareness of colour probably depends on the bombardment of certain higher-order cortical neurons by groups of primary cortical neurons, each group sending a different message by virtue of the connections it makes to groups of cones, connections mediated, of course, through the neurons of the retina and lateral geniculate body.

The photochemical process. For the energy of light to exert its effect it must be absorbed; it has been stated above that the action-spectrum for vision (the sensitivity of the eye to light) in the completely dark-adapted eye has a maximum in the region of 5000 angstroms, and that this corresponds with the maximum of absorption of light by the pigment, rhodopsin, extracted from the dark-adapted retina of the same species. The chemical nature of rhodopsin must now be examined, as well as its localization in the rod and the changes it undergoes in response to the absorption of light. It must be appreciated at the outset that the amount of light energy absorbed by a single rod at the threshold for vision is extremely small—namely, one quantum—and this is quite insufficient to provide the energy required to cause an electrical change in the membrane of the rod that will be propagated from the point of absorption of the light to the rod spherule (which takes part in the synapse between rod and bipolar cell). There must, therefore, be a chemical amplification process taking place within the rod, and the absorption of a quantum must be viewed as the trigger that sets off other changes, which in turn provide the required amount of energy.

Opsin and retinal

Rhodopsin. Visual purple, or rhodopsin, is a chromoprotein, a protein, opsin, with an attached chromatophore ("pigment-bearing") molecule that gives it its colour—*i.e.,* that allows it to absorb light in the visible part of the spectrum. In the absence of such a chromatophore, the protein would only absorb in the ultraviolet and so would appear colourless to the eye. The chromatophore group was identified as retinal, which is the substance formed by oxidation of vitamin A; on prolonged exposure of the eye to light, retinal can be found, free from the protein opsin, in the retina. When the eye is allowed to remain in the dark, the rhodopsin is regenerated by the joining up of retinal with opsin. Thus one may write:

$$\text{rhodopsin} \rightleftharpoons \text{retinal} + \text{opsin}.$$

The incidence of light on the retina causes the reaction to go to the right (that is, causes rhodopsin to form retinal plus opsin), and this photochemical change causes the sensation of light. The process is reversed by a thermal—*i.e.,* non-photochemical—reaction, so that for any given light intensity a steady state is reached with the regenerative process just keeping pace with the photochemical bleaching. Dark adaptation, or one element in it, is the regenerative process. The change in the rhodopsin molecule that leads to its bleaching—*i.e.,* the splitting off of the retinal molecule—takes place in a succession of steps; and there is reason to believe that the electrical change in the rod that eventually evokes the sensation of light occurs at a stage well before the splitting off of the retinal. One may describe as a transduction process the chemical events that take place between the absorption of light and the electrical event, whatever that may be; the rod behaves as a transducer in that it converts light into electrical or neural energy.

Prelumirhodopsin

The transduction process. Immediately after absorption of a quantum, the rhodopsin molecule is changed into a substance called prelumirhodopsin, recognized by its different colour from that of rhodopsin; this product is so highly unstable that at body temperature it is converted, without further absorption of light, into a series of products. These changes may be arrested by cooling the solution to −195° C (−319° F), at which temperature prelumirhodopsin remains stable; on warming to −140° C (−220° F) prelumirhodopsin becomes lumirhodopsin, with a slightly different colour; on warming further, successive changes are permitted until finally retinal is split off from the opsin to give a yellow solution. The important point to appreciate is that only at this stage is the chromatophore group split off; the earlier products have involved some change in the structure of the chromoprotein, but not so extreme as to break off the retinal. The precise nature of these changes is not yet completely elucidated, but the most fundamental one—namely, that occurring immediately after absorption of the quantum—has been shown to consist in a change in shape of the retinal molecule while it is still attached to opsin.

Photoisomerization

Thus retinal, like vitamin A, can exist in several forms because of the double bonds in its carbon chain—the socalled *cis-trans* isomerism. In other words, the same group of atoms constituting the retinal molecule can be twisted into a number of different shapes, although the sequence of the atoms is unaltered. While attached to the opsin molecule in the form of rhodopsin, the retinal has a shape called 11-*cis,* being somewhat folded, while on conversion to prelumirhodopsin the retinal has a straighter shape called all-*trans;* the process is called one of photoisomerization, the absorption of light energy causing the molecule to twist into a new shape. Having suffered this alteration in shape, the retinal presumably causes some instability in the opsin, making it, too, change its shape, and thereby exposing to the medium in which it is bathed chemical groupings that were previously shielded by being enveloped in the centre of the molecule. It may be assumed that these changes in shape induce alterations in the light-absorbing character of the molecule that permit the recognition of the new forms of molecule represented by lumirhodopsin, metarhodopsins I and II, and so on.

The final change is more drastic because it involves the complete splitting off of the retinal; an earlier stage—namely, the conversion of metarhodopsin I to metarhodopsin II—has been shown recently to involve a bodily change in position of the retinal, which in rhodopsin is linked to the lipid (fatty) portion of the molecule, whereas in metarhodopsin II it is found to have become attached to an amino acid in the backbone-chain of the protein (amino acids are subunits of proteins). Thus, in its native unilluminated state, retinal is attached to a lipid, which is presumably linked to the protein, so that rhodopsin is more properly called a chromolipoprotein rather than a chromoprotein. The outer segments of the rods are, as has been stated, constituted by membranous disks, and it is well established that the material from which these membranes are constructed is predominantly lipid, so that one may envisage the rhodopsin molecules as being, in fact, part of the membrane structure. The techniques used for extraction presumably tear the molecules from the main body of the lipid, but some of the lipid remains with the protein and retinal to constitute the link holding these two parts together.

Within the retina these chemical changes are all reversible, so that when a steady light is maintained on the retina the latter will contain a mixture of several or all of the intermediate compounds. In the dark, all will be gradually reconverted to rhodopsin. Because lack of vitamin A, from which retinal is derived, causes night blindness, some of the retinal must get lost from the eye to the general circulation; and it is actually replaced by the cells of the pigment epithelium, which are closely associated with the rods.

As to which of these chemical changes acts as the trigger for vision, there is some doubt. The discovery that the transition from metarhodopsin I to metarhodopsin II involves an actual shift of the retinal part of the molecule from linkage to lipid to linkage to protein reinforces the belief that this particular shift is sufficient to lead ultimately to electrical discharges in the optic nerve.

Cone pigments. So far as colour vision is concerned, the changes that take place in the three cone pigments have not been analyzed, simply because, so far, they have defied isolation, presumably because their concentrations are so much less than that of the rod pigment.

THE HIGHER VISUAL CENTRES

Partial decussation

The visual pathway. The axons of the ganglion cells converge on the region of the retina called the papilla or optic disk. They leave the globe as the optic nerve, in which they maintain an orderly arrangement in the sense that fibres from the macular zone of the retina occupy the central portion, the fibres from the temporal half of the retina take up a concentric position, and so on; when outside the orbit, there is a partial decussation (crossover). The fibres from the nasal halves of each retina cross to the opposite side of the brain, while those from the temporal halves remain uncrossed. This partial decussation is called the chiasma. The optic nerves after this point are called

By permission from Eugene Wolff, *Anatomy of the Eye and Orbit,* London: H. K. Lewis & Co. Ltd.

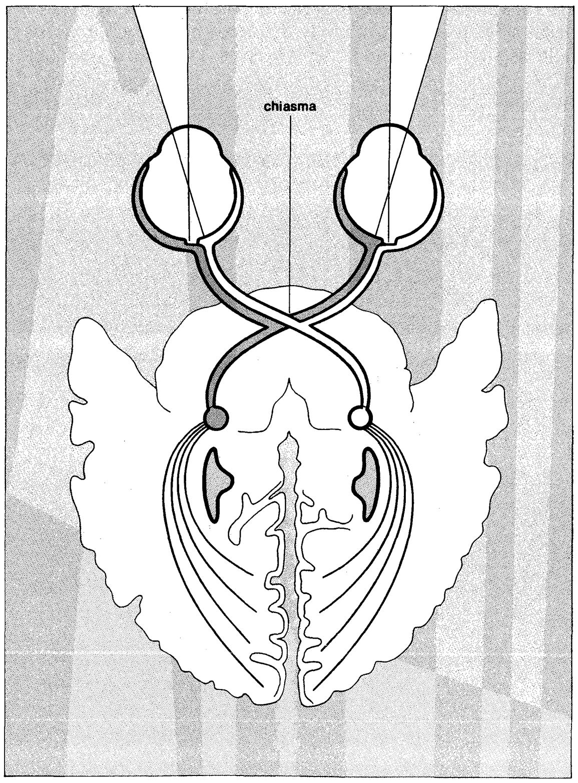

Figure 43: *Visual pathways.*
Fibres from the nasal side of the retina cross over in the chiasma to join the uncrossed fibres of the temporal half of the retina.

the optic tracts, containing nerve fibres from both retinas. The result of the partial decussation is that an object in, say, the right-hand visual field produces effects in the two eyes that are transmitted to the left-hand side of the brain only. With cutaneous (skin) sensation there is a complete crossing-over of the sensory pathway; thus, information from the right half of the body, and the right visual field, is all conveyed to the left-hand part of the brain by the time that it has reached the diencephalon (the posterior part of the forebrain, Figure 43).

Fusion of retinal images. Partial decussation is an arrangement that serves the needs of frontally directed eyes and permits binocular vision, which consists in the fusion of the responses of both eyes to a single object—more loosely, one speaks of the fusion of the retinal images. In many lower mammals, with laterally directed eyes and therefore limited binocular vision, the degree of decussation is much greater, so that in the rat, for example, practically all of the optic nerve fibres pass to the opposite side of the brain.

The fibres of the optic tracts relay their messages to nerve cells in those parts of the diencephalon called the lateral geniculate bodies, and from the lateral geniculate bodies the messages are relayed to nerve cells in the occipital cortex of the same side. (The occipital cortex is the outer substance in the posterior portion of the brain.)

The visual field. If one eye is fixed on a point in space, the visual field for this eye may be thought of as the part of a surface of a sphere on to which all visible objects are projected. The limits to this field will be determined by the sensitivity and extent of the retina and the accessibility of light rays from the environment. Experimentally or clinically, the field is measured on a perimeter, a device for ascertaining the point on a given meridian where a white spot just appears or disappears from vision when moved along this meridian. (A meridian is a curve on the surface of a sphere that is formed by the intersection of the sphere surface and a plane passing through the centre of the sphere.) The field is recorded on a chart, illustrated by Figure 44. On the nasal side, the field is restricted to about 60° from the midline. This is due to the obstruction caused by the nose, since the retina extends nearly as far forward on the temporal side of the globe as on the nasal side. It is customary to refer to the binocular visual field as that common to the two eyes, the uniocular field being the extreme temporal (outside) region peculiar to each eye. It will be clear from the field of the single eye shown in Figure 44 that the binocular field is determined in the horizontal meridian by the nasal field of each eye, and so will amount to about 60° to either side of the vertical meridian.

From H. Davson and M.G. Eggleton (eds.), *Principles of Human Physiology*

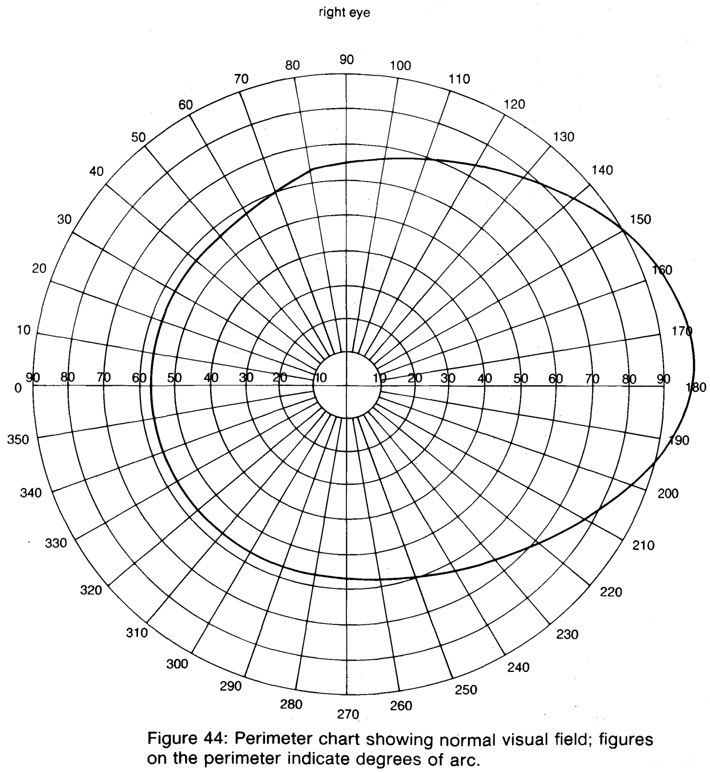

Figure 44: Perimeter chart showing normal visual field; figures on the perimeter indicate degrees of arc.

Lateral geniculate body. The dorsal (posterior) nucleus of the lateral geniculate body, where the optic tract fibres relay, has six layers, and the crossed fibres relay in layers 1, 4, and 6, while the uncrossed relay in layers 2, 3, and 5; thus, at this level, the impulses from the two eyes are kept separate, and when the discharges in geniculate neurons are recorded electrically it is rare to find any responding to stimuli in both eyes.

Point of awareness of visual stimulus

Striate area. The optic tract fibres make synapses with nerve cells in the respective layers of the lateral geniculate body, and the axons of these third-order nerve cells pass upward to the calcarine fissure (a furrow) in each occipital lobe of the cerebral cortex. This area is called the striate area because of bands of white fibres—axons from nerve cells in the retina—that run through it. It is also identified as Brodmann's area 17. It is at this level that the impulses from the separate eyes meet at common cortical neurons, or nerve cells, so that when the discharges in single cortical neurons are recorded it is usual to find that they respond to light falling in one or the other eye. It is probable that it is when the retinal messages have reached this level of the central nervous system, and not before, that the human subject becomes aware of the visual stimulus, since destruction of the area causes absolute blindness in man. Because of the partial decussation, however, the removal of only one striate cortex will not cause complete blindness in either eye, since only messages from two halves of the retinas will have been blocked; the same will be true if one optic tract is severed or one lateral geniculate body is destroyed. The result of such lesions will be half-blindness, or hemianopia, the messages from one half of the visual field being obliterated.

Pupillary pathways. Some of the fibres in the optic tracts do not relay in the lateral geniculate bodies but pass instead to a midbrain region—the pretectal centre—where they mediate (transmit) reflex alterations in the size of the pupil. Thus, in bright light, the pupils are constricted; this happens by virtue of the pupillary light reflex mediated by these special nerve fibres. Removal of the occipital cortex, although it causes blindness in the opposite visual field, does not destroy the reaction of the pupils to light; if the optic nerve is cut, however, the eye will be both completely blind and also unreactive to light falling on this eye. The pupil of the blind eye will react to light falling on the other eye by virtue of a decussation in the pupillary reflex pathway.

Point-to-point representation. Because of the ordered manner in which the optic tract fibres relay in the lateral geniculate bodies and from there pass in an orderly fashion to the striate area, when a given point on the retina is stimulated, the response recorded electrically in either the lateral geniculate body or the striate area is localized to a small region characteristic for that particular retinal spot. When the whole retinal field is stimulated in this point-to-point way, and the positions on the geniculate or striate gray matter on which the responses occur are plotted, it is possible to plot on these regions of the brain maps of the retinal fields or, more usually, maps of the visual fields.

Peristriate and parastriate areas

Visuopsychic or circumstriate areas. Area 17, the striate area, is the primary visual centre in the sense that, in primates at any rate, all of the geniculate fibres project onto it and none projects onto another region of the cortex. There are two other areas containing neurons that have close connections with the eye; these are the parastriate and peristriate areas, or Brodmann's areas 18 and 19, respectively, in close anatomical relationship to one another and to area 17. They are secondary visual areas in the sense that messages are relayed from area 17 to area 18 and from area 18 to area 19, and, because area 17 does not relay to regions beyond area 18, these circumstriate areas are the means whereby visual information is brought into relation with more remote parts of the cortex. Thus in writing, the eyes direct the activities of the fingers, which are controlled by a region of the frontal cortex, so that one may presume that visual information is relayed to this frontal region. In the monkey, bilateral destruction of the areas causes irrecoverable loss of a learned visual discrimination, but this can be relearned after the operation. In man, lesions in this region are said to cause disturbances in spatial orientation and stereoscopic vision, but much more knowledge is required before specific functions can be attributed to these circumstriate areas, if, indeed, this is possible.

Integration of the retinal halves. The two halves of the retina, and thus of the visual field, are represented on opposite cerebral hemispheres, but the visual field is perceived as a unity and hence one would expect an intimate connection between the two visual cortical areas.

Corpus callosum. The great bulk of the connections between the two sides of the cerebral mantle are made by the interhemispheric commissure (the point of union between the two hemispheres of the cerebrum) called the corpus callosum, which is made up of neurons and their axons and dendrites that make synapses with cortical neurons on symmetrically related points of the hemispheres. Thus, electrical stimulation of a point on one hemisphere usually gives rise to a response on a symmetrically related point on the other, by virtue of these callosal connections. The striate area is an exception, however, and it is by virtue of the connections of the striate neurons with the area 18 neurons that this integration occurs, the two areas 18 on opposite hemispheres being linked by the corpus callosum.

Stereopsis in the midline. Usually stereopsis, or perception of depth, is possible by the use of a single hemisphere because the images of the same object formed by right and left eyes are projected to the same hemisphere; however, if the gaze is fixed on a distant point and a pin is placed in line with this but closer to the observer, a stereoscopic perception of the distant point and the pin can be achieved by the fusion of disparate images of the pin, but the images of the pin actually fall on opposite retinal halves, so that this fusion must be brought about by way of the corpus callosum.

Callosal transfer. In experimental animals it is possible, by section of the chiasma, to ensure that visual impulses from one eye pass only to one hemisphere. If this is done, an animal trained to respond to a given pattern and permitted to use only one eye during the training is just as efficient, when fully trained, in making the discrimination with the other eye. There has thus been a callosal transfer of the learning so that the hemisphere that was not directly involved in the learning process can react as well as that directly involved. If the corpus callosum is also sectioned, this transfer is impossible, so that the animal, trained with one eye, must be trained again if it is to carry out the task with the other eye only.

Effect of cutting the corpus callosum

Superior colliculi. The visual pathway so far described is called the geniculostriate pathway, and in man it may well be the exclusive one from a functional aspect because lesions in this pathway lead to blindness. Nevertheless, many of the optic tract fibres, even in man, relay in the superior colliculi, a paired formation on the roof of the midbrain. From the colliculi there is no relay to the cortex, so that any responses brought about by this pathway do not involve the cortex. In man, as has been said, lesions in the striate area, which would of course leave the collicular centres intact, cause blindness, so that the visual fibres in these centres serve no obvious function. In lower animals, including primates, removal of the striate areas does not cause complete blindness; in fact, it is often difficult to determine any visual impairment from a study of the behaviour of the animals. Thus, in reptiles and birds, vision is barely affected, so that a pigeon that has been subjected to the operation can fly and avoid obstacles as well as a normal one. In rodents, such as the rabbit, removal of the occipital lobes causes some impairment of vision, but the animal can perform such feats as avoiding obstacles when running and recognizing food by sight. In the monkey, the effects are more serious, but the animal can be trained to discriminate lights of different intensity and even the shapes of objects, provided that these are kept in continual motion. It seems likely, then, that it is the visual pathway through the colliculi that permits the use of the eyes in the absence of visual cortex, although the connections of the optic tract fibres with the pulvinar of the thalamus (an area in the diencephalon), established in some animals, may well permit the use of regions of the cortex other than those denoted as visual.

SOME PERCEPTUAL ASPECTS OF VISION

So far, the visual process has been considered from rather elementary aspects; the ability to detect light and changes in its intensity, and to discriminate colour and form. It is now time to deal with more complex features, particularly some phenomena of binocular vision. It will then be in order to return to the electrophysiology of the visual pathway to see how some of the phenomena can be interpreted.

Projection of the retina. Objects are perceived in definite positions in space—positions definite in relation to each other and to the percipient. The first problem is to analyze the physiological basis for this spatial perception or, as it is expressed, the projection of the retina into space.

Relative positions of objects. The perception of the positions of objects in relation to each other is essentially a geometrical problem. Take, for the present, the perception of these relationships by one eye, monocular perception: a group of objects, as in Figure 45, produces images on the retina in a certain fixed geometrical relationship; for the perception of the fact that *C* is to the left of *D*, that *D* is to the left of *E*, and so on, it is necessary that the incidence of images at *c*, *d*, and *e* on the retina be interpreted in a similar, but, of course, inverted geometrical relationship. The neural requirements for this interpretation are (1) that the retina be built up of elements that behave as units throughout their conducting system to the visual cortex, and (2) that the retinal elements have "local signs." The local sign could represent an innate disposition or could result from experience—the association of the direction of objects in space, as determined by such evidence as that provided by touch, with the retinal pattern of stimulation. In neurophysiological terms, the retinal elements are said to be connected to cortical cells, each being specific for a given element, so that when a given cortical cell is excited the awareness is of a specific local sign. Studies of the projection of the retina on the cerebral cortex have confirmed this.

From H. Davson, M.D., *Physiology of the Eye*

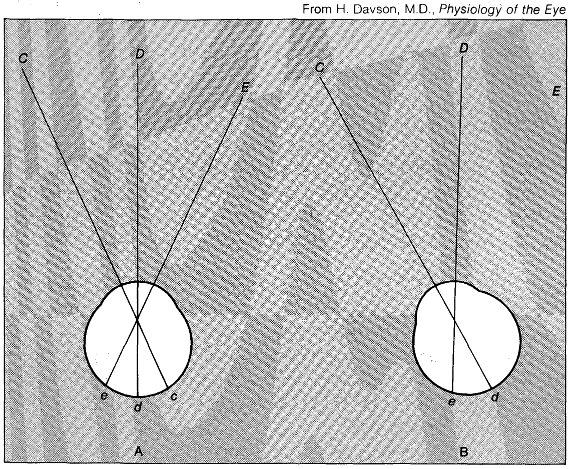

Figure 45: *Projection of retinal images into space.*
(A) A group of objects, *C,D,E,* produces images on the retina, *c,d,e;* the retinal images are projected outward in space toward the points evoking them. (B) The eye has moved to the left so that the image of *c* falls on *d,* previously projected to *D* but now projected to *C; E* no longer produces an image on the retina.

The retinal stimuli at *c*, *d*, and *e* in Figure 45 are appreciated as objects outside the eye, the retina is said to be projected into space, and the field of vision is thus the projection of the retina through the nodal point. (In Figure 45 the nodal point is the point of intersection of *Cc*, *Dd*, and *Ee*.) It will be seen that the geometrical relationship between objects and retinal stimuli is reversed; in the retina *c* is to the right of *d*, and so on.

Position in relation to observer. The recognition of the directions of objects in relation to the observer is more complex. If the eye (Figure 45B) is turned to the left, the image of *C* falls on the retinal point *d,* so that if *d* were always projected into the same direction in space, *C* would appear to be in *D*'s place. In practice, one knows that *C* is perceived as fixed in space in spite of the movements of the eye; hence, the direction of projection of a retinal point is constantly modified to take into account movements of the eye; this may be called psychological compensation. It will be seen that correct projection is achieved by projecting the stimulated retinal point through the nodal point of the eye. Movements of the eye caused by movements of the head must be similarly compensated. As a result, any point in space remains fixed in spite of movements of the eye and head. Given this system of compensated projection, the recognition of direction in relation to the individual is now feasible. *D* may be said to be due north or, more vaguely, "over there"; when the head is turned, since *D* is perceived to be in the same place, it is still due north or "over there." In some circumstances, the human subject makes an error in projecting his retinal image, so that the object giving rise to the image appears to be in a different place from its true one; the image is said to be falsely projected. If the eye is moved passively, for example, by pulling on the conjunctiva with forceps, the subject has the impression that objects in the outside world are moving in a direction opposite to that of the eye.

False projection

The apparent movement of an afterimage, when the eye moves, is an excellent illustration of psychological compensation. A retinal stimulus, being normally projected through the nodal point, is projected into different points in space as the eye moves; an afterimage can be considered to be the manifestation of a continued retinal impulse, and its projection changes as the eye moves. The afterimage thus appears to move in the same direction as that of the movement of the eye. Whether the drift of an afterimage across the field of view is entirely due to eye movements is difficult to say. One certainly has the impression that the eye is chasing the afterimage.

Visual estimates. *The directions of lines.* So far, consideration has been given to the problem of estimating the positions of points in relation to each other and to the percipient. The estimate of the directions of lines involves no really new principles, since, if two points, *A* and *B,* are exactly localized, the direction of the line *AB* can be appreciated. As will be seen, the organization of the neural connections of the retina and higher visual pathway is such as to favour the accurate recognition of direction; for the moment, the question of the maintenance of a frame of reference must be considered, in the sense that a map has vertical and horizontal lines with which to compare other directions. In fact, the vertical and horizontal meridians of the retina seem to be specialized as frames of reference; the accuracy with which a human subject can estimate whether a line is vertical or horizontal is very great.

An important point in this connection is that of the effects of eye movements on interpretation of the directions of lines because, when the eye moves to positions different from the primary straight-ahead position, the images of vertical lines will not necessarily fall on its vertical meridian. This can be due to an actual torsion of the eye about its anteroposterior (fore and aft) axis or to distortion of the retinal image. This means, then, that the line on the retina that corresponds to verticality in one position of the eye does not correspond to verticality in another, so that, once again, the space representation centre must take account not only of the retinal elements that have been stimulated but also of the corollary motor discharge.

Effects of eye movements

Comparison of lengths. The influence of the movements of the eyes in the estimation of length was emphasized by Helmholtz. An accurate comparison of the lengths of two parallel lines *AB* and *CD* can be made, whereas if an attempt is made to compare the nonparallel lines *A′B′* and *C′D′*, quite large errors occur. According to Helmholtz, the eye fixates first the point *A,* and the line *AB* falls along a definite row of receptors, thereby indicating its length. The eye is now moved to fixate *C,* and if the image of *CD* falls along the same set of receptors the length of *CD* is said to be the same as that of *AB.* Such a movement of the eye is not feasible with lines that are not parallel. Similarly, the parallelism, or otherwise, of pairs of lines can be perceived accurately because on moving the eye over the lines the distance between them must remain the same.

Fairly accurate estimates of relative size may be made, nevertheless, without movements of the eyes. If two equal lines are observed simultaneously, the one with direct fixation and the other with peripheral vision, their images fall, of course, on different parts of the retina; if the images were equally long it could be stated that a certain length of stimulated retina was interpreted as a certain length of line in space. It is probable that this is roughly the basis on which rapid estimates of length depend, although there are such complications as the fact that the retina is curved so that lines of equal length in different parts of the retina do not produce images of equal length on the retina.

Optical illusions. Many instances have been cited of well-defined and consistent errors in visual estimates under special conditions. There is probably no single factor by which the errors can be explained, but the tendency for distinctly perceptible differences to appear larger than those more vaguely perceived is important.

The perception of depth. *Monocular cues.* The image of the external world on the retina is essentially flat or two-dimensional, and yet it is possible to appreciate its three-dimensional character with remarkable precision; to a great extent this is by virtue of the simultaneous presentation of different aspects of the world to the two eyes, but even when the subject views the world with a single eye it does not appear flat to him and he can, in fact, make reasonable estimates of the relative positions of objects in all three dimensions. Examples of monocular cues are the apparent movements of objects in relation to each other when the head is moved. Objects nearer the observer move in relation to more distant points in the opposite direction to the movement of the head. Perspective, by which is meant the changed appearance of an object when it is viewed from different angles, is another important clue to depth. Thus the projected retinal image of an object in space may be represented as a series of lines on a plane—*e.g.,* a box—these lines, however, are not a unique representation of the box because the same lines could be used to convey the impression of a perfectly flat object with the lines drawn on it, or of a rectangular, but not cubical, box viewed at a different angle. In order that a three-dimensional object be correctly represented to the subject on a two-dimensional surface, he must know what the object is; *i.e.,* it must be familiar to him. Thus a bicycle is a familiar object. If it is viewed at an angle from the observer the wheels seem elliptical and apparently differ in size. Because the observer knows that the wheels are circular and of the same size, he perceives depth in a two-dimensional pattern of lines. The perception of depth in a two-dimensional pattern thus depends greatly on experience—the knowledge of the true shape of things when viewed in a certain way. Other cues are light and shade, overlapping of contours, and relative sizes of familiar objects.

Perspective

Binocular vision. The cues to depth mentioned above are essentially uniocular; they would permit the appreciation of three-dimensional space with a single eye. When two eyes are employed, two additional factors play a role, the one not very important—namely, the act of convergence or divergence of the eyes—and the other very important—namely, the stereoscopic perception of depth by virtue of the dissimilarity of the images presented by a three-dimensional object, or array of objects, to the separate eyes.

When a three-dimensional object or array is examined binocularly, the nearer points or objects require greater convergence for fixation than the more distant points or objects, so that this provides a cue to the three-dimensional character of the presentation. It is by no means a necessary cue, since presentation of the array for such a short time that movements of the eyes cannot occur still permits the three-dimensional perception, which is achieved under these conditions by virtue of the dissimilar images received by the two retinas.

A stereogram contains two drawings of a three-dimensional object taken from different angles, chosen such that the pictures are right- and left-eyed views of the object. When the stereogram is placed in a stereoscope, an optical device for enabling the two separate pictures to be fused and seen single, the impression created is one of a three-dimensional object. The perception is immediate, and is not a matter of interpretation. Clearly, with the stereoscope the situation is simulated as it normally occurs. To appreciate the full implications of the stereoscopic perceptual process, one must examine some simpler aspects of binocular vision.

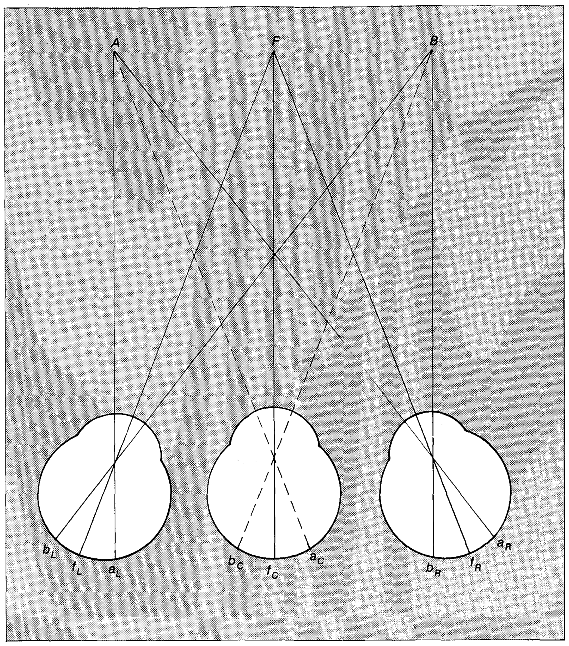

Figure 46: *The Cyclopean system of projection.* The images of the points *F, A,* and *B* on the two retinas are transposed to the retina of a hypothetical eye midway between the two. The pairs of images, a_L and a_R, b_L and b_R, and so on, coincide on the cyclopean retina indicating that the stimulated retina points are projected to a common direction (see text).

Figure 46 illustrates the situation in which a subject is fixating (fixing his gaze on) the point *F* so that the images of *F* fall on the foveal (retinal) points f_L and f_R, respectively. *F* is seen as a single point because the retinal points f_L and f_R are projected to the same point in space, and the projection is such that the subject says that the point *F* is straight in front of him, although it is to the right of his left eye and to the left of his right eye. The two eyes in this case are behaving as a single eye, "the cyclopean eye," situated in the centre of the forehead, and one may represent the projection of the two separate retinal points, f_L and f_R, as the single projection of the point f_C of the cyclopean eye. As will be seen, the cyclopean eye is a useful concept in consideration of certain aspects of stereoscopic vision.

Corre-
sponding
points

The points f_L and f_R may be defined as corresponding points because they have the same retinal direction values. The images formed by the points *A* and *B,* in the same frontal plane as *F,* fall on a_L and a_R and b_L and b_R; once again the pairs of retinal points are projected to the same points, namely, to *A* and *B,* and they are treated as being on the left and right of *F,* respectively. On the cyclopean projection, they may be said to be localized by the outward projections of a_C and b_C, respectively.

In Figure 47, the subject is once again fixing the point *F,* but the point *A* is now no longer in the same frontal plane as the point *F,* but closer to the observer. The images of *F* fall on corresponding points and are projected to a single point in front. The images of *A,* on a_L and a_R, do not fall on corresponding points and are, in fact, projected into space in different directions, as indicated by the cyclopean projection. This means that *A* is seen simultaneously at two different places, a phenomenon called physiological diplopia, and this in fact does happen, as can be seen by fixing one's gaze on a distant point and holding a pencil fairly close to the face; with a little practice the two images of the pencil can be distinguished. Thus, when the eyes are directed into the distance the objects closer to the observer are seen double, although one of the double images of any pair is usually suppressed. To return to Figures 46 and 47, *F* and *A* in Figure 46 are seen single and in the same plane because their images each fall on corresponding points. *F* is seen single and *A* double in Figure 47 because the images of *A* fall on noncorresponding, or disparate, points. *A* is appreciated as being closer to the observer than *F* in Figure 47 by virtue of these double images but, in general, although it is retinal disparity that creates the percept of three-dimensional space, it is not necessarily the formation of double images, since if the disparity is not large the point will be seen single, and this single point will appear to be in a different frontal plane from that containing the fixation point.

To appreciate the nature of this stereoscopic perception one must examine what is meant by corresponding points in a little more detail. In general, it seems that the two retinas are, indeed, organized in such a way that pairs of points are projected innately to the same point in space, and the horopter is defined as the outward projection of these pairs. One may represent this approximately by a sphere passing through the fixation point, or, if one confines attention to the fixation plane, it may be represented by the so-called Vieth-Müller horopter circle, as illustrated in Figure 48. On this basis, the corresponding points are arranged with strict symmetry, and each pair projects to a single point in space on the horopter circle. Theoretically, then, all points on the circle passing through the fixation point, *F,* will be seen single, and the point *X* will be seen double because it will be projected by the left eye to *F* and by the right eye to *A.* The actual situation is somewhat more complex than this, since experimentally the horopter turns out to have different shapes according to how close the fixation point is to the observer. The point to appreciate, however, is that the experimentally determined line, be it circular or straight or elliptical, is such that when points are placed on it they all appear to be in the same frontal plane—*i.e.,* there is no stereoscopic perception of depth when one views these points—and one may say that this is because the images of points on the horopter fall on corresponding points of the two retinas.

In Figure 49, to the left, are two eyes viewing an arrow

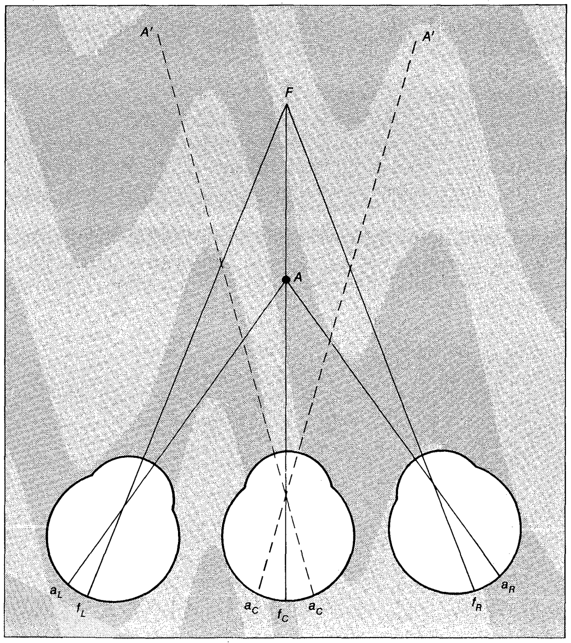

Figure 47: Physiological diplopia caused by an object, *A,* closer to the observer than the fixation point, *F.* The images of *A* fall on disparate or noncorresponding points on the two retinas, and these are projected to different points *A'* and *A'* (see text).

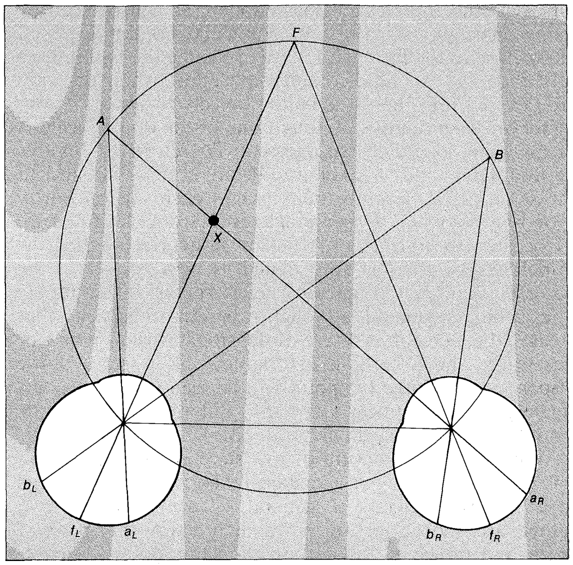

Figure 48: *The Vieth-Müller horopter circle.*
F is the fixation point. If corresponding points are symmetrically distributed about the foveas, the points in space in the fixation plane, whose images fall on the corresponding points, lie on the circle. The images of the point *X* lie on disparate points (see text).
From H. Davson, M.D., *Physiology of the Eye*

Fusion of disparate images

lying in the frontal plane—*i.e.*, with no stereopsis—and to the right the arrow is inclined into the third dimension—*i.e.*, it tends to point toward the observer. All points on the arrow are, in fact, seen single under both conditions, and yet it is clear from the right-hand figure that, if the gaze is fixed on *A*, the images of *B′* will fall on noncorresponding points. *B′* is not seen double but, instead, the noncorresponding points, b'_L and b'_R, are projected to a common point *B′* and a stereoscopic percept is achieved. Thus the noncorresponding, or disparate, points on the retinas can be projected to a single point, and it is essentially this fusion of disparate images by the brain that creates the impression of depth. If the point *B′* were brought much closer to the eyes, its images would fall on such disparate points that fusion would no longer be possible, and *B′* would be seen double, or one double image would be suppressed. There is thus a certain zone of disparity that, if not exceeded, allows fusion of disparate points. This is called Panum's fusional area; it is the area on one retina such that any point in it will fuse with a single point on the other retina.

To return to the stereoscopic perception of three-dimensional space, one may recapitulate that it is because the two eyes receive different images of the same object that the stereoscopic percept happens; when the two images of the object are identical, then, except under very special conditions, the object has no three-dimensionality. A special condition is given by a uniformly illuminated sphere; this is three-dimensional, but the observer would have to use special cues to discriminate this from a flat disk lying in the frontal plane. Such a cue might be the different degree of convergence of the eyes required to fixate the centre from that required to fixate the periphery, or the different degree of accommodation.

From H. Davson, M.D., *Physiology of the Eye*

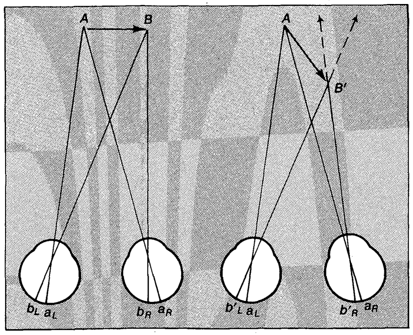

Figure 49: The distinction between corresponding points (a_L and a_R, b_L and b_R) and points that do not correspond (b'_L and b'_R; see text).

The difference in the two aspects of the same object (or group of objects), measured as the instantaneous parallax, is illustrated in Figure 50. *B* is closer to the observer than *A;* the fact is perceived stereoscopically because the line *AB* subtends different angles at the two eyes, and the instantaneous parallax is measured by the difference between the angles *a* and *b.* The binocular parallax of any point in space is given by the angle subtended at it by the line joining the nodal points of the two eyes; hence, the binocular parallax of *A* is *a;* that of *B* is *b;* the instantaneous parallax is thus the difference of binocular parallax of the two points considered.

Accuracy of stereoscopic perception

If one places three vertical wires in front of an observer in the frontal plane, one may move the middle one in front of, or behind, the plane containing the other two and ask the subject to say when he perceives that it is out of the plane; under correct experimental conditions the only cue will be the difference of binocular parallax, and it is found that the minimum difference is remarkably small, of the order of five seconds of arc, corresponding to a disparity of retinal images far smaller than the diameter of a single cone. With two editions of the same book, it is not possible, by mere inspection, to detect that a given line of print was not printed from the same type as the same line in the other book. If the two lines in question are placed in the stereoscope, it is found that some letters appear to float in space, a stereoscopic impression created by the minute differences in size, shape, and relative position of the letters in the two lines. The stereoscope may thus be used to detect whether a bank note has been forged, whether two coins have been stamped by the same die, and so on.

From Hugh Davson, M.D. *Physiology of the Eye*

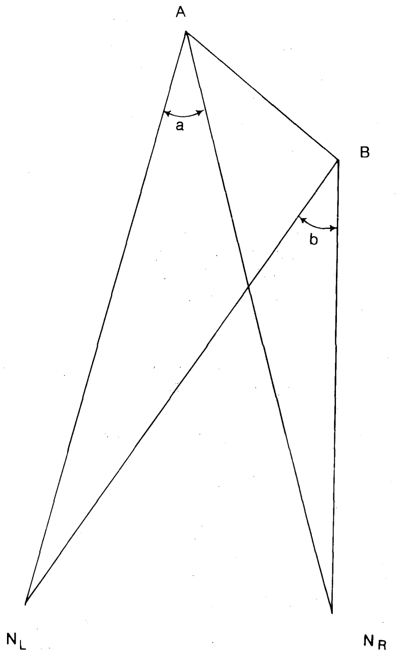

Figure 50: *Binocular and instantaneous parallax.*
N_L and N_R are the nodal points of the left and right eyes, respectively (see text).

The stereoscopic appearance obtained by regarding two differently coloured, but otherwise identical, plane pictures with the two eyes separately, is probably due to chromatic differences of magnification. If the left eye, for example, views a plane picture through a red glass and the right eye views the same picture through a blue glass, an illusion of solidity results. Chromatic difference in magnification causes the images on the two retinas to be slightly different in size, so that the images of any point on the picture do not fall on corresponding points; the conditions for a stereoscopic illusion are thus present.

Retinal rivalry. Stereoscopic perception results from the presentation to the two eyes of different images of the same object; if two pictures that cannot possibly be related as two aspects of the same three-dimensional object are presented to the two eyes, single vision may, under some conditions, be obtained, but the phenomenon of retinal rivalry enters. Thus, if the letter *F* occupies one side of a stereogram, and *L* the other, the two letters can be fused by the eyes to give the letter *E;* the letters *F* and *L* cannot, however, by any stretch of the imagination be regarded as left and right aspects of a real object in space, so that the final percept is not three-dimensional, and, moreover, it is not a unitary percept in the sense used in this discussion; great difficulty is experienced in retaining the appearance of the letter *E,* the two separate images, *F* and *L,* tending to float apart. This is a mode of binocular vision that may be more appropriately called simultaneous perception; the two images are seen simultaneously, and it is by superimposition, rather than fusion, that the illusion of the letter *E* is created. More frequent than superimposition is the situation in which one or the other image is completely suppressed; thus, if the right eye views a vertical black bar and the left eye a horizontal one, the binocular percept is not that of a cross; usually the subject is aware of the vertical bar alone or the horizontal bar alone. Moreover, there is a fairly characteristic rhythm of suppression, or alternation of dominance, as it is called.

Ocular dominance. Retinal rivalry may be viewed as the competition of the retinal fields for attention; such a notion leads to the concept of ocular dominance—the condition when one retinal image habitually compels attention at the expense of the other. While there seems little doubt that a person may use one eye in preference to the other in acts requiring monocular vision—*e.g.,* in aiming a rifle—it seems doubtful whether, in the normal individual, ocular dominance is really an important factor in the final awareness of the two retinal images. Where the retinal images overlap, stereoscopic perception is possible and the two fields, in this region, are combined into a single three-dimensional percept. In the extreme temporal fields (*i.e.,* at the outside of the fields of vision), entirely different objects are seen by the two eyes, and the selection of what is to dominate the awareness at any moment depends largely on the interest it arouses; as a result, the complete field of view is filled in and one is not aware of what objects are seen by only one eye. Where the fields overlap, and different objects are seen by the two eyes—*e.g.,* on looking through a window the bars may obscure some objects as seen by one eye but not as seen by the other—the final percept is determined by the need to make something intelligible out of the combined fields. Thus, the left eye may see a chimney pot on a house, while the other eye sees the bar of a window in its place; the final perceptual pattern involves the simultaneous awareness of both the bar and the chimney pot because the retinal images have meaning only if both are present in consciousness. So long as the individual retinal images can be regarded as the visual tokens of an actual arrangement of objects, it is possible to obtain a single percept, and there seems no reason to suppose that the final percept will be greatly influenced by the dominance of one or other eye. When a single percept is impossible, retinal rivalry enters; this is essentially an alternation of awareness of the two fields—the subject apparently makes attempts to find something intelligible in the combined presentation by suppressing first one field and then the other—and certainly it would be incorrect to speak of ocular dominance as an absolute and invariable imposition of a single field on awareness, since this does not occur. Dominance, however, has a well-defined physiological meaning in so far as certain cells of the cerebral cortex may be activated exclusively by one eye, either because the other eye makes no neural connections with it or because the influence of the other eye is dominant.

The choice of what is perceived

Ocular dominance

Binocular brightness sensation. When the two eyes are presented with differently illuminated objects or surfaces some interesting phenomena emerge. Thus fusion may give rise to a sensation of lustre. In other instances, rivalry takes place, the one or other picture being suppressed, while in still others the brightness sensation is intermediate between those of the two pictures. This gives rise to the paradox whereby a monocularly viewed white surface appears brighter than when it is viewed binocularly in such a way that one eye views it directly and the other through a dark glass. In this second case the eyes are receiving more light, but because the sensation is determined by both eyes, the result is one that would be obtained were one eye to look at a less luminous surface.

ELECTROPHYSIOLOGY OF THE VISUAL CENTRES

To elucidate the functions of the various stages in the visual pathway, one must examine the responses to a retinal light-stimulus of the individual neurons at the different stages.

Ganglion cells. The main features of the responses of ganglion cells have already been touched upon. These have receptive fields that indicate a dual type of connection with the rods and cones, as indicated by the centre-periphery organization. A spot of light falling on receptors in the centre of this field may provoke a discharge in the ganglion cell or its optic nerve fibre; it is called an on-response and consists usually in an increase in the background discharge occurring in darkness. If a spot of light falls on a ring of retina surrounding this central region, the effect is one of inhibition of the background while the light is on, and as soon as it is switched off there is a pronounced discharge, the off-response. Other ganglion cells have been shown to have a directional sensitivity, responding to a moving spot of light only if this moves in a preferred direction and showing inhibition of background discharge if movement is in the null direction.

Geniculate neurons. In general, the lateral geniculate neuron is characterized by an accentuation of the centre-periphery arrangement, so that the two parts of the receptive field tend to cancel each other out completely when stimulated together, by contrast with the ganglion cell in which one or another would predominate. Thus, when the retina is illuminated uniformly there is little response in the geniculate cells because of this cancellation. This represents a useful elaboration of the messages from the retina because, to the animal, uniformity is uninteresting; it is the nonuniformity created by a contour or a moving object that is of interest, and the brain is therefore spared from being bombarded by unnecessary information that would result if every receptor response were transmitted to the brain.

Cortical neurons. When investigators made records of responses from neurons in area 17 there was an interesting change in the nature of the receptive fields; there was still the organization into excitatory (on) and inhibitory (off) zones, but these were linearly arranged, so that the best stimulus for evoking a response was a line, either white on black or black on white. When this line fell on the retina in a definite direction, and on a definite part of the retina, there was, say, an on-response, while if it fell on adjacent areas there was an off-response. Changing the orientation of the line by as little as 15° could completely abolish the responses. The simplest interpretation of this type of receptive field is based on the connection of the cortical cell with a set of geniculate cells with their receptive fields arranged linearly.

Variations in response

Eye dominance. Most of these units (*i.e.,* cortical cells plus connections) could be excited by a light stimulus falling on either eye, although there was usually dominance of one eye, in the sense that its response was greater; when both eyes were stimulated together, the effects summated. In general, then, when a large number of units are studied, a certain proportion are fired by one eye alone, others by the opposite eye alone, others by both eyes with dominance of one or other eye, while still others respond only when both eyes are stimulated. It is interesting that when kittens are deprived of the use of one eye from birth for several months, this deprived eye is virtually blind and the distribution of dominance in the cortical neurons is changed dramatically; if the left eye is deprived, the right hemispherical cortical neurons show a marked fall in dominance by the left eye, and an increase by the right eye. Thus, the ability of the eye to make use of cortical neurons is not fully developed at birth.

Cortical architecture. When an electrode is directed downward into the cortex it picks up responses in individual units at successive depths; units having the same directional sensitivity are arranged in columns so that the receptive fields of successive neurons are similarly oriented. When units were classified on the basis of eye dominance, a similar vertical distribution of units was found, overlapping with those based on directional preference. The columns for eye preference were about one millimetre wide, but those for directional preference were considerably finer. This columnar organization of cortical cells is not peculiar to the visual area.

Complex neurons. The cortical units (cells) described above, with receptive fields organized on a linear basis, have been called simple units in contrast to complex and hypercomplex units. Four types of complex units have been described; as with the simple units, the orientation of a slit stimulus (that is, a line) is of the utmost importance for obtaining maximal response, but unlike the situation with the simple unit, the position on the retina is unimportant. This type of unit makes abstractions of a higher order, responding to direction of orientation but not to position. It is this type of neuron that would be concerned, for example, with determining the verticality or horizontality of lines in space. Space does not permit of a description of the receptive field of a hypercomplex cell, but in general its features could be explained on the basis of connections with complex cells.

Stereoscopic vision. Of special interest is the behaviour of binocularly driven (stimulated) cortical cells, since their responses provide a clue to the fusion of retinal images. The cortical nerve cell receiving impulses emanating from both retinas must select those parts of the two retinal images that are the images of the same point on an object; second, for stereopsis, the nerve cell must assess the small displacements from exact symmetry that give the binocular parallax. In experiments, maximal response was often obtained only when the stimuli fell on disparate parts of the two retinas; these cortical cells were obviously disparity detectors, in contrast to others that gave maximal response when the stimuli fell on strictly symmetrically related parts of the two retinas—*i.e.,* on corresponding points. When successive units, during penetration of the electrode, were recorded, it was found that those requiring the same degree of disparity for maximal response were arranged in columns, as with direction sensitivity, so that, in effect, all these nerve cells were responding to stimuli in a strip of space at a definite distance from the fixation point. (H.Da.)

Eye diseases and visual disorders

The human visual apparatus includes the eyeball or globe, and its socket, or orbit, and auxiliary structures such as the lids and the muscles that control eye movement. These organs and their normal functioning are covered in detail above. This section briefly describes the more common diseases of the eye and its associated structures, and the methods used in examination and diagnosis; it also indicates the treatment and prognosis. The first part deals with conditions affecting the orbit, lids, and external eye, and the second with diseases of structures within the globe. Later sections deal with injuries, ocular conditions associated with general disease, disorders of vision, methods of examining the eye, and devices for correcting visual defects.

THE OUTER EYE AND AUXILIARY STRUCTURES

The orbit and lacrimal apparatus. The orbit is the bony cavity in the skull that contains the globe of the eye, the muscles that move the eye, the lacrimal gland, and the blood vessels and nerves required to supply these structures. The remaining space within the orbit is filled with a fatty pad that acts as a cushion for the eye and allows free movement of the globe. In old age this pad of fat tends to atrophy so that the globe recedes, causing the sunken appearance often seen in old people.

Inflammatory conditions of the orbit. As the bone that separates the orbit from the nose and the nasal sinuses is rather thin, infection sometimes spreads from the nasal sinuses into the orbit, causing the orbital tissue to swell and the eye to protrude. The condition is serious because of the possibility that the infection may spread into the cranial cavity along the pathways of the cranial nerves that enter the orbit to reach the eye. Infections can also spread to the cranial cavity by way of the blood vessels that lie in the upper part of the orbit, from lesions such as a boil on the skin of the lids or face in the neighbourhood of the eye. Large doses of an antibiotic such as penicillin, given immediately, in most cases eliminate such infections. The lacrimal glands, the small glands that secrete tears and are behind the outer part of each upper lid, are rarely inflamed but may become so as a complication of mumps. Inflammations of the lacrimal sac are much more common. The lacrimal or tear sac lies in a hollow at the corner of the eye in the front part of the nasal wall of the orbit; under normal conditions tears run along the edges of the lids toward the nose and are drained through two tiny holes connected by small tubes to the upper part of the lacrimal sac. The lower part of the sac is connected to the nose by a duct, the nasolacrimal duct, and infection may ascend this passage from the nose and cause an acute painful swelling at the inner corner of the eye. Blockage of the nasolacrimal duct prevents the passage of tears into the nose and results in a watering eye. Such a blockage, which is nearly always accompanied by chronic inflammation in the lacrimal sac, is usually best treated by an operation in which a new opening from the lacrimal sac to the nasal cavity is made.

Infections of nasal origin

Tumours of the orbit. Tumours in this area are comparatively rare, the most common being a tumour of the lacrimal gland. If the tumour is behind the globe in the optic nerve, it will cause a slow and gradual protrusion of the eye; such an abnormal position of the eye may prevent ocular movements from being coordinated with those of the normal eye, and the images of the two eyes, which are normally fused, may separate and give rise to double vision (or diplopia).

The lids. *Inflammatory conditions.* The chronic inflammation of the lid margins known as blepharitis is a common and distressing condition. The inflammation may be mild and consist simply of redness of the lid margin with scaling of the skin, or more severe, affecting the follicles of the eyelashes and leading to their destruction and distortion. Both types tend to be associated with greasiness of the skin and dandruff. The skin of the lids is particularly sensitive to allergic processes, and itching and scaling of the lids is a common reaction to drugs or cosmetics applied to the eye of a sensitized person.

Another common inflammatory condition of the lid is a sty; *i.e.,* an infection of a lash follicle—the sheath of the eyelash root—corresponding to a boil on the skin elsewhere. It starts as a painful swelling of the whole lid, so that at first it may be difficult to find a localized lesion; but soon one area becomes more swollen and, as pus forms, a yellow point associated with an eyelash can be seen near the lid margin. A rather similar appearance can be produced by an inflammation of the meibomian glands; *i.e.,* tiny glands in the thickness of the lid, opening on the lid margin. As the glands are embedded in tough fibrous tissue, the pain and reaction may be more severe than in an ordinary sty. Examination of the internal surface of the lid will show a red velvety area with a central yellow spot through which pus will later discharge. Sometimes the meibomian glands suffer from a chronic infection, and a painless firm lump appears in the lid and slowly increases in size. The skin can be moved freely over the surface of the lump, showing that the latter is in the deeper tissue of the lid. The inner surface of the lid will show a grayish area surrounded by a little inflammation. The lesion is treated by making an incision on the inner surface of the lid, and scraping out the contents.

Herpes zoster (shingles) may affect the skin of the eyelids and is of particular importance because the cornea (the transparent covering of the front of the eyeball) and the inner eye may also be affected. The condition starts with pain and redness of one part of the forehead and the eyelids of the same side. Vesicles, or small blisters, form later in the affected area. The pain may be severe, and some constitutional disturbance is usual.

Ectropion and entropion

Displacements of the lid. Malpositioning of the lid is common in elderly people, and although not serious in itself gives rise to considerable discomfort and irritation. The commonest condition is called ectropion, in which the lower lid falls away from the globe so that the tears overflow the lid. This constant wetting of the skin of the lower lid excoriates the skin and causes it to retract, which in turn increases the tendency of the lid to turn out. In the early stages, massage of the lid and the use of a bland ointment on the skin may help, but usually some plastic procedure is necessary to bring the lid back into its normal position.

The opposite condition is entropion, in which the lid turns inward and the lashes cause much irritation by rubbing on the eye. Unlike ectropion, it may affect either the upper or the lower lid. It may be caused by scarring of the deeper tissues of the lid following infection, or may be due to senile changes in muscle tone in which a band of fibres of the circular muscle surrounding the lids contracts more strongly than the peripheral fibres, thus tending to turn the lid inward. Surgical treatment is required to restore the lid to its normal position.

Tumours. Benign overgrowths of the blood vessels, called hemangiomas, may occur in the lids and give rise to soft bluish swellings that can be reduced by pressure over them. They are present at birth and tend to grow rapidly in the first few years of life. Often they disappear spontaneously, but they can be treated by surgical removal or the insertion of radioactive material. Simple overgrowths of skin, called papillomas, are common along the lid margin but require no special treatment except excision for cosmetic reasons.

The lids and the skin of the nose near the inner margins of the lids are common sites for the development of skin cancer in older people; the most usual type, called a rodent ulcer, starts as a small nodule in the skin that gradually enlarges and breaks down to form an ulcer with a hard base and rolled edges. Bleeding may occur from the base of the ulcer. Although rodent ulcers are malignant in the sense that they destroy tissue locally, they do not spread to distant areas of the body by means of the lymph system or the blood vessels. A more serious malignant tumour of the lids is a carcinoma, which develops as a more irregular ulcer of the lid and may spread to involve the underlying bone. If left untreated the growth may spread to the lymph nodes in front of the ear or under the jaw.

Development of binocular vision; definition of squint

Squint. In the lower vertebrates such as the fish the eyes are situated on either side of the head, to give the maximum view of the surroundings and an early warning of the presence of predators. The field of vision of each eye is separate except for a narrow sector immediately in front of the animal, where the two visual fields overlap. From the evolutionary point of view the improved judgment of distance obtained by viewing an object with both eyes conferred considerable biological advantage in the struggle for survival. In the higher animals, particularly the predatory species of birds and mammals, binocular vision became more and more important and structural changes in the placement of the eyes in the head permitted a larger overlap of the two visual fields, until the situation was reached in the higher mammals in which the visual axes—that is, the line of direct sight—became parallel. This desirable visual function has been fully attained in man. The structural changes necessary to bring this about have, however, lagged behind the function, and the geometrical axes of most eyes are still slightly divergent (*i.e.,* the two eyes at rest are directed slightly away from the nose). The bony structure of the orbit has lagged even further behind, so that the axes of the two orbits make an angle of about 45°.

It is in fact the function of using two eyes together that keeps the optic axes straight in a normal person. If, for example, one eye becomes blind, it tends to revert to an anatomical position of rest in line with the axis of the orbit. A blind eye will therefore appear to be diverging. The visual axes can remain straight only if each eye has reasonably good vision, the ocular muscles can move the eyes in the required direction of gaze, and the complex neuromuscular reflexes required to coordinate the movements of the two eyes are intact. Failure to maintain the visual axes parallel may therefore result from a visual defect in one or both eyes, a muscular defect resulting in loss of normal movement of the eye, or a defect in the central nervous system involving the coordinating nervous pathways. A true squint is a condition in which the visual axes are no longer parallel. An apparent squint may be seen in children as the result of prominent skin folds in the inner sides of the eyes, which make the eyes appear to be converging (*i.e.,* appear to cross). These skin folds usually disappear when the bony structure of the nose develops more fully.

Clinically, squints are divided into concomitant, in which the abnormal angle between the visual axes remains constant in all positions of gaze, and paralytic, in which the angle of squint varies with the direction of gaze. The commonest type of squint is the convergent concomitant type seen in small children (*i.e.,* the children are consistently or intermittently cross-eyed). It is usually first noticed between the ages of one and two and may be precipitated by a systemic disease such as measles. There is often a family history of squint. Children of this age are particularly interested in objects close to them, and in order to view an object clearly at close range two things are necessary: first, the visual axes must converge, so that both eyes can view the same object; and second, the focus of the eye must be adjusted for near vision. The link between convergence of the eyes and focussing, or accommodation, is very strong, and normally the two actions work in harmony. Most small children, however, are long-sighted, which means that, in order to see clearly close to, they have to exert an extra amount of accommodative effort. As accommodation and convergence are closely linked, the extra effort of accommodation tends to produce an overconvergence; but, provided that the visual acuity of each eye is normal and the motor control of the eyes is normal, this tendency is controlled. If the vision of one eye is reduced, for example by disease or an error of refraction, binocular vision breaks down and overconvergence occurs.

Double vision; suppression of one image

Once parallelism of the visual axes is lost, the image of objects no longer lies on a familiar area of retina, and instead of the images from the two eyes being fused into one, two images are perceived. This condition of double vision, or diplopia, is intolerable to the child, who reacts by "suppressing" the image from the squinting eye. If the suppression is allowed to continue, the central vision of the affected eye drops rapidly to a low level, so that even if the original disturbance that started the squint is corrected, this loss of vision, or amblyopia, of the squinting eye will prevent the restoration of normal binocular vision and thus perpetuate the squint. The longer the suppression is allowed to continue, the less likely is the child to regain normal vision in the squinting eye. Covering the good eye will usually encourage the recovery of the suppressed vision but must be started as soon as the squint is noticed. Any refractive error present—any defect that prevents light rays from focussing properly on the retina—must be corrected by glasses, and retraining of the binocular reflexes can be aided by special exercises. Early treatment on these lines may be all that is necessary, but if the visual axes are still abnormal surgery of the extraocular muscles will be required to correct the deviation.

Paralysis of one of the muscles that control the movement of the eyes results in limitation of movement of the globe in the direction of action of the muscle, with the result that double vision with separation of the images occurs on attempts to move the eye in this direction.

As earlier stated, accommodation and convergence are normally perfectly linked together so that the movements of the two eyes bring the visual axes to the point of focus. In many people this balance is not quite perfect and the eyes tend to converge or diverge too much for a given distance—a condition known as heterophoria.

The conjunctiva. The marine origin of the human species is betrayed by the need for the anterior surface of the eye to be bathed in salt water. A thin membrane lines the lids and covers the anterior surface of the globe, forming a sac, the conjunctival sac, the contents of which are lubricated by the tear glands. This warm, moist habitat provides a suitable environment for the growth of bacteria and other organisms, leading to conjunctivitis, inflammation of the conjunctiva. Bacterial conjunctivitis starts with a feeling of grittiness and discomfort, the eye is red and there is a discharge from it. The discharge is particularly noticeable after sleep, when the lids may be stuck together by the exudate on the lashes. Vision is not affected except by the strands of mucus, which can be blinked away from the cornea. Antibiotic drops usually clear the condition in a few days. Vernal conjunctivitis or spring catarrh is, as its name suggests, an allergic condition occurring in the early summer; it is more common in young people and probably results from sensitivity to external irritants such as dust and pollen. It usually responds well to treatment with drops of corticosteroid hormone.

Chronic conjunctivitis, causing a gritty feeling, with redness of the eyes and a slight mucoid discharge, is a common condition, the cause of which may be difficult to find. Often there is an infective element such as a chronic inflammation of the lid margin, and sometimes the condition is allergic and may result from sensitivity to cosmetics or to drugs applied to the eye. An unsuspected foreign body or a deficiency of tear secretion may cause similar symptoms.

Viral conjunctivitis. With the enormous increase in the use of antibiotics since the 1940s, bacterial infections in general are becoming less common. This is also true of infections of the eye, and in most western countries bacterial conjuctivitis is now less common than viral infection. Viruses tend to attack the cornea as well as the conjunctiva; the infection is contagious and may be responsible for outbreaks of epidemic keratoconjunctivitis (inflammation of the cornea and the conjunctiva). The onset is acute, with redness and swelling of the eye and lids and a tender swelling of the lymph node in front of the ear.

Trachoma

Trachoma can truly be described as one of the scourges of mankind. Although rare in England and North America, it is the largest single cause of blindness in the world as a whole. Widespread in some Middle East countries, it has become more common in Asia, India, Central and South America, and Africa. It occurs sporadically in southern and eastern Europe. The agent responsible has now been isolated and shown to belong to the group of organisms known as chlamydiae. They occupy a taxonomic position between bacteria and true viruses and unlike the latter are susceptible to treatment with sulfonamides and some antibiotics. The disease is contagious and thrives where populations are crowded together in poor hygienic surroundings. Shortage of water for washing, and the myriads of flies attracted to human waste, aid the dissemination of the disease. In some ways trachoma is more of a social than a medical problem; if living standards can be improved, overcrowding reduced, flies discouraged, and adequate water supplies ensured, the incidence of trachoma decreases rapidly.

The early symptoms of infection are pain, watering of the eye, and sensitivity to light. At this stage the conjunctival lining of the lids is red and velvety in appearance, and the cornea shows gray areas. Later, the conjunctiva appears to have grains of sand embedded in its tissue. Blood vessels grow into the cornea, which becomes thickened and hazy. Secondary bacterial infections are common, but the real dangers of trachoma lie in the scarring and contracture of tissue that occur when healing takes place. These changes affect the upper lid in particular, causing it to buckle inward so that the lashes rub across the already diseased cornea, and it is the corneal scarring thus produced that can cause blindness.

Degenerative conditions. Exposure to wind and dust frequently causes degenerative changes in the exposed part of the conjunctiva, particularly in older people. A yellow nodule forms, first on the nasal side of the cornea and later on the other side. It is without blood vessels and is frequently unnoticed until an incidental conjunctivitis causes it to stand out clearly against the red background of dilated conjunctival vessels. It causes no symptoms and requires no treatment.

A more serious degeneration is that known as a pterygium, found particularly in people who live in hot, dusty climates. It appears as a fleshy growth at the edge of the cornea, with a tendency to progress across its front surface, where it may interfere with vision. Treatment consists of surgical removal, but recurrences are common.

The cornea and sclera. The cornea is the clear window of the eye and its most important refractive surface. Any surface irregularity, any scar in the substance of the cornea, is likely to have a profound effect on vision. Almost the whole nerve supply of the cornea consists of nerve fibres sensitive to pain, so that corneal diseases are always painful and elicit a flow of tears by a reflex action that is part of the protective system of the eye.

Infection of cornea with herpes virus; bacteria; fungi

Inflammation of the cornea. As with inflammations of the conjunctiva, bacterial infection of the cornea has become much less common and viral infections are increasingly important. Of these, the herpes viruses, which cause the common "cold sore" of the lips and skin and the venereal form of herpes, are the most frequent cause of corneal ulceration. Infection is spread by personal contact. The herpes virus causes a typical ulcer of the cornea called, from the pattern of the lesion, dendritic ("branching"). The disease starts with an acutely painful eye, with tearing, and sensitivity to light. The ulcer may heal spontaneously or after medical treatment, but the virus often lies dormant in the tissues; recurrences are common, and with each recurrence there is more danger that the virus will extend deeper into the cornea and cause an intractable inflammation.

Application of the drug deoxyuridine (5-iodo-2-deoxyuridine) to the cornea causes the ulcer to heal more rapidly and reduces the recurrence rate. The action of the drug depends upon its limiting the multiplication of the virus by interfering with the formation of virus deoxyribonucleic acid (DNA) in the host cell.

Bacterial infections of the cornea still occur, usually after injury to the corneal surface, as few bacteria have the power to penetrate the intact surface layers of the cornea. Such ulcers may be extremely severe, and there is always a danger of perforation of the eye, particularly in debilitated patients.

The spores of fungi are commonly present in the atmosphere. The normal cornea is resistant to infection by these organisms, but a fungal infection of the cornea can develop after a corneal injury or other lesion, particularly if corticosteroid drugs have been used in treatment. Intensive treatment with antifungal drugs is usually effective in killing the organisms, but a dense scar is usually left.

A corneal inflammation may start in the deeper layers, usually by spread of infection from the bloodstream. It is seen most commonly in adolescents who have congenital syphilis. Both eyes are usually attacked, although there may be an interval before the second eye is affected. The cornea rapidly becomes hazy, and blood vessels grow in from the surrounding tissues to form a red patch. With the decline in congenital syphilis in developed countries, the condition is now becoming a rarity.

Inflammation of the sclera. The sclera is the fibrous covering of the eye that shows up as a dense white layer beneath the transparent conjunctiva. A relatively mild nodular inflammation sometimes occurs in the superficial layers of the sclera; it is thought to be allergic in nature and usually responds well to anti-inflammatory treatment. Inflammation of the deeper sclera is more severe and often is painful. It occurs more frequently in older people and may be associated with tuberculosis or rheumatism; however, the cause of the condition is often not discovered.

Degenerative conditions. Keratoconus is the name of a curious condition in which the central part of the cornea, normally spherical in shape, begins to bulge and protrude forward as a cone. The only symptom is deterioration of vision due to the irregular astigmatism caused by the changing corneal curvature. Ordinary spectacles cannot correct the irregular refraction, but contact lenses are often of great value, and in more advanced cases corneal grafting is required.

There are numerous other rare types of corneal degeneration, some of which are familial; all produce a deterioration in vision that cannot be corrected with spectacles. Many of these conditions respond well to corneal grafting.

THE INNER EYE

The uveal tract. The uveal tract is a vascular layer of tissue—that is, a layer rich in blood vessels—lying next to the inner surface of the sclera. It is divided into three structures: the choroid, a highly vascular layer that supplies blood to the outer layers of the retina; the ciliary body, largely muscle tissue, which by its contraction and relaxation alters the focussing of the lens; and the iris, the coloured part of the eye, which forms the variable aperture of the eye, the pupil. The ciliary body, which lies at the base of the iris, also functions by forming the aqueous humour, the production and drainage of which regulate intraocular pressure; the aqueous humour also is the source of nutriment to the lens and cornea, which are avascular (without blood vessels).

Inflammation. Inflammations of the uveal tract are always potentially serious because of the secondary effects they may have on the retina and the lens. In most cases the disease affects either the anterior part of the uvea—that is, the iris and ciliary body—or the posterior part, the choroid. An attack of acute anterior uveitis starts with pain, redness, and mistiness of vision. The eye is sensitive to light, and, although there is no discharge as in conjunctivitis, the eye may water. The pupil tends to contract and the normally clear iris markings become less distinct. In chronic anterior uveitis the main symptom is blurring of vision. Acute choroiditis starts with sudden onset of blurring of vision with many black spots floating about in front of the sight.

Except for cases in which the uveitis follows a perforating injury or a corneal ulcer, it is believed that the inflammation is caused by an infective process within the body or by some other mechanism associated with systemic disease. Many infective conditions and parasitic diseases are known to cause uveitis. In a large proportion of cases, however, particularly when the inflammation is confined to the anterior segment, it proves impossible to be sure of the cause in any individual instance, and the investigation of a case of uveitis often poses one of the biggest problems in ophthalmology today. In men, a proportion of cases of anterior uveitis are associated with ankylosing spondylitis, a chronic disease of the joints of the spine, the cause of which is still obscure. Another association, again in men, is with Reiter's disease, a condition that starts as an infection of the urogenital tract with the later development of joint changes, particularly in the sacroiliac joints of the lower back, and recurrent attacks of anterior uveitis. The organism that is responsible for this venereally contracted infection is still unknown, but may be a virus. Infections in the teeth and tonsils have long been held to be a cause of uveitis, and eradication of dental decay does occasionally have a favourable effect on the course of the disease.

Toxoplasmosis and its effect on fetus

Inflammations of the choroid—the posterior portion of the uveal tract—and the retina are more likely to be infective in origin. One of the organisms most commonly involved is *Toxoplasma gondii,* a protozoon of worldwide distribution among domestic animals, small mammals, and man. Although antibodies to the organism can be found in a high proportion of most populations, showing that infection is widespread, overt signs of disease are rarely seen; most people can acquire the infection without being aware of any systemic disturbance at all, and only in special circumstances does the organism cause disease. One of these special circumstances is pregnancy. If a woman becomes infected during pregnancy there is a short period in which invasion of the tissues takes place before circulating antibodies are formed by the mother. During this period it is possible for the organism to pass through the placenta and infect the unborn child. Fetuses appear to be particularly susceptible to the organism, nearly half of those exposed showing some evidence of infection with toxoplasmosis. In severe cases the child may be stillborn or may be born with congenital toxoplasmosis, a serious disease affecting many organs of the body and particularly the brain and eye. In less serious cases small foci of infection are left in the nervous system and the retina of the eye; these may not be apparent at birth and may remain quiescent, only to become active 15 or 20 years later in the form of an inflammation of the choroid and the retina. Children of subsequent pregnancies are unaffected.

The treatment of uveitis has been transformed by the advent of corticosteroid drugs. Even when a specific infection cannot be discovered and treated with the appropriate specific drug, therapy with corticosteroids is usually successful in controlling the worst ravages of the inflammation.

Tumours of the uveal tract. Pigmented tumours are the commonest tumours involving the uveal tract. They may be benign (the nevus or mole) or malignant. The choroid is the commonest site of these lesions, which push the retina forward and cause a retinal detachment. Disturbances of vision are the commonest symptom, but the tumour if neglected may enlarge and cause inflammation and raised pressure within the eye. Small portions of the tumor often enter the bloodstream and settle in distant organs, particularly the liver. The growth of these secondary deposits is often slow; they may not be apparent until many years after the diagnosis of the tumour in the eye.

The lens. The lens is a transparent, avascular organ surrounded by an elastic capsule. It lies behind the pupil and is suspended from the ciliary body by a series of fine ligaments. Its transparency is the result of the regular arrangement of the lens fibres; since these are being formed continuously, the lens continues to grow throughout life. Interference with this growth pattern will result in the formation of abnormal lens fibres that cannot transmit light as well as the normal lens fibres. A small opacity is thus seen in the lens. Minor irregularities are common in otherwise perfectly normal eyes. If the opacity is severe enough to affect vision it is called a cataract.

Cataract in newborn child; in adult

Congenital lens opacities of many varieties have been recognized and described since the early days of ophthalmology, but they remained curiosities until the work of an Australian ophthalmologist, Norman M. Gregg, threw new light on their cause, and, indeed, on that of many other congenital defects. In 1941 Gregg noticed that after an epidemic of German measles (rubella) many of the children whose mothers had contracted the disease in the first two months of pregnancy were born with cataract, sometimes associated with deafness and congenital heart disease. It is now known that the virus can be recovered from the lens for several months after birth.

Cataract in the adult may be the result of injury to the lens by a perforating wound, by exposure to radiation such as X-rays, or as the result of the ingestion of toxic substances or even of some drugs. The lens relies for its nutrition on the aqueous humour secreted by the ciliary body and, if the latter is severely damaged as the result of long-continued uveitis or a tumour, the metabolism of the lens suffers and a cataract develops. The commonest form of cataract is senile cataract, so called because it becomes progressively more common with advancing age. In spite of a large amount of work on the biological and biochemical changes that take place in the lens, the underlying cause of senile cataract is still unknown. Whatever the underlying biochemical changes may be, they result in an increasing clouding of the lens until the whole lens loses its normal transparency and becomes white and opaque. The only symptom is progressive diminution of vision. In the early stages of the condition some visual improvement can usually be obtained with spectacles, but, as the cataract progresses, the visual deterioration becomes sufficiently severe to warrant surgical treatment.

With modern techniques cataract extraction can be done as soon as the visual deterioration interferes with normal activities, and it is no longer necessary for patients to wait for many years in semiblindness to allow the cataract to become mature. Cataract extraction is one of the most successful and satisfying operations in ophthalmic surgery; if the eye is otherwise normal the visual results are excellent, although the refractive power of the lens has to be replaced by a rather thick spectacle lens or special contact lens.

The retina. Developmentally, the retina is part of the brain and as such has only a limited capacity for repair of its damaged tissue. In particular, the highly specialized rods and cones (the photoreceptors), which are the structures sensitive to light, and the nerve cells of the retina, like those of the brain, cannot be replaced if they are damaged. Death of these cells inevitably has a permanent effect on vision.

The retina is a thin transparent membrane that lines the inner eye. Its outermost layer, the pigment epithelium, is formed of pigmented cells that are closely adherent to the underlying blood vessels of the choroid. The layer of rods and cones is more loosely attached to the pigment epithelium and has complicated nervous networks that culminate in the innermost layer of nerve fibres. These fibres run back through the optic nerve to the brain. The inner two-thirds of the retina derives its blood supply from a special complex of vessels that enters the eye through the optic nerve.

Detachment of retina

Retinal detachment. A retinal detachment is a condition in which the main part of the retina becomes separated from the pigment epithelium. This may follow an injury to the eye or a tumour; or inflammation of the underlying choroid. The commonest type of detachment, however, has no such predisposing factors: the distinctive feature is the formation of a small hole or tear in the retina, usually at the periphery where the retina is thinner. In most cases the hole is caused by an adhesion forming between the retina and the jelly-like substance called the vitreous humour that fills the interior of the eye. Sudden movement of the eye, or an injury, causes the vitreous to pull on the retina, thus creating a tear or hole. When this has happened, fluid can pass through the hole and strip the retina off the pigment epithelium. Myopic (nearsighted) eyes are particularly prone to retinal detachment because they are larger than normal, and the coats of the eye are thinned and stretched. The periphery of the retina, in particular, often shows weak areas, and the vitreous is usually unduly thin and fluid.

The history is often quite typical. The pull of the vitreous on part of the retina creates a sensation of light noticed by the person affected as flashes that occur on movement of the eye. When an actual tear has developed, the retina starts to become detached and the person has the sensation of a shadow coming down over the vision.

The essential factor in treatment is to seal off the hole in the retina. The part of the retina containing the hole must be brought into close contact with the choroid and then by means of a gentle inflammatory reaction caused by using heat, cold, or intense light, the retina is made to stick to the underlying choroid and seal off the leak. The remaining fluid can then be drained away, allowing the retina to fall back into place. Provided that the detachment has not been of long standing, the retinal function recovers quite well once the retina is reattached. The small central area of retina, however, that subserves the most acute vision has only one source of blood supply, the underlying choroid; once it is separated from this some permanent damage ensues, even if the retina is subsequently replaced in its correct position. Thus, it is most important therefore that retinal detachments be treated early, before the central area of the retina becomes detached.

Retinal degeneration. Cases of retinal degeneration can be grouped in two broad classes: hereditary and genetic, and senile. A large number of genetically determined degenerations of the retina have been described. Although they are quite rare, the bizarre appearances of the retina and the inexorable advance of the disease have excited considerable interest among ophthalmologists. These conditions are typified by the disease known as retinitis pigmentosa, a hereditary condition. The earliest symptom is night blindness, which may first be noticed in childhood and is due to alteration in the function of the rods, which are the visual receptors used in dim light. The more peripheral parts of the retina are affected first, and while central vision may be good the field of vision progressively decreases until only a small "tubular field" remains. Cause of the disease is unknown. It is easily recognizable by the narrowing of retinal vessels and the scattering of clumps of pigment throughout the retina.

In senile degeneration, unlike the hereditary type, it is the central part of the vision that is first affected. The central part of the retina, known as the macula, derives its blood supply only from the choroid, and it is probably for this reason that it is likely to suffer first from the slowing of the metabolic changes and from the deficiency of circulation that occur in old age. While degeneration of the macula does not cause blindness, in the sense that the person affected is unable to see anything, it is extremely disturbing because it affects central visual acuity and makes reading or fine work difficult or impossible. There is as yet no satisfactory medical or surgical treatment, but considerable improvement can be obtained by the use of special magnifying spectacles.

The retinal changes that may occur in diabetes, arteriosclerosis, and vascular hypertension are described in a later section.

The optic nerve. The optic nerve, which carries about one million nerve fibres, leaves the globe from the back of the eye and passes through the apex of the orbit into the cranial cavity. It is surrounded by an extension of the membranes that surround the brain and this connection with the intracranial cavity is of some importance, because in some intracranial diseases the pressure within the skull rises and is transmitted along the sheaths of the optic nerve to cause swelling of the optic nerve head, which is visible inside the eye. This swelling of the nerve head, or papilledema, is one of the most important signs of increased intracranial pressure. If the swelling persists, damage to the fibres of the optic nerve takes place, with subsequent loss of vision.

Causes and effects of swelling of optic nerve head

Swelling of the optic nerve may also be caused by inflammatory changes in the nerve itself or in the surrounding sheath; this condition is known as optic neuritis. The symptoms are loss of vision in the central part of the visual field and pain on moving the eye. The condition is most common in young adults and may be due to the spread of infection from the adjacent nasal sinuses. The majority of cases, however, are manifestations of multiple sclerosis, a condition in which the sheath of the nerves becomes altered and interferes with the transference of nervous impulses. This may occur in any part of the nervous system, but the optic nerve is a common site, and the lesion is often the first to be noticed by the patient because of the visual symptoms that result from it. The disease is characterized by long periods of remission from symptoms, and after optic neuritis it may be 10 years or more before other signs are apparent. Usually the function of the optic nerve recovers after an attack of optic neuritis, leaving little, if any, visual disturbance, but there is some atrophy of the fibres.

Optic atrophy may follow any serious disease of the retina involving a large amount of destruction of neural tissue. It may also follow damage to the optic nerve within the skull, or the optic chiasma—that is, the place where the optic nerves crisscross, close to the pituitary gland. Tumours of the pituitary gland nearly always compress the optic nerve fibres and cause some degree of atrophy with loss of vision in that part of the visual field subserved by the fibres concerned. Usually it is the fibres on the inner side of the optic nerve and those that cross at the chiasma that are most involved: these fibres supply the retina on the nasal half. This part of the retina receives visual images from the outer part of the visual field, and in pituitary lesions it is common to find that the outer parts of both visual fields are affected.

Certain chemicals and some drugs can also cause optic atrophy: among them are quinine and methyl alcohol. Optic atrophy is most unlikely to follow normal medical doses of quinine, and when it occurs it is usually from the large doses taken to cause abortion. Methyl alcohol (wood spirit or methylated spirits) is broken down in the body to acetyl aldehyde, which is toxic to neural tissue, and the risks of blindness from drinking methylated spirits are high.

Glaucoma. The thin coats of the eye are not sufficiently rigid in themselves to withstand distortion following the pull of the extraocular muscles when the eye is moved. The eyeball is kept rigid by the action of the ciliary body, which secretes sufficient amounts of the fluid called the aqueous humour to pump up the pressure of the eye to a level above the atmospheric pressure. This fluid is constantly being formed and drains away at the base of the iris through specialized drainage channels. Should these channels become blocked the pressure within the eye rises to abnormally high levels and impedes the entry of blood into the eye. The fibres of the optic nerve where it enters the eye are particularly susceptible to a reduction in blood supply, and if the intraocular pressure remains raised for long some of these nerve fibres will atrophy, causing loss of function of the retina from which they are derived. Glaucoma is the name given to a condition in which the intraocular pressure is raised to abnormal levels. In some persons this is due to other disease within the eye—such as inflammation or a tumour—but most have one of two distinct diseases, chronic simple glaucoma or closed-angle glaucoma.

Chronic simple glaucoma

Chronic simple glaucoma is a common disease that may affect one percent of people in the older age groups. Although the actual cause is not known it is almost certainly due to degenerative changes in the outflow channels for aqueous fluid. It is rare below the age of 40 but after this its incidence increases; in one recent survey it was found to affect 10 percent of those examined over the age of 80. Genetic influences are important and relatives of patients with glaucoma are five times more likely than others to develop the disease.

The symptoms are slight or absent in the early stages. The slow rise in pressure does not cause pain, and the early visual loss is in the peripheral parts of the visual field, affecting central vision only late in the disease. Both eyes are usually involved, although one may be more severely affected than the other. Since vision lost from glaucoma cannot be restored, successful treatment can only prevent further loss of vision. It is of great importance, therefore, that the disease be diagnosed as early as possible. Measurement of the intraocular pressure is of great value in the diagnosis of glaucoma: this is a simple test that can be applied as a screening method for surveys of the normal population.

From H.G. Scheie, *Medical Ophthalmology: Ophthalmalogic Manifestations of Systemic Diseases*

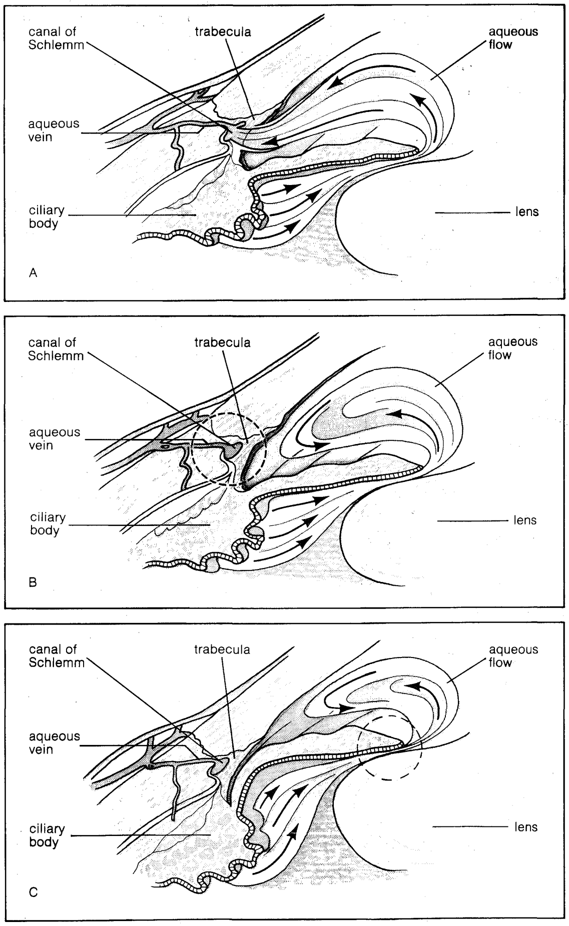

Figure 51: *Normal flow of aqueous humour contrasted with two types of obstruction.*
(A) Normal flow of aqueous humour. (B) Obstruction to flow of aqueous humour in chronic glaucoma. (C) Obstruction to flow of aqueous humour in closed-angle, or acute, glaucoma. Dotted circles indicate site of obstruction.

The medical treatment of chronic simple glaucoma consists of the use of drops that lower the intraocular pressure. Inhibitors of the enzyme carbonic anhydrase, when taken by mouth, reduce the formation of aqueous humour and are used as an additional measure when necessary. If the pressure remains raised in spite of all medical treatment, then surgical methods must be used to increase the drainage of fluid from the eye.

The other common type of glaucoma is called closed-angle glaucoma. This again has a familial incidence and occurs in people who have a rather small, long-sighted eye. Continued growth of the lens in these patients pushes the iris forward and narrows the gap at the root (the outer edge) of the iris where aqueous humour flows out of the eye. This fluid is formed in the ciliary body behind the iris and flows forward through the pupil to the angle of the anterior chamber. The lens pushing against the iris acts as a valve and impedes the flow of aqueous humour through the pupil. The root of the iris, which is rather thin, is then pushed forward and may eventually completely close the exit for aqueous humour, so that the intraocular pressure rises rapidly. The eye becomes painful and the vision is lost; the pain may be so severe as to cause vomiting and prostration. The eye becomes red and stony hard to the touch. Urgent treatment is required to lower the pressure and prevent strangulation of the blood vessels entering the eye.

In some cases an acute attack such as this heralds the onset of the disease, but more frequently minor, subacute, attacks, which are relieved by rest and sleep, occur for months or years. Modern methods of medical treatment are usually effective in lowering the pressure in the acute attack; an operation is usually necessary to prevent further recurrences.

OCULAR INJURIES

The bony orbit provides excellent protection for the eye from blunt injuries. A blow from in front with a rounded instrument such as a fist or tennis ball, however, can cause a shock wave to travel through the eye and damage the retina at the back of the eye. Central vision may be reduced after such injuries without any very obvious changes in the appearance of the eye. In severe cases the bones of the orbit may be fractured. Perforating wounds from glass, sharp metal fragments, and so on, are always serious. Injuries to the lens will result in the formation of a cataract, and often after penetrating injuries the eye remains inflamed for a considerable time.

Sympathetic ophthalmitis

One type of inflammation following injury, sympathetic ophthalmitis, is of particular importance; fortunately it is now rarely seen. The sequence of events is that an injured eye remains irritable and after some weeks, months, or even years, the fellow—previously normal—eye may take part in the inflammation. This is the "sympathizing eye." The cause of sympathetic ophthalmitis is not known, but it is known that if an injured eye is removed within 10 days sympathetic ophthalmitis never occurs in the other eye. In the past there was little effective treatment for the condition, but therapy with corticosteroid hormones has proved effective in controlling the inflammation in most cases, so that even if the disease becomes established the consequences are not as serious as they were previously.

Foreign bodies. Most foreign bodies that enter the eye remain near the surface. When they touch the cornea they cause intense pain and a flow of tears. The tears may be sufficient to wash the foreign body out of the eye, but if it becomes embedded in the cornea it may have to be removed surgically. Many small foreign bodies lodge in the under surface of the upper lid so that every time the eye blinks the foreign body rubs on the cornea, causing pain and irritation.

Small foreign bodies travelling at high speeds may penetrate the interior of the eye with remarkably few symptoms, and their presence may not be recognized until weeks or months later when inflammatory changes occur. The commonest foreign bodies to enter the eye in this way are fragments of metal from hammer-and-chisel accidents, or from moving parts of machinery. Whenever such injuries are suspected, it is important to locate the position of the fragment as carefully as possible, and to remove it by surgery. If the foreign body is magnetic, a large electromagnet is invaluable in attracting the foreign body to the site of the incision in the eye, making extraction comparatively simple.

Chemical and radiation injuries. Strong acids and alkalis always cause severe injury if they enter the eye. Speed is the vital factor in first-aid treatment, and copious irrigation with water the first essential. Delay of first-aid treatment in the hope of finding a neutralizing substance is a serious error, as strong acids and alkalis quickly become bound to the ocular tissues and cause severe necrosis (death of tissue).

Effects of ultraviolet and infrared rays

Except for extremely intense light such as that from a laser, the visible wavelengths of the electromagnetic spectrum—*i.e.,* visible light rays—rarely cause ocular injury. Ultraviolet light, however, is strongly absorbed by the cornea and is the cause of the not uncommon condition known as snow blindness. Symptoms, consisting of intense pain and copious flow of tears, may not occur until some time after exposure. Exposure to light is painful. The treatment consists of cold compresses to the eye and soothing lotions; usually the eyes recover without any permanent damage.

Long-continued exposure to infrared radiation, without adequate protection for the eyes, can cause cataract formation. The lens is also susceptible to X-rays, and the eyes must be shielded when therapeutic irradiation is used for growths around or near the eye. High-intensity microwaves such as those used in some military applications can also cause ocular damage. The widespread use of lasers in research departments and in industry has created a new ocular hazard, and a few cases of accidental exposure have already been reported.

MANIFESTATIONS OF SYSTEMIC DISEASE

The central nervous system. Since the optic nerve and retina are, embryonically, an extension of the brain, it is not surprising that central nervous system diseases frequently affect the eye, and visual defects may be the earliest evidence of the general disease. The nerve supply to the ocular muscles, particularly the extraocular muscles, may also be involved early in some diseases of the central nervous system: this will result in defective movement of the eyes, causing lack of coordination between the two eyes and diplopia, or double vision.

The nerve fibres that connect the retina with the site of visual sensation in the occipital cortex—*i.e.,* the outer brain substance at the back of the head—are arranged throughout the brain in a regular pattern, and many lesions of the brain, such as tumours, impinge on part of this pathway. From a detailed examination of the sensitivity of the different parts of the retina, using tests of the visual field, it is often possible to localize the exact site of an intracranial lesion. An optic neuritis causing sudden onset of loss of central vision in one eye is a frequent first symptom of multiple sclerosis. Detailed ophthalmic examination is therefore essential in the case of any patient suspected of having disease of the central nervous system.

Arteriosclerosis and vascular hypertension. The eye is the one structure in the body in which the blood vessels are easily visible to the examiner, and the changes that can be observed in the retinal vessels mirror those that are taking place in other parts of the body, particularly those in the brain. In arteriosclerosis degenerative changes occur in the walls of the arteries: this leads to thickening of the walls and narrowing of the bloodstream and may give rise to complete occlusion, or blockage of the vessel. If the central retinal artery is affected, loss of vision is complete and sudden and, unless the obstruction can be relieved within an hour or so, permanent. Occlusion of the retinal veins is more common than arterial occlusion and also has dramatic effects: the damming up of blood in the eye results in the bursting of small vessels, and multiple hemorrhages are scattered all over the fundus (that part of the inner eye which can be inspected through the pupil). Some degree of recovery of vision is usual but depends on whether a branch of the central vein or the vein itself is occluded.

Vascular hypertension, or raised blood pressure, usually occurs in association with arteriosclerosis. Typical changes can be recognized in the small vessels of the fundus, and in severe cases multiple hemorrhages and exudates, with swelling of the optic disk (the head of the optic nerve), may be present.

Diabetes. The satisfactory control of diabetes with insulin has increased the incidence of eye complications, for it has become apparent that it is the duration of the disease rather than its severity that determines the onset of ocular changes. A special type of cataract may occur in young diabetics with severe untreated disease, but the most serious complication involves the blood vessels of the retina. The actual cause of the changes in the retinal vessels is still unknown, but the natural history of the disease is well recognized. The retinal capillaries dilate at weak points in the vessel wall—*i.e.,* form small aneurysms; these weak portions of the vessel wall may give way and cause hemorrhages into the retina. In the later stages the hemorrhages become more extensive and spread into the vitreous. New vessels grow into hemorrhagic areas and are followed by fibrous changes that may pull on the retina and cause detachment. Extensive changes of this nature lead invariably to blindness.

Destruction of the pituitary gland, either by direct surgery or by the implantation of a radioactive material, has given some hope of alleviating these severe retinal changes. The procedure is, however, a drastic one. Destruction of affected areas of the retina by the use of an intense beam of light, a process called photocoagulation, promises to be a useful form of treatment in selected cases. Degenerative changes in the retina remain the most serious complication of diabetes.

Thyroid disease. The staring appearance of persons suffering from thyrotoxicosis, also called exophthalmic goitre or Graves' disease, is believed to be due to the stimulation of smooth muscle in the lids and orbit, causing the lid to retract a little from the globe and the globe itself to advance forward slightly. These changes normally regress if the thyrotoxicosis is treated. There is a more serious ocular complication of thyroid disease, which may follow excision of the thyroid for thyrotoxicosis or may, in some cases, arise in persons with normal or subnormal thyroid activity. It is characterized by swelling of the orbital tissues, including the extraocular muscles, so that the eyes cannot be moved properly and project forward between the lids to such an extent that the cornea becomes permanently exposed; the cornea may then ulcerate and even perforate and cause loss of the eye. Sewing the lids together may be sufficient to protect the cornea, but in many cases surgery to relieve the pressure in the orbit is necessary.

Rheumatism. The ocular complications of rheumatoid arthritis mainly involve the sclera, patches of inflammation occurring under the conjunctiva in the scleral and episcleral tissues (the latter are connective tissues between the conjunctiva and the sclera). Although the condition may respond to treatment with corticosteroids, recurrences are common.

VISUAL DISORDERS

"Floaters"; blind areas; flashing lights

Subjective symptoms. One of the commonest visual symptoms is the sensation of small, black objects floating in front of the eye. These move with the eye but lag slightly at the beginning of an eye movement and overshoot when the movement stops. They are due to cells and fragments of debris in the vitreous cavity of the eye. In certain conditions, as when looking at an empty sky, almost everybody can perceive them, and they are normal phenomena. A sudden increase in their number may indicate degenerative changes in the vitreous, which are particularly likely to occur in shortsighted eyes and in older people. These changes, although annoying, are of no serious import. The appearance of many "floaters," however, may be associated with inflammation or bleeding in the eye.

Blind areas in the field of vision occasionally force people to seek medical advice. Any condition that causes failure of function of part of the retina, the optic nerve, or the optic pathway to the brain, can cause such a blind spot, and the symptom requires careful investigation. There is a naturally occurring "blind spot" in each visual field that corresponds with the lack of retinal elements where the optic nerve enters the eye. The brain is so skillful in filling in the visual pattern that the normal blind spot can be detected only by special methods.

Flashing lights in the field of vision are caused by stimulation of the retina by mechanical means. Most commonly this occurs when the vitreous becomes degenerate and fluid and pulls slightly on its peripheral attachment to the retina. Similar symptoms also arise when the retina becomes detached, causing flashing lights to be seen.

Night blindness and defects of colour perception. Defective vision under reduced illumination may be a rare congenital condition or may be acquired as a result of severe deficiency of vitamin A.

Defective colour vision affects about four percent of men and 0.4 percent of women. Total colour blindness is extremely rare and is nearly always associated with poor vision in ordinary light. The colour-defective person is rarely aware of his disability until special matching tests are used, when it is discovered that he is unable to distinguish between hues in one or another part of the visual spectrum. Other visual functions are perfectly normal, and the only disadvantage is the restriction of certain types of occupation.

Eyestrain. Eyestrain, or asthenopia, is the term used to describe symptoms of fatigue and discomfort following the use of the eyes. Although such symptoms may result from intensive close work, particularly if this is unaccustomed, in people with perfectly normal eyes, they may indicate abnormalities of muscle balance or refractive errors. Eyestrain is more likely to be manifest during periods of fatigue or stress and is common among students working for examinations. Refractive errors require correction and muscle imbalance treatment. Psychological factors are often more important than physical factors.

Presbyopia; short sight; long sight

Refractive errors. In a normal eye rays of light from distant objects come to a focus on the retina. In near vision, the refractive power of the eye is increased by altering the shape of the lens to focus the image on the retina. A twelve-year-old can focus on an object four inches away from the eye but, with age, the ability of the lens to alter its shape decreases so that at the age of 40 the shortest distance at which an object can be kept in focus is about 10 inches. The near point continues to recede with age until fine print, for example, cannot be read at a normal reading distance. This condition is known as presbyopia; it is corrected by the use of convex lenses for reading.

In some eyes rays of light from distant objects are not brought to a focus on the retina but are focused on a plane in front of the retina, as in myopia (short sight), or behind the retina, as in hypermetropia (long sight). In myopia, near objects are brought into focus on the retina but distant objects can only be seen clearly with the aid of concave lenses. In hypermetropia, distant objects can usually be brought into focus by using the accommodative power of the lens, and in young people there is usually sufficient accommodation to enable them to see reasonably near to them. The constant accommodative effort required, however, may produce symptoms, and the necessity for accommodating for distance can be overcome by wearing convex glasses.

Another type of refractive error is astigmatism. In this condition the refractive power of the eye varies in different axes because of variation in curvature so that vision at all distances is distorted and can only be corrected by the use of cylindrical lenses or contact lenses.

Minor degrees of refractive error are extremely common. The refractive state is genetically determined and there are marked racial differences. Myopia, for example, is common in the Far East and rare in the African Negro. Although most refractive errors are easily correctible by spectacles and such errors are rarely accompanied by any serious disease of the eyes, hypermetropia is a factor in the development of some kinds of squint and high degrees of myopia are often associated with serious degenerative changes within the eye.

OPHTHALMOLOGICAL EXAMINATION AND CORRECTIVE DEVICES

Ophthalmological examination. An ophthalmological examination comprises a history of a patient's symptoms and signs, subjective tests to determine the visual function, and physical examination of the eyes by means of special devices. The most important subjective test is for visual acuity, and this is usually performed by presenting to the patient a series of letters of graded sizes at a set distance. He is required to read the lowest line legible to him; visual acuity can then be expressed in terms of the size of the letter and the distance at which it is read.

The visual field is assessed by moving an illuminated target inward from the periphery toward a central point viewed by the eye: the area in which the target is seen can then be drawn as a map of the visual field for that eye.

Other subjective examinations include colour-vision testing and tests of visual perception under reduced illumination. Examination of the external eye and part of the anterior segment is facilitated by the use of a binocular microscope mounted horizontally, to which is attached a slit-lamp, a variable source of light that projects the image of a slit onto the eye. The ophthalmoscope has an illuminating system that lights up the interior of the eye and a viewing system through which the fundus can be observed. Photography of the anterior part of the eye and of the fundus is both possible and widely used.

Other specialized methods of examination include examination of the angle of the anterior chamber by means of a specially designed contact lens with the slit-lamp microscope. The electrical responses of the retina and brain to light entering the eye can also be recorded and are of great value in certain conditions.

Estimation of the intraocular pressure is an important part of an ophthalmological examination and is accomplished by an instrument called a tonometer. This instrument is designed specifically to measure the tension or pressure that exists within the eyeball.

The refractive state of the eye can be measured objectively, or subjectively, or by a combination of both methods. The simplest method is subjective, using lenses of different powers to give a trial-and-error estimate of the best correcting lenses. More accurate results can be obtained by using an instrument known as a retinoscope, which gives an objective assessment of the refraction that can subsequently be modified by subjective methods to suit the individual requirements of the patient.

Types of spectacles

Optical aids. The most widely used optical aids are spectacles, and the technical design of spectacle lenses has advanced considerably in the last 50 years. A simple biconcave or biconvex lens causes considerable distortion of appearances if objects are viewed through the periphery of the lens, but if the back surface of the lens is made concave and the required power attained by altering the curvature of the front surface, improvement in peripheral definition results. All modern spectacle lenses are of this form.

Most older people require an additional lens for reading, and this can be incorporated with the distance correction in the form of a bifocal lens. In some occupations an intermediate distance is also required, and a third segment can be added, forming a trifocal lens. The complete range of correction from distance to near can only be achieved by means of a multifocal lens, and these are now available: the upper segment provides the correction for distance; as the eye moves lower down the lens its power increases, the lowest segment of the lens representing the reading correction. By slightly tilting the head it is possible to find the optimum correction for any intermediate distance.

The distortion of peripheral view when using conventional spectacles occurs because the correcting lens does not move when the eye moves. This problem can be completely overcome by the use of contact lenses, which are thin shells of plastic made to fit the anterior surface of the cornea and thus move with the eye. The earliest types of contact lens were larger than the cornea and were uncomfortable to wear, but the modern small "corneal" lenses have greatly increased the scope and usefulness of contact lenses and offer a practical alternative to the wearing of spectacles. Even so, there is a limit to the length of time for which they can be worn, and they should not be kept in at night. Their small size makes them easy to lose and difficult to manipulate, particularly for elderly persons. Further advances in design and in the use of new materials—for example, the flexible soft lenses—will doubtless extend the use of contact lenses even further.

For those persons who cannot obtain useful vision with ordinary spectacles or contact lenses, much can still be done by the use of compound lens systems known as low vision aids. These devices provide a magnified image but inevitably reduce the visual field. Their main value is to enable a person to read normal print who would otherwise be unable to read. They can be of use for distance, particularly when viewing conditions are relatively static, as with the cinema, theatre, or television.

Finally, for those who are completely blind from ocular causes there is new hope in the development of implants into the visual cortex that can be connected to a small television camera in such a way that electrical signals can be applied to the visual cortex, completely bypassing the normal optic pathways. The miniaturization of electrical circuitry resulting from space research has made the design of such devices a practical possibility. Their application to human subjects is, however, still in the experimental stage.

BLINDNESS

It is difficult to obtain reliable statistical information on the incidence of blindness on a worldwide basis. Even in countries in which the registration of blind people is attempted, the definitions of "blindness" vary from one country to another; in large parts of the world there is no registration, and the only estimate that can be made depends on random surveys of small parts of the population. An incidence of about 200 per 100,000 is fairly representative of countries in which the standard of medical care is high; it is probable that the incidence is 10 times higher in countries in which medical care is rudimentary.

There is wide variation in the causes of blindness in different parts of the world. This is partly due to geographic and climatic conditions but, more important, it is also due to differences in standards of hygiene and the availability of medical care. Infections, particularly trachoma, spread most easily in warm countries where the population is often crowded into small villages with lack of adequate hygienic facilities. Cataract is still high on the list of causes of blindness in many countries in the world, and this is all the more tragic in that it is so easily curable by surgical means. As the standards of general medical care increase and the expectation of life increases, so the pattern of blindness changes and degenerative conditions, diabetic disorders of the retina, and genetically determined diseases become predominant. Advances in the prevention and the medical and surgical treatment of blindness can only be of benefit to a population that has access to medical care. Until the nutritional and hygienic standards of a large part of the world population can be improved, preventable blindness will remain at its present high level. (E.S.P.)

HUMAN HEARING: STRUCTURE AND FUNCTION OF THE EAR

Anatomy of the auditory apparatus

Parts of the ear

The human ear, like that of other mammals, has three distinguishable parts: the external, the middle, and the inner ear. The external ear consists of the portion projecting from the side of the head, called the auricle or pinna, and the external auditory canal, which ends blindly at the eardrum. The middle ear is a narrow, air-filled space within the temporal bone, separated from the outside by the tympanic (eardrum) membrane and crossed by a chain of three tiny bones, the auditory ossicles. The inner ear is a complicated system of fluid-filled passages and cavities, deep in the rock-hard petrous portion of the temporal bone. It contains the sensory organs of hearing and equilibrium, the specialized endings of the auditory, or eighth cranial, nerve (Figure 52).

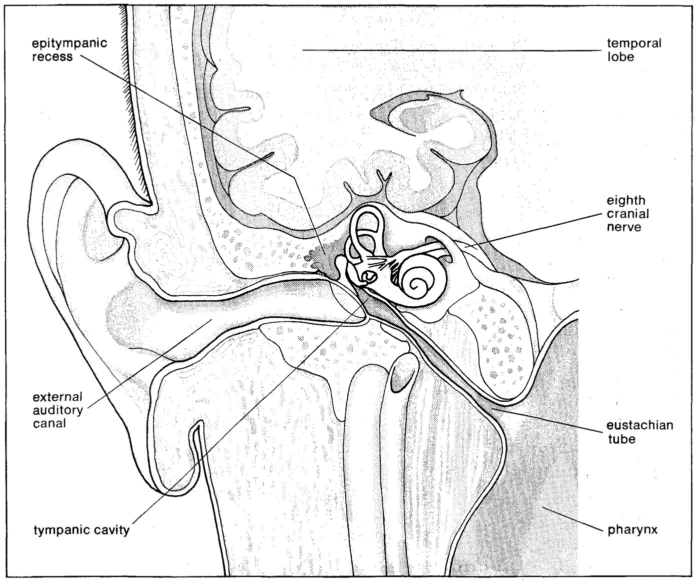

Figure 52: Section through the right side of the head showing the parts of the ear and the auditory area in the temporal lobe of the cerebral cortex.

EXTERNAL EAR

The most striking differences between the ear of man and that of many other mammals are seen in the structure of the auricle itself. In man the auricle is an almost rudimentary, usually immobile shell, more or less closely applied to the side of the head. It consists of a thin plate of yellow fibrocartilage covered by closely adherent skin. The cartilage is molded into the characteristic shape with clearly defined hollows, ridges, and furrows, forming an irregular, shallow funnel (Figure 53). The deepest depression, leading directly to the external auditory canal, or meatus, is called the concha. It is partly covered by two small projections, the tongue-like tragus in front and the antitragus behind. Above the tragus, a prominent ridge, the helix, arises from the floor of the concha and continues as the incurved rim of the upper portion of the auricle. An inner, concentric ridge, the antihelix, surrounds the concha and is separated from the helix by a furrow, the scapha (also called the fossa of the helix). In some ears a little prominence, known as Darwin's tubercle, is seen along the upper, posterior portion of the helix, the vestige of the folded-over point of the ear of a remote prehuman ancestor. The lobule, the fleshy, lower portion of the auricle, is the only part of the external ear that contains no cartilage. The auricle also has several small rudimentary muscles, which connect it to both the skull and the scalp. These muscles are usually without function but in some persons are capable of limited movements.

External auditory canal

The external auditory canal is a slightly curved tube, extending inward from the floor of the concha and ending blindly at the tympanic membrane. In the outer third the wall consists of cartilage; in the inner two-thirds, of bone. The entire length of the passage (24 millimetres, or almost one inch) is lined with skin, which also covers the surface

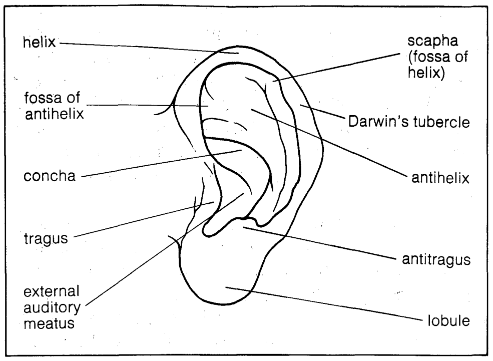

Figure 53: Structure of the outer ear.

of the eardrum membrane. Fine hairs directed outward and modified sweat glands producing earwax, or cerumen, discourage insects from entering the canal.

TYMPANIC MEMBRANE AND MIDDLE EAR

Tympanic membrane. The tympanic membrane lies obliquely across the end of the external canal in the form of a flattened cone with its apex directed inward. Its edges are attached to a ring of bone, the tympanic annulus. The diameter of the membrane is about nine millimetres (0.35 inch). The appearance and mobility of the membrane are important for the diagnosis of middle-ear disease. The healthy membrane is pearl gray; sometimes it has a pinkish or yellowish tinge.

The drum membrane is made up of three layers. The outer layer is continuous with the skin of the external canal; the inner with the mucous membrane lining the middle ear. Between them is a layer of circular and radial fibres that give the drum its stiffness and tension. It is well supplied with blood vessels and with sensory nerve fibres that make it acutely sensitive to pain.

The cavity, including the eustachian tube. The cavity of the middle ear is a narrow, air-filled space. A slight constriction divides it into two chambers, the tympanum (eardrum) proper, or atrium below, and the epitympanum, or attic above. Its outer wall is formed largely by the tympanic membrane, its inner wall by the bony capsule of the inner ear. Its roof and floor are thin plates of bone separating it from the cranial cavity and the brain above and from the carotid artery and the jugular vein below. Its posterior bony wall has an opening leading to a second air space, the tympanic antrum, and to the small air cells of the mastoid process, the portion of the temporal bone directly in back of the external auditory canal. In the narrow anterior wall is the opening of the eustachian or auditory tube.

The eustachian tube and its function

The eustachian tube, about 45 millimetres (1.75 inches) in length, leads downward and inward from the tympanic cavity to the nasopharynx, the space that is behind and continuous with the nasal passages and above the soft palate. At its upper end the tube is rather narrow and surrounded by bone. Toward the pharynx it widens and becomes cartilaginous. Its mucous lining is continuous with that of the middle ear. The cilia (small motile hairlike projections) that cover it help to speed the drainage of mucous secretions from the middle ear to the pharynx.

The major function of the tube is to ventilate the middle ear and thus maintain equal air pressure on both sides of the drum membrane. The tube is closed at rest and opens during swallowing, so that minor pressure differences are adjusted without conscious effort. During a dive or a rapid descent in an airplane the tube may remain tightly closed. The discomfort that is felt as the atmospheric pressure increases can usually be overcome by attempting a forced expiration with the mouth and nostrils tightly shut. This manoeuvre, which raises the air pressure in the pharynx and causes the tube to open, is named for the Italian anatomist Antonio Maria Valsalva (1666–1723), who recommended it for clearing pus from an infected middle ear.

Auditory ossicles. Three auditory ossicles with somewhat fanciful names form a short chain crossing the middle ear. From the outside inward, they are the malleus (hammer), the incus (anvil), and the stapes (stirrup). In appearance the malleus more nearly resembles a club, and the incus a premolar tooth with widely spreading roots. The stapes, on the other hand, is unmistakably a stirrup.

The head of the malleus and the body of the incus lie in the attic above the upper margin of the drum. The two small bones have a tightly fitting joint between them. The handle of the malleus is firmly attached to the upper half of the drum membrane. Its head is anchored to the walls and roof of the attic by three small ligaments. Another ligament fixes the short process (projection) of the incus in a slight depression in the rear wall of the cavity. Its long process is bent near its lower end and carries a small bony knob that forms a loose joint with the head of the stapes. This last, the smallest and lightest of the ossicles, is about three millimetres (about 0.1 inch) in height and weighs scarcely three milligrams (0.0001 ounce). It lies almost horizontally, at right angles to the long process of the incus. Its footplate fits nicely in the oval window, one of the two openings in the wall of the bony labyrinth, where it is held in place by a ringlike ligament called the annular ligament.

Two minute muscles are found in the middle ear. One, the slender muscle called the tensor tympani, emerges from a bony canal just above the opening of the eustachian tube, runs backward, changes direction as it passes over a pulley-like projection, and attaches to the upper part of the handle of the malleus. Its contractions tend to pull the malleus inward and thus increase the tension of the drum membrane. The other, called the stapedius, rises in the posterior wall and sends its minute tendon forward to attach to the neck of the stapes. Its contractions tend to pull the footplate out of the oval window by tipping the stapes backward.

When the healthy tympanic membrane is examined with the otoscope (an instrument designed for visual inspection of the interior of the ear), through the membrane the handle of the malleus is clearly seen projecting from above downward and backward and dividing the upper portion of the membrane into two almost equal parts. Behind and parallel to it, the long process of the incus can sometimes be made out. Above the malleus is a small triangular area in which the membrane is thin and slack. Behind this area, called the pars flaccida (as opposed to the pars tensa, which makes up the much larger portion of the membrane), lies the bare chorda tympani, a slender branch of the facial nerve that passes through the middle ear on its way to join the lingual nerve. It carries important secretory fibres to the parotid (salivary) gland, and sensory fibres to the taste buds of the tip of the tongue.

INNER EAR

Structure as a whole. The inner ear is enclosed in a bony case called the otic capsule, a part of which forms the inner wall of the middle ear. There, two openings between the middle and inner ear are found: the oval window above, which is filled by the footplate of the stapes, and the round window, which is covered by a thin membrane, sometimes referred to as the secondary tympanic membrane. Between them is a bulge called the promontory.

Because of its complicated galleries and chambers, the inner ear as a whole is referred to as the labyrinth. There are, in fact, two labyrinths, one inside the other. The passages hollowed out in the otic capsule constitute the bony labyrinth. In it is suspended a delicate system of ducts and sacs that constitutes the membranous labyrinth (Figure 54).

The bony labyrinth

The bony labyrinth consists of a central chamber called the vestibule, the three semicircular canals, and the spirally coiled cochlea. The last strongly resembles the shell of a snail, and its name is derived from the Greek word for a snail. The canals are designated, according to their position, superior, lateral, and posterior. The superior and posterior canals are in diagonal vertical planes that intersect at right angles. The lateral canal is often referred to as the horizontal because it lies approximately in that plane. Each canal has an expanded end, the ampulla, which opens into the vestibule. The ampullae of the lateral and superior canals lie close together, just above the

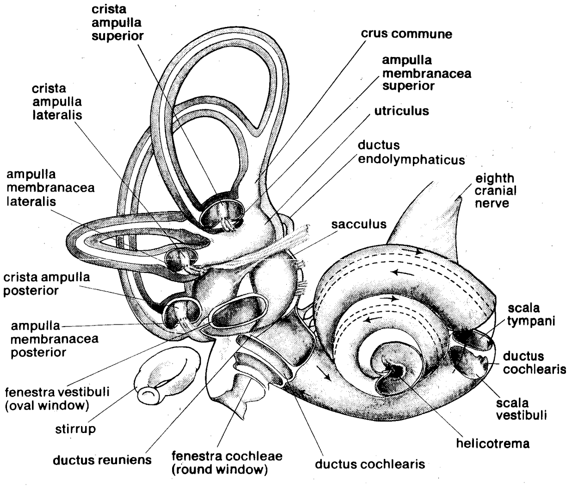

Figure 54: The membranous labyrinth, within the bony labyrinth. The stapes has been removed from the oval window.

By courtesy of Abbott Laboratories, North Chicago, Illinois

oval window, but the ampulla of the posterior canal opens on the opposite side of the vestibule. The other ends of the superior and posterior canals join to form a common stem, or crus, which also opens into the vestibule. Nearby is the mouth of a canal called the vestibular aqueduct, which opens into the cranial cavity. The lateral canal has an independent opening at its opposite end. Thus the vestibule, in effect, completes the circle for each of the semicircular canals.

The cochlea, a tube consisting of two and one-half spiral turns around a hollow central pillar, the modiolus, forms a cone approximately nine millimetres (0.35 inch) in diameter at its base and five millimetres (0.2 inch) in height. The tube is approximately 30 millimetres (1.2 inches) in total length, tapering from a width of two millimetres (0.08 inch) where the basal coil joins the vestibule and ending blindly in the cupula at the apex. The hollow centre of the modiolus is a spiral canal, containing the fibres and ganglion cells of the cochlear nerve; this enters the base of the modiolus through an opening in the petrous portion of the temporal bone called the internal meatus. A thin bony shelf, the osseous lamina, winds around the modiolus like the thread of a screw. It projects about half way across the cochlear canal, partly dividing it into two ramps, or galleries, the scala vestibuli above and the scala tympani below. The round window is in the wall of the scala tympani at its basal end. Nearby is the opening of the narrow cochlear aqueduct, through which passes the perilymphatic duct, connecting the interior of the cochlea with the posterior cranial fossa (the rear portion of the floor of the cranial cavity).

Suspended in the bony labyrinth, the membranous labyrinth occupies only a fraction of the available space. Each of the semicircular canals contains a narrow membranous semicircular duct, which by no means fills the channels or lumen of the canal, with a rounded expansion, the ampulla, at one end. In the same way that the semicircular canals communicate with the vestibule, the semicircular ducts open into an elongated tubular sac, the utricle, located in the upper part of the vestibule. The utricle is also connected, through a narrow duct, with a similar structure, the saccule, which occupies the lower part of the vestibule. The cochlear duct is a coiled, tapered tube, suspended between the scala vestibuli and scala tympani of the cochlea, ending blindly at both its basal and its apical ends. It communicates with (opens into) the saccule through a narrow connecting duct (the ductus reuniens) near the basal end. The duct that unites the utricle and the saccule is also connected to another narrow channel, the endolymphatic duct, which passes through the vestibular aqueduct and ends in a pouch on the cranial surface of the petrous bone, the endolymphatic sac.

Perilymph and endolymph

The space within the bony labyrinth that is not occupied by the various parts of the membranous labyrinth is filled with a watery fluid, the perilymph, which in composition closely resembles the cerebrospinal fluid, the aqueous humour of the eye, and other extracellular fluids of the body tissues. Like them, it is apparently formed locally from the blood plasma by ultrafiltration through the walls of the minute blood vessels called capillaries. Since it is possible for cerebrospinal fluid to enter the cochlea by way of the perilymphatic duct, a portion of the perilymph may come from that source.

The membranous labyrinth is filled with a second watery fluid of different composition, the endolymph. Chemical analysis has shown that perilymph is like most other extracellular fluids, being high in its concentration of sodium ions (about 150 milliequivalents per litre) and low in its concentration of potassium ions (about five milliequivalents per litre), but that endolymph is unique among the extracellular fluids in that it has potassium as the dominant ion (about 140 milliequivalents per litre), with a much reduced concentration of sodium (about 15 milliequivalents per litre). Contrary to the statement sometimes found in textbooks, mammalian endolymph is not a viscous fluid. Recent studies indicate that its viscosity is approximately that of water.

The process of formation of the endolymph and the maintenance of the difference in composition between it and perilymph is not yet completely understood. The tissue known as the stria vascularis, in the wall of the cochlear duct, is thought to play an important role in its secretion, but other tissues of the cochlea and the vestibular organs are probably also involved. Since the membranous labyrinth is a closed system, the question of removal of the endolymph is also of interest. Reabsorption is thought to occur from the endolymphatic sac, but this is probably only part of the story. In all probability other tissues also have important roles in regulating the inner-ear fluids.

Utricle and saccule

Parts of the inner ear. *Vestibule.* The vestibule includes the utricle and saccule, each of which contains a single sensory patch called a macula. In the utricle the macula projects from the anterior wall as an oval spot on a small rounded shelf. In the saccule, the macula lies against the medial (inner) wall of the vestibule directly overlying the bone. It is more elongated than the utricular macula and somewhat resembles the letter J in shape. Each macula is covered by neuroepithelium. This covering consists of sensory cells—called hair cells because of their hairlike projections—and supporting cells. The cells are separated by a basement membrane from the underlying connective tissue. Fibres from the vestibular branch of the vestibulocochlear (eighth cranial, or auditory) nerve enter the macula and pierce the basement membrane to end either at the base of the hair cells or as cuplike formations called calyces surrounding their cell bodies. The hair cells are thus the essential sensory receptor elements of the macula. Each hair cell is topped by a bundle consisting of about 100 fine, nonmotile "hairs" (stereocilia) of graded lengths and a single motile hairlike projection called a kinocilium. Covering the entire macula is a delicate acellular structure, the otolithic (or statolithic) membrane, which is often described as gelatinous although it has a distinct fibrillar (minute-fibre-like) pattern. The surface of the membrane is covered by a blanket of rhombohedral crystals, the otoconia (or statoconia), consisting of calcium carbonate in the form of calcite. These crystalline particles, which range in length from one to 20 microns (there are about 25,000 microns in an inch), have a specific gravity almost three times that of the membrane itself and thus add consider-

able mass to it. The hair cells of the maculae are of two types. One type has a rounded body enclosed by a nerve calyx, the other a cylindrical body with nerve endings at its base. The surfaces of the utricular and saccular maculae show characteristic organization and orientation of the two types of cells in definite mosaic patterns. The larger, rounded cells tend to have a curvilinear arrangement near the centre of the macula, with the cylindrical cells around the periphery. The significance of these patterns is poorly understood, but they are presumed to favour increased directional sensitivity to movements of the head (Figure 55).

The utricle and saccule with their maculae are often referred to as otolith organs. Because they respond to gravitational forces, they are also called gravity receptors.

Sensory end organ of semicircular duct

Semicircular canals. The sensory end organ of each semicircular duct is located in the expanded end, or ampulla. It consists of a saddle-shaped ridge of tissue covered with a sensory epithelium containing the same types of cells as do the maculae. The ridge, called the crista, extends across the ampulla from side to side, at right angles to the direction of the duct (Figure 56). It is covered by a gelatinous structure, the cupula, which extends to the roof of the ampulla immediately above it, dividing the interior of the ampulla into two approximately equal parts. On each of the hair cells of the sensory epithelium of the crista there are about 100 stereocilia, or "hairs," anchored in the dense cuticular plate. The single kinocilium springs from a small area at one side of the surface of the cell, where it is covered only by the thin plasma membrane. The stereocilia stand straight, in orderly rows. The longest are those nearest the kinocilium, which is motile. The height of the others decreases in stepwise fashion away from the kinocilium. Together with the longest stereocilia, the kinocilia extend well up into the substance of the cupula, occupying fine parallel channels. The cupula is thus attached at its base to the crista, but is free to move in either direction in response to pressure in the endolymph toward or away from the utricle. Its motion is transmitted to the hairs, causing them to bend just above the cuticular plate. This bending is the stimulus to the hair cells and elicits impulses in the vestibular fibres of the auditory nerve. Each macula and each crista is supplied by fibres from the vestibular nerve, one of the two parts of the vestibulocochlear (auditory, or eighth cranial) nerve.

From H.H. Lindeman, "Studies on the Morphology of the Sensory Regions of the Vestibular Apparatus," *Ergebnisse der Anatomie und Entwicklungsgeschichte*, vol. 42.1 (1969); Springer-Verlag, New York

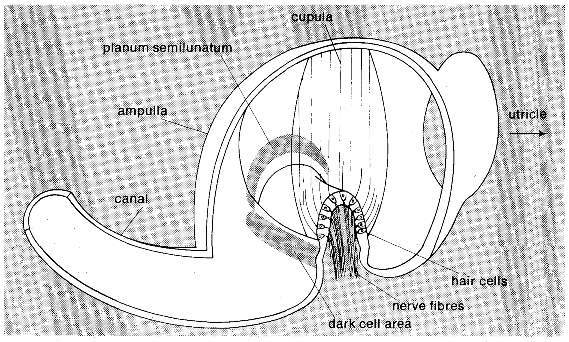

Figure 56: Ampulla of semicircular duct, showing hair cells and cupula.

Cochlea. The interior of the cochlea is divided longitudinally into three spiral ramps or scalae: the scala vestibuli, which communicates with the vestibule; the scala tympani, which ends blindly at the round window; and the scala media, or cochlear duct, which lies between the other two scalae and ends blindly both at the round window and at the apex. The scala vestibuli and scala tympani communicate at the apex, through an opening called the helicotrema (Figure 54).

The scala media

In cross section the scala media resembles a right triangle. Its base is formed by a thin bony shelf, the spiral osseous lamina, and by the basilar, or supporting, membrane, which separate it from the scala tympani, and its side by two important tissues lining the bony wall of the cochlea, the delicate stria vascularis and the tough, fibrous spiral ligament. The hypotenuse is formed by the thin membrane of Reissner, consisting of only two layers of flattened cells. A low ridge, the spiral limbus, rests on the margin of the osseous lamina. Reissner's membrane stretches from the inner margin of the limbus to the upper border of the stria, behind which it is inserted (Figure 57).

Upon the surface of the basilar membrane the sensory cells are arranged in more or less orderly rows. Together with their supporting cells they form a complex neuroepithelium called the basilar papilla or organ of Corti, named after the Italian microscopist, the Marchese Alfonso Corti, who first described it, in 1851. Viewed in cross section its most striking feature is the arch, or tunnel, of Corti, formed by two rows of pillar cells, or rods. The pillar cells furnish the major support of Corti's organ. They separate a single row of larger, more or less pear-shaped inner hair cells on the inner side of the tunnel from three or more rows of smaller, cylindrical, outer hair cells on the outer side. The inner hair cells are supported and enclosed by the inner phalangeal cells, which rest on the thin outer portion, called the tympanic lip, of the spiral limbus. On the inner side of the inner hair cells and the cells that support them is a curved furrow called the inner sulcus. This is lined with more or less cuboidal cells.

Each outer hair cell is supported by a cell known as a phalangeal cell of Deiters, which holds the base of the hair cell in a cup-shaped depression. From each Deiters cell a projection extends upward to the stiff membrane, the reticular lamina, that covers the organ of Corti. The top of the hair cell is firmly held by the lamina, but the body is suspended in fluid that fills the so-called space of Nuel and the tunnel. Although this fluid is sometimes referred to as the cortilymph, it appears to have the same composition as the perilymph. Beyond the hair cells and the cells of Deiters are epithelial cells of three other types, usually called the cells of Hensen, Claudius, and Böttcher, after the 19th-century microscopists who first described them. Their function has not been established, but they are assumed to help in maintaining the composition of the endolymph by secretory and absorptive activity.

The basilar membrane consists of two zones, the pars arcuata under the arch, and the pars pectinata extending from the feet of the outer pillars to the spiral ligament. The fibres of the membrane are fine and inconspicuous in the pars arcuata. Under the feet of the outer pillars the

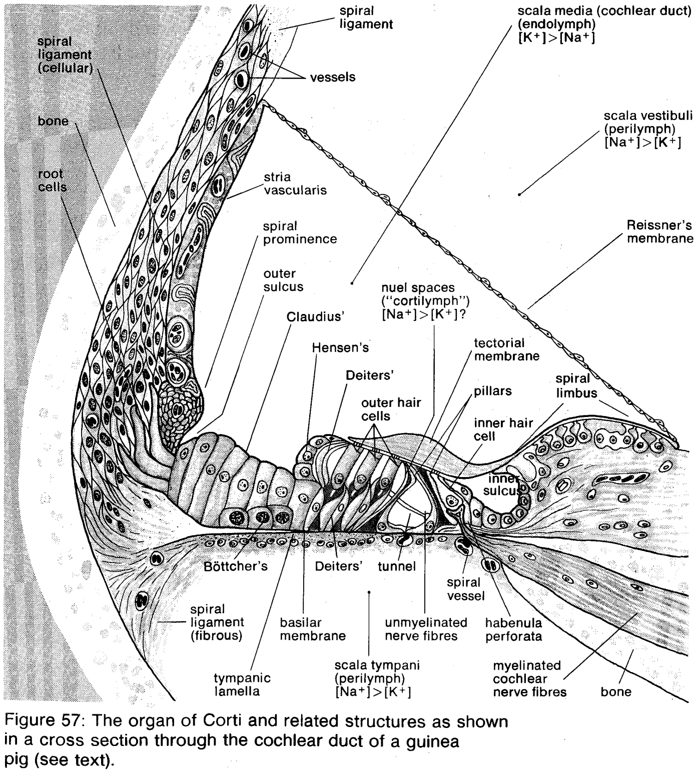

Figure 57: The organ of Corti and related structures as shown in a cross section through the cochlear duct of a guinea pig (see text).

membrane splits into two distinct layers, the upper one containing stout, parallel, radial fibrils that give the membrane its stiffness. These fibrils decrease in calibre and increase in length from the basal end of the cochlea to the apex, so that the basilar membrane as a whole decreases in stiffness as it increases in width from base to apex.

Beneath the fibrillar layer is the acellular ground substance of the membrane, which is covered in turn by a single layer of mesothelial cells forming the tympanic lamella on the tympanic surface.

The spiral vessels

Capillary blood vessels are found beneath the tympanic lip of the limbus and, in many species, beneath the tunnel. These vessels, called spiral vessels, do not enter the organ of Corti but are thought to furnish the major part of the supply of oxygen and nutrients to its various cells, including the hair cells. Although the outer spiral vessel is seldom found in adult animals of certain species such as the dog and cat and is somewhat irregularly distributed in man, it is always present during fetal development. To judge by its size in the fetus, it plays a major part in bringing blood to the rapidly differentiating organ of Corti.

Each hair cell is capped by a plate, which bears the stereocilia or hairs. On the inner hair cells 40 to 60 stereocilia are arranged in two or more irregularly parallel rows. On the outer hair cells approximately 100 stereocilia form a W pattern. Below the notch of the W the plate is incomplete. At this point is the base of the kinocilium, although the motile "hair" is absent.

The stereocilia are about three to five microns in length and extend upward from the cuticular plate to the underside of the tectorial membrane. This is an acellular, gelatinous structure that covers the top of the limbus spiralis as a thin layer and extends outward over the inner sulcus and the reticular lamina. Its fibrils extend radially and somewhat obliquely to end in finger-like projections at its free margin; these make contact with the stereocilia of the outermost hair cells.

The myelinated (sheathed) fibres of the vestibulocochlear nerve fan out in spiral fashion from the modiolus to pass into a channel near the root of the osseous lamina called the canal of Rosenthal. There, the bipolar cell bodies of these neurons, or nerve cells, are located, forming the spiral ganglion. Beyond the ganglion their dendrites extend radially outward in the lamina beneath the limbus to pass through the small pores of a structure called the habenula perforata, directly under the inner hair cells. At this point the fibres abruptly lose their multilayered coats of myelin and continue as thin, naked, unmyelinated fibres into the organ of Corti. They form a longitudinally directed bundle running beneath the inner hair cells and another at the foot of the inner pillars just inside the tunnel. The majority of the fibres end beneath the inner hair cells, but some of them cross the tunnel to form longitudinal bundles beneath the outer hair cells, on which they eventually terminate.

The endings of the nerve fibres beneath the hair cells are of two distinct types. The larger and more numerous endings contain many minute vesicles (liquid-filled sacs), which are related to impulse transmission at neural junctions. As described below these endings belong to a special bundle of nerve fibres arising in the brainstem and constituting an efferent system or feedback loop. The smaller and less numerous endings contain few vesicles or other cell structures (organelles). They are the terminations of the afferent fibres of the cochlear nerve, transmitting impulses from the hair cells to the brainstem.

The outer membranous wall of the cochlear duct is lined, as has been mentioned above, by the stria vascularis, a dense cellular layer containing a network of capillary blood vessels. The surface cells of the stria, called dark cells, are of secretory type. Interspersed among the dark cells is an intermediate layer of cells called light cells. Several layers of flat basal cells bound the stria and separate it from the spiral ligament.

Reissner's membrane is inserted at the upper margin of the stria. At the lower margin of the stria is the spiral prominence, a low ridge containing its own set of longitudinally directed capillary vessels. Below the prominence is a depression called the outer sulcus, the floor of which is lined by cells of epithelial origin that send long projections into the substance of the spiral ligament. Between these so-called root cells, capillary vessels descend from the spiral ligament. This region appears to have an absorptive rather than a secretory function, and it may be concerned with the removal of waste materials from the endolymph.

The spiral ligament

The spiral ligament lies between the stria vascularis and the bony wall of the cochlea. Extending above the attachment of Reissner's membrane, it is there in contact with the perilymph in the scala vestibuli; and extending below the insertion of the basilar membrane, it is there in contact with the perilymph in the scala tympani. It contains many stout fibres that anchor the basilar membrane, and numerous cells, mainly connective tissue cells (fibrocytes). Behind the stria the structure of the spiral ligament is denser than near the upper and lower margins.

Like the stria, the spiral ligament is well supplied with blood vessels. It receives the radiating arterioles that pass outward from the modiolus in bony channels of the roof of the scala vestibuli. Branches from these vessels form a network of capillaries above Reissner's membrane that is thought to be largely responsible for the formation of the perilymph as an ultrafiltrate of the blood plasma. Other branches enter the stria, and still others pass behind it to the spiral prominence and the floor of the outer sulcus. From these separate capillary networks, which are not interconnected, venules (small veins) descending below the attachment of the basilar membrane collect the blood and deliver it to the spiral vein in the floor of the scala tympani.

Viewed from above, the organ of Corti with its covering, the reticular lamina, forms a well-defined mosaic pattern. In man the arrangement of the outer hair cells in the basal turn of the cochlea is quite regular, with three distinct and orderly rows; but in the higher turns of the cochlea, it becomes increasingly irregular, as scattered cells appear representing incomplete fourth and fifth rows. The spaces between the outer hair cells are filled by the oddly shaped extensions (phalangeal plates) of the supporting cells. The double row of head plates of the inner and outer pillar cells cover the tunnel and separate the inner from the outer hair cells. The reticular lamina extends from the inner border cells near the inner sulcus to the Hensen cells but does not include either of these cell groups. When a hair cell degenerates and disappears as a result of injury, its place is quickly covered by the adjacent phalangeal plates, which form an easily recognized "scar."

The basilar membrane

The length of the basilar membrane (and of the organ of Corti that covers it) is about 35 millimetres (1.4 inches) in man. Its width varies from less than 0.001 millimetre near its basal end to 0.005 millimetre near the apex. The membrane is not under tension but decreases remarkably in stiffness from the base to the apex of the cochlea. Furthermore, at the basal end the osseous lamina is broader, the stria vascularis wider, and the spiral ligament stouter than at the apex. The mass of the organ of Corti, on the other hand, is least at the base and greatest at the apex. These considerations indicate that there is a certain degree of "tuning" provided in the structure of the cochlear duct and its contents. With greater stiffness and less mass, the basal end is more attuned to the higher frequencies of vibrations. Decreased stiffness and increased mass render the apical end more responsive to the lower frequencies.

The total number of outer hair cells in the cochlea has been estimated at 12,000, and the number of inner hair cells at 3,500. Although there are almost 30,000 fibres in the cochlear nerve, there is considerable overlap in the innervation of the outer hair cells. A single fibre may supply endings to many hair cells, which thus share a "party line." Furthermore, a single hair cell may receive nerve endings from many fibres. The actual distribution of the nerve fibres in the organ of Corti has not been worked out in any detail, but the inner hair cells appear to receive the lion's share of the afferent fibre endings (fibres bearing impulses to the brain), with less of the overlapping and sharing of fibres that are characteristic of the outer hair cells.

The auditory process

TRANSMISSION OF SOUND WAVES

Transmission to the inner ear. *Air conduction.* The auricle, or visible portion of the outer ear, because of its small size and virtual immobility in man, has lost most of the importance that it has in many animals as an aid in sound gathering and direction finding. For airborne sounds of relatively short wavelength—*i.e.,* those above 3,000 hertz (cycles per second)—the concha serves as a funnel, directing them into the canal. The canal itself contributes little of acoustic importance apart from a broad resonance centred at 3,800 hertz, which helps to determine the frequencies to which the ear is most sensitive.

Acoustic impedance

Sounds reaching the drum membrane are in part reflected and in part absorbed. Only that portion of the sound that is absorbed is effective in setting the drum membrane and the ossicles in motion and thus eventually reaching the inner ear. This tendency of the ear to oppose the passage of sound is called its acoustic impedance. The magnitude of the impedance depends upon the mass and stiffness of the drum membrane and the ossicular chain and on the frictional resistance that they offer. Direct or indirect measurement of the impedance of the ear in hard-of-hearing patients can give important information about the condition of the middle-ear mechanism.

The central portion of the drum membrane vibrates as a stiff cone in response to sound, at least at frequencies below 2,400 hertz. Its motion is transmitted to the handle of the malleus, the tip of which is at the umbo, or centre, of the membrane. At higher frequencies the motions of the drum membrane are no longer simple, and transmission to the malleus may be somewhat less effective. The malleus and incus are suspended by small elastic ligaments and are finely balanced, so that their masses are evenly distributed above and below their common axis of rotation. The head of the malleus and the body of the incus are tightly bound together, with the result that they move in and out as a unit with the movements of the drum membrane. At moderate sound pressures the stapes follows them, and the whole ossicular chain vibrates as a single mass. There may, however, be considerable freedom of motion and some loss of energy at the joint between the incus and the stapes because of the relatively loose coupling. The stapes itself does not move in and out, however, but rocks about the lower pole of its footplate as it transmits the vibrations to the perilymph that fills the vestibule. Its motion thus resembles that of a bell-crank lever rather than that of a piston (Figure 58).

Matching of impedances

The acoustic problem solved by the middle-ear mechanism of drum membrane and ossicular chain is that of transmitting sound from the air to the watery perilymph of the inner ear. Because of the great difference in density between the gas and the liquid, there is a serious mismatch of impedance between them. Ordinarily, this mismatch causes 99.9 percent of airborne sound striking a water surface to be reflected, so that only 0.1 percent passes into the water. In the ear this would represent a transmission loss of 30 decibels, enough to seriously limit its performance, were it not for the transformer action of the middle ear. The matching of impedances is accomplished in two ways, primarily by the reduction in area between the drum membrane and the stapes footplate and secondarily by the mechanical advantage of the lever formed by the malleus and incus. Although the total area of the drum membrane is about 69 square millimetres (0.1 square inch), the area of its central portion that is free to move has been estimated at about 43 square millimetres (0.07 square inch). All of the sound that causes this area of the membrane to vibrate is transmitted and concentrated in the 3.2-square-millimetre (0.005-square-inch) area of the stapes footplate. Thus the pressure (*i.e.,* force per unit area) is increased at least 13 times over. The mechanical advantage of the ossicular lever, because the handle of the malleus is longer than the long projection of the incus, amounts to about 1.3. The total increase in pressure at the footplate is, therefore, not less than 17-fold, depending upon the area of the drum membrane actually vibrating. At frequencies in the range of 3,000 to 5,000 hertz, to which the ear is most sensitive, the increase may be even greater because of the resonant properties of the ear canal as a closed tube.

Adapted from S.S. Stevens and H. Davis, *Hearing: Its Psychology and Physiology* (1938); John Wiley and Sons, Inc.

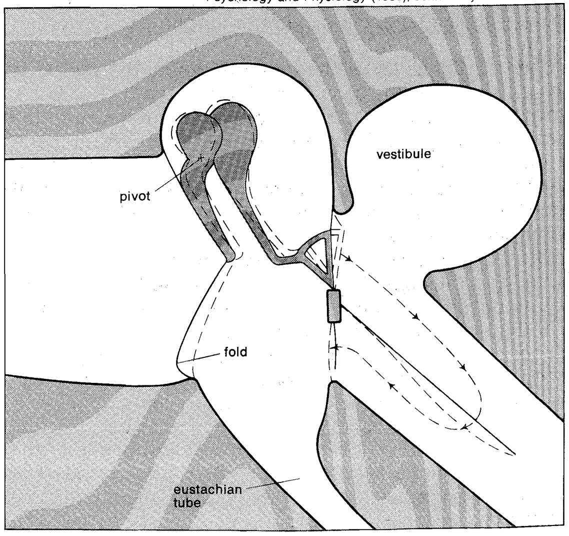

Figure 58: Mechanics (diagrammatic) of the drum membrane and ossicular chain (see text).

The ossicular chain not only concentrates sound in a small area but also applies sound preferentially to one window of the cochlea—*i.e.,* to the oval window, in which the footplate fits so neatly. If the oval and the round windows were equally exposed to airborne sound crossing the middle ear, the vibrations in the perilymph of the scala vestibuli would be opposed by those in the perilymph of the scala tympani, and little effective movement of the basilar membrane would result. As it is, sound is delivered selectively to the oval window, and the round window moves in reciprocal fashion, bulging outward in response to an inward movement of the stapes footplate and vice versa. The passage of vibrations through the air across the middle ear from the drum membrane to the round window is of negligible importance.

Thanks to these mechanical features of the middle ear, the hair cells of the normal cochlea are able to respond at the threshold of hearing to vibrations of the tympanic membrane no greater than one angstrom unit (0.0000001 millimetre) in amplitude. On the other hand, when the ossicular chain is immobilized by disease, as in otosclerosis, which causes the stapes footplate to become fixed in the oval window, increase in the threshold of hearing of as much as 60 decibels is common. Bypassing the ossicular chain through the surgical creation of a new window, as in the so-called fenestration operation, can restore hearing to within 25 or 30 decibels of the normal. Only if the stapes is removed and replaced by a tiny artificial stapes can normal hearing be approached. Fortunately, defects of the middle ear causing so-called conductive impairment can often be corrected by surgical means so that useful hearing is restored.

Action of middle-ear muscles

The muscles of the middle ear, the tensor tympani and stapedius, can influence the transmission of sound by the ossicular chain. Contraction of the tensor tympani pulls the handle of the malleus inward and, as the name of the muscle suggests, tenses the drum membrane. Contraction of the stapedius tends to pull the stapes footplate outward from the oval window and thereby reduces the intensity of sound reaching the cochlea. The stapedius responds reflexly with quick contraction to sounds of high intensity applied either to the same ear or to the opposite ear. The reflex has been likened to the eyeblink or constriction of the pupil in response to light and is thought to have protective value. Unfortunately, the contractions of the middle-ear muscles are not instantaneous, so that they do not protect the cochlea against damage by sudden intense noise, as of gunfire. They also fatigue rather quickly and thus offer little protection against injury by sustained high level noise, as in industry. Because dangerously intense noises are rare in nature, it has been argued that the chief biological significance of the aural reflex is not protection of the inner ear but selective high pass filtering of sound. In other words, since the contractions stiffen the ossicular chain, they favour the transmission of the higher frequencies. These carry more information than the lower frequencies, whether in the consonant sounds of human speech or in the rustle of leaves and the snap of a twig that may signal the approach of an enemy in the wild. At the same time, they reduce the transmission of the lower frequencies, which may otherwise mask those of greater significance for survival. The intra-aural muscle reflexes may also have a role in listening and attention, but this function is by no means fully understood.

Bone conduction. There is another route by which sound can reach the inner ear—that is, by conduction through the bones of the skull. When the handle of a vibrating tuning fork is placed on a bony prominence such as the forehead or the mastoid process behind the ear, its note is clearly audible. Similarly, the ticking of a watch held between the teeth can be distinctly heard. When the external canals are closed with the fingers, the sound becomes louder, indicating that it is not entering the ear by the usual channel. Instead, it is producing vibrations of the skull that are passed on to the inner ear, either directly or indirectly.

The higher audible frequencies cause the skull to vibrate in segments, and these vibrations are transmitted to the cochlear fluids by direct compression of the otic capsule, the bony case inclosing the inner ear. Since the round window membrane is more freely mobile than the stapes footplate, the vibrations set up in the perilymph of the scala vestibuli are not cancelled out by those in the scala tympani, and the resultant movements of the basilar membrane can stimulate Corti's organ. This type of transmission is known as compressional bone conduction.

At lower frequencies—*i.e.,* 1,500 hertz and below—the skull moves as a rigid body. The ossicles, because of their inertia and because they are suspended in the middle-ear cavity and only loosely coupled to the skull, are less affected and move less freely than the cochlea and the margins of the oval window. The result is that the oval window moves with respect to the footplate of the stapes, which gives the same effect as if the stapes itself were vibrating. This form of transmission is known as inertial bone conduction. The fixed stapes in otosclerosis interferes with this type of bone conduction, but not with compressional bone conduction.

Hearing aids for conduction deafness

In the presence of middle-ear disease, hearing aids with special vibrators are sometimes used to deliver sound to the mastoid process (the part of the temporal bone that is behind the ear) and then by bone conduction to the inner ear. Bone conduction is also the basis of some of the oldest and most useful tests in the repertory of the otologist, those employing tuning forks to distinguish between a conductive impairment affecting the middle ear and amenable to surgery and a sensorineural impairment—that is, an impairment affecting the inner ear and the cochlear nerve—for which surgery is usually not indicated. In the Rinne test the sounding tuning fork is placed on the mastoid process, and the person being tested is asked to report when he can no longer hear it. The examiner then removes the fork quickly and holds the prongs close to the open ear canal. The normal ear continues to hear it for about 45 seconds, and this "positive" result occurs also with incomplete sensorineural impairment of hearing. When the result is "negative" and the fork is heard longer by bone conduction than by air conduction, a conductive type of deafness is present. In the Schwabach test the presence of a sensorineural impairment is indicated when the patient is unable to hear the bone-conducted sound as long as the examiner with normal hearing can. The patient with a conductive hearing loss, on the other hand, can hear the fork longer than can the examiner because the conductive lesion excludes the extraneous masking noise of the surroundings. A bone-conduction audiometer would give the same result.

For the Weber test, the fork is simply placed on the patient's forehead, and the examiner asks in which ear he hears it. If a sensorineural lesion is present in one ear, the patient will localize the sound in the opposite, or "better," ear. If a conductive lesion is present, he will localize it in the "worse" ear—*i.e.,* in the one that is protected from interference by extraneous sounds. This simple test is a valuable aid in the diagnosis of otosclerosis.

Transmission through liquid of inner ear to organ of Corti. The vibrations of the stapes footplate at the oval window are transmitted through the perilymph of the vestibule and that of the scala vestibuli to the cochlear duct. Normally, they do not affect the semicircular canals, the utricle, or the saccule. Only the cochlear fluids and the membranes of the cochlear duct are free to vibrate in response to alternating pressures at the oval window, because only the cochlea has the round window as a "relief valve."

What takes place in the cochlea is both an analysis or sorting out of the frequencies of a complex sound and a transduction of the mechanical vibrations into nerve impulses for transmission to the brainstem by the fibres of the cochlear nerve. The analysis occurs because the cochlea is a tuned structure, different parts of which vibrate in response to different frequencies; the transduction because the hair cells of Corti's organ are capable of changing minute amounts of mechanical energy into an electrochemical form that stimulates the endings of the nerve fibres.

The ear's analysis of complex sounds

The idea of the inner ear as a resonant structure was proposed by several authors in the 17th and 18th centuries but received its most explicit statement just over a century ago by the German physicist and physiologist Hermann von Helmholtz. Inspired by the anatomical studies of Corti, Helmholtz postulated in the cochlea a series of resonators capable of analyzing complex sounds into their component frequencies. After considering various other structures, he concluded that the transverse fibres of the basilar membrane, which increase in length and decrease in stiffness from the basal end to the apex, were the resonators he sought. Although Helmholtz' resonance theory in its original form is no longer accepted, much experimental and clinical evidence supports the closely related "place theory," which holds that sounds of different frequency activate different regions of the basilar membrane and organ of Corti, there being an orderly progression from the basal end, where the highest tones are effective, to the apical end, where the lowest tones are received.

From the experiments of Georg von Békésy (for which he was awarded the Nobel Prize for Physiology or Medicine in 1961) it is clear that the frequency analysis performed by the cochlea occurs not because of a series of separate tuned resonators as postulated by Helmholtz but because the basilar membrane and organ of Corti vary continuously in stiffness and mass from base to apex, stiffness decreasing and mass increasing as the width of the basilar membrane increases. Vibrations reaching the basal end through the perilymph can be shown to proceed as travelling waves, attaining a maximum amplitude at a certain point along the membrane and then rapidly subsiding. The higher the frequency of the sound imposed, the shorter is the distance that the waves travel. Since the hair cells are arrayed in orderly ranks on the basilar membrane and the nerve fibres fan out in orderly fashion to innervate them, a tone of a given frequency causes a certain "place" on the basilar membrane to vibrate, the hair cells overlying it are stimulated, and the corresponding nerve fibres convey impulses to the brain.

The brain can recognize the place on the basilar membrane and thus the pitch of the stimulating tone, depending upon the particular group of nerve fibres activated. For the lower frequencies the rate of stimulation is also an important indicator of pitch because the frequency of the nerve impulses tends to follow the frequency of the tone. For the higher frequencies, place alone seems to be decisive. The intimate nature of the events that occur at the hair cells when they are stimulated by movements of the basilar membrane is by no means fully understood. The up-and-down movements of the basilar membrane are thought to be converted into shearing movements between the reticular lamina and the tectorial membrane, which overlies it. The stereocilia, or hairs of the hair cells, in contact with the tectorial membrane are displaced or bent by the shearing forces, and it is this bending of the stereocilia that triggers the electrochemical events in the hair cells that excite the endings of the cochlear nerve fibres.

Present understanding of the events occurring in the cochlea is based in part on von Bêkésy's experiments with cochlear models, in part on his direct microscopic observations by stroboscopic illumination of vibratory patterns in the human cochlea removed from the body after death and subjected to intense sound. Important insights have also been obtained through the study of the small electrical potentials that are produced by the living cochlea in response to sound. These alternating current potentials, first reported in 1929, reproduce the frequency and wave form of the stimulating sound and can be picked up by means of two electrodes, one of which is placed in contact with the round window membrane or with the bony wall of the cochlea. The potentials were shown to consist of two separate components, the microphonic potentials, which appear to be related to the transduction process at the hair cells, and the action potentials, which represent the nerve impulses in the terminal fibres of the cochlear nerve. There is also a direct current potential difference, the endocochlear potential of some 80 millivolts between the endolymph in the cochlear duct and the perilymph in the scala tympani. The alternating current potentials depend upon an intact organ of Corti, the direct current potential upon the stria vascularis. All require an adequate supply of oxygen to the cochlea and soon disappear when oxygen is lacking. When the organ of Corti is damaged by drugs or by intense sound, the potentials are diminished or abolished. In young children suspected of congenital deafness, the cochlear potentials can give important information about the state of the inner ear.

Electrical potentials of the cochlea

THE COCHLEAR NERVE AND THE CENTRAL AUDITORY PATHWAYS

The vestibulocochlear (acoustic, or eighth cranial) nerve consists of two anatomically and functionally distinct parts, the cochlear nerve, distributed to the organ of hearing, and the vestibular nerve, distributed to the organs of equilibrium. The fibres of the cochlear nerve have their peripheral terminals around the bases of the inner and outer hair cells and their central terminals in the groups of nerve cells called the dorsal and ventral cochlear nuclei, in the medulla oblongata, at the base of the brain. The cell bodies of these neurons (nerve cells), numbering some 30,000 in all, fill the spiral canal of Rosenthal at the root of the osseous lamina of the cochlea. Their peripheral, dendritic portions extend radially in the lamina to the habenula perforata, beneath the inner hair cells. At this point they lose their myelin sheaths and enter the organ of Corti as thin, unmyelinated fibres. The greater number are distributed as radial fibres directly to the inner hair cells, whereas others cross the tunnel either as radial fibres supplying a few outer hair cells or as spiral fibres that turn to run for relatively long distances and make contact with many outer hair cells. The central or axonal portions of the bipolar cochlear neurons unite to form the cochlear nerve trunk, the fibres of which are twisted like the strands of a rope. Leaving the modiolus through the internal meatus or passageway, they pass directly to the medulla. There each fibre divides into two, sending one branch to the dorsal and the other to the ventral cochlear nucleus.

Central auditory pathways

The central auditory pathways extend from the medulla to the cerebral cortex and consist of a series of nuclei (groups of nerve cell bodies) connected by fibre tracts made up of their axons. They form a more or less direct route for relaying acoustic information, encoded in the form of nerve impulses, directly to the highest cerebral levels in the cortex. At lower levels information as to pitch, loudness, and localization of sounds is processed, and appropriate responses, such as contractions of the intra-aural muscles, turning of the eyes and head, or movements of the body as a whole, are initiated.

Some fibres from the ventral cochlear nucleus pass across the midline to the cells of the superior olivary complex, whereas others make connection with the olivary complex of the same side. Together, these fibres form the trapezoid body. Fibres from the dorsal cochlear nucleus cross the midline to end on the cells of the nuclei of the lateral lemniscus. There they are joined by fibres from the ventral cochlear nuclei of both sides, and from the olivary complex. The lemniscus is a major tract, most of the fibres of which end in the inferior colliculus, the auditory centre of the midbrain, although some fibres may by-pass the colliculus and end at the next higher level, the medial geniculate body. From the medial geniculate there is an orderly projection of fibres to a portion of the cortex of the temporal lobe.

In man and other primates the primary acoustic area in the cerebral cortex is in the superior transverse temporal gyrus, a ridge in the temporal lobe, on the lower edge, or lip, of a cleft known as the sylvian fissure.

Because about half of the fibres of the auditory pathways cross the midline while others ascend on the same side, each ear is represented in both the right and the left cortex. For this reason both ears can continue to function normally, even if the auditory cortical area of one side is destroyed. Impaired hearing due to bilateral cortical injury involving both auditory areas has been reported, but it is extremely rare.

Parallel with the pathway ascending from the cochlear nuclei to the cortex is a pathway descending from the cortex to the cochlear nuclei. In both pathways some of the fibres remain on the same side, while others cross the midline to the opposite side of the brain. There is also evidence of a "spur" line ascending from the dorsal cochlear nucleus to the cerebellum and another descending from the inferior colliculus, the auditory centre of the midbrain, to the cerebellum. The significance of these cerebellar connections is not clear, but they may antedate the development of the cerebral cortex. In general, the descending fibres may be regarded as exercising an inhibitory function by means of a sort of "negative feedback." They may also determine which ascending impulses shall be blocked and which shall be allowed to pass on to the higher centres of the brain.

From the olivary complex, a region in the medulla oblongata, there arises also a fibre tract called the olivocochlear bundle. It constitutes an efferent system or feedback loop, by which nerve impulses, thought to be inhibitory in nature, reach the hair cells. This system, which apparently utilizes acetylcholine as a chemical synaptic transmitter, is presumably involved in sharpening the analysis that is made in the cochlea.

Evidence of an orderly spatial representation of the organ of Corti at the lower levels of the auditory pathway has been reported by many investigators. Such a pattern would seem to be required by the place theory of cochlear analysis of sound.

Physiological evidence of "tuning" of the auditory system has also been obtained by recording the electrical potentials from individual neurons at various levels by means of microelectrodes. Most neurons of the auditory pathway show a "best frequency"—*i.e.,* a frequency to which the individual neuron responds at minimal intensity. With each increase in the intensity of the sound stimulus, the neuron is able to respond to a wider band of frequencies, thus reflecting the broad tuning of the basilar membrane. With sounds of lower frequency, the rate of response of the neuron tends to reflect the stimulus frequency. Increased intensity of stimulation causes a more rapid rate of responding. In general, pitch tends to be coded in terms of the neurons that are responding, loudness in terms of the rate of response and the total number of active neurons.

Auditory function of the cortex

Although extensive studies have been made of the responses of single cortical neurons, the data do not yet fit any comprehensive theory of auditory analysis. Experiments in animals have indicated that the cortex is not even necessary for frequency recognition, which can be carried out at lower levels, but that it is essential for the recognition of temporal patterns of sound. It appears likely, therefore, that in man both pitch and loudness are distinguished at lower levels of the auditory pathways and that the cortex is reserved for the analysis of more complex acoustic stimuli, such as speech and music, for which the temporal sequence of sounds is equally important.

Presumably it is also at cortical levels that the "meaning" of sounds is recognized and behaviour is adjusted in accordance with their significance. Such functions were formerly attributed to an "auditory association area" immediately surrounding the primary area, but such a term might equally well be interpreted as embracing the entire cerebral cortex, thanks to the multiple interconnections between the various areas.

The localization of sounds is known to depend upon the recognition of minute differences in intensity and in the time of arrival of the sound at the two ears. A sound that arrives at the right ear a few microseconds sooner than it does at the left or that sounds a few decibels louder in that ear is recognized as coming from the right. In a real-life situation the head may also be turned to pinpoint the source of sound by maximizing these differences. For low-frequency tones a difference in phase at the two ears is the criterion for localization, but for higher frequencies the difference in loudness caused by the sound shadow of the head becomes all-important.

The superior olivary complex

Each cochlear nucleus receives impulses only from the ear of the same side. A comparison between the responses of the two ears first becomes possible at the superior olivary complex, which receives fibres from both ears. Electrophysiological experiments in animals have shown that some units of the accessory nucleus of the olivary complex respond to impulses from both ears. Others respond to impulses from one side exclusively, but their response is modified by the simultaneous arrival of impulses from the other side.

This system appears to be capable of making the extraordinarily fine discriminations of time and intensity that are necessary for sound localization. By virtue of such complex neural interconnections in the brain, the two ears together can be much more effective than one ear alone in picking out a particular sound in the presence of a background of noise. They also permit attention to be directed to a single source of sound, such as one instrument in an orchestra or one voice in a crowd. This is the basis of the "cocktail-party effect," whereby a listener with normal hearing can attend to different conversations in turn or concentrate on one speaker despite the surrounding babble. Whether the muscles within the ear play a part in filtering out unwanted sounds during such selective listening has not been established.

HEARING TESTS: AUDIOMETRY

Before the development of electroacoustic equipment for generating and measuring sound, the tests of hearing at the disposal of the otologist gave approximate answers at best. A patient's ability to hear could be specified in terms of whether he could distinguish the ticking of a watch or the clicking of coins or at what distance he could understand a whispered voice. Alternatively, the examiner might note the length of time a patient could hear the gradually diminishing note of the tuning fork, comparing the performance with his own. Other specialized tuning fork tests have been described above.

The electronic audiometer, introduced in the 1930s, makes it possible to measure the patient's threshold of hearing for a series of pure tones ranging from a lower frequency of 125 hertz to an upper frequency of 8,000 or 10,000 hertz. This span includes the three octaves between 500 and 4,000 hertz that are most important for speech.

Components of an audiometer

The audiometer consists of an oscillator or signal generator, an amplifier, a device called an attenuator, which controls and specifies the intensity of the tones produced, and an earphone. The intensity range is usually 100 decibels in steps of five decibels. The "zero dB" level represents "normal hearing" for young adults under favourable, noise-free laboratory conditions and was established in 1964 as an international standard.

For pure-tone audiometry, the patient wears the earphone and is asked simply to indicate when he hears a tone. The examiner proceeds to determine the lowest intensity for each frequency at which the patient reports that he is just able to hear the tone 50 percent of the time. If, for example, he hears 4,000 hertz only at 40 decibels, he is said to have a 40-decibel hearing level for that frequency—*i.e.,* a threshold 40 decibels above the normal threshold. A graph showing the hearing level for each frequency is called an audiogram. The shape of the audiogram for a hard-of-hearing patient can give the otologist or audiologist important information for diagnosing the nature and cause of the defective hearing. (The otologist is concerned with diseases of the ear; the audiologist focusses his attention on the measurement of hearing impairment.)

With the Békésy automatic recording audiometer, the patient himself controls the level of the tone presented. He is required to press a button so long as he is able to hear the tone, which is automatically reduced in intensity as the button is pressed. When it is released the intensity increases until the patient again signals that he hears it by pressing the button. In this way the patient's threshold is "tracked." At the same time the frequency is slowly increased and a graphic recording is made. Thus a complete, continuous audiogram can be obtained in less than 10 minutes.

A calibrated bone conduction vibrator is usually furnished with the audiometer so that hearing by bone conduction can also be measured. In the presence of otosclerosis or other conductive defect of the middle ear, there may be a sizable difference between the air-conduction and bone-conduction audiograms, the so-called "air-bone gap." This difference is a measure of the loss in transmission across the middle ear and indicates the maximum improvement that may be obtained through successful corrective surgery. When the defect is confined to the organ of Corti, the bone-conduction audiogram shows a loss similar to that for air conduction. In such cases of sensorineural impairment, surgery is seldom if ever capable of improving the hearing, but a hearing aid may prove useful.

Although faint sounds may not be heard at all by the ear with a sensorineural impairment, more intense sounds may be as loud as to a normal ear. This rapid increase in loudness above the threshold level is called recruitment. When the opposite ear has normal hearing, recruitment can be measured by the alternate binaural loudness balance (ABLB) test. The subject is asked to set the controls so that the loudness of the tone heard in his defective ear matches that of the tone heard in his normal ear. By repetition of the comparison at several intensity levels, the presence or absence of recruitment can be demonstrated. When recruitment is excessive, the range of useful hearing between the threshold and the level at which loudness becomes uncomfortable or intolerable may be extremely narrow, so that the amplification provided by a hearing aid is of limited value to the patient.

Speech reception threshold and discrimination

Although hearing thresholds for pure tone give some indication of the patient's hearing for speech, direct measurement of this ability is of interest to the otologist. Two types of tests are most often used. In one, the speech reception threshold (SRT) is measured by presenting words of spondee pattern—words containing two syllables of equal emphasis, as in "baseball" or "cowboy"—at various intensity levels until the level is found at which the patient can just hear and repeat half of the words correctly. This level usually corresponds closely to the average of the patient's thresholds for frequencies of 500, 1,000, and 2,000 hertz. A more important measure of socially useful hearing is the discrimination score. For this test a list of selected monosyllabic words is presented at a comfortable intensity level, and the subject is scored in terms of the percentage of the words heard correctly. This test is helpful in evaluating certain forms of hearing impairment in which the sounds may be audible but words remain unintelligible. Such tests are usually carried out in a quiet, sound-treated room that excludes extraneous noise. They may give a mistaken impression of the ability of the patient with sensorineural impairment to understand speech in ordinary noisy surroundings. Because such persons often have increased difficulty in understanding speech in the presence of noise, speech tests are best carried out against a standardized noise background as well as in the quiet. A person with a conductive defect may be less disturbed by noise than may the normal subject.

Tests suitable for young persons

For very young persons or others who are unable to cooperate in the usual audiometric tests, thresholds for pure tones may be established by electrophysiological means. A brief tone causes a small variation in the electrical potentials that can be recorded from the scalp and constitute the electroencephalogram, EEG (a recording of the brain waves). By repetition of the stimulus up to 100 times and by an averaging of the responses in a small computer, the responses can be selectively enhanced while the more or less random background of elctrical activity is cancelled out. In this way auditory thresholds can be established that closely approximate those obtained in conventional audiometry. If the responses indicate impaired hearing, they give little or no indication of the site of the defect.

Another form of electrophysiological hearing test is the electrocochleogram. Electrical potentials representing impulses in the cochlear nerve are recorded from the cochlea by means of a fine, insulated needle electrode inserted through the eardrum membrane to make contact with the promontory of the basal turn. This test gives a direct measure of cochlear function.

More elaborate tests, often involving speech or sound localization, are available for testing hearing impaired by defects of the central nervous system. The interpretation of the results is often difficult, and the diagnostic information furnished by the tests is seldom clear-cut.

A simple and objective means of testing hearing at the level of the cochlea and brainstem is supplied by impedance audiometry. Two small tubes are sealed into the external canal. Through one tube sound from a small loud-speaker is injected into the canal. The portion that is reflected from the drum membrane is picked up by the other tube and led to a microphone, amplifier, and recorder. When a sudden, moderately intense sound is applied to the opposite ear, the stapedius muscle contracts, the impedance is increased, and the recorder shows a slight excursion as more sound is reflected. This test can give valuable information not only about the condition of the cochlea and the auditory pathways of the medulla but also about the facial nerve that supplies fibres to the stapedius muscle. On the other hand, it does not give an actual measurement of the acoustic impedance of the ear, representing the state of the ossicular chain and the mobility of the eardrum. This information can be obtained by means of the acoustic bridge—a device that enables the observer to listen to a sound as reflected from the subject's eardrum and at the same time to a similar sound of equal intensity as reflected in an artificial cavity, the volume of which is adjusted to equal that of the external canal of the ear being tested. When the two sounds are matched by varying the acoustic impedance of the cavity, the impedance of the ear is equal to that of the cavity, which can be read directly from the scale of the instrument. Conductive defects of the middle ear, including discontinuity (disarticulation) of the ossicular chain and immobility of the malleus or stapes, can be recognized by the characteristic changes they cause in the impedance of the ear. Profound sensorineural deafness can occur as a result of viral and other infections, including mumps, measles, and meningitis. Rubella (German measles) in the mother during pregnancy can cause the child to be born with a severely damaged organ of Corti and profound hearing loss. Cochlear abnormalities may be present also as a result of genetic defects. In all such cases of deafness in young children it is essential that the condition be recognized as early as possible so that special educational measures may be instituted to minimize the handicap. The newer electrophysiological hearing tests described above—*i.e.,* electroencephalographic audiometry and the electrocochleogram—offer the best possibilities for detecting such losses in infants. (For further discussion of deafness and hearing impairments, see below *Ear diseases and hearing disorders.*)

VESTIBULAR FUNCTION

Equilibrium sense

The vestibular system represents the equilibrium sense and is concerned primarily with controlling the position of the head and the posture of the body. The adequate stimulus for its end organs is acceleration: angular acceleration for the semicircular canals; linear acceleration for the utricle and saccule. Functionally these organs are closely related to the cerebellum and to the reflex centres that govern the movements of the eyes, the neck, and the limbs. The information they deliver is proprioceptive in character, dealing with events within the body itself, rather than exteroceptive, dealing with events outside the body, as in the case of the responses of the cochlea to sound. Although the vestibular organs and the cochlea are derived embryologically from the same formation, the otic vesicle, their association seems to be a matter more of convenience than of necessity. Both from the developmental and from the structural point of view, the kinship of the vestibular organs with the lateral line system of the fishes is easily recognized. This system is made up of organs located in the skin at the side of the body and contains cristae with innervated hair cells and a cupula, like those of the semicircular canals. They are sensitive to waterborne vibrations and to pressure changes.

The anatomists of the 17th and 18th centuries were impressed by the orientation of the semicircular canals in the head, in three planes more or less perpendicular to one another. Since it was generally assumed that the entire labyrinth is devoted to hearing, the suggestion was put forward that the canals must perceive the direction of sound.

The first investigator to present evidence that the vestibular labyrinth is the organ of equilibrium was a French experimental neurologist, Marie-Jean-Pierre Flourens, who, in 1824, reported a series of experiments in which he had produced abnormal head movements in the pigeon by cutting each of the semicircular canals in turn. The plane of the movements was always the same as that of the injured canal. Hearing was not affected by destroying the nerve fibres to the vestibular organs, but it was abolished by cutting the cochlear nerve.

Endolymph and the "hydrodynamic concept"

It was almost half a century later that the significance of these experiments was appreciated and the semicircular canals were recognized as specific sense organs concerned with the position of the head. The German physiologist Friedrich Goltz in 1870 suggested in his "hydrostatic concept" that the canals are stimulated by the weight of the fluid they contain, the pressure it exerts varying with the head position. Three years later the Austrian scientists Ernst Mach and Josef Breuer, and the Scottish chemist Crum Brown, working independently, proposed their "hydrodynamic concept." They held that head movements cause a flow of endolymph in the canals, which are stimulated by the fluid movement or pressure changes. A German physiologist, J.R. Ewald, showed that the compression of the lateral canal in the pigeon by a small pneumatic hammer caused endolymph movement toward the crista and turning of the head and eyes toward the opposite side. Decompression reversed both the direction of endolymph movement and the turning of the head and eyes.

Later investigators have proved that the hydrodynamic concept is correct and that the cupula is deflected by endolymph movement in response to rotation. They were able to keep track of the deflection in live fish by means of a droplet of oil injected into the canal. At the start of rotation in the plane of the canal, the cupula was deflected in the opposite direction and then returned slowly to its position of rest. At the end of rotation it was deflected again, this time in the same direction as the rotation, and then returned once more to its upright resting position. These deflections were due to the inertia of the endolymph, which tended to lag behind at the start of rotation and to continue in motion after rotation had stopped. The slow return was a function of the elasticity of the cupula itself.

Polarization of hair cells

Other researchers found that they could keep the labyrinth of a cartilaginous fish, the thornback ray (*Raja clavata*), active for some time after it was removed from the animal and could record from the vestibular fibres of the vestibulocochlear nerve impulses arising in one of the ampullar cristae. At rest there was a slow continuous discharge, which was increased by rotation in one direction and decreased by rotation in the other. In other words, the level of excitation rose or fell depending upon the direction of rotation. Later studies with the electron microscope showed a remarkable polarization of the hair cells of the ampullar cristae. Each hair cell of the horizontal canals has its kinocilium facing toward the utricle, whereas each hair cell of the vertical canals has its kinocilium facing away from the utricle. In the horizontal canals deflection of the cupula toward the utricle—*i.e.,* bending of the stereocilia toward the kinocilium—depolarizes the hair cells and increases the rate of discharge. Deflection away from the utricle causes hyperpolarization and decreased discharge. In the vertical canals these effects are reversed.

The relation between the two labyrinths is reciprocal. When the head is turned to the left, the discharge from the left horizontal canal is increased while that from the right horizontal canal is decreased, and vice versa. Normal posture is the result of their acting both in cooperation and in opposition. When one labyrinth is injured, the unrestrained activity of the other causes a continuous false sense of turning (vertigo) and rhythmical, jerky movements of the eyes (nystagmus), both toward the normal side. When both labyrinths are injured or destroyed, as by the action of the antibiotic streptomycin, there may be a serious disturbance of posture and gait (ataxia) as well as severe vertigo and general disorientation. In younger persons the disturbance tends to subside as reliance is placed on vision and on proprioceptive impulses from the muscles and joints to compensate for the loss of information from the labyrinth. In elderly persons, the loss of labyrinthine function may be disabling.

The two otolith organs or gravity receptors, the maculae of the utricle and saccule, are more or less perpendicular to each other. The left and right utricular maculae lie in the same approximately horizontal plane; the saccular maculae in parallel, vertical planes. Both types of receptors are stimulated by shearing forces between the otolithic membrane and the cilia of the hair cells beneath it. The otolithic membrane is covered with a layer of crystals of calcite (otoconia), which add to its weight and increase the shearing forces set up in response to a slight displacement when the head is tilted. These receptors, particularly the utricle, have an important role in the righting reflexes and in reflex maintenance of tonic contraction of the muscles that keep the body in the upright position. The role of the saccule is less completely understood, and some investigators have suggested that it is responsive to vibration as well as to rectilinear acceleration of the head in the sagittal (fore-and-aft) plane. Of the two receptors, the utricle appears to be the dominant partner.

Tests of vestibular function depend mainly upon stimulation of the semicircular canals. Rotation, which can cause vertigo and nystagmus, as well as temporary disorientation and a tendency to fall, stimulates both labyrinths simultaneously. Since the otoneurologist is usually more interested in examining the right and left labyrinths separately, he usually employs warmth as a stimulant. Syringing the ear canal with warm water at 44° C (111° F) or cool water at 30° C (86° F) elicits nystagmus by setting up convection currents in the horizontal canal. The duration of the nystagmus may be timed with a stopwatch, or the movements of the eyes can be accurately recorded by picking up the direct current potentials of the eyeballs by means of electrodes pasted to the skin of the temples (a process called electronystagmography, or ENG). An abnormal labyrinth usually gives a reduced response or none. (J.E.H.)

Caloric stimulation

Ear diseases and hearing disorders

The ear has two important but quite different functions: the maintenance of equilibrium and hearing. For biped locomotion, the sense of equilibrium is especially necessary; and it is even more pressing in the dark, in which the eyes cannot help to maintain balance, or on uneven terrain, where sensations from the feet do not assist in maintaining the sense of equilibrium. Hearing, which developed later than equilibrium in the process of evolution, has become, with sight, one of the senses most needed by animals for flight and survival. For humankind, hearing is also the chief means of receiving communication by language and is so taken for granted that its importance is rarely appreciated until it is impaired or lost.

The human auditory system and its natural function are treated in detail above. This section deals with the more important diseases and disorders of the outer, the middle, and the inner ear. It concludes with brief discussions of the causes of deafness and impaired hearing; rehabilitation of hearing impairment and deafness; and the social and economic implications of deafness.

THE OUTER EAR

Each of the three main parts of the ear is afflicted by a particular set of diseases, according to the structure, tissues, and function of that part. Diseases of the outer ear are those that afflict skin, cartilage, and the glands and hair follicles in the outer ear canal. The sound-transmitting function of the outer ear is impaired when the ear canal becomes filled with tumour, infected material, or earwax, so that sound cannot reach the eardrum membrane. The most common diseases of the outer ear are briefly described in the following paragraphs.

Infections and injuries. *Frostbite.* The exposed position of the outer ear makes it the part of the body most frequently involved by freezing or frostbite. Humidity, duration of exposure, and, most of all, wind, in addition to degrees of temperature below freezing, predispose to occurrence of frostbite. The frozen area begins along the upper and outer edge of the ear, which becomes yellow-white and waxy in appearance, cold and hard to the touch, and numb with loss of skin sensation.

In treatment of frostbite the victim is placed as soon as possible in a warm room, but the frozen ear is kept cool until the returning blood circulation gradually thaws the frozen part from within. Massage of the frozen ear is avoided, for it is likely to injure the skin. Heat applied to the frozen area before circulation is established can result in clotting of the blood in the blood vessels. This in turn can result in death of that part of the ear, which turns black and eventually falls off, a process called dry gangrene.

Hematoma. Injury to the outer ear can cause bleeding between the cartilage and the skin, producing a smooth, rounded, nontender purplish swelling called hematoma. The accumulation of clotted blood is removed by a surgeon because, if it is left, it will become transformed into scar tissue and cause a permanent, irregular thickening of the outer ear commonly called cauliflower ear and seen in boxers and wrestlers whose ears receive much abuse.

Infections of the outer ear

Perichondritis. Infection of the cartilage of the outer ear, called perichondritis, is unusual but may occur from injury or from swimming in polluted water. It is due to a particular microorganism, *Pseudomonas aeruginosa.* There is a greenish or brownish, musty or foul-smelling discharge from the outer ear canal, while the affected outer ear becomes tender, dusky red, and two to three times its normal thickness. Prompt medical treatment is necessary to prevent permanent deformity of the outer ear.

External otitis. Infection of the outer ear canal by molds or various microorganisms occurs especially in warm, humid climates and among swimmers. The ear canal itches and becomes tender; a small amount of thin, often foul-smelling material drains from it. If the canal becomes clogged by the swelling and drainage, hearing will be impaired. Careful and thorough cleaning of the outer ear canal by a physician, application of antiseptic or antibiotic eardrops, and avoidance of swimming are indicated to clear up the infection.

Boil in the ear (furuncle). Infection of a hair follicle anywhere on the body is known as a boil, or furuncle. This can occur in a hair follicle in the outer ear canal, especially when there is infection of the skin of the canal. It always occurs because of a particular type of germ known as staphylococcus. Because the skin of the ear canal is closely attached to the underlying cartilage, a boil in the ear canal is especially painful, with swelling, redness, and tenderness but generally without fever. Heat applied to the outer ear by a hot-water bottle or electric pad helps the infection to come to a head and begin to drain. Antiseptic eardrops and careful cleaning of the outer ear canal are needed to prevent other hair follicles from becoming infected with a series of painful boils in the ear.

Erysipelas of the outer ear. Erysipelas is an infection in the skin caused by a particular type of streptococcus that causes a slowly advancing red, slightly tender thickening of the skin. It begins at the ear and spreads to the face and neck. Centuries ago erysipelas epidemics caused severe and often fatal infections. In AD 1089 one of the most severe epidemics was known as St. Anthony's fire; those who prayed to St. Anthony were said to recover; others, who did not, died. Today erysipelas is a rather mild and comparatively rare infection that clears up rapidly when sulfanilamide is taken by mouth or penicillin by injection.

Leprosy. Leprosy, seen rarely outside of the tropics today, was another scourge of ancient times that sometimes affected the outer ear. It is caused by the leprosy bacillus, *Mycobacterium leprae,* which causes a painless, slowly progressing thickening and distortion of the affected tissues. The diagnosis is made by examining a bit of the infected tissue under a microscope and finding the leprosy bacilli, which in appearance are not unlike the bacilli that cause tuberculosis. Fortunately, the antibiotics effective against tuberculosis are effective today in arresting the ravages of leprosy.

Osteoma of the bony ear canal. Osteoma of the bony ear canal is a bony knob that grows close to the eardrum membrane, especially in those who swim a great deal in cold water. It is not dangerous and does not need to be removed unless the bony overgrowth becomes large enough to block the ear canal.

Cyst of the ear. A cyst is a sac filled with liquid or semisolid material. A cyst of the ear is most often caused by a gland that lubricates the skin behind the earlobe, less often at the entrance of the ear canal. If the duct of this gland becomes stopped, the lubricating fatty material accumulates as a soft rounded nodule in the skin. Infection of the cyst causes a tender abscess to form and drain. The cyst will re-form unless it is removed completely by surgery.

Another type of cyst occurs above the ear canal, just in front of the outer ear or, rarely, in the neck behind and below the ear. This is a remnant of the primitive gill of the early embryo, a reminder of our ancient fishy ancestors. It may appear as a tiny pitlike depression that discharges a little moisture from time to time, or a cystic swelling may develop when the opening of the pit is closed, requiring surgical removal.

Enlargement of earlobe

Keloid of the ear. In dark-skinned people, overgrowth of scar tissue from any skin incision or injury causes a thickened elevation on the scar called a keloid. Having the earlobes pierced for earrings sometimes results in a large, painless nodular keloid enlargement of the earlobe, harmless but unsightly. Keloids are removed surgically (see also INTEGUMENTARY SYSTEMS).

Deformities. *Absence of the outer ear.* Congenital deformity or absence of the outer ear, usually on one side, sometimes on both, is often accompanied by absence of the outer ear canal. This failure of the primitive gill structures to become properly transformed into the normal outer and middle ear is, in rare instances, hereditary. More often it occurs for no known reason. In some cases it can be traced to the damaging effects on the embryo of rubella (German measles) in the mother during the first three months of her pregnancy. Since the inner ear and nerves of equilibrium and hearing come from the otocyst, separate from the gill structure, in most cases of deformed or absent outer ear the hearing nerve is normal. Surgical construction of a new ear canal and eardrum membrane can then often improve the hearing, which has been impaired by the failure of sound conduction to reach the hearing nerve in the inner ear.

Lop ear. Lop ear, excessive protrusion of the ear from the side of the head, is a more frequent and less serious deformity of the outer ear. Surgery may be performed to bring the ears back to a more normal and less conspicuous position.

Other ailments. *Eczema.* Eczema of the skin of the outer ear, like eczema elsewhere, is an itching, scaling redness, sometimes with weeping of the affected skin. It is often the result of an allergy to a food or substance such as hair spray that comes in contact with the skin. The best treatment is discovery and avoidance of the causative agent.

Impacted earwax. The waxy substance produced by glands in the skin of the outer ear canal normally is carried outward by slow migration to the outer layers of skin. When wax is produced too rapidly it can accumulate as a hard plug, firmly filling the outer ear canal and blocking the passage of sound to the eardrum membrane, causing a painless impairment of hearing. Large plugs of earwax need to be removed by a physician. Smaller amounts may be softened by a a few drops of baby oil left in the ear overnight, then syringed out with warm water and a soft-rubber baby ear syringe.

Cancer of the outer ear. Cancer of the outer ear occurs chiefly in areas exposed for many years to the direct sun. A small and at first painless ulcer, with a dry scab covering it, that slowly enlarges and deepens may be a skin cancer. Removal of a small bit of tissue from the edge (biopsy) and examining it under a microscope comprise the method of diagnosis. Complete removal by surgery or properly applied irradiation is needed for a cure. Cancer that begins in the ear canal is more serious, for it may deepen into the bone before it is diagnosed. It is then more difficult to cure by removal. Cancers of the ear canal are rather rare, while cancers of the skin of the outer ear are more common, as well as more readily cured by removal.

THE MIDDLE EAR

Location of middle ear

The air-filled middle-ear cavity and the air cells in the mastoid bone that extend backward from it are located a third of the distance from the side of the head toward its centre. The brain cavity lies just above and behind the middle ear and mastoid air spaces, separated from them only by thin plates of bone. The nerve that supplies the muscles of expression in the face passes through the middle-ear cavity and mastoid bone; it, too, is separated from them by only a thin layer of bone. In some instances this bony covering is incomplete, so that the facial nerve lies directly against the mucous membrane that lines the middle ear and mastoid air cells. This mucous membrane, an extension of a similar mucus-producing membrane that lines the nose and upper part of the throat, extends all the way through the eustachian tube into the middle ear and mastoid. It is subject to the same allergic reactions and infections that afflict the nasal passages. Thus, an acute head cold or other infection of the nose and throat, such as measles or scarlet fever, may extend through the eustachian tube into the middle ear and mastoid air cells. The proximity of the brain cavity to the mastoid air cells is such that an infection, if severe and untreated, may lead to meningitis (inflammation of the covering of the brain) or brain abscess. The large vein that drains blood from the brain passes through the mastoid bone on its way to the jugular vein in the neck. Infection from the middle ear can extend to this vein, resulting in "blood poisoning" (infection of the bloodstream, also called septicemia). Paralysis of the facial nerve and infection extending from the middle ear to the labyrinth of the inner ear are other possible complications of middle-ear infection. All of these possibilities spring from the particular location of the small but important middle-ear cavity.

Acute middle-ear infection. Fortunately, acute middle-ear infections, called acute otitis media, are nearly always due to microorganisms that respond quickly to antibiotics. As a result, acute infection of the mastoid air cells resulting in a dangerous mastoid abscess with the possibility of meningitis, brain abscess, septicemia, infection of the labyrinth, or facial nerve paralysis, complicating an acute infection of the middle-ear cavity, have become rare. Abscess of the mastoid and the other complications of acute middle-ear infection are seen chiefly in remote regions and countries lacking adequate medical attention.

Chronic otitis media

While serious and life-threatening acute infections of the middle ear and mastoid air cells have become rare, chronic infections, mentioned below, continue to occur, and another type of middle-ear disease, secretory otitis media, is frequent.

Secretory otitis media. In secretory otitis media the middle-ear cavity becomes filled with a clear, pale-yellowish, noninfected fluid. The disorder is the result of inadequate ventilation of the middle ear through the eustachian tube. The air in the middle ear, when it is no longer replenished through this tube, is gradually absorbed by the mucous membrane, fluid taking its place. Eventually, the middle-ear cavity is completely filled with fluid instead of air. The vibratory movements of the eardrum membrane and the ossicular chain are impeded by the fluid, with a painless impairment of hearing.

The usual causes for secretory otitis media are an acute head cold with swelling of the membranes of the eustachian tube; an allergic reaction of the membranes in the eustachian tube; and an enlarged adenoid (nodule of lymphoid tissue) blocking the entrance to the eustachian tube. The condition is cured by finding and removing the cause and then removing the fluid from the middle-ear cavity, if it does not disappear by itself within a week or two. Removal of the fluid requires puncturing the eardrum membrane and forcing air through the eustachian tube to blow out the fluid. In some cases a tiny plastic tube is inserted through the eardrum membrane to aid in reestablishing normal ventilation of the middle-ear cavity. After a time, when the middle ear and hearing have returned to normal, this plastic tube is removed. The small hole left in the eardrum membrane quickly heals.

Aero-otitis media. The sudden change of altitude by a rapid descent in a nonpressurized or poorly pressurized plane during a head cold or allergic reaction may not permit the normal equalization of air pressure that occurs by the periodic opening of the eustachian tube on swallowing or yawning. The eardrum membrane becomes sharply retracted when the air pressure becomes less within than without, while the opening of the tube into the upper part of the throat becomes pressed tightly together by the increased air pressure in the throat, so that the tube cannot be opened by swallowing. A severe sense of pressure in the ear is accompanied by pain and a decrease in hearing. Sometimes the eardrum membrane ruptures because of the difference in pressure on its two sides. More often, the pain continues until the middle ear fills with fluid, or surgical puncture of the eardrum membrane is done. This condition occurring from airplane flights is called aero-otitis media. Usually, however, pain and hearing loss produced during a flight is of a temporary nature and disappears of its own accord.

Chronic middle-ear infection. Chronic infection of the middle ear occurs when there is a permanent perforation of the eardrum membrane that allows dust, water, and germs from the outer air to gain access to the middle-ear cavity. This results in a chronic drainage from the middle ear through the outer ear canal. There are two distinct types of chronic middle-ear infection, one relatively harmless, the other caused by a dangerous bone-invading process that leads, when neglected, to serious complications.

The harmless type of chronic middle-ear disease is recognized by a stringy, odourless, mucoid discharge that comes from the surface of the mucous membrane that lines the middle ear. Medical treatment with applications of antiseptic solutions and powders is all that is needed to dry up the chronic drainage. The perforation in the eardrum membrane may then be closed, restoring the normal structure and function of the ear with recovery of hearing.

The dangerous type of chronic middle-ear drainage is recognized by its foul-smelling discharge, often scanty in amount, coming from a bone-invading process beneath the mucous membrane. Such cases are usually caused by a condition known as cholesteatoma of the middle ear. This is an ingrowth of skin from the outer ear canal that forms a cyst within the middle ear and mastoid. If untreated, the cyst enlarges slowly but progressively, gradually eroding the bone until the cyst reaches the brain cavity or the nerve that supplies the muscles of the face or a semicircular canal of the inner ear. The infected material within the cyst then produces a complication: meningitis or brain abscess, paralysis of the facial nerve, or infection of the labyrinth of the inner ear with vertigo, often leading to total deafness.

Dangers of neglected cholesteatoma

Fortunately, cholesteatoma of the middle ear is now rarely so neglected as to permit development of a serious complication. By careful examination of the eardrum-membrane perforation and by X-ray studies, the bone-eroding cyst can be diagnosed; it can then be removed surgically before it has caused serious harm. This operation is known as a radical mastoid or a modified radical mastoid operation. If at the same procedure the perforation in the eardrum membrane is closed and the ossicular chain repaired, the operation is known as a tympanoplasty, or plastic reconstruction of the middle-ear cavity.

Ossicular interruption. The ossicular chain of three tiny bones needed to carry sound vibrations from the eardrum membrane to the fluid that fills the inner ear may be disrupted by infection or by a jarring blow on the head. Most often the separation occurs at its weakest point, where the anvil (incus) joins the stirrup (stapes). If the separation is partial there is a mild impairment of hearing; if it is complete there is a severe hearing loss. Testing of the hearing in such a case demonstrates that the nerve of hearing in the inner ear is functioning normally but that sound fails to be conducted from the eardrum membrane to the inner ear. The separated ossicles can be brought back together by repositioning, thus restoring the conduction of sound to the inner ear. This is one of the most successful of hearing-restoring operations.

Otosclerosis. The commonest cause for progressive hearing loss in early and middle adult life is a disease process of the hard shell of bone that surrounds the labyrinth of the inner ear. This disease of bone is known as otosclerosis, a name that is misleading, for in its early and actively expanding stage the nodule of diseased bone is softer than the ivory-hard bone that it replaces. The more appropriate name otospongiosis is sometimes used, but such is the tenacity of tradition that the older name, applied before the process was well understood, has persisted and is the term generally used.

The cause for the occurrence of the nodule of softened otosclerotic bone is unknown. There is a certain familial tendency, half the cases occurring in families in which one or several relatives have the same condition. It is one-tenth as common among blacks as among whites, and is twice as common in women as in men. The nodule of softened otosclerotic bone first appears in late childhood or in early adult life. Fortunately, in most cases it remains quite small and harmless, producing no symptoms, and is discoverable only if the ear bones are removed after death and examined under a microscope. Such evidence indicates that approximately one in 10 white adult men and one in five white adult women will be found to have such a nodule of otosclerotic bone by middle adult life.

In about 12 percent of cases of otosclerosis the nodule of softened bone becomes large enough to reach the oval window containing the footplate of the stirrup. Increasing pressure caused by the expanding nodule begins to impede its vibratory movements in response to sound striking the eardrum membrane. Gradually and insidiously, such an affected person begins to lose his sharpness of hearing. First he begins to lose the ability to hear faint sounds of low pitch; next he begins to have difficulty hearing the whispered voice; then he has difficulty in hearing conversation from a distance; and finally he can hear and understand the spoken voice only when it is quite loud or close to the ear. One of the characteristics of impaired hearing due to stirrup fixation by otosclerosis is retained ability to hear over the telephone by pressing the receiver against the head so that the sound is carried to the inner ear by bone conduction. Another characteristic of this type of impaired hearing is that hearing seems to be better while one is riding in an automobile, in a plane, or on a train. The reason is that the low-pitched roar of motors causes normally hearing persons to unconsciously raise their voices, while the individual with stirrup fixation fails to hear the low-pitched roar and thus hears better and enjoys the raised voices around him.

Diagnosis of stirrup fixation

The diagnosis of stirrup fixation by otosclerosis is made on the basis of a history of a gradually increasing impairment of hearing with absence of any chronic infection of the middle ear or of perforation of the eardrum membrane and with hearing tests showing that the nerve of hearing in the inner ear is functioning but that sound fails to be conducted properly to it. The hearing tests demonstrate that the hearing by bone conduction is better than by air conduction.

The final and conclusive diagnosis of otosclerosis is made by surgical exploration and finding that the stirrup bone (stapes) is fixed and unable to be moved because of a nodule of bone that has grown against it. A special type of X-ray of the ear called polytomography is sometimes used to demonstrate that the footplate of the stirrup bone has been invaded by otosclerosis.

Fixation of the stirrup bone can be corrected surgically. This was accomplished formerly by constructing a new window into the inner ear to admit sound to the hearing nerve. This operation originated in Europe in 1924 and in 1937 was brought to the United States, where it was improved and named the fenestration operation. In 1952 it was found possible to mobilize (loosen) the fixed stirrup bone in some cases, thus restoring hearing without the need of constructing a new opening. In 1956 it was found that the fixed stirrup bone could be removed and replaced by a plastic or wire substitute in cases in which it could not be mobilized. Today this operation, known as stapedectomy, is the one most often used to correct fixation of the stapes (stirrup bone) by otosclerosis.

The otosclerotic bone disease in some cases expands as far as the cochlea of the inner ear, causing a gradual deterioration of the hearing nerve. This progressive nerve deafness may precede, accompany, or follow fixation of the stapes. In some cases it may occur without fixation of the stapes.

While the exact cause for the softening of a nodule of bone known as otosclerosis is not known, it may be associated in some cases with lack of fluoride in drinking water. There is evidence, not yet conclusive, that increasing the intake of fluoride may promote hardening of the softened nodule of otosclerotic bone, thus arresting or retarding its expansion. In this way it is possible that the gradual impairment of hearing-nerve function that often occurs with fixation of the stapes may be retarded or arrested.

THE INNER EAR

The labyrinth of the inner ear contains the nerve endings of the vestibular nerve—the nerve of equilibrium—and the auditory nerve, or nerve of hearing. The vestibular-nerve ends supply the semicircular canals and the otolithic membranes in the vestibule. The auditory nerve supplies the cochlea (see above *Anatomy of the auditory apparatus: inner ear).* Diseases of the labyrinth of the inner ear may affect both the vestibular nerve and the auditory nerve; or they may affect only the auditory nerve, with loss of hearing, or the vestibular nerve, bringing on vertigo. The commoner inner-ear diseases are touched upon in the following paragraphs.

Nerve deafness. *Congenital nerve deafness.* Congenital nerve deafness, a defect of the hearing nerve in the cochlea, may be present at birth or acquired during or soon after birth. Usually both inner ears are affected to a similar degree, and as a rule there is a severe impairment of hearing, although, in some cases of congenital nerve loss the impairment is moderate in degree. Many cases of congenital nerve deafness have been caused by the rubella (German measles) virus in the mother during the first three months of her pregnancy, causing arrest of development of the otocyst. This can happen during a rubella epidemic, even when the mother has no symptoms of the infection. In most cases the vestibular nerve is not affected or is affected to a lesser degree, and in most (but not all) cases the outer- and middle-ear structures are not affected. A vaccine against the rubella virus that has recently been introduced promises to result in a marked reduction in the number of cases of congenital nerve deafness if it is given to prospective mothers who have not had rubella before becoming pregnant and thus have not had an opportunity to build up immunity against infection when they are carrying a child.

Anoxia and kernicterus

Congenital nerve deafness, acquired at or soon after birth, may result from insufficient oxygen (anoxia) during a difficult and prolonged delivery or from the condition known as kernicterus, in which the baby becomes jaundiced because of incompatibility between its blood and that of the mother. In a few cases congenital nerve deafness is an inherited failure of the cochlea to develop properly. There is no medical or surgical treatment that can improve or restore hearing in cases of congenital nerve deafness. When the hearing loss is severe, speech cannot be acquired without special training. Children so afflicted must attend special classes or schools for the severely deafened, where they can be taught lipreading and speech. Electrical hearing aids can be helpful, especially during classes, to utilize the remnants of hearing usually present in such cases.

Viral nerve deafness. Virus infections can cause severe degrees of hearing-nerve loss in one ear and sometimes in both, at any age. The mumps virus is one of the most common causes of severe hearing-nerve loss in one ear. The measles and influenza viruses are less common causes. There is no effective medical or surgical treatment to restore hearing impaired by a virus.

Effect of injury and trauma. *Ototoxic drugs.* Ototoxic (ear-poisoning) drugs can cause temporary and sometimes permanent impairment of hearing-nerve function. Salicylates such as aspirin in large enough doses may cause ringing in the ears and then a temporary decrease in hearing that recovers when the person stops taking the drug. Quinine can have a similar effect but with a permanent impairment of hearing-nerve function in some cases. Certain antibiotics, such as streptomycin, dihydrostreptomycin, neomycin, and kanamycin, may cause permanent damage to the hearing-nerve function. The susceptibility to damage to the hearing from ototoxic drugs varies greatly among individuals. In most cases, except when streptomycin is the drug taken, the more durable and less easily damaged vestibular-nerve function is not affected. Streptomycin affects the vestibular nerve more than the auditory nerve.

Skull fracture and concussion. Skull fracture and concussion from a severe blow on the head can impair the functioning of the hearing nerve and of the nerve of balance in varying degrees. The greatest hearing loss arises when a fracture of the skull passes through the labyrinth of the inner ear, totally destroying its function.

Exposure to noise. The effects of noise exposure on hearing depend on the intensity and duration of the noise. The effects may be temporary or permanent. A single exposure to an extremely intense sound, such as an explosion, may produce a severe and permanent loss of hearing. Repeated exposures to sounds in excess of 80 to 90 decibels may cause gradual deterioration of hearing by destroying the hair cells of the inner ear and possible subsequent degeneration of nerve fibres (Figure 59). The levels of noise produced by rock music bands frequently exceed 110 decibels. The noise generated by farm tractors, power mowers, and snowmobiles may reach 100 decibels. In the United States, legislation requires that workers exposed to sound levels greater than 90 decibels for an eight-hour day be provided some form of protection, such as earplugs or earmuffs.

Sources of high level noise

By courtesy of Lars-Goran Johnsson

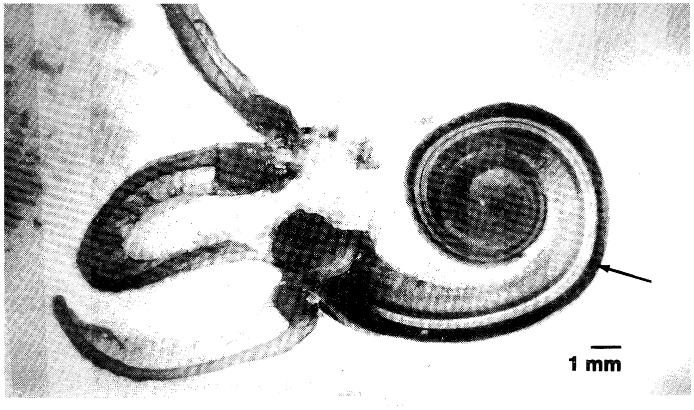

Figure 59: Dissection of the human cochlea and semicircular canals. The arrow indicates an area of degeneration of Corti's organ and the cochlear nerve fibres in the basal turn, corresponding to a loss of hearing for frequencies of 4,000 hertz and higher, presumably caused by noise exposure.

Individuals differ in their susceptibility to hearing loss from noise exposure. Because hearing loss typically begins at the higher frequencies of 4,000 to 6,000 cycles per second, the effects of noise exposure may go unnoticed until the hearing loss spreads to the lower frequencies of 1,000 to 2,000 cycles per second.

Inflammation and tumour. *Labyrinthitis.* Labyrinthitis, an inflammation of the labyrinth of the inner ear, occurs when microorganisms enter as a result of meningitis, syphilis, acute otitis media and mastoiditis, or chronic otitis media and cholesteatoma. Loss of both equilibrium and hearing occurs in the affected ear. Prompt treatment sometimes arrests the damage with the possibility of partial recovery of the function of the inner ear.

Acoustic neuroma. An acoustic neuroma is a benign tumour that grows on the acoustic nerve near the point where it enters the labyrinth of the inner ear. The tumour causes gradual and progressive loss of auditory- and vestibular-nerve function on one side. Eventually the tumour grows out into the brain cavity, causing headache and paralysis. If it is not removed, blindness and death may result. Fortunately, acoustic neuroma can be diagnosed early and removed before it has serious consequences.

Menière's disease. Menière's disease, also called endolymphatic hydrops, is a fairly common involvement of the labyrinth of the inner ear that affects both the vestibular nerve, with resultant attacks of vertigo, and the auditory nerve, with impairment of hearing. It was first described in 1861 by a French physician, Prosper Menière. It is now known that the symptoms are caused by an excess of endolymphatic fluid in the inner ear. The diagnosis is made from the recurring attacks of vertigo, often with nausea and vomiting, ringing or roaring in the ear, impairment of hearing with a distortion of sound in the affected ear that fluctuates in degree, and a sense of fullness or pressure in the ear. The cause of Menière's disease is not always known, although in many cases it results from defective functioning of the endolymphatic duct and sac, the structures that normally resorb endolymphatic fluid from the inner ear as fast as it is produced. The treatment of Menière's disease is directed toward controlling the excess of endolymphatic fluid. If medical treatment does not relieve the repeated attacks of vertigo, surgery may be necessary.

Presbycusis. Presbycusis, the gradual decline of hearing function of old age, is similar to other aging processes because it affects some people more rapidly and at an earlier age than others. Usually the slow diminishing of hearing does not begin until after age 60. The affected individual notices increasing difficulty in hearing sounds of high pitch and in understanding conversation. There is no medical or surgical treatment that can restore hearing in uncomplicated presbycusis. The physician must make certain that the patient does not have a correctible impairment, such as accumulated earwax, secretory otitis media, or stirrup fixation by otosclerosis, as part of his difficulty. An electrical hearing aid is of limited help to some, while others find that a hearing aid makes voices louder but less clear and therefore is of little help. Lipreading must then be used.

DEAFNESS AND IMPAIRED HEARING

Causes. Impaired hearing is, with rare exception, the result of disease or abnormality of the outer, middle, or inner ear, located in the temporal bone of the skull. One rare exception has already been mentioned, loss of hearing, usually on one side only, caused by a tumour, acoustic neuroma, on the acoustic nerve; an even rarer exception is impairment because of a brain lesion. Since nerve fibres from each ear go to both sides of the brain, a brain tumour or stroke causing paralysis of one side of the body rarely affects hearing.

Serious impairment of hearing (deafness) at birth is nearly always of the nerve type and cannot be improved by medical or surgical treatment. Nerve deafness arising from rubella infection of the mother during the first three months of her pregnancy, from insufficient oxygen during birth, and from kernicterus have already been mentioned.

Causes in childhood

In early and late childhood the most frequent cause for impaired hearing is poor functioning of the eustachian tubes with the accumulation of a clear, pale-yellowish fluid in the middle-ear cavity, known as serous or secretory otitis media. The vibratory movements of the tympanic (eardrum) membrane and ossicular chain in response to sound are impeded by the fluid, causing a moderate loss of hearing. Since this hearing loss is due to impairment of sound conduction to the inner ear, it is known as a conductive loss. In these children, evacuation of the fluid from the middle ear and its replacement with air restores normal sound conduction and normal hearing. The enlarged adenoid or allergic swelling of the membrane lining the eustachian tube needs to be corrected to prevent recurrences of secretory otitis media.

In early and middle adult life the usual cause for progressive impairment of hearing is otosclerosis, the disease process of bone surrounding the inner ear that has been described above. The conductive hearing loss caused by fixation of the stirrup bone (stapes) can be relieved by surgical mobilization of the stirrup or its replacement with a fine stainless-steel wire. In some cases the otosclerotic bone nodule grows inward to the inner ear, resulting in a gradual loss of hearing-nerve function. This may occur at the same time as the fixation of the stapes; it may precede stapes fixation; or it may occur some years after fixation of the stirrup bone, whether or not the stapes has been successfully operated upon. Hearing-nerve deterioration due to otosclerosis or any other cause cannot be improved surgically or by medical treatment. The progressive loss of hearing caused by the enlarging otosclerotic nodule may stop after a time, if the nodule becomes matured and inactive. Treatment of the patient with sodium fluoride tablets taken by mouth is a promising method for promoting inactivation of an active otosclerotic process but has not yet been proved conclusively to be of value.

The usual cause of impaired hearing after the age of 60 is presbycusis, the normal aging of the auditory system, for which there is no effective medical or surgical treatment.

Other varieties of ear disease causing impaired hearing have been mentioned above in the sections on diseases of the ear. In most cases when loss of hearing is of the conductive type surgical restoration of useful hearing by correcting the defect in the outer or middle ear is a possibility. When loss of hearing is of the sound-perceiving (nerve) type, surgical restoration cannot be expected. Medical treatment for nerve types of hearing loss is helpful only in rare cases when the loss is due to syphilis and in some early cases of Menière's disease.

More important than cure for nerve types of hearing loss is prevention. Preventable especially are cases of deafness in the newborn due to rubella in the mother. Excessive and prolonged noise-exposure nerve deafness is preventable by early detection (routine testing of the hearing of persons engaged in noisy occupations), by a change of occupation, or by the wearing of ear protectors, either specially designed earplugs or earmuffs.

The incidence of impaired hearing in the general population depends upon the degree of hearing loss defined as impaired. According to U.S. statistics, by age six, 0.2 percent of all children have impaired hearing in one or both ears sufficient to warrant consultation of an ear specialist (otologist). By age 18 the number of children with loss of hearing sufficient to require diagnostic examination reaches 2.5 to 3 percent. By age 65 the number of adults with a recognizable hearing impairment reaches 5 percent. Beyond 65 the incidence of impaired hearing rises rapidly as presbycusis, the normal aging of the auditory system takes its toll.

Comparable figures from Britain show that one in six persons is estimated to have some hearing difficulty, but only a quarter of these have any real handicap, with a third of this latter group needing hearing aids and one in 20 being deaf to all speech and beyond useful help with a hearing aid. With British children, one in 1,000 is severely deaf and as high as seven per thousand are estimated to have sufficient impairment to need some form of help.

Rehabilitation. The child born deaf or with a severe hearing impairment cannot acquire speech by the normal process. He must attend special classes or a school for the deaf to be taught speech and lipreading. Most of these children have remnants of the sense of hearing that can be utilized in their schooling by the use of aids to amplify sound. The child with a moderate or mild hearing impairment is able to acquire speech by himself but a little more slowly than the child with normal hearing, while speech-correction instruction is usually required to improve his diction.

Advances in hearing-aid technology have served to increase the proportion of hearing-impaired individuals who can benefit substantially from amplification. Selection of an appropriate hearing aid for individuals with sensorineural (or nerve-type) hearing loss may be difficult and time-consuming. Research has demonstrated repeatedly, however, that the ability of listeners with sensorineural hearing loss to understand speech at conversational levels often can be enhanced significantly by use of an appropriate hearing aid. For those individuals whose hearing loss causes severe distortion of speech, use of a hearing aid in combination with lipreading may increase the amount of speech the individual can understand through lipreading alone. One the other hand, selection of a hearing aid is often a simpler matter for listeners with hearing loss of the conductive type. Careful selection is necessary to ensure that maximum understanding of speech is obtainable in noisy environments. The hearing-impaired individual should consult with trained professionals such as audiologists, who are trained in evaluating the benefit derived from the use of a hearing aid.

Lipreading

Lipreading, which actually entails attentive observation of the entire facial expression rather than the movements of the lips alone, is utilized even by persons with normal hearing who, in the presence of background noise, need these visual clues to supplement hearing. As hearing begins to be impaired, lipreading, which might better be termed speechreading, becomes increasingly valuable and important.

The hearing-impaired individual who knows a spoken language can learn lipreading by careful observation of a speaker of that language. Formal instruction in lipreading by a teacher individually or in classes is necessary for those hearing-impaired persons who have not acquired knowledge of a spoken language. The greater the loss of hearing, the more essential becomes lipreading, for which good lighting is essential.

Speech-correction instruction, needed for the young with serious degrees of impaired hearing, also becomes necessary for the adult who suddenly loses all hearing in both ears. Without the monitoring effect of hearing his own voice, his speech begins to deteriorate and to acquire the flat, toneless quality of the profoundly deaf.

Social and economic handicaps. The social handicap of severe degrees of hearing impairment is particularly important to the individual and his family. An individual who has a hearing impairment can feel isolated and embarrassed by being unable to join group conversations. He therefore tends to withdraw within himself and often develops false ideas that others are talking about him and ridiculing him. No one has more poignantly written of this isolation than Beethoven, who is generally believed to have suffered from otosclerosis. Had he lived today, his hearing might have been restored or improved through surgery. As it was, it gradually became worse until, after conducting the first performance of his ninth and last symphony, he had to be told to turn around to face the audience to acknowledge the tremendous applause because he could not hear it.

Small devices, such as installing a buzzer instead of a high-pitched door and telephone bell for the nerve-deafened person who cannot hear tones of high pitch, using an amplifier on the telephone, and being patient when communicating with the hard-of-hearing person, make life easier both for him and for those around him.

The economic handicap of impaired hearing is in proportion to the degree of loss. Nevertheless, persons with a hearing disability, while unable to engage in jobs that require keen hearing, tend to have better records of dependability and fewer days away because of illness than persons with normal hearing. (G.E.S.)

EAKIN, "Lines of Evolution of Photoreceptors," in DANIEL MAZIA and ALBERT TYLER (eds.), *General Physiology of Cell Specialization* (1963), and "Structure of Invertebrate Photoreceptors," in H.J.A. DARTNALL (ed.), *Photochemistry of Vision* (1972); three articles on photoreceptor structure and function; BRADLEY R. STRAATSMA *et al.* (eds.), *The Retina* (1969), on the morpholgy, function, and clinical characteristics of the vertebrate retina; HUGH DAVSON (ed.), *The Eye,* vol. 2, *The Visual Process* (1962), a textbook of photoreception and function of the visual system; the *Journal of the Optical Society of America,* vol. 53, no. 1 (1963); the Cold Spring Harbor Symposia on Quantitative Biology, vol. 30, *Sensory Receptors* (1965); and the Proceedings of the International School of Physics, "Enrico Fermi," course 43, ed. by W. REICHARDT, *Processing of Optical Data by Organisms and by Machines* (1969), all contain recent research on photoreception and retinal function; H.J.A. DARTNALL, *The Visual Pigments* (1957); and GEORGE WALD, "Molecular Basis of Visual Excitation," *Science,* 162:230–239 (1968), reviews of visual pigment chemistry; T.H. BULLOCK and G.A. HORRIDGE, *Structure and Function in the Nervous Systems of Invertebrates,* vol. 2 (1966), contains a broad survey of invertebrate sensory receptors; H.K. HARTLINE, "Visual Receptors and Retinal Interaction," *Science,* 164: 270–278 (1969); FLOYD RATLIFF, *Mach Bands: Quantitative Studies on Neural Networks in the Retina* (1965), physiological effects on vision of neural activity in the retina. Physiology of vision is also explored in JONATHAN STONE, *Parallel Processing in the Visual System* (1983); LEO M. HURVICH, *Color Vision* (1981); EBERHART ZRENNER, *Neurophysiological Aspects of Color Vision in Primates* (1983); GERALD H. JACOBS, *Comparative Color Vision* (1981).

Sound reception: There are no general texts on sound reception. Included below are some of the specialized references dealing with this subject in a technical manner.

J. SCHWARTZKOPFF, "Mechanoreception," in MORRIS ROCKSTEIN (ed.), *The Physiology of Insecta,* vol. 1, pp. 509–561 (1964); M.L. WOLBARSHT, "Electrical Characteristics of Insect Mechanoreceptors," *J. Gen. Physiol.,* 44:105–122 (1960); E.G. GRAY, "The Fine Structure of the Insect Ear," *Phil. Trans. R. Soc.,* Series B, 243:75–94 (1960); C. WALCOTT and W.G. VAN DER KLOOT, "The Physiology of the Spider Vibration Receptor," *J. Exp. Zool.,* 141:191–244 (1959); E.G. WEVER and J.A. VERNON, "The Auditory Sensitivity of Orthoptera," *Proc. Natn. Acad. Sci. U.S.A.,* 45:413–419 (1959); H. and M. FRINGS, "Uses of Sounds by Insects," *A. Rev. Ent.,* 3:87–106 (1958); R.J. PUMPHREY, "Hearing in Insects," *Biol. Rev.,* 15:107–132 (1940); "Sensory Organs: Hearing," in A.J. MARSHALL (ed.), *Biology and Comparative Physiology of Birds,* vol. 2. (1961). See also BRIAN LEWIS, *Bioacoustics: A Comparative Approach* (1983); WILLIAM C. STEBBINS, *The Acoustic Sense of Animals* (1983); JAMES F. WILLOTT (ed.), *The Auditory Psychobiology of the Mouse* (1983).

Human sensory reception: E.G. BORING, *Sensation and Perception in the History of Experimental Psychology* (1942), a classic historical account of the early work in sensation and perception; J. FIELD (ed.), *Handbook of Physiology, Section 1, Neurophysiology,* vol. 1 (1959), a technical and detailed review of modern sensory physiology; F.A. GELDARD, *The Human Senses* (1953), a scholarly overview of the senses, suitable as an introduction to the subject; D.R. KENSHALO (ed.), *The Skin Senses* (1968), a rather specialized report of a symposium held in 1968 that gives the reader with a special interest in this field a good idea of current research; P.M. MILNER, *Physiological Psychology* (1970), an advanced textbook in general physiological psychology with a good section on the senses; C. PFAFFMANN (ed.), *Olfaction and Taste, III* (1969), a somewhat specialized but good overview of current research in both olfaction and taste; J.S. WILENTZ, *The Senses of Man* (1968), an excellent popular account for the general reader that serves as a good introduction to the field. Later monographs on human sensory physiology include discussions of modern theories of pain, and on space perception, in addition to tradional studies of smell, taste, vision, and hearing. See CHRISTIAAN BARNARD and JOHN ILLMAN (eds.) *The Body Machine* (1981); HERBERT HENSEL, *Thermal Sensations and Thermoreceptors in Man* (1982); TRYGG ENGEN, *The Perception of Odors* (1982); RONALD MELZACK and PATRICK D. WALL, *The Challenge of Pain,* rev. ed. (1983); LAWRENCE KRUGER and JOHN C. LIEBESKIND (eds.), *Neural Mechanisms of Pain,* (1984); HERBERT L. PICK, Jr., and LINDA P. ACREDOLO (eds.), *Spatial Orientation: Theory, Research, and Application: Proceedings of a Conference on Spatial Orientation and Perception, July 14–*

16, 1980 (1983); R. ROBIN BAKER, *Human Navigation and the Sixth Sense* (1982); MICHAEL POTEGAL (ed.), *Spatial Abilities: Development and Physiological Foundations* (1982).

Structure and function of the human eye: H. DAVSON (ed.), *The Eye,* 4 vol. (1962; 2nd ed., vol. 1, 1969), covers the whole field of eye physiology, written by a group of experts in their particular fields; W.S. DUKE-ELDER *et al.* (eds.), *System of Ophthalmology,* 15 vol. (1958–), authoritative accounts of the anatomy and physiology of the eye; E. WOLFF, *Anatomy of the Eye and Orbit,* 5th ed. (1961), the classic work on this aspect; H. DAVSON, *Physiology of the Eye,* 3rd ed. (1971), an up-to-date account of eye physiology covering all aspects; M.H. PIRENNE, *Vision and the Eye,* 2nd ed. (1967), a simple account of certain features of eye physiology; R.A. WEALE, *The Eye and Its Function* (1960), a short and elementary account; H. VON HELMHOLTZ, *Handbuch der physiologischen Optik,* 3rd ed. (1886–96; Eng. trans., *Physiological Optics,* 3 vol., 1924–25; reprinted in 2 vol., 1962), a classic account of the psychological aspects of vision—not at all out of date, although written nearly 100 years ago; H.H. EMSLEY, *Visual Optics,* 5th ed., 2 vol. (1952–53), a technical account of the detailed optics of the eye. Physiological aspects of vision are discussed in HITOSHI SHICHI, *Biochemistry of Vision* (1983). Psychology of vision, including motion, depth, binocular vision, visual effects, color, etc., is discussed in MARK FINEMAN, *The Inquisitive Eye* (1981).

Eye diseases and visual disorders: SIR STEWART DUKE-ELDER (ed.), *Parsons' Diseases of the Eye,* 15th ed. (1970), a textbook for students concentrating on the more common eye conditions, and (ed.), *System of Ophthalmology,* vol. 1–5, 7–12 (1958–71; vol. 6, 13–15 in prep.) perhaps the most comprehensive textbook on any medical subject; F.W. NEWELL, *Ophthalmology,* 2nd ed. (1969), an up-to-date standard textbook; E.S. PERKINS and P. HANSELL, *Atlas of Diseases of the Eye,* 2nd ed. (1971), illustrations of common eye conditions with brief text; D.T. VAIL, *The Truth About Your Eyes,* 2nd ed. (1959), a description for the layman of the function of the eye and management of the more common eye diseases; F.B. WALSH and W.F. HOYT, *Clinical Neuro-Ophthalmology,* 3rd ed., 3 vol. (1969), a very detailed account of ophthalmic conditions associated with neurological diseases. A wide range of disorders and visual defects is covered in ROBERT SEKULER, DONALD KLINE, and KEY DISMUKES (eds.), *Aging and Human Visual Function* (1982); and JOHN H. DOBREE and ERIC BOULTER, *Blindness and Visual Handicap, the Facts* (1982).

Structure and function of the human ear: Reliable and readable introductory treatises are S.S. STEVENS and FRED WARSHOFSKY, *Sound and Hearing* (1965); and W.A. VAN BERGEIJK, J.R. PIERCE, and E.E. DAVID, *Waves and the Ear* (1960). HALLOWELL DAVIS and S.R. SILVERMAN, *Hearing and Deafness,* 3rd ed. (1970), although somewhat more technical, is also written for the non-specialist. A useful account of the anatomy of the ear may be found in WILLIAM BLOOM and D.W. FAWCETT, *A Textbook of Histology,* 9th ed. (1968). B.J. ANSON and J.A. DONALDSON, *The Surgical Anatomy of the Temporal Bone and Ear* (1967), presents the gross and microscopic structure of the ear from the point of view of the surgeon. Details of inner ear anatomy can be studied in SALVATORE IURATO, *Submicroscopic Structure of the Inner Ear* (1967); HANS ENGSTROM, H.W. ADES, and ANTON ANDERSSON, *Structural Pattern of the Organ of Corti* (1966); and HEINRICH SPOENDLIN, *The Organization of the Cochlear Receptor* (1966). For the comparative anatomy of the ear from fish to man, the illustrations in GUSTAF RETZIUS' two folio volumes *Das Gehörorgan der Wirbelthiere* (1881–84), are still unsurpassed, but available only in a few medical libraries. The physiology of hearing and of vestibular function is discussed in four chapters by JOSEPH E. HAWKINS in C.H. BEST and N.B. TAYLOR (eds.), *The Physiological Basis of Medical Practice,* 8th ed. (1966). Modern classics in the field of hearing are: S.S. STEVENS and HALLOWELL DAVIS, *Hearing* (1938, reprinted 1960), equally divided between psychological and physiological aspects of the subject; E.G. WEVER, *Theory of Hearing* (1949, reprinted 1970), including a good historical treatment of auditory theories developed through the centuries; and E.G. WEVER and MERLE LAWRENCE, *Physiological Acoustics* (1954), concerned mainly with middle-ear and inner-ear mechanics. G. VON BEKESY, *Experiments in Hearing* (1960), is the best source of information about the experimental work that won von Békésy the Nobel Prize, but it is not recommended for the novice. Biochemical aspects of cochlear physiology and pathology are treated in SIGURD RAUCH, *Biochemie des Hörorgans* (1964); and in *Biochemical Mechanisms in Hearing and Deafness,* ed. by MICHAEL M. PAPARELLA (1970). I.C. WHITFIELD, *The Auditory Pathway* (1967), gives a useful summary of our imperfect knowledge of auditory processes in the central nervous system. Later monographs on acoustic perception include ÅAGE R. MØLLER, *Auditory Physiology* (1983); SANFORD E. GERBER and GEORGE T. MENCHER, (eds.), *The Development of Auditory Behavior* (1983); JOHN M. PALMER, *Anatomy for Speech and Hearing,* 3rd ed. (1984); M.E. LUTMAN, and M.P. HAGGARD (eds.), *Hearing Science and Hearing Disorders* (1983).

The measurement of human hearing is described in numerous textbooks of audiology. *Audiometry: Principles and Practices,* ed. by ARAM GLORIG (1965), gives a good overview of the field. A thorough, sober, and factual account of studies concerning *The Effects of Noise on Man* has been written by K.D. KRYTER (1970). There are few comprehensive publications devoted to vestibular function, but the symposium volume, ed. by R.J. WOLFSON, *The Vestibular System and Its Diseases* (1966), is a good source of information, as is the NASA series ed. by ASHTON GRAYBIEL, *The Role of the Vestibular Organs in Space Exploration,* 4 vol. (1965–68).

Ear diseases and hearing disorders: G.E. SHAMBAUGH, "A Restudy of the Minute Anatomy of Structures in the Cochlea with Conclusions Bearing on the Solution of the Problem of Tone Perception," *Amer. J. Anat.,* 7:245–257 (1907), the first detailed description of the hearing nerve end-organ in the cochlea, where sound waves are converted into nerve impulses depending upon the pitch of the tone; GEORG VON BEKESY, "The Ear," *Scient. Am.,* 197:66–78 (1957), a description in lay terms of the mechanism of hearing by today's foremost research authority on the ear; G.E. SHAMBAUGH, JR., *Surgery of the Ear,* 2nd ed. (1967), a well-illustrated text on diseases of the ear and their surgical correction; and with A. PETROVIC, "Effects of Sodium Fluoride on Bone," *J.A.M.A.,* 204:969–973 (1968), a summary of recent research on the arrest of progressive deafness due to otosclerosis by means of sodium fluoride; PHILIP H. BEALES, *Noise, Hearing and Deafness* (1965), a useful review, written in lay language, of the problem of deafness and the adverse influence on hearing of excess noise exposure. Hearing disorders are also discussed in ERNEST J. MOORE (ed.), *Bases of Auditory Brain-stem Evoked Responses* (1983); JAMES JERGER (ed.), *Hearing Disorders in Adults* (1984); KATHRYN P. MEADOW, *Deafness and Child Development* (1980); SHIRLEY HANAWALT MCARTHUR, *Raising Your Hearing-Impaired Child* (1982).

Seoul

Seoul (Sŏul-t'ŭkpyŏlsi [Special City of Seoul]) was, except for a brief interregnum (1399–1405), the capital of Korea from 1394 until the formal division of the country in 1948, when it became the capital of the Republic of Korea (South Korea). The name itself has come to mean "capital" in the Korean language. The city was popularly called Seoul in Korean during both the Yi dynasty (1392–1910) and the period of Japanese rule (1910–45), although the official names in those periods were Hansŏng and Kyŏngsŏng, respectively. The city was also popularly and, during most of the 14th century, officially known as Hanyang. Seoul became the official name of the city only with the founding of the Republic of Korea.

This article is divided into the following sections:

PHYSICAL AND HUMAN GEOGRAPHY

The landscape. *The city site.* Modern Seoul was founded in 1394 by Gen. Yi Sŏng-gye, the founder of Korea's Yi dynasty, as the capital of a unified nation. The site was a militarily defensible natural redoubt that was also an especially suitable site for a capital city, lying at the centre of an undivided Korea and adjoining the navigable Han-gang (Han River), one of the peninsula's major rivers flowing into the Yellow Sea. The contact afforded by this riverain site both with inland waterways and with coastal sea routes was particularly important to Yi because these were the routes by which grain, taxes, and goods were transported. In addition to the practical advantages, the site was well situated according to *p'ungsuchirisol,* the traditional belief in geomancy. The district chosen by Yi remains, after 600 years, the centre of Seoul; it is located immediately north of the Han-gang in the lowland of a topographic basin surrounded by low hills of about 1,000 feet (300 metres). The natural defensive advantages of the basin were reinforced two years after the city's founding by the construction of an 11-mile (18-kilometre) wall along the ridges of the surrounding hills.

Today, the remains of the fortifications are a popular attraction. The old city centre is drained by a small tributary of the Han-gang, which has been covered over by streets and expressways. Main streets and major shopping areas occupy the lower part of the basin. The original city district served to contain most of the city's growth until the early 20th century; for, although the population had grown to approximately 100,000 by the census of 1429, it had risen to only about 250,000 by the time of the Japanese annexation in 1910, almost five centuries later. The modernizations brought by the Japanese began the first of several cycles of growth during the 20th century that extended the city limits by successive stages, so that they now contain both banks of the Han-gang river plain, as well as the banks of several tributary rivers. The city's boundaries now form a ragged oval about eight to 12 miles distant from the original site, except to the northwest, where they are approximately half that distance. The present boundary of Seoul is largely that established in 1963 and encompasses roughly 234 square miles (605 square kilometres), more than twice the city area of 1948. Seoul has grown rapidly since the Korean War (1950–53). Suburbs have sprung up in the rural areas surrounding the city, and such satellite cities as Sŏngnam, Suwŏn, and Inch'ŏn have undergone considerable expansion as the capital has grown.

Climate. Seoul's climate is characterized by a large annual range of temperature. The coldest month, January, has a mean temperature of 26° F (−3° C), and the warmest month, August, has a mean temperature of 78° F (25° C). Yearly precipitation in the city is about 54 inches (1,370 millimetres), with a heavy concentration during the summer months. Air pollution in the basin and in Yŏngdŭng-p'o, an industrial area, has become a serious problem, caused in large part by the increasing number of automobiles and factories. For years the Han-gang was highly polluted, but since the early 1980s pollution levels have been reduced significantly by measures to control the river's water level and by the construction of large-scale sewage treatment facilities.

The city plan. Street patterns in the city centre are basically rectangular. Streets and buildings stretch out in all directions from the old city wall's four major gates that still stand: toward Mia-dong and Suyu-dong to the north, Ch'ŏngnyang-ni to the east, Yongsan and Yŏngdŭng-p'o to the south, and Map'o and Hongje-dong to the west. Main streets, such as Ŭlchi-ro and Chong-no, are oriented east to west, but, toward the foot of the surrounding hills, topographic irregularities have some influence on the pattern. Outside the basin area of the central city, however, there are a number of radiating streets, which are interconnected by a series of circular roads. The Capitol Building and other government offices are concentrated along Sejong-no, although the National Assembly building is on Yŏido island; banks, department stores, and other business offices are located along Namdaemun-no and T'aep'yŏng-no. The area of Chong-no, Myŏng-dong, and Ŭlchi-ro constitutes the central business district. The district has been transformed from an area of wooden, tile-roofed houses to one of concrete high-rise office buildings. Much of the city's expansion has been to the south of the Han-gang, resulting in the creation of three new urban centres at Yŏido-Yŏngdŭngp'o, Yŏngdong, and Chamshil.

Housing. A shortage of housing has been a chronic problem. A number of large-scale apartment blocks were built, especially along the banks of the Han-gang. In addition, much residential housing has been developed along the suburban fringes of the city. Old-style houses—with the traditional heated floors (*ondol*) designed for the cold winters—are still found in areas of the old city and adjacent to the remains of the city wall.

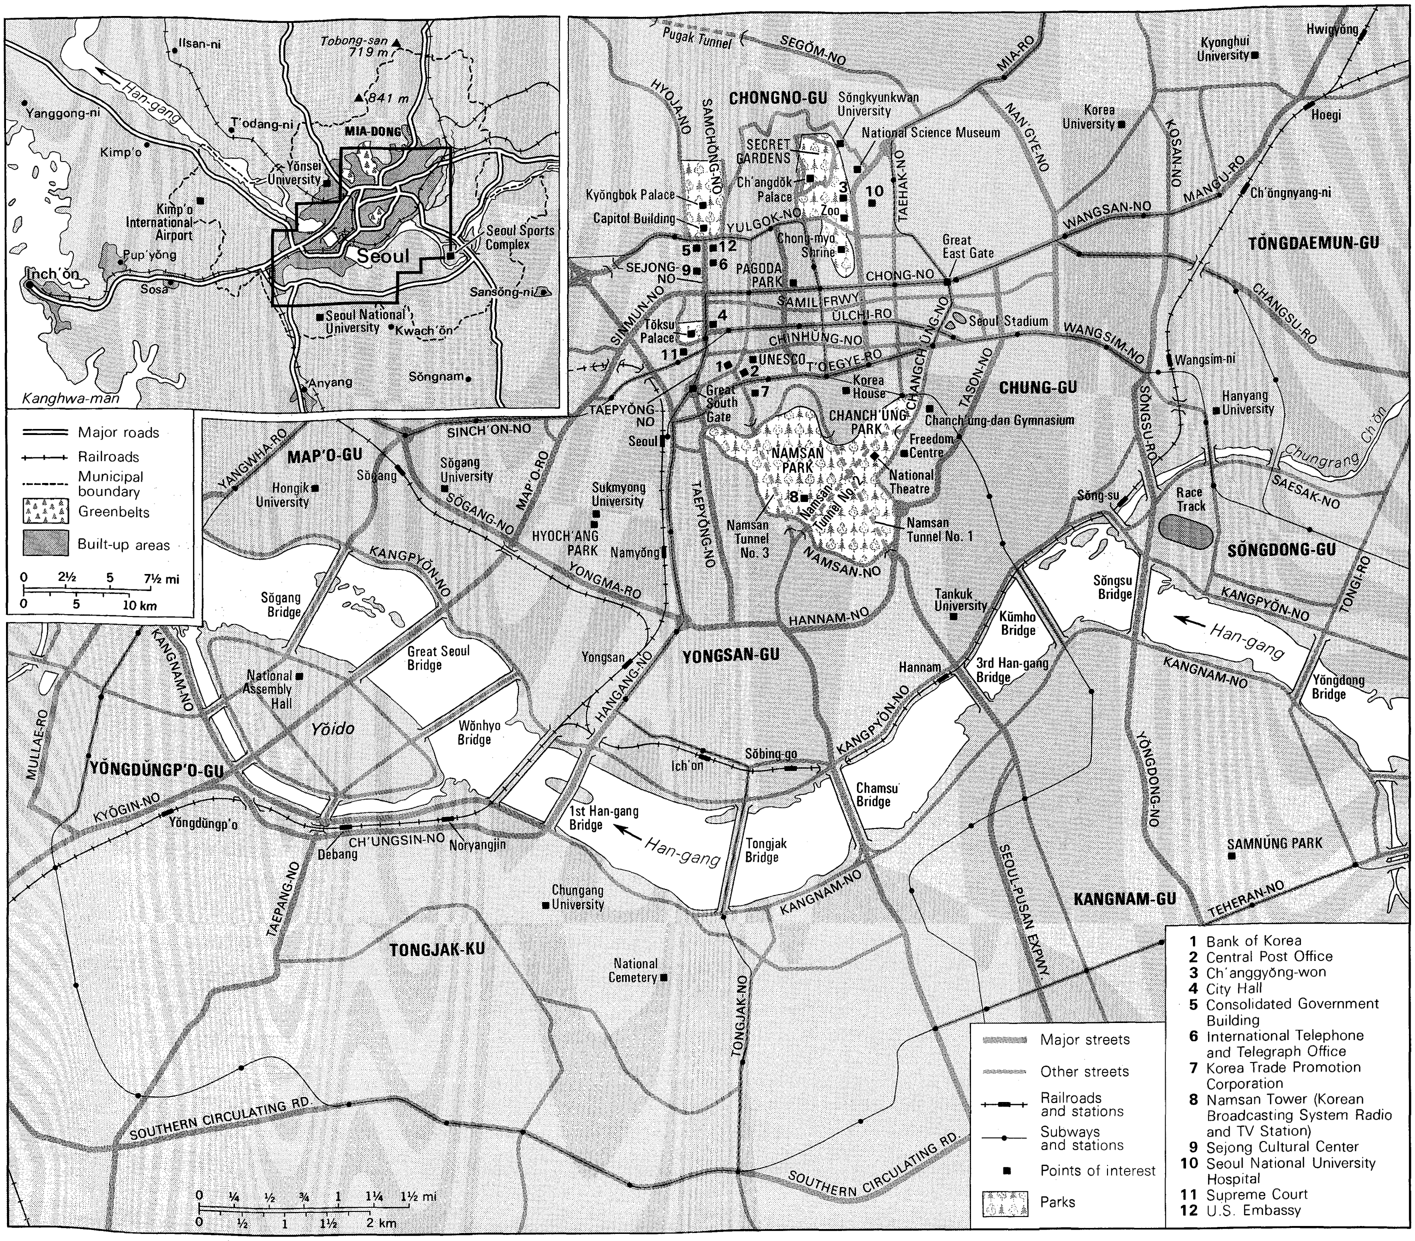
The people. The population of Seoul has grown extremely rapidly since 1950, and the city now has one of the highest population densities in the world. The most densely populated areas are distributed within and outside the old city and in the apartment belts along the Han-gang, while residential areas in the suburbs have a relatively low density. Koreans constitute nearly all of the population, the number of foreign residents being insignificant.

Principal employers

The economy. *Industry and commerce.* Manufacturing, commerce, and service industries are the principal employers. The textile, machinery, and chemical industries are the chief sectors in manufacturing, but food and beverage processing, printing, and publishing are also important.

The two most important traditional shopping areas are the extensive Great East Gate Market (Tongdaemun Sijang) and the smaller Great South Gate Market (Namdaemun Sijang), located near their respective gates. Comprising numerous individually owned shops, these markets serve not only Seoul but the entire country. There are also several large downtown department stores and modern shopping centres in the apartment blocks.

Seoul is the centre of finance for the country. The headquarters of the major stock exchanges and banks are



Central Seoul and (inset) its metropolitan area.

located there, and the city plays host to many annual trade shows.

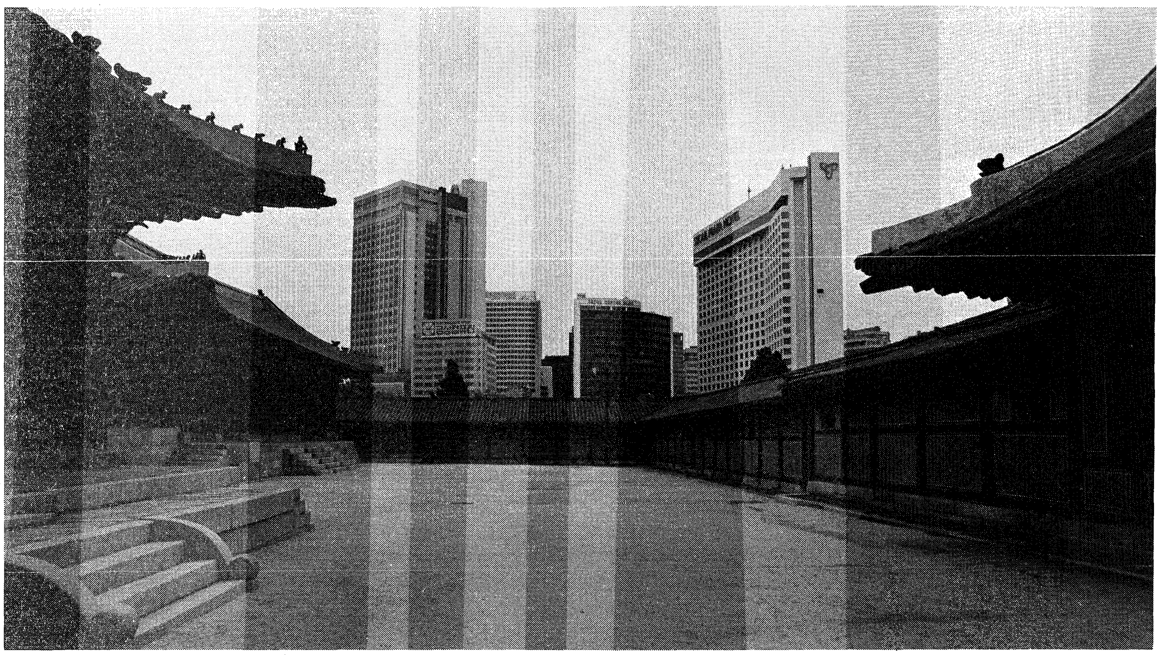
Transportation. Although Seoul is an old city, it has a good road system; vast improvements have been made in the system since the Korean War, notably in the construction of more than a dozen bridges across the Han-gang. Transportation facilities, however, have not been able to keep up with the demands of a large and expanding population, resulting in crowded streets. An extensive subway system has replaced the older streetcars; this has alleviated traffic congestion and has become, with buses and railways, one of the main forms of public transport. The capital is the hub of railway lines connecting it with most provincial cities and ports, including Inch'ŏn and Pusan. Before the Korean War, small vessels navigated up the river 37 miles to Seoul, but the demilitarized zone that now divides Korea into North and South runs partly through the mouth of the river and has deprived Seoul of its role as a river port. Hence, most goods are transported to and from the city on railways and highways. Kimp'o International Airport, located in the western part of Seoul, serves as the centre of the nation's airline network.

Administration and social conditions. Water and sewage-disposal facilities are inadequate, notwithstanding strenuous efforts to keep up with the demand stemming from rapid expansion of the city. Medical facilities are relatively good, and there are many small clinics as well as numerous doctors of herbal medicine. Fires occur frequently during winter and spring (the cold, dry season), placing a heavy demand on the city's fire services.

Compulsory education applies only to the six-year elementary school, but a large proportion of elementary school graduates receive a secondary education. There is a shortage of elementary school facilities because of the rapid increase in population. Most of South Korea's major universities, colleges, and research institutes are located in Seoul.

Cultural life. Seoul is the country's cultural centre. It is the home of the National Academy of Arts and the National Academy of Sciences and nearly all of the nation's learned societies and libraries. The National Classical Music Institute, engaged in the preservation of the traditional court music of Korea and in the training of musicians, is complemented by two Western-style symphony orchestras. In addition, there are a national theatre, an opera, and a number of public and private museums, including the National Museum on the grounds of the Kyŏngbok Palace. The Sejong Cultural Center, to the south of the palace, has facilities for concerts, plays, and exhibitions.

Surrounded by hills, Seoul has numerous small and large



Downtown Seoul seen from the Tŏksu Palace.
Woon Gu Kang

parks within easy reach. Places of historical interest—including Ch'anggyŏng, Ch'angdŏk, Kyŏngbok, and Tŏksu palaces and Chong-myo Shrine—annually attract large numbers of citizens and tourists. The city also has excellent sports and recreational facilities, notably the Seoul Sports Complex, which was built for the Asian Games in 1986 and the Olympic Games in 1988.

HISTORY

The earliest historical mention of Seoul and the surrounding area dates from the 1st century BC. During the Three Kingdoms period (57 BC–AD 668) of Silla, Koguryŏ, and Paekche, the area formed a borderland between the three countries, although during the early part of the period it was most closely associated with the Kingdom of Paekche. Historical accounts as well as archaeological records indicate that the original site of Paekche's capital, Wiryesŏng, was in the northeastern part of present-day Seoul. Shortly thereafter the capital was moved south across the Han-gang; a number of remains, including earthen walls, dwellings, and tombs have been uncovered at that site. It was not, however, until King Munjong of Koryŏ built a summer palace in 1068 that a fairly large settlement existed on the site of the modern city.

After the formal establishment of Seoul as the capital of the unified Yi state in 1394, construction and growth were very rapid. Construction on the Kyŏngbok Palace began in 1392; it was the residence of the Yi kings from 1395 until 1592. Before residence had even been established, the construction of the city's defensive walls had been completed, although so hastily that they had to be reconstructed in 1422. The Tŏksu Palace, the construction of which began in the late 15th century, was the residence of the Yi kings from 1593 until 1611. The Ch'angdŏk Palace, begun in 1405, was the residence from 1611 to 1872, when the king moved back into the reconstructed Kyŏngbok Palace (it had been burned by the Japanese in 1592 and was not rebuilt until 1867). Throughout this period Seoul remained the centre of the "Hermit Kingdom," with little contact permitted with the outside world. The opening of Korea to diplomatic contacts with the West in 1876, at a time when the weakening Yi dynasty was unable to control Western influence, led in 1905 to the establishment of a Japanese protectorate over the kingdom.

Seoul under Japanese rule

A year after the annexation of Korea to Japan in 1910, the name of the Seoul area was changed to Kyŏngsŏng, and minor changes were made in the boundary. Seoul served as the centre of Japanese rule, and modern technology was imported. Roads were paved, old gates and walls partly removed, new Western-style buildings built, and streetcars introduced.

After the end of Japanese control in 1945, Seoul came under the direct control of the central government, and in 1962 it was placed directly under the control of the prime minister. The city was left devastated by the Korean War. Out of the rubble has risen a modern city of skyscrapers and highways that has become one of the largest metropolises in the world.

BIBLIOGRAPHY. Upon its completion, the Korean-language *Sŏul yukpaengnyŏnsa* ("Six Hundred Year History of Seoul"; 1977–), issued by the SŎUL T'ŬKPYŎLSI SA P'YŎNCH'AN WIWŎNHOE (History Compilation Committee of the Special City of Seoul), will be the most authoritative source; 5 vol. had appeared to 1985. Also published by SŎUL T'ŬKPYŎLSI SA P'YŎNCH'AN WIWŎNHOE is *The Hyangto Seoul: The Special City of Seoul Historical Review* (annual). In Western languages, JONG-KI KIM, *Seoul: Host City of the '88 Olympics* (1983), is a comprehensive guidebook with numerous colour pictures and maps. ALLEN D. CLARK and DONALD N. CLARK, *Seoul: Past and Present* (1969), is a well-written and comprehensive guidebook concentrating on antiquities. EDWARD B. ADAMS, *Through Gates of Seoul*, 2nd ed., 2 vol. (1974–77), is a more extensive work, well prepared and containing numerous pictures and maps, some in colour.

(C.Le.)

Set Theory

Between the years 1874 and 1897, the German mathematician and logician Georg Cantor created a theory of abstract sets of entities and made it into a mathematical discipline. This theory grew out of his investigations of certain concrete problems regarding certain types of infinite sets of real numbers (see ANALYSIS: *Real analysis*). A set, wrote Cantor, is a collection of definite, distinguishable objects of perception or thought conceived as a whole. The objects are called elements or members of the set.

The theory had the revolutionary aspect of treating infinite sets as mathematical objects that are on an equal footing with those that can be constructed in a finite number of steps. Since antiquity, a majority of mathematicians had carefully avoided the introduction into their arguments of the actual infinite (*i.e.,* of sets containing an infinity of objects conceived as existing simultaneously, at least in thought). Since this attitude persisted until almost the end of the 19th century, Cantor's work was the subject of much criticism to the effect that it dealt with fictions; indeed, that it encroached on the domain of philosophers and violated the principles of religion. Once applications to analysis began to be found, however, attitudes began to change, and in the 1890s Cantor's ideas and results were gaining acceptance. By 1900, set theory was recognized as a distinct branch of mathematics.

At just that time, however, it received a severe setback through the derivation of several contradictions in its superstructure (see below *Cardinality and transfinite numbers*). The main thrust of this article is to present an account of one response to such contradictions as these. The purpose of the development here related has been to provide an axiomatic basis for the theory of sets analogous to that developed for elementary geometry. The degree of success that has been achieved in this development, as well as the present stature of set theory, has been well expressed in the Bourbaki *Éléments de mathématique:* "Nowadays it is known to be possible, logically speaking, to derive practically the whole of known mathematics from a single source, The Theory of Sets." (R.R.S./Ed.)

See the article MATHEMATICS, THE FOUNDATIONS OF for further discussion of the role and scope of set theory in the study of mathematics.

This article is divided into the following sections:

Introduction to set theory

FUNDAMENTAL SET CONCEPTS

If the elements and sets to be considered are restricted to some fixed class of objects, such as the letters of the alphabet, the universal set (or the universe), which is commonly denoted by U, can then be defined as that which includes all of the elements—in this case, the set of all of the 26 letters. Thus, if A is one of the sets being considered, it will be understood that A is a subset of U. Another set may now be defined that includes all of the elements of U that are not elements of A. This set, which is called the complement of A, is denoted by A'. (Some writers, employing the convention of "difference sets," speak of "the complement of A with respect to U," which they denote by "$U-A$.")

Empty set

The empty (or void, or null) set, which is usually symbolized by Ø, contains no elements. One description of the empty set is that of all whole numbers that are neither even nor odd.

Operations on sets. The symbol $\cup$ is employed to denote the union of two sets. Thus, the set $A \cup B$—read "A union B" or "the union (or join) of A and B"—is defined as the set that consists of all elements belonging either to set A or set B. If sets A and B, however, have one or more members in common, their union will not duplicate those members. A committee, for example, consisting of Jones, Blanshard, Nelson, Smith, and Hixon (Committee A) may for some common purpose sit in joint session with Committee B, consisting of Blanshard, Morton, Hixon, Young, and Peters. Clearly, the union of Committees A and B must then consist of eight members rather than 10, namely, Jones, Blanshard, Nelson, Smith, Morton, Hixon, Young, and Peters.

The intersection operation is denoted by the symbol $\cap$. $A \cap B$—read "A intersect B" or "the intersection of A and B"—is defined as that set composed of all elements that belong to both A and B. Thus the intersection of the two committees in the foregoing example is the set consisting of Blanshard and Hixon.

If the set E denotes all positive even numbers and the set Q denotes all positive odd numbers, then the union of the two yields the entire sequence of positive natural numbers, and their intersection is the empty set. Any two sets the intersection of which is the empty set are said to be disjoint.

A product of two sets A and B, called a Cartesian product, is denoted by $A \times B$. This product is defined in terms of ordered pairs, analogous to the coordinates (or x and y values) of points on a Cartesian grid in analytic geometry. It is conventional to denote such pairs by enclosure in parentheses to differentiate them from unordered pairs, or sets, the members of which are enclosed in braces. In other words, the set $\{x, y\}$ is identical to the set $\{y, x\}$, but (x, y) is not the same as (y, x); two ordered pairs (a, b) and (c, d) are defined to be equal if and only if $a = c$ and $b = d$. The Cartesian product $A \times B$ may now be defined as the set consisting of all ordered pairs (x, y) for which x is an element of A and y is an element of B. An example is easily constructed: $A = \{x, y\}$, $B = \{3, 6, 9\}$, $A \times B = \{(x, 3), (x, 6), (x, 9), (y, 3), (y, 6), (y, 9)\}$.

Relations involved in set theory. The relations between sets can be of many sorts; *e.g.,* "is a subset of" ($\subseteq$), "is equivalent to" ($\sim$), "is a complement of" ($'$), "is in one-to-one correspondence with," and "has the same cardinal number as" (see below). In addition, pairing relations, defined in terms of some specific criterion, can exist between the individual elements of a set. Examples of pairing relations are: "is parallel to" ($\parallel$), "is equal to" ($=$), "is less than" ($<$), and "is the same colour as." More broadly

Pairing relations between elements

conceived, pairing can include the relations depicted on charts and graphs, on which, for example, calendar years may be paired with automobile production figures, weeks with Dow-Jones averages, and degrees of angular rotation with the lift accomplished by a cam.

The relation of one-to-one correspondence between two sets can be conceived as one in which each element of a set A is matched with an element of another set B. If $A = \{x, z, w\}$, for example, and $B = \{4, 3, 9\}$, then A is in one-to-one correspondence with B if and only if a matching such as 4 with x, 3 with z, and 9 with w obtains without any element in either set left unmatched as a remainder.

Many relations display identifiable similarities. The relations "is parallel to," "is the same colour as," and "is in one-to-one correspondence with," for example, all bear the stated relation to themselves as well as to other elements; thus, these relations are said to be reflexive. These same relations share, in addition, the property that, if an element bears the stated relation to a second element, then the second also bears that relation to the first—a property known as symmetry. Relations also have the property that, if two elements bear the stated relation to a third element, then they bear it to one another as well—a property known as transitivity.

Equivalence classes and numbers

Those relations that have all three properties—reflexivity, symmetry, and transitivity—are called equivalence relations. In an equivalence relation, all elements related to a particular element are related to each other, thus forming what is called an equivalence class. For the relation "is parallel to," for example, the equivalence class of a particular line ℓ is the set of all lines parallel to ℓ.

For each of the equivalence classes of sets, it is possible to construct an ordered set—for which not only the membership but also the sequence of its elements is significant—that can be used to name the class.

With appropriate qualifications, the cardinal of the empty set $\varnothing$ can be defined as 0; *i.e.,* $n(\varnothing) = 0$. The number 1, then, is assigned to be the cardinal of the set $\{0\}$ that contains only a single element; it is thus called the successor of 0. Similarly, the number 2, the cardinal of $\{0, 1\}$, is called the successor of 1; and 3, the cardinal of $\{0, 1, 2\}$, is the successor of 2. Continuing in this manner, the set $\mathfrak{N}$ of the natural numbers in the proper sequence $\{0, 1, 2, 3, 4, \cdot \cdot \cdot\}$ is obtained, for which the ordering is given by the successor relation.

It is this ordering that is used when one learns to count. The words one, two, three, four, · · · in proper sequence are associated with the elements in the set that are being counted. If this process stops, the set is said to be finite. Otherwise, it is said to be infinite.

There is a technical difference between cardinal and ordinal numbers. The distinction can be seen in the way that these numbers are used. A number used to designate the size of a set—*i.e.,* to answer the question, "How many?"—is used cardinally. Any use that depends on the position of the number in the prescribed sequence is the ordinal use of the number. The number found at the top or bottom of a page in a book is an example of the ordinal use of the number. (Jo.Ha./Ed.)

ESSENTIAL FEATURES OF CANTORIAN SET THEORY

At best, the foregoing description presents only an intuitive concept of a set. Essential features of the concept as Cantor understood it include: (a) that a set is a grouping into a single entity of objects of any kind; and (b) that, given an object x and a set A, exactly one of the statements "x is an element of A" (symbolized $x \in A$) and "x is not an element of A" (symbolized $(x \notin A)$) is true and the other is false. The definite relation that may or may not exist between an object and a set is called the membership relation.

Extension and abstraction

A further intent of this description is conveyed by what is called the principle of extension, viz., that a set is determined by its members: that sets A and B are equal (symbolized $A = B$) if and only if every element in A is also in B and every element in B is in A; or, in other terms, $x \in A$ implies $x \in B$ and vice versa. There exists, for example, exactly one set the members of which are 2, 5, and 7; and this set will be written by listing its elements in some order (which order is immaterial) between small braces, possibly $\{5, 2, 7\}$.

A set A is finite if for some natural number n there is a pairing of the elements of A with those of the initial segment $0, 1, \cdot \cdot \cdot, n-1$ of the natural numbers $0, 1, 2, \cdot \cdot \cdot$ in their usual order. This definition amounts to classifying a set as finite if it has a natural number n as its cardinal number (see below *Cardinality and transfinite numbers*). In principle, the brace notation is adequate for defining all finite sets.

To define infinite (*i.e.,* nonfinite) sets, Cantor used (sentential) formulas. The phrase "x is a professor" is an example of a formula; if the symbol "x" in this phrase is replaced by the name of a person, there results a declarative sentence that is true or false. The notation "$S(x)$" will be used to represent such a formula. The phrase "x is a professor at university y and x is a male" is a formula with two variables. If the occurrences of x and y are replaced by names of appropriate, specific objects, the result is a declarative sentence that is true or false. Given any formula $S(x)$ that contains the letter "x" (and possibly others) but not the letter "A," Cantor's principle of abstraction asserts the existence of a set A such that for each object x, $x \in A$ if and only if $S(x)$ holds. The unique (because of the principle of extension) set A corresponding to $S(x)$ is symbolized by $\{x \mid S(x)\}$ and read "The set of all objects x such that $S(x)$." For instance, $\{x \mid x \text{ is blue}\}$ is the set of all blue objects. This illustrates the fact that the principle implies the existence of sets the elements of which are all objects having a certain property. It is actually more comprehensive. For example, it asserts the existence of a set B corresponding to "Either x is an astronaut or x is a natural number." Astronauts have no property in common with numbers (other than both being members of B). The formula "$x \neq x$" defines the only set without elements. It is called the empty set and symbolized by $\varnothing$. The empty set is finite, for its members can be paired with those of the initial segment defined by $n = 0$.

Equivalent sets. Cantorian set theory is thus founded on the principles of extension and abstraction. To describe some results based upon these principles the notion of equivalence of sets will be defined. The set A is defined as equivalent to the set B (symbolized $A \sim B$) if and only if there exists a third set the members of which are ordered pairs such that: (a) the first member of each pair is an element of A and the second is an element of B, and (b) each member of A occurs as a first member and each member of B occurs as a second member of exactly one pair. Thus, if A and B are finite and $A \sim B$, then the third set that establishes this fact provides a pairing or matching of the elements of A with those of B. Conversely, if it is possible to match the elements of A with those of B, then $A \sim B$, because a set of pairs meeting requirements (a) and (b) can be formed (if $a \in A$ is matched with $b \in B$, then the ordered pair (a, b) is one member of the set). By thus defining equivalence of sets in terms of the notion of matching, it is formulated independently of finiteness. As an illustration involving infinite sets, $\mathfrak{N}$ may be taken to denote the set of natural numbers $0, 1, 2, \cdot \cdot \cdot$ (some authors exclude 0 from the natural numbers). Then $\{(n, n^2 \mid \in \mathfrak{N}\}$ establishes the equivalence of $\mathfrak{N}$ and the set of the squares of the natural numbers. (R.R.S.)

Equivalence and subsets

A set B is included in, or is a subset of, a set A (symbolized $B \subseteq A$) if every element of B is an element of A. So defined, a subset may possibly include all of the elements of A, so that A can be a subset of itself. Furthermore, the empty set, because it by definition has no elements that are not included in other sets, is a subset of every set.

If every element of set B is an element of set A, but the converse is false (hence $B \neq A$), then B is said to be properly included in, or is a proper subset of, A (symbolized $\mathrm{B} \subset \mathrm{A}$). Thus, if A is $\{3, 1, 0, 4, 2\}$, both $\{0, 1, 2\}$ and $\{0, 1, 2, 3, 4\}$ are subsets of A; but the latter is not a proper subset. A finite set is nonequivalent to each of its proper subsets. This is not so, however, for infinite sets, as is illustrated with the set $\mathfrak{N}$ in the earlier example. (The equivalence of $\mathfrak{N}$ and its proper subset of the even natural numbers was essentially the paradox noted by Galileo in 1638.) (R.R.S./Ed.)

Infinite sets and power sets

Cardinality and transfinite numbers. The application of the notion of equivalence to infinite sets was first systematically explored by Cantor. His initial significant finding was that the set of all rational numbers (see ARITHMETIC; ANALYSIS: *Real analysis*) is equivalent to $\mathfrak{N}$ but that the set of all real numbers is not equivalent to $\mathfrak{N}$. The existence of nonequivalent infinite sets justified Cantor's introduction of transfinite cardinal numbers as measures of size for such sets. Cantor defined the cardinal of an arbitrary set A as the concept that can be abstracted from A taken together with the totality of other equivalent sets. Gottlob Frege, in 1884, and Bertrand Russell, in 1902, both mathematical logicians, defined the cardinal number $\overline{\overline{A}}$ of a set A somewhat more explicitly, as the set of all sets that are equivalent to A; this definition thus provides a place for cardinal numbers as objects of a universe whose only members are sets.

These definitions are consistent with the usage of natural numbers as cardinal numbers. A natural number, 2 for example, is first assigned to the set $\{0, 1\}$ as a measure of its size; then 2 is assigned to every set equivalent to $\{0, 1\}$. Turning matters around, 2 is the concept that can be abstracted from the collection of sets equivalent to $\{0, 1\}$, or 2 may be defined as this collection of sets. Intuitively, a cardinal number, whether finite (*i.e.,* a natural number) or transfinite (*i.e.,* nonfinite), is a measure of the size of a set. Exactly how a cardinal number is defined is unimportant; what is important is that $\overline{\overline{A}} = \overline{\overline{B}}$ if and only if $A \sim B$.

To compare cardinal numbers, an ordering relation—denoted by $<$—may be introduced by means of the definition: $\overline{\overline{A}} < \overline{\overline{B}}$ if A is equivalent to a subset of B and B is equivalent to no subset of A. Clearly this relation is irreflexive $\overline{\overline{A}} \not< \overline{\overline{A}}$ and transitive $\overline{\overline{A}} < \overline{\overline{B}}$ and $\overline{\overline{B}} < \overline{\overline{C}}$ imply $\overline{\overline{A}} < \overline{\overline{C}}$.

When applied to natural numbers used as cardinals, $<$ coincides with the familiar ordering relation for $\mathfrak{N}$, so that $<$ is an extension of that relation.

The symbol $\aleph_0$ (aleph-null) is standard for the cardinal number of $\mathfrak{N}$ (sets of this cardinality are called denumerable) and $\aleph$ (aleph) is usually used for that of the set of real numbers. Then $n < \aleph_0$ for each $n \in \mathfrak{N}$ and $\aleph_0 < \aleph$.

This, however, is not the end of the matter. If the power set of a set A—symbolized $P(A)$—is defined as the set of all subsets of A, then, as Cantor proved, $\overline{\overline{A}} < \overline{\overline{P(A)}}$ for every set A—a relation that is known as Cantor's theorem. It implies an unending hierarchy of transfinite cardinals: $\overline{\overline{N}} = \aleph_0$, $\overline{\overline{P(N)}}$, $\overline{\overline{P(P(N))}}$, $\cdot\ \cdot\ \cdot$ Cantor proved that $\aleph = \overline{\overline{P(N)}}$ and was led to the question whether there is a cardinal number between $\aleph_0$ and $\aleph$, which is known as the continuum problem. A solution was completed in 1963 (see below).

There is an arithmetic for cardinal numbers based on natural definitions of addition, multiplication, and exponentiation (squaring, cubing, and so on), which deviates, however, from that of the natural numbers when transfinite cardinals are involved. For example, $\aleph_0 + \aleph_0 = \aleph_0$ (because the set of integers is equivalent to $\mathfrak{N}$), $\aleph_0 \cdot \aleph_0 = \aleph_0$ (because the set of ordered pairs of natural numbers is equivalent to $\mathfrak{N}$), and $c + \aleph_0 = c$ for every transfinite cardinal c (because every infinite set includes a subset equivalent to $\mathfrak{N}$).

The extension of the natural numbers as cardinal numbers to transfinite numbers described earlier is a typical facet of Cantorian set theory.

The Cantor paradox

The so-called Cantor paradox, discovered by Cantor himself in 1899, is the following: By the principle of abstraction, the formula "x is a set" defines a set U. It is the set of all sets. Now $P(U)$ is a set of sets and so $P(U)$ is a subset of U. By the definition of $<$ for cardinals, however, if $A \subseteq B$, then it is not the case that $\overline{\overline{B}} < \overline{\overline{A}}$. Hence, by substitution, $\overline{\overline{U}} \not< \overline{\overline{P(U)}}$. But by Cantor's theorem, $\overline{\overline{U}} < \overline{\overline{P(U)}}$. This is a contradiction. In 1902, Bertrand Russell devised another paradox of a less technical nature. The formula "x is a set and $(x \notin x)$" defines a set R of all sets not members of themselves. Using proof by contradiction, however, it is easily shown that (A) $R \in R$. But then by the definition of R it follows that (B) $(R \notin R)$. Together, (A) and (B) form a contradiction.

Axiomatic set theory

The attitude adopted in an axiomatic development of set theory is that it is not necessary to know what the "things" are that are called "sets" nor what the relation of membership means. Of sole concern are the properties assumed about sets and the membership relation. Thus, in an axiomatic theory of sets, the terms set and the membership relation $\in$ are undefined. The assumptions adopted about these notions are called the axioms of the theory. Its theorems are the axioms together with the statements that can be deduced from the axioms using the rules of inference provided by a system of logic. Criteria for the choice of axioms include: (A) their consistency (*i.e.,* that it should be impossible to derive as theorems both a statement and its negation), (B) their plausibility (*i.e.,* that they should be in accord with intuitive beliefs about sets), and (C) their richness (*i.e.,* that desirable results of Cantorian set theory can be derived as theorems).

These points are elaborated upon below.

POSTULATES OF AXIOMATIC SET THEORY

The Zermelo–Fraenkel axioms: discussion. The first axiomatization of set theory was given in 1908 by Ernst Zermelo, a German mathematician. From his analysis of the paradoxes, he concluded that they are associated with sets that are "too big," such as the set of all sets in Cantor's paradox. Thus, the axioms that Zermelo formulated are restrictive insofar as the asserting or implying of the existence of sets is concerned. As a consequence, there is no apparent way, in his system, to derive the known contradictions from them. On the other hand, the results of classical set theory short of the paradoxes can be derived. Zermelo's axiomatic theory is here discussed in a form that incorporates modifications and improvements suggested by later mathematicians, principally Thoralf Albert Skolem, a pioneer in metalogic, and Abraham Adolf Fraenkel, an Israeli mathematician. In the literature on set theory, it is called Zermelo–Fraenkel set theory (symbolized ZF), though it would seem historically more correct to call it Zermelo–Fraenkel–Skolem set theory. The 10 axioms are first discussed and then formally listed (see below *The Zermelo-Fraenkel axioms: formal presentation*).

Zermelo's pioneering work

Schemas for generating well-formed formulas. In the axioms that follow, "set" and "$\in$" are undefined terms. Lowercase Latin letters are used for variables; and variables denote sets. Equality (symbolized $=$) is taken as part of the underlying logic.

The first axiom (see axiom 1, below) conveys the idea that, as in classical set theory, a set is determined by its members. It should be noted that this is not merely a logically necessary property of equality but an assumption about the membership relation as well.

The set defined by the second axiom (see 2) is the empty (or null) set $\varnothing$.

For an understanding of the third axiom (see 3) considerable explanation is required. Zermelo's original system included the assumption (*Aussonderung* axiom) that, if a formula $S(x)$ is "definite" for all elements of a set s, then there exists a set the elements of which are precisely those elements x of s for which $S(x)$ holds. This is a version of the principle of abstraction, for it provides for the existence of sets corresponding to formulas. It restricts that principle, however, in two ways. Instead of asserting the existence of sets unconditionally, it can be applied only in conjunction with pre-existing sets. Further, only "definite" formulas (for which Zermelo offered only a vague description) may be used. Clarification was given, however, by Skolem (1922) by way of a precise definition of what will be called simply a formula of ZF. Using tools of modern logic, the definition may be made as follows:

a. For any variables x and y, $x \in y$ and $x = y$ are formulas (such formulas are called atomic).

b. If A and B denote formulas and x is any variable, then each of the following is a formula: If *A*, then *B; A* if and only if *B; A* and *B; A* or *B;* not *A;* for all *x, A;* for some *x, B.*

Formulas are constructed recursively (in a finite number of systematic steps) beginning with the (atomic) formulas of (a) and proceeding via the constructions permitted in (b). "Not ($x \in y$)," for example, is a formula (which is abbreviated to $x \notin y$), and "There exists an *x* such that for every *y*, $y \notin x$" is a formula. A variable is free in a formula if it occurs at least once in the formula without being introduced by one of the phrases "for some *x*" or "for all *x*." Henceforth, a formula *P* in which *x* occurs as a free variable will be called a "condition on *x*" and symbolized *P*(*x*). The formula "For every *y*, $x \in y$," for example, is a condition on *x*. It is to be understood that a formula is a formal expression—*i.e.,* a term without meaning. Indeed, a computer could be programmed to generate atomic formulas and build up from them other formulas of ever-increasing complexity using logical connectives ("not," "and," etc.) and operators ("for all" and "for some"). A formula acquires meaning only when an interpretation of the theory is spelled out; *i.e.,* when (A) a nonempty collection (called the domain of the interpretation) is specified as the range of values of the variables (thus the term set is assigned a meaning, viz., an object in the domain), (B) the membership relation is defined for these sets, (C) the logical connectives and operators are interpreted as in everyday language, and (D) the logical relation of equality is taken to be identity among the objects in the domain.

Intuitive interpretation

The terminology "a condition on *x*" for a formula in which *x* is free is merely suggestive; relative to an interpretation, such a formula does impose a condition on *x*. Thus, the intuitive interpretation of the third axiom schema is: given a set *a* and a condition on *x*, *P*(*x*), those elements of *a* for which the condition holds form a set. It provides for the existence of sets by separating off certain elements of existing sets. Calling the third axiom schema an axiom schema is appropriate, for it is a schema for generating axioms—one for each choice of *P*(*x*).

Axioms for compounding sets. Although the third axiom schema has a constructive quality, further means of constructing sets from existing sets must be introduced if some of the desirable features of Cantorian set theory are to be established. Each of the next three axioms is of this sort.

Using five of the axioms (see 2–6), a variety of basic concepts of classical set theory (*e.g.,* the operations of union, intersection, and Cartesian product; the notions of relation, equivalence relation, ordering relation, and function) can be defined with ZF. Further, the standard results about these concepts that were attainable in classical set theory can be proved as theorems of ZF.

Axioms for infinite and ordered sets. If *I* is an interpretation of an axiomatic theory of sets, the sentence that results from an axiom when a meaning has been assigned to "set" and "∈," as specified by *I*, is either true or false. If each axiom is true for *I*, then *I* is called a model of the theory. If the domain of a model is infinite, this fact does not imply that any object of the domain is an "infinite set." An infinite set in the latter sense is an object *d* of the domain *D* of *I* for which there is an infinity of distinct objects *d′* in *D* such that *d′Ed* holds (*E* standing for the interpretation of ∈). Though the domain of any model of the theory of which the axioms thus far discussed are axioms is clearly infinite, models in which every set is finite have been devised. For the full development of classical set theory, including the theories of real numbers and of infinite cardinal numbers, the existence of infinite sets is needed; thus the seventh axiom (see 7) is included.

The existence of a (unique) minimal set, ω, having properties expressed in the seventh axiom can be proved; its distinct members are Ø, {Ø}, {Ø, {Ø}}, {Ø, {Ø}, {Ø, {Ø}}}, · · · . These elements are denoted by 0, 1, 2, 3, · · · and are called natural numbers. Justification for this terminology rests with the fact that the Peano axioms, which can serve as a base for arithmetic, can be proved as theorems. Thereby the way is paved for the construction within ZF of entities that have all the expected properties of the real numbers.

The origin of the next axiom was Cantor's recognition of the importance of being able to well-order arbitrary sets; *i.e.,* to define an ordering relation for a given set such that each nonempty subset has a least element. The virtue of a well-ordering for a set is that it offers a means of proving that a property holds for each of its elements by a process (transfinite induction) similar to mathematical induction. Zermelo (1904) gave the first proof that any set can be well-ordered. His proof employed a set-theoretic principle that he called the axiom of choice, which, shortly thereafter, was shown to be equivalent to the so-called well-ordering theorem. One form of this principle is expressed as an eighth axiom (see 8).

Well-ordering arbitrary sets

Intuitively, the axiom asserts the possibility of making a simultaneous choice of an element in every nonempty member of any set; this guarantee accounts for its name. The assumption is significant only when the set has infinitely many members. Zermelo was the first to state explicitly the axiom, although it had been used but essentially unnoticed earlier. It soon became the subject of vigorous controversy because of its unconstructive nature. Some mathematicians rejected it totally on this ground. Others accepted it but avoided its use whenever possible. Some changed their minds about it when its equivalence with the well-ordering theorem was proved as well as the assertion that any two cardinal numbers *c* and *d* are comparable (*i.e.,* that exactly one of $c < d$, $d < c$, $c = d$ holds). There are many other equivalent statements, though even today there are a few mathematicians who feel that the use of the axiom of choice is improper. To the vast majority, however, it, or an equivalent assertion, has become an indispensable and commonplace tool.

Schema for transfinite induction and ordinal arithmetic. One more axiom has been added to the list of axioms (with modifications) postulated by Zermelo. When Zermelo's eight were found to be inadequate for a fullblown development of transfinite induction and ordinal arithmetic, Fraenkel and Skolem independently proposed an additional axiom schema to eliminate the difficulty. As modified by John von Neumann, a Hungarian-born U.S. mathematician, it says, intuitively, that if with each element of a set there is associated exactly one set, then the collection of the associated sets is itself a set; *i.e.,* it offers a way to "collect" existing sets to form sets. As an illustration, each of ω, *P*(ω), *P*(*P*(ω)), · · · is a set in the theory based on the first eight axioms. But there appears to be no way to establish the existence of the set having these sets as its members. An instance of the next schema, however, provides for its existence.

Intuitively, the ninth axiom or schema (see 9) is the assertion that if the domain of a function is a set then so is its range. That this is a powerful schema (in respect to the further inferences that it yields) is suggested by the fact that the third axiom can be derived from it and that, when applied in conjunction with the sixth axiom, the axiom of pairing can be deduced. The ninth axiom has played a significant role in developing a theory of ordinal numbers. In contrast to cardinal numbers, which serve to designate the size of a set, ordinal numbers are used to determine positions within a prescribed sequence. Following an approach conceived independently by Zermelo and von Neumann, if *x* is a set, the successor *x′* of *x* is the set obtained by adjoining *x* to the elements of *x* ($x' = x \cup \{x\}$). In terms of this notion the natural numbers, as defined above, are simply the succession 0, 0′, 0″, 0‴, · · · ; *i.e.,* the natural numbers are the sets obtained starting with Ø and iterating the prime operation a finite number of times. The natural numbers are well-ordered by the ∈ relation, and with this ordering they constitute the finite ordinal numbers. The axiom of infinity secures the existence of the set of natural numbers; and this set, ℜ ω, is the first infinite ordinal. Greater ordinal numbers are obtained by iterating the prime operation beginning with ω. An instance of the ninth axiom or schema asserts that ω, ω′, ω″, · · · form a set. The union of this set and ω is the still greater ordinal that is denoted by ω2 (employing notation from ordinal arithmetic). A repetition of this process beginning with ω2 yields the ordinals (ω2)′, (ω2)″, · · · ; next after all of those of this form is ω3. In this way the sequence of ordinals ω, ω2, ω3, · · ·

is generated. An application of the ninth axiom schema then yields the ordinal that follows all of these in the same sense in which ω follows the finite ordinals; using notation from ordinal arithmetic, it is ω^2. At this point the iteration process can be repeated. In summary, the axiom of replacement makes possible the extension of the counting process as far beyond the natural numbers as one chooses.

Cardinal and ordinal numbers

In the ZF system, cardinal numbers are defined as certain ordinals. From the well-ordering theorem (a consequence of the axiom of choice), it follows that every set a is equivalent to some ordinal number. Also, the totality of ordinals equivalent to a can be shown to form a set. Then a natural choice for the cardinal number of a is the least ordinal to which a is equivalent. This is the motivation for defining a cardinal number as an ordinal that is not equivalent to any smaller ordinal. The arithmetics of both cardinal and ordinal numbers have been fully developed. That of finite cardinals and ordinals coincides with the arithmetic of the natural numbers. For infinite cardinals, the arithmetic is uninteresting since, as a consequence of the eighth axiom, the sum and product of two such cardinals are each equal to the maximum of the two. In contrast the arithmetic of infinite ordinals is interesting and presents a wide assortment of oddities.

In addition to the guidelines already mentioned for the choice of axioms of ZF, another guideline is taken into account by some set theorists. For the purposes of foundational studies of mathematics, it is assumed that mathematics is consistent; for otherwise any foundation would fail. It may thus be reasoned that, if a precise account of the intuitive usages of sets by mathematicians is given, an adequate and correct foundation will result. Traditionally, mathematicians deal with the integers, with real numbers, and with functions. Thus an intuitive hierarchy of sets in which these entities appear should be a model of ZF. It is possible to construct such a hierarchy explicitly from the empty set by iterating the operations of forming power sets and unions in the following way.

The intuitive hierarchy of sets

The first level of the hierarchy is composed of the sequence of sets $s_0 = \varnothing, s_1, \cdots, s_n, \cdots$, in which s_{n+1} is the power set of s_n. The second level consists of the sets at the first level together with those sets obtained by iterating the power set operation any finite number of times. The third level has as its members the union of all sets constructed thus far together with those obtainable by iterating the power set operation as before. The hierarchy of sets envisaged, therefore, consists of all sets that can be obtained by proceeding to an arbitrarily large transfinite level. The domain of the intuitive model of ZF is conceived as the union of all sets in the hierarchy. In other words, a set x is in the model if it is an element of some set of the hierarchy.

Axiom for eliminating infinite descending species. From the assumptions that this system is sufficiently comprehensive for mathematics and that it is the model to be "captured" by the axioms of ZF, it may be argued that models of the first nine axioms that differ sharply from this system should be ruled out. The discovery of such a model led to the formulation by von Neumann of the tenth axiom (see 10).

This axiom eliminates from the models of the first nine axioms those in which there exist infinite descending ∈-chains (*i.e.*, sequences $x_1, x_2, x_3, \cdots$ such that $x_2 \in x_1$, $x_3 \in x_2, \cdots$), a phenomenon that does not appear in the heuristic model described above. (The existence of models having such chains was discovered by D. Mirimanoff in 1917.) It also has other attractive consequences; *e.g.*, a simpler definition of the notion of ordinal number is possible. Yet there is no unanimity among mathematicians whether there are sufficient grounds for adopting it as an additional axiom, since it does not have the immediate plausibility that even the axiom of choice has nor has it ever been shown to have any mathematical applications.

The Zermelo–Fraenkel axioms: formal presentation.

(1) *Axiom of extension.* If a and b are sets and if, for all x, $x \in a$ if and only if $x \in b$, then $a = b$.

(2) *Axiom of the empty set.* There exists a set a such that for all x, it is false that $x \in a$.

(3) *Axiom schema of separation.* If a is a set, there exists a set b such that for all x, $x \in b$ if and only if $x \in a$ and $P(x)$. Here, $P(x)$ is any condition on x in which b is not free (it must be bound by a quantifier such as "all" or "some").

(4) *Axiom of pairing.* If a and b are sets, there exists a set (symbolized $\{a, b\}$ and called the unordered pair of a and b) having a and b as its sole members.

(5) *Axiom of union.* If c is a set, there exists a set a such that $x \in a$ if and only if $x \in b$ for some member b of c.

(6) *Axiom of power set.* If a is a set, there exists a set b such that $x \in b$ if and only if $x \in a$.

(7) *Axiom of infinity.* There exists a set a such that $\varnothing \in a$ and, if $x \in a$, then $(x \cup \{x\}) \in a$, in which $x \cup \{x\}$ is the set x with x adjoined as a further member.

(8) *Axiom of choice.* If a is a set the elements of which are nonempty sets, then there exists a function f with domain a such that for member b of a, $f(b) \in b$.

(9) *Axiom schema of replacement.* If a is a set and $B(x, y)$ a formula (in which x and y are free) such that for $x \in a$ there is exactly one y such that $B(x, y)$, then there exists a set b the members of which are the y's determined by $B(x, y)$ as x ranges over a.

(10) *Axiom of restriction.* Every nonempty set a contains an element b such that $a \cap b = \varnothing$; *i.e.*, a and b have no elements in common.

The Neumann–Bernays–Gödel axioms: discussion. The second axiomatization of set theory originated with von Neumann in the 1920s. His formulation differed considerably from ZF because the notion of function, rather than that of set, was taken as primitive. In a series of papers beginning in 1937, however, the Swiss logician Paul Bernays, a collaborator with the formalist David Hilbert, modified the von Neumann approach in a way that put it in much closer contact with ZF. In 1940, the Czech-born logician Kurt Gödel, known for his undecidability proof, further simplified the theory. This version will be called NBG.

For expository purposes it is convenient to adopt two undefined notions for NBG: class and the binary relation, ∈, of membership (though, as is also true in ZF, ∈ suffices). In the axioms, capital Latin letters are used as variables. For the intended interpretation, variables take classes—the totalities corresponding to certain properties—as values. A class is defined to be a set if it is a member of some class; those classes that are not sets are called proper classes. Lowercase Latin letters are used as special restricted variables for sets. For example, "for all x, $A(x)$" stands for "for all X, if X is a set, then $A(X)$"; *i.e.*, the condition holds for all sets. Intuitively, sets are intended to be those classes that are adequate for mathematics, and proper classes are thought of as those collections that are "so big" that, if they were permitted to be sets, contradictions would follow. In NBG, the classical paradoxes are avoided by proving in each case that the collection on which the paradox is based is a proper class—*i.e.*, is not a set.

Comments about the axioms that follow are limited to features that distinguish them from their counterpart in ZF. The axioms are listed later (see 11–20, below *The Neumann–Bernays–Gödel axioms: statement*).

The third axiom or schema (see 13) is presented in a form to facilitate a comparison with the third axiom schema of ZF. In a detailed development of NBG, however, there appears, instead, a list of seven axioms (not schemas) that state that for each of certain conditions there exists a corresponding class of all those sets satisfying the condition. From this finite set of axioms, each an instance of the above schema, the schema (in a generalized form) can be obtained as a theorem. When obtained in this way, the third axiom schema of NBG is called the class existence theorem.

In brief, the fourth to eighth axioms of NBG (see 14–18) are axioms of set existence. The same is true of the next axiom, which for technical reasons is usually phrased in a more general form.

Finally there may appear in a formulation of NBG an analogue (see 20) of the last axiom of ZF.

Comparison of ZF and NBG axiomatizations

A comparison of the two theories that have been formulated is in order. In contrast to the ninth schema of ZF (see 9), that of NBG (see 19) is not an axiom schema but an axiom. Thus, with the comments above about the third axiom in mind, it follows that NBG has only a finite number of axioms. On the other hand, since the ninth axiom or schema of ZF provides an axiom for each formula, ZF has infinitely many axioms—which is unavoidable because it is known that no finite subset yields the full system of axioms. The finiteness of the axioms for NBG makes the logical study of the system simpler. The relationship between the theories may be summarized by the statement that ZF is essentially the part of NBG that refers only to sets. Indeed, it has been proved that every theorem of ZF is a theorem of NBG and that any theorem of NBG that speaks only about sets is a theorem of ZF. Finally, it has been shown that ZF is consistent if and only if NBG is consistent.

The Neumann–Bernays–Gödel axioms: statement.

(11) *Axiom of extension.* If A and B are classes and if, for all (sets) x, $x \in A$ if and only if $x \in B$, then $A = B$.

(12) Same as axiom (2).

(13) *Axiom schema for class formation.* If $P(x)$ is a condition on x in which (a) only set variables are introduced by the phrase "for all" or "for some" and (b) B is not free, then there exists a class B such that $x \in B$ if and only if $P(x)$.

(14) *Axiom of pairing.* Same as axiom (4).

(15) *Axiom of union.* Same as axiom (5).

(16) *Axiom of power set.* Same as axiom (6).

(17) *Axiom of infinity.* Same as axiom (7).

(18) *Axiom of choice.* Same as (8).

(19) *Axiom of replacement.* If (the class) X is a function and a is a set, then there exists a set b such that $y \in b$ if and only if for some x, $(x, y) \in X$ and $x \in a$; *i.e.*, the range of the restriction of a function X to a domain that is a set is also a set.

(20) *Axiom of restriction.* Every nonempty class A contains an element b such that $A \cap b = \emptyset$.

LIMITATIONS OF AXIOMATIC SET THEORY

The fact that NBG avoids the classical paradoxes and that there is no apparent way to derive any one of them in ZF does not settle the question of the consistency of either theory. One method for establishing the consistency of an axiomatic theory is to give a model; *i.e.*, an interpretation of the undefined terms in another theory such that the axioms become theorems of the other theory. If this other theory is consistent, then that under investigation must be consistent. Such consistency proofs are thus relative: the theory for which a model is given is consistent if that from which the model is taken is consistent. The method of models, however, offers no hope for proving the consistency of an axiomatic theory of sets. In the case of set theory and, indeed, of axiomatic theories generally, the alternative is a direct approach to the problem.

If T is the theory of which the (absolute) consistency is under investigation, this alternative means that the proposition "There is no sentence of T such that both it and its negation are theorems of T" must be proved. The mathematical theory (developed by the formalists) to cope with proofs about an axiomatic theory T is called proof theory, or metamathematics. It is premised upon the formulation of T as a formal axiomatic theory; *i.e.*, the theory of inference (as well as T) must be axiomatized. It is then possible to present T in a purely symbolic form; *i.e.*, as a formal language based on an alphabet the symbols of which are those for the undefined terms of T and those for the logical operators and connectives. A sentence in this language is a formula composed from the alphabet according to prescribed rules. The hope for metamathematics was that by using only intuitively convincing, weak number-theoretic arguments (called finitary methods), unimpeachable proofs of the consistency of such theories as axiomatic set theory could be given.

Gödel's theorem and the consistency of S

That hope suffered a severe blow in 1931 from a theorem proved by Gödel about any formal theory S that includes the usual vocabulary of elementary arithmetic. By coding the formulas of such a theory with natural numbers (now called Gödel numbers) and by talking about these numbers, Gödel was able to make the metamathematics of S to become part of the arithmetic of S and hence to be expressible in S. The theorem in question asserts that the formula of S that expresses (via a coding) "S is consistent" in S is unprovable in S if S is consistent. Thus, if S is consistent, then the consistency of S cannot be proved within S; rather, methods beyond those that can be expressed or reflected in S must be employed. Because, in both ZF and NBG, elementary arithmetic can be developed, Gödel's theorem applies to these two theories. Although there remains the possibility of a finitary proof of consistency that cannot be reflected in the foregoing systems of set theory, no hopeful, positive results have been obtained.

Other theorems of Gödel when applied to ZF (and there are corresponding results for NBG) assert that if the system is consistent, then (A) it contains a sentence such that neither it nor its negation is provable (such a sentence is called undecidable), (B) there is no algorithm (or iterative process) for deciding whether a sentence of ZF is a theorem, and (C) these same statements hold for any consistent theory resulting from ZF by the adjunction of further axioms. Apparently ZF can serve as a foundation for all of present-day mathematics because every mathematical theorem can be translated into and proved within ZF, or within extensions obtained by adding suitable axioms. Thus, the existence of undecidable sentences in each such theory (which entails the existence of true sentences of ZF not provable in ZF) points out the hopelessness of any attempt to base all of conceivable mathematics on a single axiomatic theory and hence implies the inadequacy of the axiomatic approach to mathematics, in particular, via axiomatic set theory.

PRESENT STATUS OF AXIOMATIC SET THEORY

The foundations of axiomatic set theory are in a state of significant change as a result of new discoveries. The situation is analogous to the 19th-century revolution in geometry, set off by the discovery of non-Euclidean geometries. It is difficult to predict the ultimate consequences of these late 20th-century findings for set theory, but already they have had profound effects on attitudes about certain axioms and have forced the realization of a continuous search for additional axioms. These discoveries have focussed attention on the concept of the independence of an axiom. If T is an axiomatic theory and S is a sentence (*i.e.*, a formula) of T that is not an axiom, and if $T + S$ denotes the theory that results from T upon the adjunction of S to T as a further axiom, then S is said to be consistent relative to T if $T + S$ is consistent and independent of T whenever both S and $\sim S$ (the negation of S) are consistent relative to T. Thus, assuming that T is consistent, if S is independent of T, then the addition of S or $\sim S$ to T yields a consistent theory. The role of the axiom of restriction (AR) can be clarified in terms of the notion of independence. If ZF′ denotes the theory obtained from ZF by deleting AR and either retaining or deleting the axiom of choice (AC), then it can be proved that if ZF′ is consistent, AR is independent of ZF′.

Relations of axiom of choice to continuum hypotheses

Of far greater significance for the foundations of set theory is the status of AC relative to the other axioms of ZF. The status in ZF of the continuum hypothesis (CH) and its extension, the generalized continuum hypothesis (GCH) are also of profound importance. (If $q(a)$ denotes "There does not exist a set b such that $\overline{\overline{a}} < \overline{\overline{b}} < \overline{\overline{P(a)}}$ the CH is $q(a)$ for $\overline{\overline{a}} = \aleph_0$ and GCH is $q(a)$ for all infinite sets a.) In the following discussion of these questions, ZF denotes Zermelo–Fraenkel set theory without AC. The first finding was obtained by Gödel in 1938. He proved that AC and GCH are consistent relative to ZF (*i.e.*, if ZF is consistent, then so is ZF + AC + GCH), by showing that a contradiction within ZF + AC + GCH can be transformed into a contradiction in ZF. In 1963, Paul J. Cohen, a U.S. mathematician, proved that (1) if ZF is consistent, then so is ZF + AC + ~CH, and (2) if ZF is consistent, then so is ZF + ~AC. Since in ZF + AC it can be demonstrated that GCH implies CH, Gödel's theorem together with Cohen's establishes the independence of AC and CH. For his proofs Cohen introduced a new method (called forcing) of constructing interpretations of ZF + AC. The method of forcing is applicable to many problems in set theory, and since 1963 it has been used to give independence proofs for a wide variety of highly technical propositions. Some of these results have opened new avenues for attacks on important foundational questions.

The current unsettled state of axiomatic set theory can be sensed by the responses that have been made to the ques-

Status of the continuum hypothesis

tion of how to regard CH in the light of its independence from ZF + AC. Someone who believes that set theory deals only with nonexistent fictions will have no concern about the question. But for most mathematicians sets actually exist; in particular, ω and *P*(ω) exist. Further, it should be the case that every nondenumerable subset of *P*(ω) either is or is not equivalent to *P*(ω); *i.e.*, either CH is true or is false. Followers of this faith regard the axioms of set theory as describing some well-defined reality—one in which CH must be either true or false. Thus there is the inescapable conclusion that the present axioms do not provide a complete description of that reality. A search for such axioms is in progress. One who hopes to prove CH as a theorem must look for axioms that restrict the number of sets. There seems to be little hope for this restriction, however, without changing the intuitive notion of the set. Thus the expectations favour the view that CH will be disproved. This disproof requires an axiom that guarantees the existence of more sets; *e.g.*, of sets having cardinalities greater than those that can be proved to exist in ZF + AC. So far, none of the axioms that have been proposed that are aimed in this direction (called "generalized axioms of infinity") serves to prove ~CH. Although there is little supporting evidence, the optimists hope that the status of the continuum hypothesis CH will eventually be settled. (R.R.S.)

Sex and Sexuality

Sex, sexuality, and reproduction are all closely interwoven into the fabric of living things. All relate to the propagation of the race and the survival of the species. Yet there can be sex without sexuality, and reproduction need not be sexual, although for most forms of life sexual reproduction is essential both for propagation and long-term survival.

The article is divided into the following sections:

Animals and plants

SEXUAL AND NONSEXUAL REPRODUCTION

Nonsexual reproduction

Because the life-span of all individual forms of life, from microbes to man, is limited, the first concern of any particular population is to produce successors. This is reproduction, pure and simple. Among lower animals and plants it may be accomplished without involving eggs and sperm. Ferns, for example, shed millions of microscopic, nonsexual spores, which are capable of growing into new plants if they settle in a suitable environment. Many higher plants also reproduce by nonsexual means. Bulbs bud off new bulbs from the side. Certain jellyfish, sea anemones, marine worms, and other lowly creatures bud off parts of the body during one season or another, each thereby giving rise to populations of new, though identical, individuals. At the microscopic level, single-celled organisms reproduce continually by growing and dividing successively to give rise to enormous populations of mostly identical descendants. All such reproduction depends on the capacity of cells to grow and divide, which is a basic property of life. In the case of most animals, however, particularly the higher forms, reproduction by nonsexual means is apparently incompatible with the structural complexity and activity of the individual.

Although nonsexual reproduction is exploited by some creatures to produce very large populations under certain circumstances, it is of limited value in terms of providing the variability necessary for adaptive advantages. Such so-called vegetative forms of reproduction, whether of animals or plants, result in individuals that are genetically identical with the parent. All have exactly the same genetic, or inherited, traits, for better or worse. If some adverse environmental change should occur, all would be equally affected and none might survive. At the best, therefore, nonsexual reproduction can be a valuable and perhaps an essential means of propagation, but it does not exclude the need for sexual reproduction.

Sexual reproduction not only takes care of the need for replacement of individuals within a population but gives rise to populations better suited to survive under changing circumstances. In effect it is a kind of double assurance that the race or species will persist for an indefinite time. The great difference between the two types of reproduction is that individual organisms resulting from nonsexual reproduction have but a single parent and are essentially alike, whereas those resulting from sexual reproduction have two parents and are never exact replicas of either.

Sexual reproduction thus introduces a variability, in addition to its propagative function. Both types of reproduction represent the capacity of individual cells to develop into whole organisms, given suitable circumstances. Sex is therefore something that has been combined with this primary function and is responsible for the capacity of a race to adapt to new environmental conditions.

Gonads and primary sex

Sex cells. The term sex is variously employed. In the broad sense it includes everything from the sex cells to sexual behaviour. Primary sex, which is generally all that distinguishes one kind of individual from another in the case of many lower animals, denotes the capacity of the reproductive gland, or gonad, to produce either sperm cells or eggs or both. If only sperm cells are produced, the reproductive gland is a testis, and the primary sex of the tissue and the individual possessing it is male. If only eggs are produced, the reproductive gland is an ovary, and the primary sex is female. If the gland produces both sperm and eggs, either simultaneously or successively, the condition is known as hermaphroditic. An individual, therefore, is male or female or hermaphrodite primarily according to the nature of the gonad.

As a rule, male and female complement each other at all levels of organization: as sex cells; as individuals with either testes or ovaries; and as individuals with anatomical, physiological, and behavioral differences associated with the complemental roles they play during the whole reproductive process. The role of the male individual is to deliver sperm cells in enormous numbers in the right place and at the right time to fertilize eggs of female individuals of the same species. The role of the female individual is to deliver or otherwise offer eggs capable of being fertilized under precise circumstances. In the case of hermaphrodite organisms, animal or plant, various devices are employed to ensure cross-fertilization, or cross-pollination, so that full advantage of double parentage is obtained. The basic requirement of sexual reproduction is that reproductive cells of different parentage come together and fuse in pairs. Such cells will be genetically different to a significant degree, and it is this feature that is essential to the long-term well-being of the race. The other sexual distinctions, between the two types of sex cell and between two individuals of different sex, are secondary differences connected with ways and means of attaining the end.

Sexuality: complementary mating types. The complementarity of both male and female sex cells and male and female individuals is a form of division of labour. Male sex cells are usually motile cells capable of swimming through liquid, either freshwater, seawater, or body fluids, and they contribute the male cell nucleus but little else to the fertilization process. The female cell also contributes its nucleus, together with a large mass of cell substance necessary for later growth and development following fertilization. The female cell, however, is without any capacity for independent movement.

In other words, small male cells (sperm cells, spermatozoa, or male gametes) are burdened with the task of reaching a female cell (egg, ovum, or female gamete), which is relatively large and awaits fertilization. A full complement of genes is contributed by both nuclei, representing contributions by both parents, but, apart from the nucleus, only the egg is equipped or prepared to undergo development to form a new organism. A comparable division of labour is seen in the distinction between male and female individuals. The male possesses testes and whatever accessory structures may be necessary for spawning or delivery of the sperm, and the female possesses ovaries and what may be needed to facilitate shedding the eggs or to nurture developing young. Accordingly there is the basic sex, which depends on the kind of sex gland present, and sexuality, which depends on the different structures, functions, and activities associated with the sex glands.

The role of each sex

THE ADAPTIVE SIGNIFICANCE OF SEX

When two reproductive cells from somewhat unlike parents come together and fuse, the resulting product of development is never exactly the same as either parent. On the other hand, when new individuals, plant or animal, develop from cuttings, buds, or body fragments, they are exactly like their respective parents, as much alike as identical twins. Any major change in environmental circumstances might exterminate a race since all could be equally affected. When eggs and sperm unite, they initiate development and also establish genetic diversity among the population. This diversity is truly the spice of life and one of the secrets of its success; sex is necessary to its accomplishment.

In each union of egg and sperm, a complete set of chromosomes, representing a complete set of genes, is contributed by each cell to the nucleus of the fertilized egg. Consequently, every cell in the body inherits the double set of chromosomes and genes derived from the two parental cells. Every time a cell divides, during the long period of development and growth, each daughter cell receives exact copies of the original two sets of chromosomes. The process is known as mitosis. Accordingly, any fragment of tissue has the same genetic constitution as the body as a whole and therefore inevitably gives rise to an identical individual if it becomes separated and is able to grow and develop. Only in the case of the tissue that produces the sex cells do cells divide differently, and genetic differences occur as a result.

During the ripening of the sex cells, both male and female, cell divisions occur (known as meiosis) that result in each sperm and egg cell having only a single set of chromosomes. In each case the set of chromosomes is complete—*i.e.*, one chromosome of each kind—but each such set is, in effect, drawn haphazardly from the two sets present in the original cells. In other words, the single set of chromosomes present in the nucleus of any particular sperm or egg, while complete in number and kinds, is a mixture, some chromosomes having come from the set originally contributed by the male parent and some from the female. Each reproductive cell, of either sex, therefore contains a set of chromosomes different in genetic detail from that of every other reproductive cell. When these in turn combine to form fertilized eggs or fertile seeds, the double set of chromosomes characteristic of tissue cells is reestablished, but the genetic constitution of all such cells in the new individual will be the same as that of the fertilized egg—two complete sets of genes, randomly derived from sets contributed by the two different parents. Variation is thus established in two steps. The first is during the ripening of the sex cells, when each sperm or egg receives a single set of chromosomes of mixed ancestry. None of these cells will have exactly the same combination of genes characteristic of the respective parent. The second step occurs at fertilization, when the pair of already genetically unique sex cells fuse together and their nuclei combine, thus compounding the primary variation.

Reproduction and evolution. Sexual reproduction appears to be a process serving two opposing needs. The individuals produced must be almost exactly like their parents if they are to succeed; *i.e.*, to grow and reproduce in turn, under the prevailing circumstances. At the same time they should exhibit a wide range of differences so that some at least can survive under different environmental circumstances. The first business of reproduction is to produce perfect working copies of the parental organism, without any mistakes. The second is to introduce novelties; *i.e.*, new models that make possible other life styles. Extreme conservatism, in either sexual or nonsexual reproduction, may be disastrous to the species in the long run. Extreme variability may also be detrimental, resulting in the production of too high a percentage of misfits. A delicate balance has to be struck. Variability is necessary but must be kept within bounds. Sex is responsible for controlled diversity, without which adaptation and evolution could not take place.

Significance of reproduction

Natural selection operates in two ways on this basic diversity inherent in any particular population or community. In a stable environment, where there is little change during a long period of time, except for the regular changes associated with the seasons and the daily cycle, those individuals most likely to survive and produce offspring are precisely those that are most like their parents at all stages of their existence. The more radical departures from the established types fail either to grow or to compete successfully and consequently do not reproduce. The less radical departures struggle along but leave progeny in proportionately smaller numbers. If, however, a significant long-term change occurs in the environment, the previously established types are likely to suffer, while other types that previously had been weeded out generation by generation now may be favoured. They may become the more successful at surviving and growing and consequently replace themselves more readily than do others. They, in turn, become the establishment, and the older type is jeopardized. A constant interplay persists between a changeable environment and a variable population. This is adaptation. If environmental change continues in the same general direction, adaptation also continues in the initial direction, and eventually significant evolution becomes apparent.

The variability or diversity resulting from sexual reproduction is vital in two ways. It permits the process of natural selection to work and allows a population of organisms to adapt to new conditions. It also serves as a corrective mechanism. During nonsexual reproduction, particularly of single-cell organisms, large populations of virtually identical individuals are readily built up and maintained for a great many generations. Sooner or later, however, more and more abnormalities appear and, usually, a general waning of vigour ensues. When such organisms subsequently fuse together in pairs, equivalent to sexual reproduction, a rejuvenation and reestablishment of healthy strains generally follows.

Alteration of sexual and nonsexual phases

Life cycles adjusted to environmental change. Both sexual and nonsexual reproduction may be exploited or adjusted to meet widely fluctuating environmental conditions, especially those of a regular seasonal character. This phenomenon is particularly striking in the case of the smaller or simpler forms of animal and plant life that have a life-span of a year or less. The seeds of annual plants germinate in the spring, grow and set seed in turn during the summer, and die in the fall. Only the sexually produced seeds persist and represent the species during the long winter season. Certain small, though common, freshwater creatures have a similar cycle. The microscopic eggs of *Hydra* and of *Daphnia,* for example, lie at the bottom of ponds throughout the winter, each within a tough protective case. In late winter or early spring, a new generation of hydras develops, each individual becoming attached to a stone or vegetation and feeding on small crustaceans by means of its long slender tentacles. The daphnias, or so-called water fleas, emerge at about the same time and grow rapidly to maturity. In both cases the growing season, usually from spring until fall, is a time for intensive reproduction by whatever means is most effective. Hydras bud off new hydras continually, each new hydra repeating the process, with the size of populations limited only by available food. Only late in the season, when the food supply drops off and the temperature drops, does the riotous splurge of nonsexual reproduction come to an end. Then each individual ceases to bud and produces either minute ovaries or testes, and in some species, both. Eggs become fertilized, encased, drop into the mud, and await the coming of the following spring, while the parental creatures die as living conditions worsen with approaching winter. Such is a general pattern of life, widely seen among creatures whose individual existence is measured in weeks or months but whose race must persist in some form at all times if extinction is to be avoided.

So it is with *Daphnia* and many others. The *Daphnia* also changes according to the times, but it alternates between one form of sexual reproduction and another. Sexually, it is exquisitely adapted to the little world in which it lives. Under ideal conditions every member of a *Daphnia* community is female. All those first hatching out from winter eggs in the spring are females. Each produces a succession of broods during the month or two of its individual existence, all offspring being females. Each such female, generation after generation, during the spring and summer season, produces eggs that develop at once without need or opportunity of being fertilized. No males in fact are present. Every individual is a self-sufficient breeding female. Population explosions occur wherever environmental circumstances are good. Eventually, however, conditions inevitably change for the worse, either because of effects inherent in any population explosion or because every season comes to an end. Food becomes scarce because of too many consumers; space becomes crowded and in some degree polluted; chilly days succeed the warmth of summer. Whatever it is, and well before disaster can strike, the creatures respond in remarkable ways. On the first signal that conditions may be getting less than good, a certain number of the eggs produced by a population of *Daphnia* develop into males, each with testes in place of ovary, together with certain secondary sexual characteristics. A scattering of males through the virgin paradise, however, is only a first step, a preparedness in case conditions go from bad to worse. If there has been a false alarm, the females continue to produce female-producing eggs that develop parthenogenetically—*i.e.*, without benefit of fertilization—and the males die off without performing any sexual function. But if the environmental signal means the beginning of the end of congenial conditions, a cell in the ovary of each female grows to form a larger egg than usual, and it is of a type that must be fertilized. Then mating between the sexes takes place, and these special, fertilized eggs become thickly encased and alone survive the winter season after becoming separated from the parent.

Parthenogenesis

Wherever small aquatic creatures live in bodies of water that may freeze in winter or dry up in summer, similar adaptations are seen in many forms of life besides hydras and water fleas. Certain small fish, known as the annual fishes, have individual life-spans of about six months. The life-span itself is in fact adapted to the period during which active existence is possible in their particular habitat. When the water holes, swamps, and puddles in which they live begin to dry up, mating takes place, and the fertilized eggs drop into the mud. The parents die, and the eggs remain in a state of suspended development until the next rainy season occurs. The race must go on whatever the circumstances, and all sex is directed toward this end.

THE ORIGIN OF SEX AND SEXUALITY

All sexual reproduction, no matter how large or small the organisms may be, is a performance of single cells. Only at the level of single cells can the essential genetic recombinations be accomplished. So in every generation new life begins with the egg, which is a single cell, however large it may be. Egg and sperm unite at fertilization, but the fertilized egg is as much a single cell as before. When did it all begin? The generally accepted answer is that the fundamental, or molecular, basis of sexuality is an ancient evolutionary development that goes back almost to the beginning of life on earth, several billion years ago, for it is evident among the vast world of single-celled organisms, including bacteria.

In these lowest forms of life, sex and reproduction are distinct happenings. Reproduction is accomplished in most cases entirely by fission, which is simply cell division repeated regularly, as long as the environmental conditions permit. As long as crowding and other adverse changes are avoided, cells divide, and the daughter cells grow and divide again, for weeks or months on end. This process occurs in both plantlike and animal-like single-celled organisms and in bacteria as well. Under certain other conditions, such cell organisms come together and fuse in pairs, a form of sexual behaviour at its primary level and comparable to the fusion of an egg and sperm. In all such case, a combined cell is produced in which nuclear exchange or recombination has occurred. Pairing off of this sort takes place sooner or later in all forms of unicellular life, even where no outwardly distinguishable differences can be detected between the pairing individuals. The lack of discernible differences between the members of mating pairs, however, does not mean that pairing occurs between identical individuals. In the much investigated *Paramecium* and other protozoan organisms, two separate populations of cells may continue to increase almost indefinitely by ordinary cell division of single individuals, but when two such populations are mixed together, mating generally occurs immediately between individuals from the two different sources. The fusion, or pairing, has essentially the same function as the fusion of the male and female nucleus during the process of fertilization of eggs of higher forms. It is the basis of sex, the essential event in all cases being the genetic or chromosomal recombination.

Kinds of gametes

Individual mating cells (*i.e.*, eggs, sperm, or even whole single-celled organisms) may be called gametes whether or not they are distinguishable from one another. Yet even among the varius single-celled organisms, mating commonly occurs between individuals of two different kinds. This kind of mating is seen most often among the single-celled organisms known as flagellates. In some species the gametes may be alike and all are motile, progressing through the water by means of one or more whiplike flagella similar to the tail of a sperm. In other species, all individuals may still be motile, but pairing occurs between individuals of different sizes. In still others, one of the two mating types may be very small and motile, and the other, large, with stored nutritional material, and nonmotile. All degrees of differentition between male and female gametes can be found, and it is probable that the basic and characteristic distinction between the sex cells of both animal and plant life in general was established very early in the course of evolution, during the immense period of time when virtually all living organisms consisted of single cells.

This division of labour between mating types, male and female, respectively, is nature's way of attaining two ends. These are the bringing together of the gametes so that fusion may take place and the accumulation of reserves so that development of a new organism can be accomplished. The first calls for as many motile cells as possible; the second calls for cells as large as possible. These different requirements are practically impossible to satisfy by a single type of cell. Accordingly, and especially in multicelled animals of all sorts, male gametes, or spermatozoa, are extremely small, extremely motile, and are produced in enormous numbers. The larger the number, the greater the likelihood that some will encounter and fertilize eggs. On the other hand, the female gametes, or ova, individually need to be as large as possible since the larger the size and the more condensed the internal nutritional reserves, the farther along the path of embryonic development the egg can travel before hatching must occur and the new organism must fend for itself. Nevertheless, eggs in general are caught between the desirability of being individually as large as they can be and the persisting need to be produced in reasonably large numbers, so that an assortment of differing indivuduals is produced from a single pair of parents. A large number of offspring ensures that a proportion, at least, will survive the environmental hazards faced by all developing organisms in some degree.

Differentiation of the sexes. Animals and plants, apart from microscopic kinds of life, consist of enormous numbers of cells coordinated in various ways to form a single organism, and each consists of many different kinds of cells specialized for performing different functions. Certain tissues are set aside for the production of sexual reproductive cells, male or female as the case may be. Whether they are testes or ovaries or, as in some animals and plants, both together in the same parental individual, they are typically contained within the body, and therefore the sex cells usually need to be passed to the outside in order to function. Only in certain lowly creatures such as hydras is there a simpler state, for in hydras the testes and ovaries form in the outermost layer of cells of the slender, tubular body, and the sex cells when ripe burst directly from the simple, bulging gonads into the surrounding water. With few other exceptions, in all other creatures the gonads are part of the internal tissues and some means of exit is necessary. In some, such as most worms, all that is needed are small openings, or precisely placed pores, in the body wall through which sperm or eggs can escape. In most others, more is needed and a tubular sperm duct or an oviduct leads from each testis or ovary, through which the sex cells pass to the exterior. This is minimal equipment, except where none is needed. The gonad and its duct is accordingly comparable to other glands in the body; that is, the gland is generally a more or less compact mass of cells of a particular, specialized kind, together with a duct for passage of the product of the tissue to the site of action. Gonads secrete—*i.e.*, produce and transmit—sex cells that usually act outside the body.

Differentiation between the sexes exists, therefore, as the primary difference represented by the distinction between eggs and sperm, by differences represented by nature of the reproductive glands and their associated structures, and lastly by differences, if any, between individuals possessing the male and female reproductive tissues, respectively.

The value of cross-fertilization

Sex cells, sexual organs, other sexual structures, and sexual distinction between individuals constitute a series of evolutionary advances connected with various changes and persisting needs in the general evolution of animals and, to some degree, of plants as well. In other words, no matter how large or complex a creature may become, it still needs to deliver functional sex cells to the exterior. This condition is almost always the case for sperm cells. Among aquatic animals, particularly marine animals whose external medium, the ocean, is remarkably similar chemically to the internal body fluid medium of all animals, eggs are also in most cases shed to the exterior, where development of the fertilized eggs can proceed readily. Even so, time and place are important. Starfish, sea urchins, and many others, for instance, accumulate mature eggs and sperm in the oviducts and sperm ducts until an appropriate time when all can be shed at once. When one member of a group of such creatures begins to spawn, chemicals included in the discharge stimulate other members to do the same, so that a mass spawning takes place. One might say that the more they are together the more variable their offspring may be. This situation actually is the crux of the matter for nearly all forms of life, because while it may be possible for a single individual to possess both male and female gonads, producing both sperm and eggs, it remains generally desirable, if not essential, that eggs be fertilized by sperm produced by another individual. Cross-fertilization results in a much greater degree of variability than does self-fertilization. The existence of two types of individuals, male and female, is the common means of ensuring that cross-fertilization will be accomplished, since then nothing else is possible. Where the sexes are separate, therefore, all that is necessary is that members of the opposite sex get together at a time and place appropriate for the initial development of fertilized eggs. Typically, spawning of this sort is a communal affair, with many individuals of each sex discharging sex cells into the surrounding water. This process is only suitable, however, when eggs are without tough protective cases or membranes; that is, only when eggs are readily fertilizable for some time after being shed and while drifting in the sea. In this circumstance there is no need for individuals of the opposite sex to mate in pairs, nor is such mating practiced.

Mating. Mating between two individuals of the opposite sex becomes necessary when eggs must be fertilized at or before the time the eggs are shed. Whenever eggs have a protective envelope of any kind through which sperm cannot penetrate, fertilization must take place before the envelope is formed. The envelope may at first be a gluey liquid, which covers the egg and solidifies as a tough egg case, as in all crustaceans, insects, and related creatures. It may be a thick membrane of protein deposited around the egg, as in fishes generally; or it may be a material that swells up as a mass of jelly surrounding the eggs after the eggs have been shed, as in frogs and salamanders. And finally, it may be a calcified shell, as in birds and reptiles. In all of these organisms the sperm must reach the egg before the protective substance is added, except in those forms in which a small opening or pore persists in the egg membrane through which sperm can enter.

When and how such eggs need to be fertilized depends on the nature of the protective membranes and the time and place of their formation. The jelly surrounding frog and toad eggs, for instance, swells up immediately after the eggs are shed. Mating and fertilization must take place at the time of spawning. Male frogs mount the back of female frogs and each clasps his mate firmly around the body, which not only helps press the egg mass downward but brings the cloacal opening of male and female close together. Eggs and sperm are shed simultaneously, and the eggs are fertilized as they leave the female body. Fish eggs are also fertilized as or shortly after they are shed, although fish have no arms and mating generally is usually no more than a coming together of the two sexes side by side, so that simultaneous shedding of sperm and eggs can be accomplished. In other creatures the mating procedure may be much more complicated, depending on various circumstances. Crustaceans such as crabs and lobsters, for example, mate in somewhat the same manner as frogs, with the male holding on to the female by means of claw-like appendages and depositing sperm at the openings of the oviducts, which are typically situated near the middle of the undersurface of the body.

Mating modifications imposed by the land environment. Greater problems arise on land than in water. Eggs produced by truly terrestrial creatures are either retained in the parental body during their development or must be fully protected from drying up. Protective membranes must be tough indeed. More importantly, however, sperm cells must still be deposited where they can swim toward the eggs, for they cannot survive or function except in a watery solution of dilute salts. In all terrestrial creatures, except those that return to water to breed, sperm can survive only in the body of the male or female organism. All insects, therefore, must mate in order for eggs to be fertilized, and all have appendages at the rear of the body that serve as a copulatory device capable of being used even when in flight. Sperm is injected into the female's duct or storage sac, either for immediate fertilization or for later use. The queens of bees, ants, and termites, in fact, mate once and for all during a nuptial flight and thereafter use the stored sperm to fertilize all the eggs they subsequently produce.

The land vertebrates have to cope with much the same breeding circumstances as the insects. Man is more aware of these procedures because they happen mostly in much larger creatures and also because he has some fellow feeling for them. Reptiles, birds, and even the most primitive surviving mammals—namely, the platypus and spiny anteater of Australasia—produce yolky eggs encased in a more or less rigid calcareous shell. Moreover, within the shell, a thick layer of albumen surrounds the egg proper. Both the albumen and the shell are added after the ovum leaves the ovary and during its passage down the oviduct. Fertilization must take place, if at all, as the eggs enter the oviduct, for neither the albumen nor the shell can be penetrated by spermatozoa. Sperm must therefore be introduced into the female and must be able to make their way up to the end of the oviduct, which is a very long journey for so small a cell. An enormous number must begin the journey to make sure that some will reach the goal.

Necessity of internal fertilization in land animals

Sexual anatomy. In reptiles and birds of both sexes, as in amphibians and fish, a single opening to the exterior serves jointly for both the intestine and reproductive duct. This is the cloaca, or vestibule. Nevertheless, copulation of a sort occurs in all three groups of terrestrial vertebrates: the reptiles, birds, and mammals. With the exception of man, the male always mounts the female from the rear or back, and in both reptiles and birds the cloacal openings are pressed closely together to form a continuous passage from one individual to the other. With one exception, the archaic tuatara (*Sphenodon*) of New Zealand, all present-day reptiles have an erectile penis, derived from the cloacal wall, that delivers the sperm into the proper duct. One mating may serve for a long time, and there are cases known in which female snakes have laid fertile eggs after months and sometimes years of isolation in captivity. On the other hand, a penis of any sort is lacking in most kinds of birds, and the pressing together of the cloacal apertures seems to serve well enough. The most advanced copulatory procedure is that of mammals. In mammals the cloaca has become replaced by separate openings for the reproductive duct and intestine, respectively. Eggs have become microscopic, devoid of shell, yolk, and virtually all albumen, although they still need to be fertilized as they enter the upper end of the oviduct. A well-developed, erectile penis is always present in the male for the ejaculation of stored sperm well up the reproductive passage of the female. Accordingly, the two sexes have become strikingly differentiated anatomically, with regard to delivery of sperm, compared with the seemingly primitive anatomical equipment of birds.

Courtship. The coming together of two members of the opposite sex is a necessary preliminary to mating. It may be accomplished by two individuals independently of any larger congregation, or it may result from two individuals pairing off within a breeding population that may have assembled even from the ends of the earth. In the one the problem is to find one another; in the other the problem is to find the appropriate place, called the staging area. In both cases timing and some sort of navigation are important. Mass assembly appears to be the more effective, although a local crowd of any kind of animal may be an open invitation to predators, human or otherwise, and may on occasion become disastrous.

The searching out of a solitary individual by another of the opposite sex can be a difficult matter. In the dark depths of the ocean, for instance, where fish and other marine life forms are extremely scarce and scattered, the chance of encounter is rare indeed. The small angler fish (*Photocorynus spiniceps*) that cruise around at great depths are most unlikely to meet a member of the opposite sex at a time or place when the female happens to be ready to shed her eggs. As a form of insurance to this end, however, any small, young male that happens to meet a large female, apparently at any time, immediately fastens on to her head or sides by his jaws and thereafter lives a totally parasitic existence sustained by the juices of the female body. Sperm thus becomes available at any time the female may produce eggs to be fertilized.

On land this individual procedure of searching out is common among insects and the more predatory mammals. Male crickets and cicadas sound their familiar signals, by night or by day, which attract any females within hearing distance. More remarkable are those insects and other creatures that produce living light, in some cases for no apparent purpose but in others, such as the firefly, for signalling between the sexes in the dark of summer nights. The male individuals, always more dispensable than females, fly freely at considerable risk, flashing their light at regular intervals. The light of the female, perched more safely on some tall grass, winks back as though it were a landing light, and so they come together. Each of the several species of firefly has its own flash code, or rhythm, and any wasteful attempt at interspecies mixing is avoided. On the same principle, female moths send their personal perfume into the night air, and those males that detect the scent fly toward the source, the winner taking all. Mammals also depend mainly on their sense of smell, being generally colour blind, not too attentive to sound, and, apart from the grazing and browsing creatures, mainly active at night. The scented sex appeal of a cat in heat, whether domestic or wild, excites all the males in the neighbourhood and, with or without the sound of voice, male and female come quickly together in the dark. In all of these, courting is mostly uncalled for since only ready-to-mate individuals are involved in this sexual searching in the dark.

Sexual attractants

Courting is necessary whenever the male is a supplicant. A female may not be ready to mate, and stimulation in the form of dance or song may be required to create the mood; or, as is commonly the case, there is a surplus of available and eager males, and one must be chosen among many. However it may be, courting is most practiced not only when the female is in command of the final outcome but also when the mating procedure presents certain difficulties. A small male spider dances before a larger and ever ravenous female in an effort to induce her sexual interest rather than her hunger. Birds especially, however, depend on courtship as a preliminary to mating. The mating of birds represents copulation in its simplest form, without benefit of significant anatomical devices. Bird wings are a poor substitute for arms in a sexual embrace. Consequently the fullest cooperation between male and female is essential to success. In most birds a long-lasting, often lifetime, bonding becomes established between a male and female, a bonding that is usually reinforced by ritual behaviour at certain intervals, particularly during the onset of each breeding season and on various occasions when the individuals meet after short periods of separation. In some species a new mate may be taken each season or, as in sparrows, a general promiscuity may prevail.

One important aspect of courtship concerns the question of recognition. In gull colonies, for instance, members of the opposite sex look very much alike, and, at least to humans, the various individuals of one sex or the other may appear exactly the same. The advantages, with regard to successful production, incubation, and rearing of eggs and young, of permanent or semipermanent mate selection, however, are as great in gull colonies as elsewhere. The preliminaries to such a mutual selection not only establish a bond, by various posturings, but also establish the many small idiosyncrasies of action that add up to individuality and make one bird distinguishable among many within a colony, at least to its mate.

Many different forms of sex-oriented behaviour have consequently evolved among birds, depending on the character and particular needs of the various species. Penguins apparently not only look alike to human observers but also to themselves. Penguins seemingly have trouble even distinguishing between the sexes. Being unable to dance or sing, though they can make a lot of noise, male penguins can do little more than offer a pebble to a prospective female. If she accepts it as a token contribution to nest making, the match is on. If it is rejected, the suitor may have picked an unready female or even another male. In the case of most birds, however, the male can either sing, particularly the smaller kinds, or can strut and dance, with wings and feathers displayed, and some species, such as the lyre bird, continue to enchant the female by sight and sound together. In general, the need for physical mating has led to courtship and an emotional bonding between mating pairs throughout much of the animal kingdom at the higher level, particularly among birds and mammals. These are primarily utilitarian functions relating to the survival of the species, but in their fullest expression they represent what seem to man to be among the finest attributes of life.

SEX PATTERNS

Since the great value of sex as distinct from reproduction is the reassortment and recombination of genes every generation, sex cells from two separate parents ordinarily give rise to the greatest variaton, unless the parental individuals are themselves too closely related to each other. The presence of male and female individuals, respectively, generally produced in approximately equal numbers, is characteristic of so much of the animal kingdom that it appears to be the natural state. All that is certain, however, is that this condition has evolved as the most effective means to the particular end, and it may have done so independently among the various more or less unrelated groups of animals. The condition of separate sexes is not a universal fact, and two sexes within the same individual is typical of the more sluggish or actually attached kinds of animal life. Earthworms, slugs, land snails, flatworms, tapeworms, barnacles, sea squirts, and some others are all double-sexed individuals, or hermaphrodites. All have ovaries and testes producing mature eggs and sperm at the same time. Nevertheless, cross-fertilization is accomplished, and self-fertilization, even though possible, is generally avoided. Of those kinds of animal life mentioned above, all except the sea squirts have well-encased eggs that need to be fertilized before being laid. Mutual copulation, whereby each member of a mating pair of individuals introduces sperm into the body of the other member, is characteristic of these creatures, with the exception of the sea squirts.

Hermaphrodites

When animals shed sperm and comparatively naked eggs into the surrounding water, as is the case in sea squirts, self-fertilization is difficult to avoid. Most creatures have evolved an effective separation of the sexes between different individuals. Even so, there are more ways than one of accomplishing this. The common means is to produce male and female individuals that are constitutionally different, yet an equally effective procedure is for all individuals to be constitutionally the same but to become mature as male or female at different stages of the growth cycle. The oyster on its rock changes sex from male to female and back again once or twice a year. Certain shrimps also are hermaprodites. Each young shrimp of this kind grows up to be a male and is fully and functionally a male when about half the size of the females. As the next season approaches, his testes shrink, no more spermatozoa are produced, and ovaries begin to enlarge. As full growth is reached, the shrimp that had been a male becomes a typical female, ready to mate again, but this time with a young male of a newer generation. The system works as well as any other and clearly has its points. In fact the hagfish, not a true fish but a more primitive jawless vertebrate, also changes sex regularly, from year to year.

Sex differences in animals. In many animals, sexual differences are apparent in addition to the primary sex differentiation into males with testes and females with ovaries and apart from the accessory structures and tissues associated with the presence of one kind of sex gland or the other. Secondary sex differentiation in sexually distinct individuals is to be seen in many forms. In humans, for example, the beard and deep voice of the male and the enlarged breasts of the female are features of this sort. The great claw of the fiddler crab, the antlers of a moose, the great bulk and strength of a harem master in a fur seal colony, the beautiful fan tail of the peacock, and the bright feathers of other birds, are all distinctively male characteristics, and all are associated with the sexual drive of males. Females, by and large, are of comparatively quiet disposition and relatively drab appearance. Their function is to produce and nurture eggs, as safely and usually as inconspicuously as possible. The male function is to find and fertilize the female, for which both drive and display are generally required.

It is the business of sperm to be active and so find an egg. Similarly it is the busines of males to find a female and mate with her if possible. The male drive, or male eagerness, is a consequence of this special function of males. In nature, males possessing a strong eagerness to mate will find more females and leave more progeny than males lacking in sex drive. The progeny moreover will tend to inherit the drive of the parent. Males therefore are generally competitive with other males, with a premium placed on physical strength and sex drive and also on various devices for the attraction and stimulation of the female. The various exclusively male features already listed are all examples of characteristics of this sort, and they are related to the securing of female mates rather than the actual fertilization of eggs or to the problems of survival and adaptation.

Seasonal or periodic sexual cycles. In most animals sexual reproduction is seasonal or rhythmical, and so is sexual behaviour, whether in the form of courtship, drive, or other activities that lead to mating. In the marine fireworm of the West Indies, for instance, individuals of both sexes live in crevices on the sea floor but come out to breed where their fertilized eggs can drift and develop in the water above. But they can only find one another by means of the luminescence they themselves produce, which is an eerie light visible only in complete darkness. Each spring or summer month they emerge and swim to the surface about one-half hour after sunset when all daylight is gone but only before the moon can rise, a situation that confines them to a monthly breeding period of three or four days after the full of the moon. They follow a lunar rhythm. So do the grunion, a common fish along the southern California coast. Here again mating takes place when all is dark and the tide is high. Pairing occurs in the wash of the waves on the sand; fertilized eggs become immediately buried and there develop until the next high spring tides reach and wash the upper level sand nearly two weeks later. The mysterious biological clocks that apparently all living things possess adjust the rhythms of life to the needs of the particular organism. Some of these timing processes call internal signals on a regular day and night basis; others, on a somewhat longer cycle that keeps pace with the moon rather than the sun; and many, especially in the larger animals, run on a seasonal, or annual, cycle. Many activities are brought into line with the regular changes occurring in the environment. Sex and reproduction, however, are adjusted mainly with regard

Biological control of sexual cycles

to two functions; namely, safety while mating, which is therefore commonly in the dark, and the launching of the new generation at a time or season when circumstances are most favourable.

Birds lay eggs, and most mammals deliver their young in early spring, when the months ahead are warm and food is plentiful. Sex for the most part is adjusted to this end. Among the mammals, for example, the period of development within the womb varies greatly, from less than three weeks in the smallest to almost a year in the largest and certain others. Yet with few exceptions, the time for birth is in the spring. The time for mating in most cases is accordingly adjusted to this event: the larger the offspring at birth, the earlier the mating must take place. The horse and the great whales mate in spring and deliver in spring; roe deer mate in summer and deliver in spring; goat and sheep mate in the fall and deliver in spring. Even the elephant, which has a 22-month pregnancy, delivers in spring but must mate in early summer two years before. In small creatures, however, such as mice, rats, hamsters, and shrews, where the gestation, or pregnancy, period is about three weeks, reproduction is still seasonal, but there is time during the warmer months for several broods to be conceived and raised. In others, expediency may prevail, and mating may occur at a time to suit the convenience of the pairing animals. The little brown bat, for instance, mates in the fall, and yet ovulation does not take place until winter has passed; the spermatozoa survive the winter in the uterus and fertilize the eggs when they in turn arrive there five or six months later. In some other creatures mating occurs at a convenient time, eggs are fertilized, but development itself is suspended at an early stage for a time so that hatching or birthing, depending on the kind of animal, takes place when circumstances are suitable.

In all of this, the time of the mating season is clearly regulated, both with regard to the physiological condition of the animal and to the environmental conditions. The urge and capacity to mate depends on the ripeness of the gonads, male or female. In most animals, the reproductive glands wax and wane according to the seasons; that is, with an annual rhythm or else with a shorter cycle. Hormones are mainly in control of this rhythm. Sex hormones, male or female, respectively, are produced by the gonads themselves and cause or maintain their growth and at the same time cause the various secondary sexual characteristics of the male or female individual to become enhanced. Male hormone increases masculinity, even when injected into a female. Female canaries injected with male hormone no longer behave as females and shortly begin to sing loud and long and commence the courtship activities of a male. A hen thus injected grows a larger comb, starts to crow, and begins to strut.

Hormonal regulation of cycles

The production of these hormones is in turn controlled by hormones of the pituitary gland. Pituitary hormones stimulate ovarian or testicular tissue, which secretes the sex hormones. The sex hormones not only maintain the growth of the sexual tissues generally but inhibit the secretion of pituitary hormones, so that the process does not get out of hand. The pituitary activity, however, is also influenced by external conditions, particularly by stimuli received indirectly from light. The annual growth of ovaries or testes that occurs in late winter and early spring in frogs, reptiles, birds, and mammals is initiated by the steadily increasing period of daylight. In response to this changing day length, female frogs are packed with eggs and male frogs are ready to croak by the time the mating period arrives. The large eggs of reptiles and birds are ready to be fertilized, and the males are showing whatever they may have to display at the proper time. In mammals, the female comes into heat, the uterus undergoes the preparatory changes for taking care of fertilized eggs, and the male usually has but one thought in his mind. But as daylight ceases to lengthen, the sexual drive slowly diminishes.

SEX DETERMINATION

The determination of the sex of an individual, with regard to both the primary sex—*i.e.*, whether the ovaries or the testes develop—and the various secondary sexual characteristics may be rigorously controlled from the start of development or may be subject to later influences of a hormonal or environmental nature. However this may be, in order to appreciate the action of the control systems, the point of departure is that animals were primitively hermaphrodite, that during early stages of evolution every individual probably possessed both male and female gonads. Differentiation into separate sexes, each possessing male or female gonads but not both at the same time, is a device to ensure cross-fertilization of eggs, whether this is accomplished by having the two types of sexual gland mature at different stages of the growth of the individual, as in some shrimp and others, or whether by the production of two distinct types of individuals, as in most species of animals. This point of view is important because the question ceases to be how testes are caused to develop in the male organism and ovaries in the female but how, in a potentially double-sexed organism, the development of one or the other sex is suppressed. That such is the case is seen as clearly as anywhere in the human condition itself. Neither sex is completely male or female. Females have functional, well-developed mammary glands. Males also have mammary glands, undeveloped and nonfunctional although equipped with nipples. Males have a penis for delivering sperm, but females have a small, nonfunctional equivalent—the clitoris. These are secondary sexual features, to be sure, but the difference between the sexes is in the degree of their development, not a matter of absolute presence or absence.

Early development of reproductive systems in young animals

The basis for this is seen in the very beginnings of the development of the reproductive system, in frog, mouse, and man alike. In the young embryo a pair of gonads develop that are indifferent or neutral, showing no indication whether they are destined to develop into testes or ovaries. There are also two different duct systems, one of which can develop into the female system of oviducts and related apparatus and the other into the male sperm duct system. As development of the embryo proceeds, either the male or the female reproductive tissue differentiates in the originally neutral gonad of the mammal.

In the frog and other lower vertebrate animals, the picture is even clearer. The original gonad consists of an outer layer of cells and an inner core of cells. If the individual is to be a male, the central tissue grows at the expense of the outer layer. If it is to be a female, the outer tissue grows at the expense of the central core tissue. If both should grow, which is a possibility although a rare occurrence, the individual will be a hermaphrodite. Anything that influences the direction taken therefore may be said to determine sex.

Sex chromosomes. In most species of animals the sex of individuals is determined decisively at the time of fertilization of the egg, by means of chromosomal distribution. This process is the most clear-cut form of sex determination. When any cell in the body divides, except during the formation of the sex cells, each daughter cell receives the full complement of chromosomes; *i.e.*, copies of the two sets of chromosomes derived from the sperm cell and egg, respectively. The two sets are similar except for one pair of chromosomes. These are the so-called sex chromosomes, and the pair may be exactly alike or they may be obviously different, depending on the sex of the individual. The sex chromosomes are of two types, which are designated X and Y, and the pair of sex chromosomes may consist of two X chromosomes or of an X and Y paired together. In mammals (including man) and flies, the cells of males contain an XY pair and the cells of females contain an XX pair. On the other hand, in butterflies, fishes, and birds, the cells of females contain an XY pair and those of males contain an XX pair. In either case the Y chromosome is generally smaller than the X chromosome and may even be absent. What is most important concerning chromosomal sex determination is whether the cells of the individual contain one X chromosome or two X chromosomes. Human beings, for example, have cells with 22 pairs of nonsexual chromosomes, or autosomes, together with an XX pair or an XY pair. The female has a total of 46 functional chromosomes; the male has 45 plus a Y, which is mainly inert. Sex determination thus becomes a matter of balance. With one X chromosome plus the 44 autosomes in every cell, the whole course of development of primary and secondary sexual characteristics is toward the male; with two X chromosomes plus the autosomes in every cell, the whole system is swung over to the female.

The manipulation of this control system is readily accomplished during the special process of cell division that takes place in the gonads to produce sperm and eggs and their subsequent union at fertilization. In mammals, for example, since all cells in the female contain two X chromosomes, all the eggs will receive a single X chromosome when they are formed. All eggs are accordingly the same in this respect. In contrast, all cells in the male have the XY constitution, and therefore, when the double set of chromosomes is reduced to a single set during the formation of the spermatozoa, half of the spermatozoa will receive an X and half will receive a Y. Consequently, when an egg is fertilized by a sperm, the chances are about equal that the sperm will carry an X or will carry a Y, since the two types are inevitably produced in equal numbers. If it carries an X, the XX female constitution results; if a Y, then the XY male constitution results.

Abnormal chromosome effects. Occasionally, however, the processes of chromosomal reassortment and recombination occurring during sex cell formation and fertilization depart somewhat from the normal course. Sperm and eggs may be produced that are oversupplied or undersupplied with sex chromosomes. Fertilized eggs in humans may, for instance, have abnormal sex chromosome constitutions such as XXX, XXY, or XO. Those with the triple-X chromosome constitution have all the appearance of normal females and are called, in fact, superfemales, although only some will be fertile. Those with the XO (one X, but lacking Y altogether) constitution, a much more common condition, are also feminine in body form and type of reproduction system but remain immature. Individuals with the XXY constitution are outwardly males but have small testes and produce no spermatozoa. Those with the more abnormal and relatively rarer constitutions XXXXY and XXYY are typically mentally defective and in the latter case are hard to manage. Thus abnormal combinations generally result in an infertility on the one hand and an abnormal sexuality in the whole system, for either too little or too much of what is ordinarily good can be disastrous.

Very different kinds of abnormal development resulting from faulty chromosomal distribution are particularly observable in insects. The most common form in flies is an individual that is male on one side, female on the other, with a sharp line of demarcation. In other cases one-quarter of the body may be male and three-quarters female, or the head may be female and the rest of the body, male. These types are known as gynandromorphs, or sexual mosaics, and result from aberration in the distribution of the X chromosomes among the first cells to be formed during the early development of the embryo. This condition is unknown among higher animals.

Sexual mosaics

Parthenogenesis. The unfertilized, ripe egg possesses all the potentiality for full development. The process of fertilization by a spermatozoon introduces the nucleus of the male sex cell into the female egg, a process that increases the differences between parent and offspring and may determine the sex of the new individual and also stimulates the egg to begin development. These two functions are separate. Parthenogenetic development, without benefit of sperm, occurs naturally in various kinds of animals besides the waterflea (*Daphnia*), already described. Artificial, or experimental, parthenogenesis is readily brought about in many other species and by a variety of means. Mature, unfertilized eggs of starfish, sea urchins, various worms, and other marine invertebrate animals can be caused to develop by treatment with a weak organic acid. Unfertilized frog eggs can be readily caused to develop by gentle pricking of the egg surface with the tip of a fine glass needle that has been dipped in lymph. In nature the eggs of various creatures can develop with or without the aid of spermatozoa. The sex of parthenogenetically developed individuals, insofar as it depends on the chromosomal constitution of the developing egg, is consequently affected. Frog eggs developing parthenogenetically become males, since only one X chromosome is present in each cell. In nature, where varying conditions call for various responses, the system is usually more complicated, although based on the general relationship that individuals with the XX constitution will be female and those with a single X will be males. A queen honeybee, for instance, begins her reproductive life with a store of sperm received from a male during her nuptial flight. Throughout spring and summer almost all eggs become fertilized and develop into females (either as nonfertile female workers or as new fertile queens, depending on the nature of food received during growth). Toward the end of summer, when the sperm supply runs low, eggs cease to be fertilized and, when laid, develop into drones, ready to mate with a new queen should occasion arise. In other cases, even parthenogenetically developing eggs may become female individuals through a process of chromosome doubling, which takes place in the mature but unfertilized eggs. Thus certain wasps, waterfleas, and others are able to produce many exclusively female generations in succession.

Effects of environment. Sex chromosomes, however, do not determine sex directly but do so through their control of such cell activities as metabolism and hormone production. Their determinative influence, indirect though it is, may be complete. On the other hand, environmental conditions may play the dominating role. In the case of *Bonellia,* a unique kind of marine worm, all eggs develop into small larvae of a sexually indifferent kind. Those that settle freely on the sea floor grow into comparatively large females, each of which has a long, broad extension, the proboscis, at its front end. Those larvae that happen to settle on the proboscis of a female, however, fail to grow beyond a certain minute size and become dwarf males, permanently attached to the female body. The sex-determining factor appears to be the environmental carbon dioxide tension, which is relatively high at the surface of living tissue.

Hormones. Because in most developing animals the reproductive gland is essentially neutral to begin with, there is generally some possibility that agents external to the gland, particularly chemical agents—*i.e.*, hormones—circulating in the blood system, may override the sex-determining influence of the sex chromosomes. In the chick, for example, the sex can be controlled experimentally by such means until about four hours after hatching. If a female chick is injected on hatching with the male sex hormone, testosterone, it will develop into a fully functional cock. Even when injected at later stages of growth, the male hormone causes extra early growth of the comb, crowing, and aggressive behaviour after being injected in either male or female chicks. Female sex hormones, such as estrogen, on the other hand, stimulate early growth of the oviduct in the female and feminize the plumage and suppress comb growth when injected in the male.

This susceptibility of the reproductive glands, and sexuality in general, to the influence of sex hormones is particularly acute in mammals, where the egg and embryo, unprotected by any shell, develop in the uterus exposed to various chemicals filtering through from the maternal blood stream. A developing embryo eventually produces its own sex hormones, but they are not manufactured in any quantity until the anatomical sex of the embryo is already well established. One of the curious things about sex hormones, however, is that the reproductive glands are not the only tissues that produce them. The placenta, through which all exchange between fetus and mother takes place, itself produces tremendous amounts of female sex hormone, together with some male hormone, which are excreted by the mother during pregnancy. This condition is true of humans, as well as of mice and rats. As a rule these hormones are produced too late to do any harm, but not always. The female embryo is fairly immune inasmuch as additional female hormone merely causes a child to be more feminine than usual at an early age. Male embryos, however, may be seriously affected if the female hormone catches them at an early stage. Boy babies may be born that are truly males but under the impact of the feminizing hormone appear superficially to be

Production and effects of sex hormones in mammals females and are often raised as such. As a rule, even when older, they have more or less sterile, undescended testes; an imperfect penis; well-developed breasts; an unbroken voice; and no beard. One in a thousand may be like this and on occasion may have won in women's Olympic competitions. In other cases, those somewhat less severely affected, during adolescence when the hidden testes begin to secrete their own male hormones in abundance, the falsely female characteristics become suppressed, and the voice, beard, breasts, and sexual interest take on the pattern of the male. What were thought to be girls in their youth change into the men they were meant to be upon reaching maturity. (N.J.B.)

Human beings

Human sexual behaviour may be defined as any activity—solitary, between two persons, or in a group—that induces sexual arousal. There are two major determinants of human sexual behaviour: the inherited sexual response patterns that have evolved as a means of ensuring reproduction and that are a part of each individual's genetic inheritance, and the degree of restraint or other types of influence exerted on the individual by society in the expression of his sexuality. The objective here is to describe and explain both sets of factors and their interaction.

It should be noted that taboos in Western culture and the immaturity of the social sciences for a long time impeded research concerning human sexual behaviour, so that by the early 20th century scientific knowledge was largely restricted to individual case histories that had been studied by such European writers as Sigmund Freud, Havelock Ellis, and Richard, Freiherr von Krafft-Ebing. By the 1920s, however, the foundations had been laid for the more extensive statistical studies that were conducted before World War II in the United States. Of the two major organizations for sex study, one, the Institut für Sexualwissenschaft in Berlin (established in 1897), was destroyed by the Nazis in 1933. The other, the Institute for Sex Research, begun in 1938 by the American sexologist Alfred Charles Kinsey at Indiana University, Bloomington, undertook the study of many aspects of human sexual behaviour. Much of the following discussion rests on the findings of the Institute for Sex Research, which comprise the most comprehensive data available. The only other country for which comprehensive data exist is Sweden.

TYPES OF BEHAVIOUR

Human sexual behaviour may conveniently be classified according to the number and gender of the participants. There is solitary behaviour involving only one individual, and there is sociosexual behaviour involving more than one person. Sociosexual behaviour is generally divided into heterosexual behaviour (male with female) and homosexual behaviour (male with male or female with female; see *Homosexuality* below.) If three or more individuals are involved it is, of course, possible to have heterosexual and homosexual activity simultaneously.

In both solitary and sociosexual behaviour there may be activities that are sufficiently unusual to warrant the label deviant behaviour. The term deviant should not be used as a moral judgment but simply as indicating that such activity is not common in a particular society. Since human societies differ in their sexual practices, what is deviant in one society may be normal in another.

Solitary behaviour. Self-masturbation is self-stimulation with the intention of causing sexual arousal and, generally, orgasm (sexual climax). Most masturbation is done in private as an end in itself but is sometimes practiced to facilitate a sociosexual relationship.

Masturbation, generally beginning at or before puberty, is extremely common in males, particularly among young males, but becomes less frequent or is even abandoned when sociosexual activity is available. Consequently, masturbation is most frequent among the unmarried. Fewer females masturbate; in the United States, roughly one-half to two-thirds have done so, as compared to nine out of ten males. Females also tend to reduce or discontinue masturbation when they develop sociosexual relationships. There is great individual variation in frequency, so that it is impractical to try to define what range could be considered "normal."

Attitudes toward masturbation

The myth persists, despite scientific proof to the contrary, that masturbation is physically harmful. Neither is there evidence that masturbation is immature behaviour; it is common among adults deprived of sociosexual opportunities. While solitary masturbation does provide pleasure and relief from the tension of sexual excitement, it does not have the same psychological gratification that interaction with another person provides; thus, extremely few people prefer masturbation to sociosexual activity. The psychological significance of masturbation lies in how the individual regards it. For some, it is laden with guilt; for others, it is a release from tension with no emotional content; and for others it is simply another source of pleasure to be enjoyed for its own sake.

The majority of males and females have fantasies of some sociosexual activity while they masturbate. The fantasy not infrequently involves idealized sexual partners and activities that the individual has not experienced and even might avoid in real life.

Since the masturbating person is in sole control of the areas that are stimulated, the degree of pressure, and the rapidity of movement, masturbation is often more effective in producing sexual arousal and orgasm than is sociosexual activity, during which the stimulation is determined to some degree by one's partner.

Orgasm in sleep evidently occurs only in humans. Its causes are not wholly known. The idea that it results from the pressure of accumulated semen is invalid because not only do nocturnal emissions sometimes occur in males on successive nights, but females experience orgasm in sleep as well. In some cases orgasm in sleep seems a compensatory phenomenon, occurring during times when the individual has been deprived of or abstains from other sexual activity. In other cases it may result from external stimuli, such as sleeping prone or having night clothing caught between one's legs. Most orgasms during sleep are accompanied by erotic dreams.

A great majority of males experience orgasm in sleep. This almost always begins and is most frequent in adolescence, tending to disappear later in life. Fewer females have orgasm in sleep, and, unlike males, they usually begin having such experience when fully adult.

Orgasm in sleep is generally infrequent, seldom exceeding a dozen times per year for males and three or four times a year for the average female.

Most sexual arousal does not lead to sexual activity with another individual. Humans are constantly exposed to sexual stimuli when seeing attractive persons and are subjected to sexual themes in advertising and the mass media. Response to such visual and other stimuli is strongest in adolescence and early adult life and usually gradually declines with advancing age. One of the necessary tasks of growing up is learning to cope with one's sexual arousal and to achieve some balance between suppression, which can be injurious, and free expression, which can lead to social difficulties. There is great variation among individuals in the strength of sex drive and responsiveness, so this necessary exercise of restraint is correspondingly difficult or easy.

Sociosexual behaviour. By far the greatest amount of sociosexual behaviour is heterosexual behaviour between only one male and one female. Heterosexual behaviour frequently begins in childhood, and, while much of it may be motivated by curiosity, such as showing or examining genitalia, many children engage in sex play because it is pleasurable. The sexual impulse and responsiveness are present in varying degrees in most children and latent in the remainder. With adolescence, sex play is superseded by dating, which is socially encouraged, and dating almost inevitably involves some physical contact resulting in sexual arousal. This contact, labelled necking or petting, is a part of the learning process and ultimately of courtship and the selection of a marriage partner.

Petting and foreplay

Petting varies from hugging, kissing, and generalized caresses of the clothed body to techniques involving genital stimulation. Petting may be done for its own sake as an expression of affection and a source of pleasure, and it may occur as a preliminary to coitus. This last form of petting is known as foreplay. In a minority of cases, but a substantial minority, petting leads to orgasm and may be a substitute for coitus. Excluding foreplay, petting is usually very stereotyped, beginning with hugging and kissing and gradually escalating to stimulation of the breasts and genitalia. In most societies petting and its escalation are initiated by the male more often than by the female, who generally rejects or accepts the male's overtures but refrains from playing a more aggressive role. Petting in some form is a near-universal human experience and is valuable not only in mate selection but as a means of learning how to interact with another person sexually.

Coitus, the insertion of the penis into the vagina, is viewed by society quite differently depending upon the marital status of the individuals. The majority of human societies permit premarital coitus, at least under certain circumstances. In more repressive societies, such as modern Western society, it is more likely to be tolerated (but not encouraged) if the individuals intend marriage. Marital coitus is usually regarded as an obligation in most societies. Extramarital coitus, particularly by wives, is generally condemned and, if permitted, is allowed only under exceptional conditions or with specified persons. Societies tend to be more lenient toward males than females regarding extramarital coitus. This double standard of morality is also seen in premarital life. Postmarital coitus (*i.e.*, coitus by separated, divorced or widowed persons) is almost always ignored. Even societies that try to confine coitus to marriage recognize the difficulty of trying to force abstinence upon sexually experienced and usually older persons.

In the United States and much of Europe, there has been, within the last century, a progressive trend toward an increase in premarital coitus. Currently in the United States, at least three-quarters of the males and over half of the females have experienced premarital coitus. The proportions for this experience vary in different groups and socioeconomic classes. In Scandinavia, the incidence of premarital coitus is far greater, exceeding the 90 percent mark in Sweden, where it is now expected behaviour.

Extramarital coitus continues to be openly condemned but is becoming more tolerated secretly, particularly if mitigating circumstances are involved. In some areas, such as southern Europe and Latin America, extramarital coitus is expected of most husbands and is accepted by society if the behaviour is not too flagrant. The wives do not generally approve but are resigned to what they believe to be a masculine propensity. In the United States, where at least half the husbands and one-quarter of the wives have extramarital coitus at some point in their lives, there have recently developed small organizations or clubs that exist to provide extramarital coitus for married couples. Despite the publicity they have engendered, however, extremely few individuals have belonged to such organizations. Most extramarital coitus is done secretly without the knowledge of the spouse. Most husbands and wives feel very possessive of their spouses and interpret extramarital activity as an aspersion on their own sexual adequacy, as indicating a loss of affection and as being a source of social disgrace.

Human beings are not inherently monogamous but have a natural desire for diversity in their sexuality as in other aspects of life. Some societies have provided a release for these desires by suspending the restraints on extramarital coitus on special occasions or with certain individuals, and in modern Western society a certain amount of extramarital flirtation or mild petting at parties is not considered unusual behaviour.

Sexuality in ceremony and religion

Discussion of sociosexual behaviour would be incomplete without some note of the role it has played in ceremony and religion. While the major religions of today are to varying degrees antisexual, many religions have incorporated sexual behaviour into their rites and ceremonies. The ancient and continuing interest of man in the fertility of food plants, animals, and himself makes such a connection between sex and religion inevitable, particularly among peoples with uncertain food supplies. In most religions the deities were considered to have active sexual lives and sometimes took a sexual interest in humans. In this regard it is noteworthy that in Christianity sexual behaviour is absent in heaven and sexual proclivities are ascribed only to evil supernatural beings: Satan, devils, incubi, and succubi (spirits or demons who seek out sleeping humans for sexual intercourse).

Whether or not a behaviour is interpreted by society or the individual as erotic (*i.e.*, capable of engendering sexual response) depends chiefly on the context in which the behaviour occurs. A kiss, for example, may express asexual affection (a mother kissing a child or a kiss between relatives), respect (as a French officer kissing a soldier after bestowing a medal on him), reverence (kissing the hand or foot of a pope), or it may be a casual salutation and social amenity. Even something as specific as touching genitalia is not construed as sexual if done for medical reasons. In other words, the apparent motivation of the behaviour determines its interpretation.

Individuals are extremely sensitive in judging motivations: a greeting kiss, if protracted more than a second or two, takes on a sexual connotation, and recent studies show that if an adult male at a party stands closer than the length of his hand and forearm to a female, she generally imputes a sexual motive to his proximity. Nudity is construed as erotic or even as a sexual invitation—unless it occurs in a medical context, in a group consisting of but one gender, or in a nudist camp.

PHYSIOLOGICAL ASPECTS

Sexual response. Sexual response follows a pattern of sequential stages or phases when sexual activity is continued. First, there is the excitement phase marked by increase in pulse and blood pressure, an increase in blood supply to the surface of the body resulting in increased skin temperature, flushing, and swelling of all distensible body parts (particularly noticeable in the penis and female breasts), more rapid breathing, the secretion of genital fluids, vaginal expansion, and a general increase in muscle tension. These symptoms of arousal eventually increase to a near maximal physiological level, the plateau phase, which is generally of brief duration. If stimulation is continued, orgasm usually occurs. Orgasm is marked by a feeling of sudden intense pleasure, an abrupt increase in pulse rate and blood pressure, and spasms of the pelvic muscles causing vaginal contractions in the female and ejaculation by the male. Involuntary vocalization may also occur. Orgasm lasts for a few seconds (normally not over ten), after which the individual enters the resolution phase, the return to a normal or subnormal physiological state. Up to the resolution phase, males and females are the same in their response sequence, but, whereas males return to normal even if stimluation continues, continued stimulation can produce additional orgasms in females. In brief, after one orgasm a male becomes unresponsive to sexual stimulation and cannot begin to build up another excitement phase until some period of time has elapsed, but females are physically capable of repeated orgasms without the intervening "rest period" required by males.

Genetic and hormonal factors. While all normal individuals are born with the neurophysiology necessary for the sexual-response cycle described above, inheritance determines the intensity of their responses and their basic "sex drive." There is great variation in this regard: some persons have the need for frequent sexual expressions; others require very little; and some persons respond quickly and violently, while others are slower and milder in their reactions. While the genetic basis of these differences is unknown and while such variations are obscured by conditioning, there is no doubt that sexual capacities, like all other physiological capacities, are genetically determined. It is unlikely, however, that genes control the sexual orientation of normal humans in the sense of individuals being predestined to become homosexual or heterosexual. Some severe genetic abnormality can, of course, profoundly affect intelligence, sexual capacity, and physical appearance and hence the entire sexual life.

While the normal female has 44 autosomes plus two X-chromosomes (female) and the normal male 44 autosomes plus one X-chromosome and one Y-chromosome

Genetic combinations in the sexes

(male), many genetic abnormalities are possible. There are females, for example, with too many X-chromosomes (44+XXX) or too few (44+X) and males with an extra female chromosome (44+XXY) or an extra male chromosome (44+XYY). No 44+YY males exist—an X-chromosome is necessary for survival, even in the womb.

One's genetic makeup determines one's hormonal status and the sensitivity of one's body to these hormones. While a disorder of any part of the endocrine system can adversely affect sexual life, the hormones most directly influencing sexuality are the androgens (male sex hormones), produced chiefly in the testicles, and the estrogens (female sex hormones), produced chiefly in the ovaries. In early embryonic life there are neither testicles nor ovaries but simply two undifferentiated organs (gonads) that can develop either into testicles or ovaries. If the embryo has a Y-chromosome, the gonads become testicles; otherwise, they become ovaries. The testicles of the fetus produce androgens, and these cause the fetus to develop male anatomy. The absence of testicles results in the development of female anatomy. Animal experiments show that, if the testicles of a male fetus are removed, the individual will develop into what seems a female (although lacking ovaries). Consequently, it has been said that humans are basically female.

After birth and until puberty, the ovaries and testicles produce comparatively few hormones, and little girls and boys are much alike in size and appearance. At puberty, however, these organs begin producing in greater abundance, with dramatic results. The androgens produced by boys cause changes in body build, greater muscular development, body and facial hair, and voice change. In girls the estrogens cause breast development, menstruation, and feminine body build. A boy castrated before puberty does not develop masculine physical characteristics and manifests in adult life more of a feminine body build, lack of masculine body and facial hair, less muscular strength, a high voice, and small genitalia. A girl who has her ovaries removed before puberty is less markedly altered but retains a childlike body build, does not develop breasts, and never menstruates. Castrated individuals or persons producing insufficient hormones can be restored to a normal condition by administration of appropriate hormones.

Beyond their role in developing the secondary sexual characteristics of the body, the hormones continue to play a role in adult life. An androgen deficiency causes a decrease in a man's sexual responsiveness, and an estrogen deficiency adversely affects a woman's fertility and causes atrophy of the genitalia. A loss of energy may also result in both men and women.

Role of androgen and estrogen

Androgen seems linked in both males and females with aggressiveness and strength of sexual drive. When androgen is given to a female in animal experiments, she becomes more aggressive and displays behaviour more typical of males—by mounting other animals, for example. Estrogen increases her sexual responsiveness and intensifies her female behaviour. Androgen given to a male often increases his sexual behaviour, but estrogen diminishes his sex drive.

In humans the picture is more complex, since human sexual behaviour and response is less dependent on hormones once adulthood has been reached. Removing androgen from an adult male reduces his sexual capacity; but this occurs gradually, and sometimes the reduction is small. Giving androgen to a normal human male generally has little or no effect since he is already producing all he can use. Giving him estrogen reduces his sex drive. Administration of androgen to an adult human female often increases her sex drive, enlarges her clitoris, and promotes the growth of facial hair. Giving estrogen to a normal woman before menopausal age generally has no effect whatsoever—probably because human females, unlike other female mammals, do not have hormonally controlled periods of "heat" (estrus).

Hormones have no connection with the sexual orientation of humans. Male homosexuals do not have more estrogens than normal males (who have a little) nor can their preferences be altered by giving them androgen.

Nervous system factors. The nervous system consists of the central nervous system and the peripheral nervous system. The brain and spinal cord constitute the central system, while the peripheral system is composed of (1) the cerebrospinal nerves that go to the spinal cord (afferent nerves), transmitting sensory stimuli and those that come from the cord (efferent nerves) transmitting impulses to activate muscles, and (2) the autonomic system, the primary function of which is the regulation and maintenance of the body processes necessary to life, such as heart rate, breathing, digestion, and temperature control. Sexual response involves the entire nervous system. The autonomic system controls the involuntary responses; the afferent cerebrospinal nerves carry the sensory messages to the brain; the efferent cerebrospinal nerves carry commands from the brain to the muscles; and the spinal cord serves as a great transmission cable. The brain itself is the coordinating and controlling centre, interpreting what sensations are to be perceived as sexual and issuing appropriate "orders" to the rest of the nervous system.

The parts of the brain thought to be most concerned with sexual response are the hypothalamus and the limbic system, but no specialized "sex centre" has been located in the human brain. Animal experiments indicate that each individual has coded in its brain two sexual response patterns, one for mounting (masculine) behaviour and one for mounted (feminine) behaviour. The mounting pattern can be elicited or intensified by male sex hormone and the mounted pattern by female sex hormone. Normally, one response pattern is dominant and the other latent but capable of being called into action when suitable circumstances occur. The degree to which such inherent patterning exists in humans is unknown.

While the brain is normally in charge, there is some reflex (*i.e.*, not brain-controlled) sexual response. Stimulation of the genital and perineal area can cause the "genital reflex": erection and ejaculation in the male, vaginal changes and lubrication in the female. This reflex is mediated by the lower spinal cord, and the brain need not be involved. Of course, the brain can override and suppress such reflex activity—as it does when an individual decides that a sexual response is socially inappropriate.

Development and change in the reproductive system. One's anatomy and sexuality change with age. The changes are rapid in intra-uterine life and around puberty but are much slower and gradual in other phases of the life cycle.

Intra-uterine sexual development

The reproductive organs first develop in the same form for both males and females: internally there are two undifferentiated gonads and two pairs of parallel ducts (Wolffian and Müllerian ducts); externally there is a genital protrusion with a groove (urethral groove) below it, the groove being flanked by two folds (urethral folds). On either side of the genital protrusion and groove are two ridgelike swellings (labioscrotal swellings). Around the fourth week of life the gonads differentiate into either testes or ovaries. If testes develop, the hormone they secrete causes the Müllerian duct to degenerate and almost vanish and causes the Wolffian duct to elaborate into the sperm-carrying tubes and related organs (the vas deferens, epididymis, and seminal vesicles, for example). If ovaries develop, the Wolffian duct deteriorates, and the Müllerian duct elaborates to form the fallopian tubes, uterus, and part of the vagina. The external genitalia simultaneously change. The genital protrusion becomes either a penis or clitoris. In the female the groove below the clitoris stays open to form the vulva, and the folds on either side of the groove become the inner lips of the vulva (the labia minora). In the male these folds grow together, converting the groove into the urethral tube of the penis. The ridgelike swellings on either side remain apart in the female and constitute the large labia (labia majora), but in the male they grow together to form the scrotal sac into which the testes subsequently descend.

At the time of birth both male and female have all the neurophysiological equipment necessary for sexual response, although the reproductive system is not at this stage functional. Sexual interests, sexual behaviour, and sexual response are seen with increasing frequency in most children from infancy on. Even newborn males have penile erections, and babies of both sexes seem to find some pleasure in genital stimulation. What appears to be orgasm has been observed in infant boys and girls, and, later in childhood, orgasm definitely can occur in self-masturbation or sex play.

Puberty may be defined as that short period of time (generally two years) during which the reproductive system matures and the secondary sexual characteristics appear. The ovaries and testes begin producing much larger amounts of hormones, pubic hair appears, female breasts develop, the menstrual cycle begins in females, spermatozoa and viable eggs are produced, and males experience voice change and a sudden acceleration in growth. Puberty generally occurs in females around age 12–13 and in males at about 13–14, but there is much individual variation. With puberty there is generally an intensification or the first appearance of sexual interest. Puberty marks the beginning of adolescence.

Adolescence, from a physical viewpoint, is that period between puberty and the attainment of one's maximum height. By the latter point, which occurs around age 16 in females and 18 in males, the individual has adult anatomy and physiology. In late adolescence the majority of individuals are probably at their peak in terms of sexual capacity: the ability to respond quickly and repeatedly. During this period the sex drive is at its maximum in males, although it is difficult to say whether this is also true of females, since female sexuality, in many societies, is frequently suppressed during adolescence.

Following adolescence there are about three decades of adult life during which physiological changes are slow and gradual. While muscular strength increases for a time, the changes may best be described as slow deterioration. This physical decline is not immediately evident in sexual behaviour, which often increases in quantity and quality as the individual develops more social skills and higher socio-economic status and loses some of the inhibitions and uncertainties that often impede adolescent sexuality. Indeed, in the case of the United States female, the deterioration is more than offset by her gradual loss of sexual inhibition, and the effect of age is not clear until menopausal symptoms begin. In the male, however, there is no such masking of deterioration, and the frequency of sexual activity and the intensity of interest and response slowly, but inexorably, decline.

Sexual changes in later life

If one must arbitrarily select an age to mark the beginning of old age, 50 is appropriate. By then, most females have experienced menopausal symptoms, and most males have been forced to recognize their increasing physical limitations. With menopause, the female genitalia gradually begin to atrophy and the amount of vaginal secretion diminishes—this is the direct consequence of the cessation of ovarian function and can be prevented, or the symptoms reversed, by administering estrogen. If a female has had a good sexual adjustment prior to menopause and if she does not believe in the fallacy that it spells the end of sexual life, menopause will have no adverse effect on her sexual and orgasmic ability. There is reason to believe that if a woman remains in good health and genital atrophy is prevented, she could enjoy sexual activity regardless of age. Males in good health are also capable of continuing sexual activity, although with an ever-decreasing frequency, throughout old age. The male has more difficulty in achieving erection, cannot maintain erection as long, and must have longer and longer "rest periods" between sexual acts. The amount of ejaculate becomes less, but most old males are still fertile. The Cowper's gland secretion (called "precoital mucus") diminishes or disappears entirely. According to Kinsey's data, about one-quarter of males are impotent by age 65, one-half by age 75, and three-quarters by age 80. One must remember, however, that some unknown but certainly substantial proportion of this impotence may be attributed to poor health.

In general, the female withstands the onslaughts of age better than the male. The reduction in the frequency of marital intercourse or even its abandonment is more often than not the result of male deterioration.

PSYCHOLOGICAL ASPECTS

Effects of early conditioning. Physiology sets only very broad limits on human sexuality; most of the enormous variation found among humans must be attributed to the psychological factors of learning and conditioning.

The human infant is born simply with the ability to respond sexually to tactile stimulation. It is only later and gradually that the individual learns or is conditioned to respond to other stimuli, to develop a sexual attraction to males or females or both, to interpret some stimuli as sexual and others as nonsexual, and to control in some measure his or her sexual response. In other words, the general and diffuse sexuality of the infant becomes increasingly elaborated, differentiated, and specific.

The early years of life are, therefore, of paramount importance in the development of what ultimately becomes adult sexual orientation. There appears to be a reasonably fixed sequence of development. Before age five, the child develops a sense of gender identity, thinks of himself or herself as a boy or girl, and begins to relate to others differently according to their gender. Through experience the child learns what behaviour is rewarded and what is punished and what sorts of behaviour are expected of him or her. Parents, peers, and society in general teach and condition the child about sex not so much by direct informational statements and admonitions as by indirect and often unconscious communication. The child soon learns, for example, that he can touch any part of his body or someone else's body except the anal–genital region. The child rubbing its genitals finds that this quickly attracts adult attention and admonishment or that adults will divert him or her from this activity. It becomes clear that there is something peculiar and taboo about this area of the body. This "genital taboo" is reinforced by the great concern over the child's excretory behaviour: bladder and bowel control is praised; loss of control is met by disappointment, chiding, and expressions of disgust. Obviously, the anal–genital area is not only a taboo area but a very important one as well. It is almost inevitable that the genitalia become associated with anxiety and shame. It is noteworthy that this attitude finds expression in the language of Western civilizations, as in "privates" (something to be kept hidden) and the German word for the genitals, *Scham* ("shame").

Development of genital taboo

While all children in Western civilizations experience this antisexual teaching and conditioning, a few have, in addition, atypical sexual experiences, such as witnessing or hearing sexual intercourse or having sexual contact with an older person. The effects of such atypical experiences depend upon how the child interprets them and upon the reaction of adults if the experience comes to their attention. Seeing parental coitus is harmless if the child interprets it as playful wrestling but harmful if he considers it as hostile, assaultive behaviour. Similarly, an experience with an adult may seem merely a curious and pointless game, or it may be a hideous trauma leaving lifelong psychic scars. In many cases the reaction of parents and society determines the child's interpretation of the event. What would have been a trivial and soon-forgotten act becomes traumatic if the mother cries, the father rages, and the police interrogate the child.

Some atypical developments occur through association during the formative years. A child may associate clothing, especially underclothing, stockings, and shoes with gender and sex and thereby establish the basis for later fetishism or transvestism. Others, having been spanked or otherwise punished for self-masturbation or childhood sex play, form an association between punishment, pain, and sex that could escalate later into sadism or masochism. It is not known why some children form such associations whereas others with apparently similar experience do not.

Around the age of puberty, parents and society, who more often than not refuse to recognize that children have sexual responses and capabilities, finally face the inescapable reality and consequently begin inculcating children with their attitudes and standards regarding sex. This campaign by adults is almost wholly negative—the child is told what not to do. While dating may be encouraged, no form of sexual activity is advocated or held up as model behaviour. The message usually is "be popular" (*i.e.*, sexually attractive), but abstain from sexual activity. This antisexualism is particularly intense regarding young females and is reinforced by reference to pregnancy, venereal disease, and, most importantly, social disgrace. To this list religious families add the concept of the sinfulness of premarital sexual expression. With young males the double standard of morality still prevails. The youth receives a double message, "don't do it, but we expect that you will." No such loophole in the prohibitions is offered young girls. Meanwhile, the young male's peer group is exerting a prosexual influence, and his social status is enhanced by his sexual exploits or by exaggerated reports thereof.

Effects of the double standard on the sexual relations of the young

As a result of this double standard of sexual morality, the relationship between young males and females often becomes a ritualized contest, the male attempting to escalate the sexual activity and the female resisting his efforts. Instead of mutuality and respect, one often has a struggle in which the female is viewed as a reluctant sexual object to be exploited, and the male is viewed as a seducer and aggressor who must succeed in order to maintain his self-image and his status with his peers. This sort of pathological relationship causes a lasting attitude on the part of females: men are not to be trusted; they are interested only in sex; a girl dare not smile or be friendly lest males interpret it as a sign of sexual availability, and so forth. Such an aura of suspicion, hostility, and anxiety is scarcely conducive to the development of warm, trusting relationships between males and females. Fortunately, love or infatuation usually overcomes this negativism with regard to particular males, but the average female still maintains a defensive and skeptical attitude toward men.

Western society is replete with attitudes that impede the development of a healthy attitude toward sex. The free abandon so necessary to a full sexual relationship is, in the eyes of many, an unseemly loss of self-control, and self-control is something one is urged to maintain from infancy onward. Panting, sweating, and involuntary vocalization are incompatible with the image of dignity. Worse yet is any substance once it has left the body: it immediately becomes unclean. The male and female genital fluids are generally regarded with disgust—they are not only excretions but sexual excretions. Here again, societal concern over excretion is involved, for sexual organs are also urinary passages and are in close proximity to the "dirtiest" of all places—the anus. Lastly, many individuals in society regard menstrual fluid with disgust and abstain from sexual intercourse during the four to six days of flow. This attitude is formalized in Judaism, in which menstruating females are specifically labelled as ritually unclean.

In view of all of these factors working against a healthy, rational attitude toward sex and in view of the inevitable disappointments, exploitations, and rejections that are involved in human relationships, one might wonder how anyone could reach adulthood without being seriously maladjusted. The sexual impulse, however, is sufficiently strong and persistent and repeated sexual activity gradually erodes the inhibitions and any sense of guilt or shame. Further, all humans have a deep need to be esteemed, wanted, and loved. Sexual activity with another is seen as proof that one is attractive, desired, valued, and possibly loved—a proof very necessary to self-esteem and happiness. Hence, even among the very inhibited or those with weak sex drive, there is this powerful motivation to engage in sociosexual activity.

Most persons ultimately achieve at least a tolerable sexual adjustment. Some unfortunates, nevertheless, remain permanently handicapped, and very few completely escape the effects of society's antisexual conditioning. While certain inhibitions and restraints are socially and psychologically useful—such as deferring gratification until circumstances are appropriate and modifying behaviour out of regard for the feelings of others—most people labour under an additional burden of useless and deleterious attitudes and restrictions.

Sexual problems. Sexual problems may be classified as physiological, psychological, and social in origin. Any given problem may involve all three categories; a physiological problem, for example, will produce psychological effects, and these may result in some social maladjustment.

Physiological problems of a specifically sexual nature are rather few. Only a small minority of people suffer from diseases of or deficient development of the genitalia or that part of the neurophysiology governing sexual response. A large number of persons, however, experience, at some point in life, sexual problems that are byproducts of other pathologies or injuries. Vaginal infections, for example, retroverted uteri, prostatitis, adrenal tumours, diabetes, senile changes of the vagina, and cardiovascular conditions may cause disturbance of the sexual life. In brief, anything that seriously interferes with normal bodily functioning generally causes some degree of sexual trouble. Fortunately, the great majority of physiological sexual problems are solved through medication or surgery. Generally, only those problems involving damage to the nervous system defy therapy.

Psychological problems constitute by far the largest category. They are not only the product of socially induced inhibitions, maladaptive attitudes, and ignorance but also of sexual myths held by society. An example of the latter is the idea that good, mature sex must involve rapid erection, protracted coitus, and simultaneous orgasm. Magazines, marriage books, and general sexual folklore reinforce these demanding ideals, which cannot always be met and hence give rise to anxiety, guilt, and feelings of inadequacy.

Premature ejaculation and its therapy

Premature ejaculation is a common problem, especially for young males. Sometimes this is not the consequence of any psychological problem but the natural result of excessive tension in a male who has been sexually deprived. In such cases, more frequent coitus solves the problem. Premature ejaculation is difficult to define. The best definition is that offered by the American sexologists, William Howell Masters and Virginia Eshelman Johnson, who say that a male suffers from premature ejaculation if he cannot delay ejaculation long enough to induce orgasm in a sexually normal female at least half the time. This generally means that vaginal penetration with some movement (although not continuous) must be maintained for more than one minute. The average United States male ejaculates in two or three minutes after vaginal penetration, a coital duration sufficient to cause orgasm in most females the majority of the time. Various methods of preventing premature ejaculation have been tried. One is for the male to excite the female more during the foreplay so that she reaches orgasm more rapidly after penetration, but this technique often excites the male as well and defeats its purpose. Another common method is for the male to think of nonsexual matters, which may prove effective but reduces his pleasure. The most effective therapy is that advocated by Masters and Johnson in which the female brings the male nearly to orgasm and then prevents the male's orgasm by briefly compressing the penis between her fingers just below the head of the penis. The couple come to realize that premature ejaculation can thus be easily prevented, their anxiety disappears, and ultimately they can achieve normal coitus without resorting to this squeeze technique.

Erectile impotence is almost always of psychological origin in males under 40; in older males physical causes are more often involved. Fear of being impotent frequently causes impotence, and, in many cases, the afflicted male is simply caught up in a self-perpetuating problem that can only be solved by achieving a successful act of coitus. In other cases, the impotence may be the result of disinterest in the sexual partner, fatigue, distraction because of nonsexual worries, intoxication, or other causes—such occasional impotency is common and requires no therapy. Some males, however, are chronically impotent and require psychotherapy or behaviour therapy. Such impotency is thought to be the result of deep-seated causal factors such as unconscious feelings of hostility, fear, inadequacy, or guilt. Primary impotence, the inability to ever have achieved erection sufficient for coitus, is more difficult to treat than the far more common secondary impotence, which is impotence in a male who was formerly potent.

Ejaculatory impotence, the inability to ejaculate in coitus, is quite rare and is almost always of psychogenic origin.

It seems associated with ideas of contamination or with memories of traumatic experiences. Occasional ejaculatory inability may be expected in older men or in any male who has exceeded his sexual capacity and should cause no concern.

Vaginismus and dyspareunia

Vaginismus is a powerful spasm of the pelvic musculature constricting the vagina so that penetration is painful or impossible. It seems wholly due to antisexual conditioning or psychological trauma and serves as an unconscious defense against coitus. It is treated by psychotherapy and by gradually dilating the vagina with increasingly large cylinders.

Dyspareunia, painful coitus, is generally physical rather than psychological. It is mentioned here only because some inexperienced females fear they cannot accommodate a penis without being painfully stretched. This is a needless fear since the vagina is not only highly elastic but enlarges with sexual arousal, so that even a small female can, if aroused, easily receive an exceptionally large penis.

Disparity in sexual desire constitutes the most common sexual problem. It is to some extent inescapable, since differences in the strength of the sexual impulse and the ability to respond are based on neurophysiological differences. Much disparity, however, is the result of inhibition or of one person having been subjected to more sexual stimuli during the day than the other. The husband who has been seeing attractive females periodically during his work day and who may have had an opportunity to relax on his way back from the office or store is naturally more interested in coitus than his harried wife who has remained at home caring for children and doing housework. Another cause of disparity is a difference in viewpoint. Often a male will anticipate coitus as a palliative to compensate for the trials and tribulations of life, whereas many females are interested in sex only if the preceding hours have been reasonably problem-free and happy. Even in cases of neurophysiological differences in sex drive, the less-motivated partner can be trained to a higher level of interest, since most humans operate well below their sexual capacities.

Psychological fatigue, a growing disinterest in sexual behaviour with a particular partner, sometimes constitutes a problem. Humans are subject to monotony, and coitus may become routine or even a chore. Lessening frequencies of marital coitus are more often the result of this than of age. The solution lies in varying the time, the setting, and in breaking away from habitual techniques and positions.

Preferences for or antipathies toward particular position, techniques, or times not infrequently cause trouble. One partner may desire mouth–genital contact or anal stimulation that the other partner finds disagreeable or perverse. Some wish to have coitus in the light, others insist upon darkness; some prefer morning, others evening. The possibilities of disagreement are legion. Even if disagreements stemming from needless inhibition are overcome, there still remain disparities in preference, and these should be met by the philosophy that, by giving pleasure to another, one obtains pleasure. Needless to say, no partner should insist upon that which is abhorrent to the other after the latter has made honest attempts to cooperate.

Anorgasmy and frigidity

Lack of female orgasm, anorgasmy, is a very frequent problem. One should differentiate between females who become sexually aroused but do not reach orgasm and those who do not become aroused. Only the latter merit the label frigid. It is common for females not to achieve orgasm during the first weeks or months of coital activity. It is almost as though many females must learn how to have orgasm, for after having had one, they respond with increasing frequency. In some cases, the female initially has no idea how to copulate effectively and simply lies passive, expecting the male to bring her to orgasm. Other females resist orgasm because the feeling of being swept away and losing control is frightening. In most cases, however, anorgasmy is simply the result of years of inhibition—having been trained since childhood to avoid yielding to the sexual impulse, it is difficult to metamorphose into a responsive and orgasmic being. In the final analysis, anorgasmy is psychological in origin; few, if any, females lack the neurophysiology necessary for orgasm, and anthropology shows that in sexually permissive societies virtually all females have little difficulty in attaining orgasm in coitus.

Anorgasmy is treated by removing inhibitions, teaching coital techniques, and by inducing orgasm through noncoital methods. The effective therapist should also impress upon the female that not reaching orgasm is no sign of failure or inadequacy on her part or her partner's and that sexual activity is very pleasurable to both, even if orgasm does not ensue. Indeed, some females derive great pleasure and satisfaction without orgasm, a fact that should be made known to anxious husbands. Too great a concern over orgasm defeats itself. As Kinsey once pointed out, thinking is the enemy of sexual pleasure, and a female can scarcely have orgasm if she is worrying about whether she will attain it or not and if she senses that her partner is mentally turning the pages of a marriage manual.

Lastly, sexual problems are often perpetuated by the inability of the partners to communicate freely their feelings to one another. There is a curious and unfortunate reticence about informing one's partner as to what does or does not contribute to one's pleasure. The partner must function on a trial and error basis, ever on the alert for signs indicating the efficacy of his or her efforts. This muteness is even more pronounced when it comes to an individual making suggestions to the partner. Many persons feel that a suggestion or request would be interpreted by the partner that he or she had been inept or at least remiss. As with any other problems, sexual problems can be overcome or ameliorated only if the individuals concerned communicate effectively.

SOCIAL AND CULTURAL ASPECTS

The effects of societal value systems on human sexuality are, as has already been mentioned, profound. The U.S. anthropologist George P. Murdock summarized the situation, saying:

> All societies have faced the problem of reconciling the need of controlling sex with that of giving it adequate expression, and all have solved it by some combination of cultural taboos, permissions, and injunctions. Prohibitory regulations curb the socially more disruptive forms of sexual competition. Permissive regulations allow at least the minimum impulse gratification required for individual well-being. Very commonly, moreover, sex behavior is specifically enjoined by obligatory regulations where it appears directly to subserve the interests of society.

The historical heritage is, of course, the foundation upon which the current situation rests. Western civilizations are basically Greco-Roman in social organization, philosophy, and law, with a powerful admixture of Judaism derived from Christianity. This historical mixture contained incompatible elements: individual freedom was cherished, yet there was a great emphasis on law and proper procedure; the pantheism of the Greeks and Romans clashed with Judeo-Christian monotheism; and the sexual permissiveness of the Greeks met the fanatical antisexuality of early Christianity.

Effects of Christianity on sexual attitudes

In terms of sex, the most important factor was Christianity. While other vital aspects of human life, such as government, property rights, kinship, and economics, were influenced to varying degrees, sexuality was singled out as falling almost entirely within the domain of religion. This development arose from an ascetic concept shared by a number of religions, the concept of the good spiritual world as opposed to the carnal materialistic world, the struggle between the spirit and the flesh. Since sex epitomizes the flesh, it was obviously the enemy of the spirit. While Judaism subscribed to this dichotomous philosophy, it did have the saving grace of largely exempting marriage from its antisexuality. This was not the case with early Christianity, in which sex in any form outside of marriage was unmitigated evil and, within marriage, an unfortunate necessity for procreation rather than pleasure. The powerful antisexuality of the early Christians (note that neither God nor Christ has a wife and that marriage does not exist in heaven) was in part due to their apocalyptic vision of life: they anticipated that the end of the world and the Last Judgment would soon be upon them.

There was no time for a gradual weaning away from the flesh; an immediate and drastic approach was necessary. Indeed, such excessive antisexuality developed that the church itself was finally moved to curb some of its more extreme forms.

As it became evident that human existence was going to continue for some unforeseeable length of time and as occasional intelligent theologians made themselves felt, antisexuality was ameliorated to some extent but still remained a foundation stone of Christianity for centuries. This attitude was particularly unfortunate for women, to whom most of the sexual guilt was assigned. Women, like the original temptress Eve, continued to attract men to commit sin. They were spiritually weak creatures prone to yield to carnal impulses. This is, of course, a classic example of projecting one's own guilty desires upon someone else.

Ultimately, legal control over sexual behaviour passed from the church to the state, but, in most instances, the latter simply perpetuated the attitudes of the former. Priests and clergymen frequently continued to exert powerful extralegal control: denunciations from the pulpit can be as effective as statute law in some cases. Although religion has weakened as a social control mechanism, even today, liberalization of sex laws and relaxation of censorship have often been successfully opposed by religious leaders. On the whole, however, Christianity has become progressively more permissive, and sexuality has come to be viewed not as sin but as a God-given capacity to be used constructively.

Apart from religion, the state sometimes imposes purely secular restrictions. The more totalitarian a government, the more likely it is to restrict or direct sexual behaviour. In some instances, this is simply the consequence of a powerful individual (or individuals) being in a position to impose his (or their) ideas upon the public. In other instances, one cannot escape the impression that sex, being a highly personal and individualistic matter, is recognized as antithetical to the whole idea of strict governmental control and supervision of the individual. This may help explain the rigid sexual censorship exerted by most totalitarian regimes. It is as though such a government, being obsessed with power, cannot tolerate the power the sexual impulse exerts on the population.

Social control of sexual behaviour. Societies differ remarkably in what they consider socially desirable and undesirable in terms of sexual behaviour and consequently differ in what they attempt to prevent or promote. There appear, however, to be four basic sexual controls in the majority of human societies. First, to control endless competition, some form of marriage is necessary. This not only removes both partners from the competitive arena of courtship and assures each of a sexual partner, but it allows them to devote more time and energy to other necessary and useful tasks of life. Despite the beliefs of earlier writers, marriage is not necessary for the care of the young; this can be accomplished in other ways.

Four major areas of sexual control

Second, control of forced sexual relationships is necessary to prevent anger, feuding, and other disruptive retribution.

Third, all societies exert control over whom one is eligible to marry or have as a sexual partner. Endogamy, holding the choice within one's group, increases group solidarity but tends to isolate the group and limit its political strength. Exogamy, forcing the individual to marry outside the group, dilutes group loyalty but increases group size and power through new external liaisons. Some combination of endogamy and exogamy is found in most societies. All have incest prohibitions. These are not based on genetic knowledge. Indeed, many incest taboos involve persons not genetically related (father–stepdaughter, for example). The prime reason for incest prohibition seems to be the necessity for preventing society from becoming snarled in its own web: every person has a complex set of duties, rights, obligations, and statuses with regard to other people, and these would become intolerably complicated or even contradictory if incest were freely permitted.

Fourth, there is control through the establishment of some safety-valve system: the formulation of exceptions to the prevailing sexual restrictions. There is the recognition that humans cannot perpetually conform to the social code and that well-defined exceptions must be made. There are three sorts of exceptions to sexual restrictions: (1) Divorce: while all societies encourage marriage, all realize that it is in the interest of society and the individual to terminate marriage under certain conditions. (2) Exceptions based on kinship: many societies permit or encourage sexual activity with certain kin, even after marriage. Most often these kin are a brother's wife or a wife's sister. In addition, sexual "joking relationships" are often expected between brothers-in-law, sisters-in-law, and cousins. While coitus is not involved, there is much explicit sexual banter, teasing, and humorous insult. (3) Exceptions based on special occasions, ranging from sexual activity as a part of religious rites to purely secular ceremonies and celebrations wherein the customary sexual restrictions are temporarily lifted.

Turning to particular forms of sexual behaviour, one learns from anthropology and history that extreme diversity in social attitude is common. Most societies are unconcerned over self-masturbation since it does not entail procreation or the establishment of social bonds, but a few regard it with disapprobation. Sexual dreams cause concern only if they are thought to be the result of the nocturnal visitation of some spirit. Such dreams were once attributed to spirits or demons known as incubi and succubi, who sought out sleeping humans for sexual intercourse.

Petting among most preliterate societies is done only as a prelude to coitus—as foreplay—rather than as an end in itself. In some parts of sub-Saharan Africa, however, petting is used as a premarital substitute for coitus in order to preserve virginity and avoid pregnancy. There is great variation in petting and foreplay techniques. Kissing is by no means universal, as some groups view the mouth as a biting and chewing orifice ill-suited for expressing affection. While some societies emphasize the erotic role of the female breast, others—such as the Chinese—pay little attention to it. Still others regard oral stimulation of the breast unseemly, being too akin to infantile suckling. Although manual stimulation of the genitalia is nearly universal, a few peoples abstain because of revulsion toward genital secretions. Not much information exists on mouth–genital contact, and one can say only that it is common among some peoples and rare among others.

A considerable number of societies manifest scratching and biting in conjunction with sexual activity, and most of this is done by the female. Sadomasochism in any other form, however, is conspicuous by its absence in preliterate societies.

An enumeration of the societies that permit or forbid premarital coitus is complicated not only by the double standard but also by the fact that such prohibition or permission is often qualified. As a rough estimate, however, 40 to 50 percent of preliterate or ancient societies allowed premarital coitus under certain conditions to both males and females. If one were to count as permissive those groups that theoretically disapprove but actually condone such coitus, the percentage would rise to perhaps 70.

In marital coitus, when sexual access is not only permitted but encouraged, one would expect considerable uniformity in frequency of coitus. This expectation is not fulfilled: social conditioning profoundly affects even marital coitus. On one Irish island reported upon by a researcher, for example, marital coitus is best measured in terms of per year, and among the Cayapas of Ecuador, a frequency of twice a week is something to boast of. The coital frequencies of other groups, on the other hand, are nearer to human potential. In one Polynesian group, the usual frequency of marital coitus among individuals in their late 20s was 10 to 12 per week, and in their late 40s the frequency had fallen to three to four. The African Bala, according to one researcher, had coitus on the average of once or twice per day from young adulthood into the sixth decade of life.

Frequency of marital coitus

Marital coitus is not unrestricted. Coitus during menstruation or after a certain stage of pregnancy is generally taboo. After childbirth a lengthy period of time must often elapse before coitus can resume, and some peoples abstain for magical reasons before or during warfare, hunting expeditions, and certain other important events or ceremonies. In modern Western society one finds menstrual, pregnancy, and postpartum taboos perpetuated under an aesthetic or medical guise, and coaches still attempt to force celibacy upon athletes prior to competition.

Extramarital coitus provides a striking example of the double standard: it is expected, or tolerated, in males and generally prohibited for females. Very few societies allow wives sexual freedom. Extramarital coitus with the husband's consent, however, is another matter. Somewhere between two-fifths and three-fifths of preliterate societies permit wife lending or allow the wife to have coitus with certain relatives (generally brothers-in-law) or permit her freedom on special ceremonial occasions. The main concern of preliterate societies is not one of morality, but of more practical considerations: does the act weaken kinship ties and loyalty? Will it damage the husband's social prestige? Will it cause pregnancy and complicate inheritance or cause the wife to neglect her duties and obligations? Most foreign of all to Western thinking is that of those peoples whose marriage ceremony involves the bride having coitus with someone other than the groom, yet it is to be recalled that this practice existed to a limited extent in medieval Europe as jus primae noctis, the right of the lord to the bride of one of his subjects.

Sexual deviations and sex offenses are, of course, social definitions rather than natural phenomena. What is normative behaviour in one society may be a deviation or crime in another. One can go through the literature and discover that virtually any sexual act, even child–adult relations or necrophilia, has somewhere at some time been acceptable behaviour. Homosexuality is permitted in perhaps two-thirds of human societies. In some groups it is normative behaviour, whereas in others it is not only absent but beyond imagination. Generally, it is not an activity involving most of the population but exists as an alternative way of life for certain individuals. These special individuals are sometimes transvestites—that is, they dress and behave like the opposite sex. Sometimes they are regarded as curiosities or ridiculed, but more often they are accorded respect and magical powers are attributed to them. It is noteworthy, however, that aside from these transvestites, exclusive homosexuality is quite rare in preliterate societies.

In conclusion, the cardinal lesson of anthropology is that no type of sexual behaviour or attitude has a universal, inherent social or psychological value for good or evil—the whole meaning and value of any expression of sexuality is determined by the social context within which it occurs.

Class distinctions. Differences in sexual behaviour between classes within technologically developed societies are very marked. Civilizations are made up of class hierarchies, and the different subgroups normally develop their own value systems. Most of the knowledge of the sexual behaviour and attitudes of ancient cultures is that of the upper or ruling class; the behaviour and feelings of the slaves and peasants were seldom recorded. There is the impression—probably a correct one—that throughout history the lower socio-economic class was the most permissive. Sex has always been one of the few pleasures of the poor and oppressed. On the other hand, one must not overlook the fact that a fanatical Puritanism can also flourish at the bottom of the social scale, and, hence, one can never assume that low status and sexual permissiveness are inevitably linked.

Breakdown of class differences in sexual behaviour

The Kinsey studies showed considerable social class differences in sexuality in the United States, chiefly in that the lower class was more tolerant of nonmarital coitus. More recent studies indicate that these class differences have rapidly broken down. Increased literacy and the influence of mass media have made the population more homogeneous in sexual attitudes. One can find, moreover, reversals of the previous pattern: a lower class person on the way up the social ladder may be quite conservative in his sexual views, feeling that this facilitates upward mobility, whereas the person secure in his or her high social status often feels that he or she can afford to flout convention. Actually, the most sexually liberal are those at the very bottom, who have nothing to lose, and those at the very top, who are beyond social retribution.

The great middle class remains the bastion of traditionalism, and it is here that the double standard of morality is most prominent. The intellectualized liberalism of the upper level seeps down only slowly, and the pragmatic egalitarianism of the lower level does not penetrate far upward.

Economic influences. Systems of production and distribution have had a growing influence on sexual behaviour since the Industrial Revolution. The old family pattern was inexorably disrupted by the rise of the industrial state. Children were no longer kept at home to share in the work and be economic assets but left for school or for nonfamily employment, and the degree of parental control diminished. The "working wife" employed outside the home, once found only among the impoverished, has gradually become the typical wife. With her enhanced economic power and her greater association with people outside the home, she became less a chattel. As the population left the family farm and tight-knit small communities for anonymous big-city existence, not only parental but societal controls over behaviour were weakened. Society became increasingly nomadic with improved transportation and job opportunities. Cultural and ethnic subgroups that formerly would have had little contact were thrown together in the same schools, factories, offices, and neighbourhoods.

All of this vast uprooting and rearranging naturally altered sexual attitudes and behaviour. The individual no longer had the option of choosing to conform or depart from a rather clear-cut sexual moral code but instead was faced with a multiplicity of choices of varying degrees of social acceptability. The major sexual change—one still in progress—was the emancipation of women, which brought with it an increasing acceptance of premarital sexual activity, the concept of woman as a human being with her own sexual needs and rights, and the possibility of terminating an unhappy marriage without incurring serious social censure. A second major change was the erosion of simplistic value systems: with increased mobility and social mixing, the individual learned that the values and attitudes he or she had unquestioningly accepted were not necessarily shared by neighbours and co-workers. As a result, life became not only more complex but more permissive. This growing tolerance has in recent decades extended, to a limited extent, to homosexuality. There is no evidence that homosexuality or other deviant behaviour has measurably increased as a result of society's urbanization and technological progress, but one gains the impression of an increase simply because these topics, previously unmentionable, are now openly discussed in the mass media.

While the old monolithic value systems broke down and individuals were accorded a wider variety of choices in terms of sexual life, there developed a paradoxical trend toward homogeneity as a result of mobility, the mass media, and increasing economic parity. Geographical and social-class differences in sexual attitudes and behaviour have steadily lessened. The plumber's family and the banker's family are now indistinguishable in terms of dress; both have automobiles; their offspring attend the same schools; and they share the same newspapers, magazines, and television programs. One might summarize by saying that society is homogeneous in that everyone now has available a wide diversity of sexual attitudes and activities.

Legal regulation. Sex laws, the origins of which, as mentioned above, are found within the church, are unique in one important respect. Whereas all other laws are basically concerned with the protection of person or property, the majority of sex laws are concerned solely with maintaining morality. The issue of morality is minimal in other laws: one can legitimately evict an impoverished old couple from their mortgaged home or sentence a hungry man for stealing food. Only in the realm of sex is there a consistent body of law upholding morality.

Early examples of sex laws

The earliest sex laws of which there is knowledge are from the Near East and date back to the 2nd millennium BC. They are remarkable in three respects: there are great omissions—certain acts are not mentioned whereas others receive detailed attention; some laws seem almost contradictory; and penalties are often extraordinarily severe. One obtains the distinct impression that these laws were case law—that is, laws formulated upon specific cases as they arose rather than being the result of lengthy judicial deliberation done in advance. These laws influenced Judaic and, hence, Christian thinking, and some were immortalized in the Bible, chiefly in Leviticus.

As mentioned earlier, when secular law replaced religious law, there was rather little change in content. In Europe the Napoleonic Code represented a break with tradition and introduced some measure of sexual tolerance, but in England and the United States there was no such rift with the past. In the latter country, as each new state joined the union, its sex laws simply duplicated, to a great extent, those of pre-existing states; legislators were disinclined to debate sexual issues or to risk losing votes by discarding or weakening sex laws.

Sex laws may be grouped in three categories: (1) Those concerned with protection of person. These are based on the element of consent. These otherwise logical laws become problematic when society deems that minors, mental retardates, and the insane are incapable of giving consent—hence, coitus with them is rape. (2) Those concerned with preventing offense to public sensibilities. Statutes preclude public sexual activity, exhibitionism, and offensive solicitation. (3) Those concerned with maintaining sexual morality. These constitute the majority of sex laws, covering such items as premarital coitus, extramarital coitus, incest, homosexuality, prostitution, peeping, nudity, animal contact, transvestism, censorship, and even specific sexual techniques—chiefly oral or anal. Laws relating to sexual conduct and morality are generally far more extensive in the United States than in western Europe and most other areas of the world.

In recent years, in Europe and the United States, a number of highly respected legal, medical, and religious organizations have deliberated on the whole issue of the legal control of human sexuality. They have been unanimous in the conclusion that, while the laws protecting person and public sensibilities should be retained, the purely moral laws should be dropped. Specifying what consenting adults do sexually in private, it is argued, should not be subject to legal control.

In the final analysis, sexuality, like any other vital aspect of human life, must be dealt with on an individual or societal level with a combination of rationality, sensitivity, and tolerance if society is to avoid personal and social problems arising from ignorance and misconception. (P.H.Ge./Ed.)

HOMOSEXUALITY

Homosexual behaviour consists of choosing a partner of the same sex for sexual interaction. The term homosexual is used to characterize individuals who prefer romantic attachments and sexual interaction with the same sex and typically are maximally aroused by same-sex erotic imagery. The term is used for both sexes, although female homosexuality is often referred to as lesbianism. The label homosexual is sometimes inaccurately applied to individuals who predominantly experience heterosexual arousal but who have experienced occasional or fleeting desire or fantasy of same-sex erotic activity.

Because of the difficulty in classification, sex researcher Alfred C. Kinsey and his associates created a seven-point scale that included exclusively heterosexual behaviour at one extreme and exclusively homosexual behaviour at the other. Erotic fantasy could be similarly scaled. For practical purposes, the critical factors in classifying an individual as homosexual, heterosexual, or bisexual are: (1) which sex or sexes one desires to form romantic bonds with and (2) how easily one responds sexually to the chosen partners.

Kinsey data

Statistics on homosexuality. According to the extensive data gathered by Kinsey and his associates for his landmark work *Sexual Behavior in the Human Male* (1948), a study of 5,300 males, approximately 50 percent had a same-sex genital experience before puberty. Twenty-five percent had more than incidental homosexual experience for at least three years between the ages of 16 and 55 years, and 37 percent had at least one homosexual experience leading to orgasm after puberty. Ten percent were exclusively homosexual for a period of at least three years between the ages of 16 and 55.

By age 30, one-quarter of the 5,940 females interviewed by Kinsey (*Sexual Behavior in the Human Female*, 1953) had recognized erotic responses to the same sex. About 20 percent reported some same-sex erotic experience; but, because these figures included "casual" contacts that elicit erotic response, the more revealing figure is same-sex experience to orgasm: 13 percent of women had a homosexual experience to orgasm prior to age 45. Approximately 2 to 3 percent reported having exclusive homosexual experience.

More recent data from a study funded by the Playboy Foundation and from the Institute for Sex Research support the earlier Kinsey findings on homosexual experiences and indicate that the incidence figures have remained constant since the 1950s. It is likely, therefore, that, although sexual liberation movements of the late 20th century brought greater freedom to enjoy various sexual acts, including homosexual experiences, with less guilt and shame, there was not a measurable increase in the number of individuals having homosexual experiences. What increased significantly was the candour with which sexual preference could be discussed and displayed.

Prenatal and environmental influences. The "biologic versus learned" dichotomy regarding the etiology of homosexual preference—whether it is determined by inborn factors or by environmental influences—continues to muddle scientific investigation of the interacting prenatal and postnatal factors that contribute to all sexual orientation. There is now a substantial body of evidence to suggest that human beings are born with a sexual potential and that heterosexual, homosexual, bisexual, or asexual preferences unfold during the experiences of childhood and adolescence. This is not to say that prenatal and genetic factors are unimportant. A useful analogy given by psychologist John A. Money of Johns Hopkins University is that of "handedness." A human is born not right- or left-handed but bipotential. Experiences in the first few years of life define whether the individual will develop the right, the left, or both cerebral hemispheres—and handedness. There might be predispositions to handedness, which are supported by the fact that most individuals are right-handed; however, postnatal experiences probably override such predispositions. Similarly, there is some evidence that suggests possible predispositions to erotic preferences. Such predispositions, however, do not preordain homosexual or heterosexual preferences; postnatal events can override this influence.

Evidence that humans are born bipotential with regard to erotic orientation comes from several sources. The first is the study of clinical cases of intersexuality, that is, individuals born with ambiguous genitalia and raised in the opposite gender of their genetic, or chromosomal, sex. (Males have an X and a Y sex chromosome; females have two X sex chromosomes. The combination that an individual possesses can be determined by testing.) Approximately 60 individuals who were raised in the sex opposite of their genetic sex were studied by Money and his associates. In addition, in a bizarre case, chromosomal male identical twins were reared as opposite sexes owing to a circumcision accident in which the penis of one infant was cut off. The infant was subsequently castrated and a functional vagina was made through plastic surgery. In each of the intersexuality cases, as well as the twins case, the gender identity and gender role—that is, the individual's personal sense of masculinity or femininity and behavioral manifestations—that developed was compatible with the sex of rearing regardless of the genetic and prenatal classification. At puberty these individuals were generally attracted to the sex opposite of their sex of rearing. This suggests that sexual orientation is primarily established in postnatal experiences.

Acceptance of homosexual behaviour

The second source of information on the influences of nature and nurture is anthropologic research. In almost two-thirds of the 76 societies that Clellan S. Ford and Frank A. Beach reviewed in *Patterns of Sexual Behavior* (1951), homosexual activities were considered acceptable under certain circumstances. For example, homosexual activity might be ritualized during childhood and adolescence. In none of these societies was there record of exclusive homosexuality; rather, heterosexual pair-bonding occurred during adulthood, and homosexuality either stopped in adulthood or was permitted under special circumstances. So it can be seen that exclusive homosexuality—and heterosexuality—are atypical in many cultures. Polarizations to homosexuality and to heterosexuality appear to be a product of individual civilizations.

Programming of erotic orientation. The programming of erotic orientation is subsumed under the development of gender identity and role. Children learn to imitate the parent of the same sex and complement the opposite-sexed parent. A child can reliably distinguish gender by age five. Boys, for example, are aware of the sexual anatomy of both sexes as well as the stereotypic characteristics of the masculine sex role. Also, by age five, they are aware that they probably will someday marry a woman. The acculturation of heterosexuality is quite overt. C.A. Tripp, author of *The Homosexual Matrix* (1975), stated, "All the religious and social traditions directly support family living and the kinds of mateships that comprise heterosexuality. Certainly there is nothing mysterious in how family life communicates itself."

Similarly, there is nothing mysterious about the discouragement of homosexuality. Homosexual behaviour is subject to extreme prejudice in most of Western society—it has been considered "perverted and sick" by a large portion of the population. As with most prejudices, homosexuals are seen in terms of various stereotypes, such as effeminacy, characteristic gestures and mannerisms, and promiscuity. The programming that encourages heterosexuality and discourages homosexuality, even close physical contact with the same sex, generally results in the stunting of any budding homosexual fantasies or behaviour in most prepubescents. Heterosexuality is left to unfold.

Even though homosexual behaviour is not sanctioned, homosexual erotic imagery may persist. Data published by sex researchers Virginia Johnson and William Masters and by author Nancy Friday on selected samples suggested that many heterosexuals use homosexual imagery to enhance their sexual arousal when masturbating or having intercourse but do not actually have an interest in having a homosexual experience. Similarly, many homosexuals use heterosexual imagery to enhance their arousal but do not desire heterosexual experiences. Research on broader samples is necessary; unfortunately, it is unlikely that a wide cross-section of individuals of all ages and backgrounds would be willing to discuss their erotic fantasies openly.

Why some individuals develop homosexual orientations despite contrary socialization is not yet completely known. There are obviously both prenatal and postnatal contributing factors that interact to cause this particular sexual orientation, but thus far only some of the labyrinth has been explored.

Prenatal factors. There are now extensive data from lower mammals and primates, as well as indirect data from human clinical investigations, that show that the presence of differential amounts of the hormone androgen in the fetus during a short prenatal period influences the acquisition and expression of sexually dimorphic behaviour. Androgen is secreted by the fetal gonads and is present in widely differing amounts in all male and female fetuses. Males have about seven times the amount of androgen as do females.

Postnatal androgenization in females

Numerous experiments have reported that female animals exposed to excess fetal androgen behave more like males in various tests of sexually dimorphic behaviour, including a mating preference for the same sex. John Money and Anke Ehrhardt (of Columbia University) found that human females exposed to excess fetal androgen as the result of a condition known as the adrenogenital syndrome behaved throughout childhood with a high degree of energy in rough outdoor play, preferred boys as playmates, and had little interest in stereotypic activities of girls or verbalized interest in marriage or childbirth. One study found that during adolescence these girls maintained their intense interest in athletics but had difficulty finding female peers with similar interests. Their interest in dating began late; and of those who eventually did begin their sex lives in young adulthood, a significant number found themselves bisexually aroused and eventually a number had homosexual experiences. These findings support an earlier report that found that 48 percent of women who were exposed to excess prenatal androgens and developed postnatal androgenization (and therefore were partially virilized; *i.e.*, developed some male secondary sex characteristics) had experienced bisexual imagery and 18 percent had had homosexual experiences.

One approach to understanding prenatal influences on sexual orientation is to study the release of hormones from the brains of individuals who are homosexual and transsexual (individuals who, in addition to having homosexual interaction, desire to change their gender). Normally, male and female brains differ, because the female produces hormones in a cyclic manner as part of the menstrual cycle. Günter Dörner in East Germany reported a positive or male-like hormone feedback action in some homosexual women. Similar findings were noted by Lloyd Seyler at the University of Connecticut, who found a male-like hormone response in transsexual women.

Finally, some investigators have found elevated or diminished gonadal hormone levels in some homosexual men and women as compared with those of heterosexuals. The presence of variant hormone levels does not mean that raising or lowering hormone levels in homosexuals will change their sexual preference. Changing the hormone levels would usually have no effect, although if levels were lowered enough, this would raise the threshold for sexual arousal. Rather, a likely explanation for the different hormone levels is that prenatal androgen may have changed the organization of brain pathways, thereby making some individuals less susceptible to postnatal programming toward heterosexuality.

A third source of information about prenatal factors is from the study of boyhood effeminacy. For as long as 22 years Money studied nine boys who showed effeminate behaviour, including gestures, speech, play patterns, and cross-dressing, in early childhood. All nine eventually became homosexual. The appearance of this gender-divergent behaviour at an early age may be suggestive of prenatal influences.

Family patterns

Postnatal factors. Why do certain individuals move into full or partial homosexuality despite society's programming of heterosexuality and its condemnation of homosexuality? Irving Bieber reported family interactions commonly described by male homosexuals coming to him for psychotherapy because of dissatisfaction with their homosexuality. The mothers were conceived as close-binding, overprotective, and seductive, while the fathers were conceived as distant and hostile. This background has been noted by other psychotherapists for homosexuals. The reasons why such a background in particular makes the individual have difficulties in sexual interaction with women are difficult to verify. Some lesbians have been found to have similar patterns in their backgrounds, showing a history of seductive fathers and distant mothers.

The reports by various psychotherapists treating disturbed homosexuals produced the commonly held theory that homosexuality was a disease state resulting from pathological influences. It followed that treatment of such pathological influences would result in the spontaneous appearance of the nondisease state, heterosexuality.

The disease model has been criticized for various reasons. The clinical evidence has been viewed as biassed since only troubled homosexuals came to the psychotherapists' offices. Working with less biassed samples of homosexuals, Evelyn Hooker, Alan P. Bell, and Martin S. Weinberg reported very divergent family constellations.

In addition, the cross-cultural, intersexual, and sociologic data previously mentioned have made many sexologists aware that the human child is born bipotential with regard to erotic orientation. Thus, many began to catalog factors contributing to or inhibiting the unfolding of heterosexuality and homosexuality, rather than labelling the latter a pathological disease state.

Finally, aversive conditioning of the homosexual response (behaviour modification that tries to foster negative associations with erotic response to homosexual stimuli) has not led to the spontaneous appearance of heterosexuality, as the disease model would suggest. Changing individuals' sexual orientations has met with variable success and, when successful, requires that an individual's stunted heterosexual responsiveness be allowed and encouraged to unfold.

The rejection of the disease model by many sexologists was most dramatically marked by the vote of the American Psychiatric Association in 1973 to remove "ego-syntonic homosexuality" (meaning the condition of a person content with his or her homosexuality) from the categorization of psychiatric illness. Regardless of the controversies about whether or not homosexuality is a disease, there is increased scientific recognition that the same prenatal and postnatal factors that contribute to heterosexuality also contribute to homosexuality; the difference is the relative contribution of each in an individual's biography.

Self-labelling

A likely influence in the development of homosexuality is self-labelling. Some individuals discover that they have homosexual imagery, which, as previously noted, might be quite a common occurrence; however, some individuals then label themselves homosexual and polarize themselves away from heterosexuality. Milton Diamond and Arno Karlen in their book *Sexual Decisions* (1980) noted, "Like other minorities homosexuals respond by flaunting their deviance and living up to the majority's expectations." Once labelled, some male homosexuals may develop effeminate mannerisms (eloquently described by Tripp in *The Homosexual Matrix*). Individuals with low self-esteem from childhood trauma might be particularly susceptible to such labelling.

Polarization is reinforced by sexual performance concerns—Can I get an erection? Will I be orgasmic? Can I satisfy my partner?—that characterize new heterosexual relationships. Of the homosexual men with heterosexual experience, Marcel Saghir and Eli Robins, in their *Male and Female Homosexuality* (1973), found that about 30 percent were impotent with females and that 50 percent of the heterosexually inexperienced were afraid of females and were fearful of being impotent with them. Similarly, 61 percent of the 57 lesbians studied reported that they did not experience orgasm in their heterosexual experiences. Concerns about sexual performance are dramatically decreased in homosexual interaction. Thus individuals who find themselves having homosexual fantasies and who are not at ease with the opposite sex or are concerned about performance may find homosexual activity easier. The repeated conditioning of pleasure with orgasm eventually results in the fantasies becoming more unvarying, and polarization is further enhanced.

Homosexual life-styles. In an attempt to provide further empirical data, two major investigations of homosexuality were conducted in the 1960s and '70s, the results of which were published in 1978 and in 1979. The researchers were Bell and Weinberg of the Institute for Sex Research and Masters and Johnson.

Bell and Weinberg interviewed a nonrepresentative sample of some 1,500 persons, including homosexuals and heterosexuals, males and females, from the San Francisco Bay area. The major conclusion from their work, *Homosexualities: A Study of Diversity Among Men and Women* (1978), is that it is impossible to predict the social and psychologic adjustment of homosexuals or heterosexuals by identifying erotic preferences. Both groups show great diversity in a variety of characteristic categories, including life-style, occupation, type of romantic attachment, mental health, happiness, and sexual technique. In some of the characteristic categories, the differences among homosexuals are as wide as or wider than those between homosexuals and heterosexuals.

In particular, 14 percent of male homosexuals were "close-coupled" in monogamous bonds. The majority were not involved in monogamous relationships, and 25 percent called "open-coupled" lived with a special partner but did occasional "cruising" of singles' bars or "gay baths" for a sexual partner. A minority of 21 percent were described as "functional" and organized much of their life around sexual activity and cruising. Approximately 18 percent, described as "dysfunctional," were not content with their homosexuality. The last group, 23 percent, classified as "asexual," were not coupled and had little sexual activity.

Levels of activity

Homosexual men were more sexually active than homosexual women, and less emphasis in the females' thinking was placed on sexual contact. Lesbian public cruising was infrequent, and women tended to be less interested in impersonal sexual encounters than male homosexuals were. Almost 40 percent of males did not cruise or did so infrequently, and fewer than 20 percent of the females engaged in occasional cruising of gay bars and private parties. The females had fewer sexual partners in their lives and were more inclined toward stable monogamous relationships.

Males tended to have several sexual experiences soon after puberty, whereas the females discovered their homosexuality later, usually after a romantic relationship with one female. These data are similar to those of Saghir and Robins, who noted that most lesbians had heterosexual relationships during adolescence that were generally less psychosexually satisfying than those the heterosexual females reported. Generally, the lesbians were more accepting and less guilty about their homosexuality than were the men studied.

Masters and Johnson's text, *Homosexuality in Perspective* (1979), is rich in detail about human sexual behaviour regardless of sexual orientation. Their research documented that the sexual response and physiological capacity to respond to sexual stimuli were not different between homosexuals and heterosexuals. In addition, heterosexuals might have something to learn from the sexual techniques of homosexuals. The latter were generally less goal-oriented in their sexual practices. Male homosexuals in particular were less likely to have the performance demands experienced by heterosexual men for erection to accomplish vaginal penetration. Homosexuals more often concentrated on full body contact. Some heterosexuals were equally effective in stimulating their partners, but communication of desired stimulation was generally found to be of higher quality within the sexes than between the sexes.

In addition, Masters and Johnson reported on their treatment of 57 homosexual male couples and 27 lesbian couples with sexual dysfunction, using techniques similar to those used to treat heterosexual couples. Failure rates in short-term intensive therapy were similarly low as compared with heterosexual couples.

Finally, the Masters and Johnson publication demonstrated that for the 20 percent of homosexuals who were distressed with their homosexuality, short-term psychotherapy could be effective in "converting" or "reverting" them to heterosexuality. There were 54 males and 13 females requesting such therapy, and the failure rate after a five-year follow-up was 28 percent.

Knowing that a person prefers homosexual eroticism tells little else about him or her. Scientific research has confirmed what to some may be obvious—stereotypes of homosexuals are inaccurate and indeed create much of the difficulty that some homosexuals experience. Meanwhile, researchers continue to search for the multitude of determinants that contribute to various individual differences, including gender identity and sexual orientation. Having a close-binding mother and a neglecting father may be associated with relationship difficulties in adulthood and may even result in total rejection of members of the opposite sex as sexual partners. This is not the cause of homosexuality; but, in susceptible individuals, it can be an influence. Other factors such as self-labelling and anxiety over sexual performance also contribute to difficulties in forming a satisfying relationship with members of the opposite sex.

It is likely that in the future attitudes toward homosexuals in the community will become more tolerant. The majority of homosexuals will be able to live contented lives in the thriving homosexual subculture, particularly in certain metropolitan areas such as San Francisco, London, or Amsterdam. The minority who continue to be discontented will be able to seek sex therapy and change their erotic preference. (M.F.S./Ed.)

from physiological and genetic viewpoints; C.R. AUSTIN, *Fertilization* (1965), a concise general account of the nature of reproductive cells, the basic process of fertilization of the egg, and the various adaptive devices employed by animals and plants to ensure successful and normal fertilization, written for biology students; M. BASTOCK, "The Physiology of Courtship and Mating Behavior," *Advances in Reproductive Physiology,* 2:9–51 (1967), a review intended for biologists, but of general interest; N.J. BERRILL, *Sex and the Nature of Things* (1953), an award-winning inclusive account of sex, its diversity, and its significance in relation to evolution and animal behaviour, for the lay reader; *The Person in the Womb* (1968), a treatment of human development from conception to infancy, including the determination of sex at conception and the influence of hormones on sexuality during pregnancy; W.S. BULLOUGH, *The Vertebrate Reproductive Cycles,* 2nd ed. (1961), a short, concise account of reproduction, particularly in birds and mammals, with emphasis on hormonal and seasonal controls of sexual maturity and reproduction; L.J. and M.J.G. MILNE, *The Mating Instinct* (1954, paperback ed. 1968), very inclusive and detailed descriptions of the courting and mating behaviour of animals, extensively illustrated photographically; G. PINCUS, *The Control of Fertility* (1965), a highly scientific discussion, by a pioneering authority, of the reproductive process in man and other mammals, with emphasis on the action of hormones on sex cell production, on the first stages of development, and on the problems of fertility; H. WENDT, *The Sex Life of Animals* (1965), a very descriptive account of courting and mating, and sexuality generally, throughout the animal kingdom, translated from an earlier German edition; G.C. WILLIAMS, *Adaptation and Natural Selection* (1966), an illuminating and thoughtful discussion of sexual reproduction in relation to the processes of biological evolution and adaptation.

An anthropological overview of sex is given in DONALD S. MARSHALL and ROBERT C. SUGGS (eds.), *Human Sexual Behavior: Variations in the Ethnographic Spectrum* (1971); GEORGE P. MURDOCK, *Social Structure* (1949); and CLELLAN S. FORD and FRANK A. BEACH, *Patterns of Sexual Behavior* (1951); the latter also covers mammalian behaviour. Data on sexual behaviour and attitudes in the United States are in ALFRED C. KINSEY *et al., Sexual Behavior in the Human Male* (1948) and *Sexual Behavior in the Human Female* (1953); while IRA L. REISS, *The Social Context of Premarital Sexual Permissiveness* (1967), provides more recent information on attitudes. General information may be found in JAMES L. MCCARY, *Human Sexuality* (1967), a book that also serves as an excellent sex manual. The best single volume on homosexuality is that of DONALD J. WEST, *Homosexuality* (1968). Genetic, hormonal, and gender matters are summarized in two technical volumes: RICHARD GREEN and JOHN MONEY (eds.), *Transsexualism and Sex Reassignment* (1969); and ROBERT J. STOLLER, *Sex and Gender: On the Development of Masculinity and Femininity* (1968). Sexual physiology is comprehensively treated in WILLIAM H. MASTERS and VIRGINIA E. JOHNSON, *Human Sexual Response* (1966), while their second volume, *Human Sexual Inadequacy* (1970), deals with behaviour therapy. The history of Judeo-Christian attitudes toward sex is presented in detail in L.M. EPSTEIN, *Sex Laws and Customs in Judaism* (1968); and DERRICK S. BAILEY, *Sexual Relation in Christian Thought* (1959). Sex laws are covered by three volumes: RALPH SLOVENKO (ed.), *Sexual Behavior and the Law* (1965); EDWARD SAGARIN and DONAL E.J. MACNAMARA, *Problems of Sex Behavior* (1968); and the AMERICAN LAW INSTITUTE, *Model Penal Code,* 2 vol. (1955–57). BENJAMIN B. WOLMAN (ed.), *Handbook of Human Sexuality* (1980), is a collection of essays covering a wide spectrum of topics for the general reader; G. MITCHELL, *Human Sex Differences* (1981), a primotologist's investigation of the causes of gender-related differences in physiology, pathology, aging, etc.

Homosexuality is discussed in J. MARMOR (ed.), *Sexual Inversion: The Multiple Roots of Homosexuality* (1965); MARCEL SAGHIR and ELI ROBINS, *Male and Female Homosexuality: A Comprehensive Investigation* (1973); C.A. TRIPP, *The Homosexual Matrix* (1975); ALAN P. BELL and MARTIN S. WEINBERG, *Homosexualities: A Study of Diversity Among Men and Women* (1978); WILLIAM H. BULLOGH, *Homosexuality: A History* (1979); JONATHAN KATZ, *Gay American History: Lesbians and Gay Men in the U.S.A.: A Documentary* (1976); JEFFREY WEEKS, *Coming Out: Homosexual Politics in Britain from the Nineteenth Century to the Present* (1977); and GEORGE WEINBERG, *Society and the Healthy Homosexual* (1975).

Shakespeare

Widely regarded as the greatest writer of all time, William Shakespeare (or Shakspere) occupies a position unique in world literature. Other poets, such as Homer and Dante, and novelists, such as Leo Tolstoy and Charles Dickens, have transcended national barriers; but no writer's living reputation can seriously compare with that of Shakespeare, whose plays, written in the late 16th and early 17th centuries for a small repertory theatre, are now performed and read more often and in more countries than ever before. The prophecy of his great contemporary, the poet and dramatist Ben Jonson, that Shakespeare "was not of an age, but for all time," has been marvellously fulfilled. It may be audacious even to attempt a definition of his greatness, but it is not so difficult to describe the variety of gifts that enabled him to create imaginative visions of pathos and mirth that, whether read in the book or witnessed in the theatre, fill the mind and linger there. He is a writer of great intellectual rapidity, perceptiveness, and poetic power. Other writers have had these qualities. But with Shakespeare the keenness of mind was applied not to abstruse or remote subjects but to human beings and their complete range of emotions and conflicts. Other writers have applied their keenness of mind in this way. But Shakespeare is astonishingly clever with words and images, so that his mental energy, when applied to intelligible human situations, finds full and memorable expression, convincing and imaginatively stimulating. As if this were not enough, the art form into which his creative energies went was not remote and bookish but involved the vivid stage impersonation of human beings, commanding sympathy and inviting vicarious participation. Thus many of Shakespeare's great merits can survive translation into other languages and into cultures remote from that of Elizabethan England.

This article is divided into the following sections:

Shakespeare the man

LIFE

Although the amount of factual knowledge available about Shakespeare is surprisingly large for one of his station in life, many find it a little disappointing, for it is mostly gleaned from documents of an official character. Dates of baptisms, marriages, deaths, and burials; wills, conveyances, legal processes, and payments by the court—these are the dusty details. There is, however, a fair number of contemporary allusions to him as a writer, and these add a reasonable amount of flesh and blood to the biographical skeleton.

Early life in Stratford. The parish register of Holy Trinity Church, Stratford-upon-Avon, Warwickshire, shows that he was baptized there on April 26, 1564; his birthday is traditionally celebrated on April 23. His father, John Shakespeare, was a burgess of the borough, who in 1565 was chosen an alderman and in 1568 bailiff (the position corresponding to mayor, before the grant of a further charter to Stratford in 1664). He was engaged in various kinds of trade and appears to have suffered some fluctuations in prosperity. His wife, Mary Arden, of Wilmcote, Warwickshire, came from an ancient family and was the heiress to some land. (Given the somewhat rigid social distinctions of the 16th century, this marriage must have been a step up the social scale for John Shakespeare.)

Education at Stratford's grammar school

Stratford enjoyed a grammar school of good quality, and the education there was free, the schoolmaster's salary being paid by the borough. No lists of the pupils who were at the school in the 16th century have survived, but it would be absurd to suppose the bailiff of the town did not send his son there. The boy's education would consist

mostly of Latin studies—learning to read, write, and speak the language fairly well and studying some of the classical historians, moralists, and poets. Shakespeare did not go on to the university, and indeed it is unlikely that the tedious round of logic, rhetoric, and other studies then followed there would have interested him.

Instead, at the age of 18 he married. Where and exactly when are not known, but the episcopal registry at Worcester preserves a bond dated November 28, 1582, and executed by two yeomen of Stratford, named Sandells and Richardson, as a security to the bishop for the issue of a license for the marriage of William Shakespeare and "Anne Hathaway of Stratford," upon the consent of her friends and upon once asking of the banns. (Anne died in 1623, seven years after Shakespeare. There is good evidence to associate her with a family of Hathaways who inhabited a beautiful farmhouse, now much visited, two miles from Stratford.) The next date of interest is found in the records of the Stratford church, where a daughter, named Susanna, born to William Shakespeare, was baptized on May 26, 1583. On February 2, 1585, twins were baptized, Hamnet and Judith. (The boy Hamnet, Shakespeare's only son, died 11 years later.)

How Shakespeare spent the next eight years or so, until his name begins to appear in London theatre records, is not known. There are stories—given currency long after his death—of stealing deer and getting into trouble with a local magnate, Sir Thomas Lucy of Charlecote, near Stratford; of earning his living as a schoolmaster in the country; of going to London and gaining entry to the world of theatre by minding the horses of theatregoers; it has also been conjectured that Shakespeare spent some time as a member of a great household and that he was a soldier, perhaps in the Low Countries. In lieu of external evidence, such extrapolations about Shakespeare's life have often been made from the internal "evidence" of his writings. But this method is unsatisfactory: one cannot conclude, for example, from his allusions to the law that Shakespeare was a lawyer; for he was clearly a writer, who without difficulty could get whatever knowledge he needed for the composition of his plays.

Career in the theatre. The first reference to Shakespeare in the literary world of London comes in 1592, when a fellow dramatist, Robert Greene, declared in a pamphlet written on his deathbed:

Greene's attack on the "upstart" dramatist

> There is an upstart crow, beautified with our feathers, that with his *Tygers heart wrapt in a Players hide* supposes he is as well able to bombast out a blank verse as the best of you; and, being an absolute *Johannes Factotum,* is in his own conceit the only Shake-scene in a country.

It is difficult to be certain what these words mean; but it is clear that they are insulting and that Shakespeare is the object of the sarcasms. When the book in which they appear (*Greenes, groats-worth of witte, bought with a million of Repentance,* 1592) was published after Greene's death, a mutual acquaintance wrote a preface offering an apology to Shakespeare and testifying to his worth. This preface also indicates that Shakespeare was by then making important friends. For, although the puritanical city of London was generally hostile to the theatre, many of the nobility were good patrons of the drama and friends of actors. Shakespeare seems to have attracted the attention of the young Henry Wriothesley, the 3rd earl of Southampton; and to this nobleman were dedicated his first published poems, *Venus and Adonis* and *The Rape of Lucrece.*

One striking piece of evidence that Shakespeare began to prosper early and tried to retrieve the family fortunes and establish its gentility is the fact that a coat of arms was granted to John Shakespeare in 1596. Rough drafts of this grant have been preserved in the College of Arms, London, though the final document, which must have been handed to the Shakespeares, has not survived. It can scarcely be doubted that it was William who took the initiative and paid the fees. The coat of arms appears on Shakespeare's monument (constructed before 1623) in the Stratford church. Equally interesting as evidence of Shakespeare's worldly success was his purchase in 1597 of New Place, a large house in Stratford, which as a boy he must have passed every day in walking to school.

It is not clear how his career in the theatre began; but from about 1594 onward he was an important member of the Lord Chamberlain's Company of players (called the King's Men after the accession of James I in 1603). They had the best actor, Richard Burbage; they had the best theatre, the Globe; they had the best dramatist, Shakespeare. It is no wonder that the company prospered. Shakespeare became a full-time professional man of his own theatre, sharing in a cooperative enterprise and intimately concerned with the financial success of the plays he wrote.

Unfortunately, written records give little indication of the way in which Shakespeare's professional life molded his marvellous artistry. All that can be deduced is that for 20 years Shakespeare devoted himself assiduously to his art, writing more than a million words of poetic drama of the highest quality.

Private life. Shakespeare had little contact with officialdom, apart from walking—dressed in the royal livery as a member of the King's Men—at the coronation of King James I in 1604. He continued to look after his financial interests. He bought properties in London and in Stratford. In 1605 he purchased a share (about one-fifth) of the Stratford tithes—a fact that explains why he was eventually buried in the chancel of its parish church. For some time he lodged with a French Huguenot family called Mountjoy, who lived near St. Olave's Church, Cripplegate, London. The records of a lawsuit in May 1612, due to a Mountjoy family quarrel, show Shakespeare as giving evidence in a genial way (though unable to remember certain important facts that would have decided the case) and as interesting himself generally in the family's affairs.

Shakespeare's financial interests

No letters written by Shakespeare have survived, but a private letter to him happened to get caught up with some official transactions of the town of Stratford and so has been preserved in the borough archives. It was written by one Richard Quiney and addressed by him from the Bell Inn in Carter Lane, London, whither he had gone from Stratford upon business. On one side of the paper is inscribed: "To my loving good friend and countryman, Mr. Wm. Shakespeare, deliver these." Apparently Quiney thought his fellow Stratfordian a person to whom he could apply for the loan of £30—a large sum in Elizabethan money. Nothing further is known about the transaction, but, because so few opportunities of seeing into Shakespeare's private life present themselves, this begging letter becomes a touching document. It is of some interest, moreover, that 18 years later Quiney's son Thomas became the husband of Judith, Shakespeare's second daughter.

Shakespeare's will (made on March 25, 1616) is a long and detailed document. It entailed his quite ample property on the male heirs of his elder daughter, Susanna. (Both his daughters were then married, one to the aforementioned Thomas Quiney and the other to John Hall, a respected physician of Stratford.) As an afterthought, he bequeathed his "second-best bed" to his wife; but no one can be certain what this notorious legacy means. The testator's signatures to the will are apparently in a shaky hand. Perhaps Shakespeare was already ill. He died on April 23, 1616. No name was inscribed on his gravestone in the chancel of the parish church of Stratford-upon-Avon. Instead these lines, possibly his own, appeared:

Good friend, for Jesus' sake forbear
To dig the dust enclosed here.
Blest be the man that spares these stones,
And curst be he that moves my bones.

EARLY POSTHUMOUS DOCUMENTATION

Shakespeare's family or friends, however, were not content with a simple gravestone, and, within a few years, a monument was erected on the chancel wall. It seems to have existed by 1623. Its epitaph, written in Latin and inscribed immediately below the bust, attributes to Shakespeare the worldly wisdom of Nestor, the genius of Socrates, and the poetic art of Virgil. This apparently was how his contemporaries in Stratford-on-Avon wished their fellow citizen to be remembered.

The tributes of his colleagues. The memory of Shakespeare survived long in theatrical circles, for his plays remained a major part of the repertory of the King's Men until the closing of the theatres in 1642. The greatest of Shakespeare's great contemporaries in the theatre, Ben Jonson, had a good deal to say about him. To William Drummond of Hawthornden in 1619 he said that Shakespeare "wanted art." But, when he came to write his splendid poem prefixed to the Folio edition of Shakespeare's plays in 1623, he rose to the occasion with stirring words of praise:

> Triumph, my Britain, thou hast one to show
> To whom all scenes of Europe homage owe.
> He was not of an age, but for all time!

Besides almost retracting his earlier gibe about Shakespeare's lack of art, he gives testimony that Shakespeare's personality was to be felt, by those who knew him, in his poetry—that the style was the man. Jonson also reminded his readers of the strong impression the plays had made upon Queen Elizabeth I and King James I at court performances:

> Sweet Swan of Avon, what a sight it were
>   To see thee in our waters yet appear,
> And make those flights upon the banks of Thames
>   That so did take Eliza and our James!

Popularity of the plays

Shakespeare seems to have been on affectionate terms with his theatre colleagues. His fellow actors John Heminge and Henry Condell (who, with Burbage, were remembered in his will) dedicated the First Folio of 1623 to the Earl of Pembroke and the Earl of Montgomery, explaining that they had collected the plays "... without ambition either of self-profit or fame; only to keep the memory of so worthy a friend and fellow alive as was our Shakespeare, ... "

Anecdotes and documents. Seventeenth-century antiquaries began to collect anecdotes about Shakespeare, but no serious life was written until 1709, when Nicholas Rowe tried to assemble information from all available sources with the aim of producing a connected narrative. There were local traditions at Stratford: witticisms and lampoons of local characters; scandalous stories of drunkenness and sexual escapades. About 1661 the Vicar of Stratford wrote in his diary: "Shakespeare, Drayton, and Ben Jonson had a merry meeting, and it seems drank too hard; for Shakespeare died of a fever there contracted." On the other hand, the antiquary John Aubrey wrote in some notes about Shakespeare: "He was not a company keeper; lived in Shoreditch; wouldn't be debauched, and, if invited to, writ he was in pain." Richard Davies, archdeacon of Lichfield, reported, "He died a papist." How much trust can be put in such a story is uncertain. In the early 18th century, a story appeared that Queen Elizabeth had obliged Shakespeare "to write a play of Sir John Falstaff in love" and that he had performed the task (*The Merry Wives of Windsor*) in a fortnight. There are other stories, all of uncertain authenticity and some mere fabrications.

When serious scholarship began in the 18th century, it was too late to gain anything from traditions. But documents began to be discovered. Shakespeare's will was found in 1747 and his marriage license in 1836. The documents relating to the Mountjoy lawsuit already mentioned were found and printed in 1910. It is possible that further documents of a legal nature may yet be discovered, but as time passes the hope becomes more remote. Modern scholarship is more concerned to study Shakespeare in relation to his social environment, both in Stratford and in London. This is not easy, because the author and actor lived a somewhat detached life: a respected tithe-owning country gentleman in Stratford, perhaps, but a rather rootless artist in London.

Portraits. Curiosity about what Shakespeare looked like has not been adequately satisfied. Two representations have indisputable claims to authenticity: a half-length bust in the Stratford-upon-Avon parish church, which was in position within a few years of his death; and an engraving used as a frontispiece to the Folio edition of his plays in 1623. The family must have approved the memorial statue, and presumably his friends must have thought the engraving a reasonable likeness. The bust shows Shakespeare with a pen in his hand; the face is rather round, but the high forehead is striking. The engraving is by Martin Droeshout, a member of a family of Flemish artists resident in London, and it has provided the image by which Shakespeare is now best known. The "Chandos" portrait (so called because the Duke of Chandos once owned it) in the National Portrait Gallery, London, seems to have been owned by Sir William Davenant. It resembles the bust and the engraving to a certain extent and could have been a portrait painted in Shakespeare's lifetime. Many other portraits alleged to be of Shakespeare began to appear in the later 17th century and in the 18th century. These are artists' "creations," fabrications, or downright forgeries.

The Droeshout engraving

The poet and dramatist

THE INTELLECTUAL BACKGROUND

Shakespeare lived at a time when ideas and social structures established in the Middle Ages still informed men's thought and behaviour. Queen Elizabeth I was God's deputy on earth, and lords and commons had their due places in society under her, with responsibilities up through her to God and down to those of more humble rank. The order of things, however, did not go unquestioned. Atheism was still considered a challenge to the beliefs and way of life of a majority of Elizabethans, but the Christian faith was no longer single—Rome's authority had been challenged by Martin Luther, John Calvin, a multitude of small religious sects, and, indeed, the English church itself. Royal prerogative was challenged in Parliament; the economic and social orders were disturbed by the rise of capitalism, by the redistribution of monastic lands under Henry VIII, by the expansion of education, and by the influx of new wealth from discovery of new lands.

An interplay of new and old ideas was typical of the time: official homilies exhorted the people to obedience, the Italian political theorist Niccolò Machiavelli was expounding a new practical code of politics that caused Englishmen to fear the Italian "Machiavillain" and yet prompted them to ask what men do, rather than what they should do. In *Hamlet,* disquisitions—on man, belief, a "rotten" state, and times "out of joint"—clearly reflect a growing disquiet and skepticism. The translation of Montaigne's *Essays* in 1603 gave further currency, range, and finesse to such thought, and Shakespeare was one of many who read them, making direct and significant quotations in *The Tempest.* In philosophical inquiry the question "how?" became the impulse for advance, rather than the traditional "why?" of Aristotle. Shakespeare's plays written between 1603 and 1606 unmistakably reflect a new, Jacobean distrust. James I, who, like Elizabeth, claimed divine authority, was far less able than she to maintain the authority of the throne. The so-called Gunpowder Plot (1605) showed a determined challenge by a small minority in the state; James's struggles with the House of Commons in successive Parliaments, in addition to indicating the strength of the "new men," also revealed the inadequacies of the administration.

POETIC CONVENTIONS AND DRAMATIC TRADITIONS

The Latin comedies of Plautus and Terence were familiar in Elizabethan schools and universities, and English translations or adaptations of them were occasionally performed by students. Seneca's rhetorical and sensational tragedies, too, had been translated and often imitated, both in structure and rhetoric. But there was also a strong native dramatic tradition deriving from the medieval miracle plays, which had continued to be performed in various towns until forbidden during Elizabeth's reign. This native drama had been able to assimilate French popular farce, clerically inspired morality plays on abstract themes, and interludes or short entertainments that made use of the "turns" of individual clowns and actors. Although Shakespeare's immediate predecessors were known as "university wits," their plays were seldom structured in the manner of those they had studied at Oxford or Cambridge; instead, they used and developed the more popular narrative forms. Their subplots, for example, amplified the main action and theme with a freedom and awareness of hierarchical correspondences that are medieval rather than classical.

The contemporary drama of Shakespeare's time

Changes in language. The English language at this time was changing and extending its range. The poet Edmund Spenser led with the restoration of old words, and schoolmasters, poets, sophisticated courtiers, and travellers all brought further contributions from France, Italy, and the Roman classics, as well as from farther afield. Helped by the growing availability of cheaper, printed books, the language began to become standardized in grammar and vocabulary and, more slowly, in spelling. Ambitious for a European and permanent reputation, the essayist and philosopher Francis Bacon wrote in Latin as well as in English; but, if he had lived only a few decades later, even he might have had total confidence in his own tongue.

Shakespeare's literary debts. In Shakespeare's earlier works his debts stand out clearly: to Plautus for the structure of *The Comedy of Errors;* to the poet Ovid and to Seneca for rhetoric and incident in *Titus Andronicus;* to morality drama for a scene in which a father mourns his dead son, and a son his father, in *Henry VI;* to Marlowe for sentiments and characterization in *Richard III* and *The Merchant of Venice;* to the Italian popular tradition of commedia dell'arte for characterization and dramatic style in *The Taming of the Shrew;* and so on. But he did not then reject these influences; rather, he made them his own, so that soon there was no line between their effects and his. In *The Tempest* (which is perhaps the most original of all his plays in form, theme, language, and setting) folk influences may also be traced, together with a newer and more obvious debt to a courtly diversion known as the masque, as developed by Ben Jonson and others at the court of King James.

THEATRICAL CONDITIONS

The Globe and its predecessor, the Theatre, were public playhouses run by the Chamberlain's Men (later the King's Men), a leading theatre company of which Shakespeare was a member. To these playhouses almost all classes of citizens, except the Puritans, came for afternoon entertainment. The players were also summoned to court, to perform before the monarch and assembled nobility. In the summer they toured the provinces, and on occasion they performed at London's Inns of Court (associations of law students), at universities, and in great houses. Popularity led to an insatiable demand for plays: repertories were always changing, so that early in 1613 the King's Men could present "fourteen several plays." The theatre soon became fashionable too, and in 1608–09 the King's Men started to perform on a regular basis at the Blackfriars, a "private" indoor theatre where high admission charges assured the company a more select and sophisticated audience for their performances.

Shakespeare's first associations with the Chamberlain's Men seem to have been as an actor. He is not known to have acted after 1603, and tradition gives him only secondary roles, such as the ghost in *Hamlet* and Adam in *As You Like It,* but his continuous association must have given him direct working knowledge of all aspects of theatre: like Aeschylus, Molière, Bertolt Brecht, or Harold Pinter, Shakespeare was able to work with his plays in rehearsal and performance and to know his actors and his audiences and all the different potentialities of theatres and their equipment. Numerous passages in Shakespeare's plays show conscious concern for theatre arts and audience reactions. Prospero in *The Tempest* speaks of the whole of life as a kind of "revels," or theatrical show, that, like a dream, will soon be over. The Duke of York in *Richard II* is conscious of how

> . . . in a theatre, the eyes of men,
> After a well-graced actor leaves the stage
> Are idly bent on him that enters next,
> Thinking his prattle to be tedious.

And Hamlet gives expert advice to visiting actors in the art of playing.

The Elizabethan playhouse

In Shakespeare's day, there was little time for group rehearsals, and actors were given the words of only their own parts. The crucial scenes in Shakespeare's plays, therefore, are between two or three characters only, or else are played with one character dominating a crowded stage. Female parts were written for young male actors or boys, so Shakespeare did not often write big roles for them or keep them actively engaged on stage for lengthy periods. Writing for the clowns of the company—who were important popular attractions in any play—presented the problem of allowing them to use their comic personalities and tricks and yet have them serve the immediate interests of theme and action.

Theatre is a collaborative art, only occasionally yielding the right conditions for individual genius to flourish and develop, and Shakespeare's achievement must at least in part be due to his continuous association with the Chamberlain's and King's Men, who were as practiced in acting together as he was to become in writing with their ensemble skills in mind.

CHRONOLOGY OF SHAKESPEARE'S PLAYS

Despite much scholarly argument, it is often impossible to date a given play precisely. But there is a general consensus, especially for plays written 1585–1601, 1605–07, and 1609 onward. The following list of first performances is based on external and internal evidence, on general stylistic and thematic considerations, and on the observation that an output of no more than two plays a year seems to have been established in those periods when dating is rather clearer than others.

1589–92	*1 Henry VI, 2 Henry VI, 3 Henry VI*
1592–93	*Richard III, The Comedy of Errors*
1593–94	*Titus Andronicus, The Taming of the Shrew*
1594–95	*The Two Gentlemen of Verona, Love's Labour's Lost, Romeo and Juliet*
1595–96	*Richard II, A Midsummer Night's Dream*
1596–97	*King John, The Merchant of Venice*
1597–98	*1 Henry IV, 2 Henry IV*
1598–99	*Much Ado About Nothing, Henry V*
1599–1600	*Julius Caesar, As You Like It*
1600–01	*Hamlet, The Merry Wives of Windsor*
1601–02	*Twelfth Night, Troilus and Cressida*
1602–03	*All's Well That Ends Well*
1604–05	*Measure For Measure, Othello*
1605–06	*King Lear, Macbeth*
1606–07	*Antony and Cleopatra*
1607–08	*Coriolanus, Timon of Athens*
1608–09	*Pericles*
1609–10	*Cymbeline*
1610–11	*Winter's Tale*
1611–12	*The Tempest*
1612–13	*Henry VIII, The Two Noble Kinsmen*

Shakespeare's two narrative poems, *Venus and Adonis* and *The Rape of Lucrece,* can be dated with certainty to the years when the Plague stopped dramatic performances in London, in 1592 and 1593–94, respectively, just before their publication. But the sonnets offer many and various problems; they cannot have been written all at one time, and most scholars set them within the period 1593–1600. "The Phoenix and the Turtle" can be dated 1600–01.

PUBLICATION

Pirated versions of plays

During Shakespeare's early career, dramatists invariably sold their plays to an actor's company, who then took charge of them, prepared working promptbooks, and did their best to prevent another company or a publisher from getting copies; in this way they could exploit the plays themselves for as long as they drew an audience. But some plays did get published, usually in small books called quartos. Occasionally plays were "pirated," the text being dictated by one or two disaffected actors from the company that had performed it or else made up from shorthand notes taken surreptitiously during performance and subsequently corrected during other performances; parts 2 and 3 of the *Henry VI* (1594 and 1595) and *Hamlet* (1603) quartos are examples of pirated, or "bad," texts. Sometimes an author's "foul papers" (his first complete draft) or his "fair" copy—or a transcript of either of these—got into a publisher's hands, and "good quartos" were printed from them, such as those of *Titus Andronicus* (1594), *Love's Labour's Lost* (1598), and *Richard II* (1597). After the publication of "bad" quartos of *Hamlet* and *Romeo and Juliet* (1597), the Chamberlain's Men probably arranged for the release of the "foul papers" so that second—"good"—quartos could supersede the garbled versions already on the market. This company had powerful friends at court, and in 1600 a special order was entered in the Stationers' Register to "stay" the publication of *As You Like It, Much Ado About Nothing,* and *Henry V,* possibly in order to assure that good texts were available. Subsequently *Henry V* (1600) was pirated, and *Much Ado About Nothing* was printed from "foul papers"; *As You Like It* did not appear in print until it was included in *Mr. William Shakespeares Comedies, Histories & Tragedies,* published in folio (the reference is to the size of page) by a syndicate in 1623 (later editions appearing in 1632 and 1663).

The only precedent for such a collected edition of public theatre plays in a handsome folio volume was Ben Jonson's collected plays of 1616. Shakespeare's folio included 36 plays, 22 of them appearing for the first time in a good text. (For the Third Folio reissue of 1664, *Pericles* was added from a quarto text of 1609, together with six apocryphal plays.) The First Folio texts were prepared by John Heminge and Henry Condell (two of Shakespeare's fellow sharers in the Chamberlain's, now the King's Men), who made every effort to present the volume worthily. Only about 230 copies of the First Folio are known to have survived.

The following list gives details of plays first published individually and indicates the authority for each substantive edition. Q stands for Quarto: Q2, Q3, Q4, etc., stand for reprints of an original quarto. F stands for the First Folio edition of 1623.

2 Henry VI Q 1594: a reported text. F from revised fair copies, edited with reference to Q.

Titus Andronicus Q 1594: from foul papers. F from a copy of Q, with additions from a manuscript that had been used as a promptbook.

3 Henry VI Q 1595: a reported text. F as for *2 Henry VI.*

Richard III Q 1597: a reconstructed text prepared for use as a promptbook. F from reprints of Q, edited with reference to foul papers and containing some 200 additional lines.

Love's Labour's Lost Q is lost. Q2 1598: from foul papers, and badly printed. F from Q2.

Romeo and Juliet Q 1597: a reported text. Q2 from foul papers, with some reference to Q. F from a reprint of Q2.

Richard II Q 1597: from foul papers and missing the abdication scene. Q4 1608, with reported version of missing scene. F from reprints of Q, but the abdication scene from an authoritative manuscript, probably the promptbook (of which traces appear elsewhere in F).

1 Henry IV Q 1598: from foul papers. F from Q5, with some literary editing.

A Midsummer Night's Dream Q 1600: from the author's fair copy. F from Q2, with some reference to a promptbook.

The Merchant of Venice Q 1600: from foul papers. F from Q, with some reference to a promptbook.

2 Henry IV Q 1600: from foul papers. F from Q, with reference to a promptbook.

Much Ado About Nothing Q 1600: from the author's fair papers. F from Q, with reference to a promptbook.

Henry V Q 1600: a reported text. F from foul papers (possibly of a second version of the play).

The Merry Wives of Windsor Q 1602: a reported (and abbreviated) text. F from a transcript, by Ralph Crane (scrivener of the King's Men), of a revised promptbook.

Hamlet Q 1603: a reported text, with reference to an earlier play. Q2 from foul papers, with reference to Q. F from Q2, with reference to a promptbook, with theatrical and authorial additions.

King Lear Q 1608: from an inadequate transcript of foul papers, with use made of a reported version. F from Q, collated with a promptbook of a shortened version.

Troilus and Cressida Q 1609: from a fair copy, possibly the author's. F from Q, with reference to foul papers, adding 45 lines and the Prologue.

Pericles Q 1609: a poor text, badly printed with both auditory and graphic errors.

Othello Q 1622: from a transcript of foul papers. F from Q, with corrections from another authorial version of the play.

The plays published for the first time in the First Folio of 1623 are:

All's Well That Ends Well From the author's fair papers, or a transcript of them.

Antony and Cleopatra From an authorial fair copy.

1 Henry VI

As You Like It From a promptbook, or a transcript of it.

The Comedy of Errors From foul papers.

Coriolanus From an authorial fair copy, edited for the printer.

Cymbeline From an authorial copy, or a transcript of such, imperfectly prepared as a promptbook.

Henry VIII From a transcript of a fair copy, made by the author, prepared for reading.

Julius Caesar From a transcript of a promptbook.

King John From an authorial fair copy.

Macbeth From a promptbook of a version prepared for court performance.

Measure for Measure From a transcript, by Ralph Crane, of very imperfect foul papers.

The Taming of the Shrew From foul papers.

The Tempest From an edited transcript, by Ralph Crane, of the author's papers.

Timon of Athens From foul papers, probably unfinished.

Twelfth Night From a promptbook, or a transcript of it.

The Two Gentlemen of Verona From a transcript, by Ralph Crane, of a promptbook, probably of a shortened version.

The Winter's Tale From a transcript, by Ralph Crane, probably from the author's fair copy.

The texts of *Venus and Adonis* (1593) and *The Rape of Lucrece* (1594) are remarkably free from errors. Shakespeare presumably furnished a fair copy of each for the printer. He also seems to have read the proofs. The sonnets were published in 1609, but there is no evidence that Shakespeare oversaw their publication (see below *Understanding Shakespeare: The contribution of textual criticism*).

POETIC AND DRAMATIC POWERS

The early poems. Shakespeare dedicated the poem *Venus and Adonis* to his patron, Henry Wriothesley, 3rd earl of Southampton, whom he further promised to honour with "some graver labour"—perhaps *The Rape of Lucrece,* which appeared a year later and was also dedicated to Southampton. As these two poems were something on which Shakespeare was intending to base his reputation with the public and to establish himself with his patron, they were displays of his virtuosity—diploma pieces. They were certainly the most popular of his writings with the reading public and impressed them with his poetic genius. Seven editions of *Venus and Adonis* had appeared by 1602 and 16 by 1640; *Lucrece,* a more serious poem, went through eight editions by 1640; and there are numerous allusions to them in the literature of the time. But after that, until the 19th century, they were little regarded. Even then the critics did not know what to make of them: on the one hand, *Venus and Adonis* is licentiously erotic (though its sensuality is often rather comic); while *Lucrece* may seem to be tragic enough, the treatment of the poem is yet somewhat cold and distant. In both cases the poet seems to be displaying dexterity rather than being "sincere." But Shakespeare's detachment from his subjects has come to be admired in more recent assessments.

Shakespeare's bid for fame

Above all, the poems give evidence for the growth of Shakespeare's imagination. *Venus and Adonis* is full of vivid imagery of the countryside; birds, beasts, the hunt, the sky, and the weather, the overflowing Avon—these give freshness to the poem and contrast strangely with the sensuous love scenes. *Lucrece* is more rhetorical and elaborate than *Venus and Adonis* and also aims higher. Its disquisitions (upon night, time, opportunity, and lust, for example) anticipate brilliant speeches on general themes in the plays—on mercy in *The Merchant of Venice,* suicide in *Hamlet,* and "degree" in *Troilus and Cressida.*

There are a few other poems attributed to Shakespeare. When the *Sonnets* were printed in 1609, a 329-line poem, "A Lovers complaint," was added at the end of the volume, plainly ascribed by the publisher to Shakespeare. There has been a good deal of discussion about the authorship of this poem. Only the evidence of style, however, could call into question the publisher's ascription, and this is conflicting. Parts of the poem and some lines are brilliant, but other parts seem poor in a way that is not like Shakespeare's careless writing. Its narrative structure is remarkable, however, and the poem deserves more attention than it usually receives. It is now generally thought to be from Shakespeare's pen, possibly an early poem revised by him at a more mature stage of his poetical style. Whether the poem in its extant form is later or earlier than *Venus and Adonis* and *Lucrece* cannot be decided. No one could doubt the authenticity of "The Phoenix and the Turtle," a 67-line poem that appeared with other "poetical essays" (by John Marston, George Chapman, and Ben Jonson) appended to Robert Chester's poem *Loves Martyr* in 1601. The poem is attractive and memorable, but very obscure, partly because of its style and partly because it contains allusions to real persons and situations whose identity can now only be guessed at.

The sonnets. In 1609 appeared *SHAKE-SPEARES SONNETS. Never before Imprinted.* At this date Shakespeare was already a successful author, a country gentleman, and an affluent member of the most important theatrical enterprise in London. How long before 1609 the sonnets were written is unknown. The phrase "never before imprinted" may imply that they had existed for some time but were now at last printed. Two of them (nos. 138 and 144) had in fact already appeared (in a slightly different form) in an anthology, *The Passionate Pilgrime* (1599). Shakespeare had certainly written some sonnets by 1598, for in that year Francis Meres, in a "survey" of literature, made reference to "his sugared sonnets among his private friends," but whether these "sugared sonnets" were those eventually published in 1609 cannot be ascertained—Shakespeare may have written other sets of sonnets, now lost. Nevertheless, the sonnets included in *The Passionate Pilgrime* are among his most striking and mature, so it is likely that most of the 154 sonnets that appeared in the 1609 printing belong to Shakespeare's early 30s rather than to his 40s—to the time when he was writing *Richard II* and *Romeo and Juliet* rather than when he was writing *King Lear* and *Antony and Cleopatra.* But, of course, some of them may belong to any year of Shakespeare's life as a poet before 1609.

Contemporary reference to Shakespeare's "sugared sonnets"

The order of the poems. Elizabethan sonnet sequences (following the example of their Italian and French models) were generally in some kind of narrative order. Sir Philip Sidney's *Astrophel and Stella,* moreover, and Edmund Spenser's *Amoretti* each tells a reasonably well authenticated story.

Shakespeare's sonnets, however, do not give the impression of an ordered sequence as it exists in Sidney, Spenser, and others. It is only at times that a narrative can be sensed, frequently breaking off, then resuming later or reverting to an earlier stage of the "story." It is therefore often argued that there was an original order, which has been lost, and many efforts have been made to recover, by ingenious analysis, Shakespeare's "intended" order. Although some interesting observations about associations between widely separated sonnets have been the result, none of the schemes carries any conviction. Most critics feel that it is hopeless to try to replace the order of the 1609 edition with anything convincingly better, arguing that the sonnets have no pretensions to be complete or adequate as a narrative. They are mixed in mood, in quality, and in distinction. Some seem open, addressed to all the world. Some seem too cryptic and personal ever to be intelligible.

It is equally uncertain whether the 1609 arrangement bears any relation to the order in which the sonnets were actually written. It may reasonably be supposed that the printer followed, more or less, the order in which the sonnets appeared in manuscript (or manuscripts). It is quite likely, however, that single leaves of the manuscript got out of order (for the numbers attached to each poem could well be a printer's addition), which, if so, might explain why some groups or pairs of sonnets seem to be oddly separated.

Sonnets 1 to 17 are variations on one theme. A handsome young man is being persuaded to marry and beget offspring who will preserve his beauty in a new generation, though he himself will lose it as he grows old. Gradually this theme gives place to the idea that the beloved will survive through the poet's verse. (There is no discussion of the relative merits of the two kinds of immortality.)

Sonnets 18 to 126 are on a variety of themes associated with a handsome young man (who is presumably, but not necessarily, the youth of 1 to 17). The poet enjoys his friendship and is full of admiration, promising to bestow immortality on the young man by the poems he writes in his honour. But sometimes the young man seems cold. Sometimes he provokes jealousy by his admiration of another poet. The climax of the series comes when the young man seduces the poet's woman. But eventually the poet reconciles himself to the situation and realizes that his love for his friend is greater than his desire to keep the woman.

The "dark lady" of the late sonnets

Sonnet 126 seems a kind of concluding poem (and is not in sonnet form). Then begins a new series, principally about a dark lady by whom the poet is enthralled, though well aware of her faults. At one point, she is stolen from him by his best friend. This faithlessness of both friend and woman wounds the poet deeply. He nevertheless tries to rise above his disappointment. (The two concluding sonnets are impersonal translations of a familiar Renaissance theme about Cupid.)

Artistic invention or real experience. Various persons are addressed or referred to in the poems, though whether they are real people or fictions of Shakespeare's dramatic imagination is not entirely clear. But if the "story" of the sonnets is an invention, then it is badly invented, showing nothing of the skill in storytelling that Shakespeare elsewhere reveals. The relationships between "characters," moreover, are so obscure, so irritatingly cryptic, that it is difficult to believe Shakespeare was devising the story for artistic purposes. The very clumsiness and obscurity of the narrative, if it is considered a fiction, are a strong argument that the sonnets are close to real experience; yet a degree of fictionalization in the sonnets would be in accord with Shakespeare's lifelong devotion to writing plays and with the pervasive "impersonality" of his art as a dramatist.

Some critics have been tempted to declare that it does not matter who the young man and the dark lady were—that the poetry is the important thing. Though as a gesture of impatience this mood is understandable, the world will continue to be curious about the circumstances of these poems, and, if historical documents should be discovered bringing hard facts to bear on the matter, the sonnets would surely be reinterpreted in the light of those facts. But for now, the sonnets on the whole retain an obstinate privacy that is a bar to enjoyment and therefore must be judged a fault, one that would hinder altogether the appreciation of any poems less brilliant. The sonnets do not quite "create a world" within which they can be apprehended. There is the sense of a missing (or unascertainable) body of experience and reference that falls short of poetical mystery.

Attempts to discover details of his life in the poems

Human experience in the poems. From the beginning of the 19th century, explorations of Shakespeare's personality have constantly been made by studying the sonnets. William Wordsworth proclaimed that "with this key Shakespeare unlocked his heart." But many readers feel that Shakespeare the man is elusive in the sonnets, just as he is in the plays. It has been natural to look in the poems for "personal details" about the author. One can observe allusions to his insomnia, to his disapproval of false hair and painted cheeks, to his love of music, and, according to some, to his bisexuality. It does not amount to very much.

The experiences of love and friendship, as related in the sonnets, must be described as disheartening and disenchanted. On the plane of human experience, they are full of disappointment, separation, anxiety, estrangement, self-accusation, and failure. The triumph, or near triumph, of death and of time is deeply felt. Only on the transcendental plane and in the faith in the permanence of poetry does a positive or affirmative attitude assert itself and compensate for the outcast state of the poet and the dateless night of death. On the whole they are quieter and closer to normal human experience than are the plays. The storms of passion are absent. Instead, there is a refined analysis of feeling, somehow more characteristic of the method of Jane Austen and Henry James than of Shakespeare the playwright. There are, of course, many moments of comparable moral scrupulousness in the plays, but they come incidentally and sometimes a little irrelevantly, perhaps, or awkwardly. In the sonnets Shakespeare brilliantly controls the shifting texture of the words in accordance with the variations in mood and tone. Generally, a careful analysis of the words reveals the tone in which a sonnet should be read, though, it must be admitted, this can be ambiguous.

The attractions of the sonnets are indeed very great. They win the admiration of readers by a variety of virtues. They express strong feeling, but they preserve artistic control. They have a density of thought and imagery that makes them seem the quintessence of the poetical experience. They delight by a felicity of phrase and verse movement, no less memorable than that familiar in the plays. They have, in recent years, received more exegesis than any of Shakespeare's plays, except perhaps *Hamlet* and *King Lear.* This is not necessarily a testimony to their value, for they have a tantalizing quality that encourages continued commentary. But it would be ungenerous not to relate this keen interest in the sonnets to an appreciation of their poetic power, of their unembarrassed exploration of intimate human relationships, and of their sensitivity to the tragedy of human aspirations and the triumph of time.

The early plays. Although the record of Shakespeare's early theatrical success is obscure, clearly the newcomer soon made himself felt. His brilliant two-part play on the Wars of the Roses, *The Whole Contention between the two Famous Houses, Lancaster and Yorke,* was among his earliest achievements. He showed, in *The Comedy of Errors,* how hilariously comic situations could be shot through with wonder and sentiment. In *Titus Andronicus* he scored a popular success with tragedy in the high Roman fashion. *The Two Gentlemen of Verona* was a new kind of romantic comedy. The world has never ceased to enjoy *The Taming of the Shrew. Love's Labour's Lost* is an experiment in witty and satirical observation of society. *Romeo and Juliet* combines and interconnects a tragic situation with comedy and gaiety. All this represents the probable achievement of Shakespeare's first half-dozen years as a writer for the London stage, perhaps by the time he had reached 30. It shows astonishing versatility and originality.

Henry VI, 1, 2, and 3. In *The Contention,* a two-part chronicle play (called in the First Folio *2 Henry VI; 3 Henry VI*), Shakespeare seems to have discovered the theatrical excitement that can be generated by representing recent history on the stage—events just beyond living memory but of great moment in the lives of present generations. The civil wars (popularly known as the Wars of the Roses) resulted from the struggle of two families, York and Lancaster, for the English throne. They had ended in 1485 with Richard III's defeat at the Battle of Bosworth, when Henry Tudor, as Henry VII, established a secure dynasty. Queen Elizabeth I was the granddaughter of Henry VII, so the story of York and Lancaster was of great interest to Shakespeare's contemporaries. In *2 Henry VI* the power struggle turns around the ineffective King Henry VI, until gradually the Duke of York emerges as contender for the throne. The climaxes of *3 Henry VI* include the murder of the Duke of York by the Lancastrians and, in the final scene, the murder of King Henry by Richard (York's son and the future Richard III). Shakespeare already showed himself a master of tragic poetry, notably in the speech of the captured York (wounded, mocked by a paper crown on his head, and awaiting death under the cruel taunts of Queen Margaret) and in the meditation of the King on the miseries of civil war. The vigorous and comic scenes with Jack Cade, a rebel leader, and his followers anticipate the kind of political comment that Shakespeare handled with greater subtlety in introducing the mobs of plebeians in *Julius Caesar* and *Coriolanus.*

His early mastery of tragic poetry

A third play, *1 Henry VI,* about the early part of the reign of King Henry VI, concerns events preceding the opening of the first part of *The Contention.* This is less successful, and it is uncertain whether it was a first effort at a historical play, written before *The Contention,* or a preparatory supplement to it, written subsequently and less inspired. It was printed in the 1623 Folio as the first part of *King Henry VI; The Contention* appeared as the second and third parts of *King Henry VI,* on what authority is not known.

The Comedy of Errors. The title of this, Shakespeare's shortest play, speaks for itself (though the opening scene is, unexpectedly, full of pathos). The play is based on Plautus' *Menaechmi,* a play of the comic confusions deriving from the presence of twin brothers, unknown to each other, in the same town; but Shakespeare has added twin servants, and he fills the play with suspense, surprise, expectation, and exhilaration as the two pairs weave their way through quadruple misunderstandings. The play already reveals Shakespeare's mastery of construction.

Titus Andronicus. This play was highly popular and held the stage for many years. Its crude story, its many savage incidents, and its poetic style have led some critics to think it not by Shakespeare. But the tendency of recent criticism is to regard the play as wholly or essentially his, and, indeed, when considered on its own terms as a "Roman tragedy," it displays a uniformity of tone and reveals a consistency of dramatic structure as a picture of the decline of the ancient world (though, by the standards of Shakespeare's later Roman plays, this picture is much confused).

The Two Gentlemen of Verona. Shakespeare took this play's story from a long Spanish prose romance called *Diana,* by Jorge de Montemayor. He added new characters—including Valentine, one of the "Two Gentlemen," whose "ideal" friendship with Proteus is so developed that the plot is more than a love story; indeed, the play glorifies friendship to an extent that, by modern conventions, is absurd. The abrupt last scene suggests that something has gone wrong with the text, and certainly Shakespeare was never again so ready to abandon common sense in motivating the behaviour of his lovers. But it is also clear that Shakespeare is here feeling his way toward a new kind of high comedy, later to find expression in *The Merchant of Venice* and *Twelfth Night.*

The Taming of the Shrew. Often played as a boisterous farce, this play is actually a comedy of character, with implications beyond the story of the wooing, wedding, and taming of Katharina, the "shrew," by Petruchio, a man with a stronger will than her own. Shakespeare arouses more interest in these two than farce permits. They gain, for example, by contrast with the tepid, silly, or infatuated lovers (Bianca, Lucentio, Hortensio, and Gremio), and their relationship is given an admirable vitality and energy; while in the play's last scene Katharina's discourse on wifely submission—if spoken with sincerity and genuine tenderness and without irony—has a moving quality in performance. The Italianate play about the shrew taming is set inside another play (concerning a trick played upon Christopher Sly, a drunken tinker), which gave Shakespeare an opportunity for some brilliant English country scenes. Originally, Sly was made the "audience" of the shrew play, a device that is abandoned after a little while (that is, in the text of the 1623 Folio). Probably the players' company came to abandon the Christopher Sly framing because the Katharina and Petruchio story was too strong not to be acted directly at the real audience in a theatre.

Early version of *The Taming of the Shrew*

Love's Labour's Lost. Once regarded as obsolete, depending too much upon temporary and irrecoverable allusions, this play has come to life in the theatre only during the past 50 years. Its rejection by the theatre was a background for 18th- and 19th-century critics such as John Dryden, Dr. Johnson, and William Hazlitt, all of whom had severe things to say about it. But, once the play had been recovered for the theatre, it was discovered that it is full of humanity, exploring the consequences of man being made of flesh and blood. The central comic device is that of four young men, dedicated to study and to the renunciation of women, meeting four young women;

inevitably they abandon their absurd principles. For variety, and as an escape from the pretty, gay, young royalty and courtiers, there is an entertaining band of eccentrics who are allowed their "vaudeville" turns: Sir Nathaniel the curate, Holofernes the schoolmaster, Dull the constable, Costard the clown, and Jaquenetta the country girl; linking both groups is Don Adriano de Armado the ineffable (who begins by being a bore but becomes interesting as he becomes pathetic). Toward the end, the play takes on a new dramatic vitality through a brilliant *coup de théâtre:* the sudden arrival of Mercade as the messenger of death and the herald of responsibility. The deliberate abstention from the customary conclusion of comedy is remarkable: "Jack hath not Jill," but he will have her after a twelvemonth, when he has done something to deserve her. Thus the play ends with hope—perhaps the best kind of happy ending.

Romeo and Juliet. The most complex work of art among these early plays of Shakespeare, *Romeo and Juliet* is far more than "a play of young love" or "the world's typical love-tragedy." Weaving together a large number of related impressions and judgments, it is as much about hate as love. It tells of a family and its home as well as a feud and a tragic marriage. The public life of Verona and the private lives of the Veronese make up the setting for the love of Juliet and Romeo and provide the background against which their love can be assessed. It is not the deaths of the lovers that conclude the play but the public revelation of what has happened, with the admonitions of the Prince and the reconciliation of the two families.

Shakespeare enriched an already old story by surrounding the guileless mutual passion of Romeo and Juliet with the mature bawdry of the other characters—the Capulet servants Sampson and Gregory open the play with their fantasies of exploits with the Montague women; the tongues of the Nurse and Mercutio are seldom free from sexual matters—but the innocence of the lovers is unimpaired.

Romeo and Juliet made a strong impression on contemporary audiences. It was also one of Shakespeare's first plays to be pirated; a very bad text appeared in 1597. Detestable though it is, this version does derive from a performance of the play, and a good deal of what was seen on stage was recorded. Two years later another version of the play appeared, issued by a different, more respectable publisher, and this is essentially the play known today, for the printer was working from a manuscript fairly close to Shakespeare's own. Yet in neither edition did Shakespeare's name appear on the title page, and it was only with the publication of *Love's Labour's Lost* that publishers had come to feel that the name of Shakespeare as a dramatist, as well as the public esteem of the company of actors to which he belonged, could make an impression on potential purchasers of playbooks.

Shakespeare's sources for the history plays

The histories. For his plays on subjects from English history, Shakespeare primarily drew upon Raphael Holinshed's *Chronicles,* which appeared in 1587, and on Edward Hall's earlier account of *The union of the two noble and illustre famelies of Lancastre and York* (1548). From these and numerous secondary sources he inherited traditional themes: the divine right of royal succession, the need for unity and order in the realm, the evil of dissension and treason, the cruelty and hardship of war, the power of money to corrupt, the strength of family ties, the need for human understanding and careful calculation, and the power of God's providence, which protected his followers, punished evil, and led England toward the stability of Tudor rule.

The Tragedy of King Richard III. In this play, the first history to have a self-contained narrative unity, Shakespeare accentuated the moment of death as a crisis of conscience in which man judges himself and is capable of true prophecy. He centred the drama on a single figure who commits himself to murder, treason, and dissimulation with an inventive imagination that an audience can relish even as it must condemn it; and in defeat Richard discovers a valiant fury that carries him beyond nightmare fear and guilt to unrepentant, crazed defiance.

The Tragedy of King Richard II. In the group of histories written in the late 1590s, Shakespeare developed themes similar to those of *Richard III* but introduced counter-statements, challenging contrasts, and more deeply realized characters. The first of this group, *Richard II,* concentrates on the life and death of the King, but Bolingbroke, his adversary, is made far more prominent than Richmond had been as Richard III's adversary. The rightful king is isolated and defeated by Act III, and in prison he hammers out the meaning of his life in sustained soliloquy and comes to recognize his guilt and responsibility. From this moment of truth, he rediscovers pride, trust, and courage, so that he dies with an access of strength and an aspiring spirit. After the death of Richard, a scene shows Bolingbroke, now Henry IV, with the corpse of his rival in a coffin; and then Bolingbroke, too, recognizes his own guilt, as he sits in power among his silent nobles.

1 Henry IV; 2 Henry IV. In the two plays that bear his name, Henry IV is often in the background. The stage is chiefly dominated by his son, Prince Hal (later Henry V), by Hotspur the young rebel, and by Sir John Falstaff. The secondary characters are numerous, varying from prostitutes and country bumpkins to a Lord Chief Justice and country gentlemen. There is a tension underlying the two-part play that sounds in the King's opening lines:

> So shaken as we are, so wan with care,
> Find we a time for frighted peace to pant,
> And breathe short-winded accents of new broils
> To be commenced in stronds afar remote.

When the Earl of Warwick counsels hope, the King sees how "chances mock, and changes fill the cup of alteration":

> O, if this were seen,
> The happiest youth, viewing his progress through,
> What perils passed, what crosses to ensue,
> Would shut the book, and sit him down and die.
> (Pt. 2, Act III, scene 1, 51–56)

Yet the two plays of *Henry IV* are full of energy. In Falstaff—that "reverend vice . . . that father ruffian, that vanity in years"—Shakespeare has created a character who becomes a substitute father of license and good fellowship for Prince Hal and who comments on the political situation with inglorious, reckless, egotistical good sense.

Falstaff's characterization

Falstaff is Shakespeare's major introduction into English history. His characterization is wholly original, for, although Shakespeare uses something of the earlier "vice" figure from early tragedies and comedies, something of the glutton and coward from allegorical, or morality, plays, something of the braggart soldier and the impotent old lecher from neoclassical comedy, he also studied life for this character of an out-of-work soldier, a knight without lands or alliances, a childless man whose imagination far outruns his achievement.

King John. Already in *King John,* Shakespeare had developed a subsidiary character to offset kings and princes. Here the Bastard, the son of Sir Robert Faulconbridge, is a supporter of the King and yet has soliloquies, asides, and speeches that mock political and moral pretensions. King John provides the central focus of the play, which ends with his death, but Shakespeare presents him on a rapidly changing course, surrounded by many contrasting characters—each able to influence him, each bringing irresolvable and individual problems into dramatic focus—so that the King's unsteady mind seems no more than one small element in an almost comic jumble of events.

Henry V. Henry V is the last of this group of history plays and the last until *Henry VIII* at the end of Shakespeare's career. Structurally the King is again central and dominant, but the subsidiary characters far outnumber those of the earlier plays. In the first two acts Henry is shown in peace and war, politic, angry, confident, sarcastic, and then vowing to weep for another man's revolt. There is an account of Falstaff's death, and, after scenes of military achievement, there is a nervous watch before the Battle of Agincourt when the King walks disguised among his fearful soldiers and prays for victory while acknowledging his own worthless repentance for his father's treason. The presentation of the battle avoids almost all fighting on stage, but recruits, professional soldiers, and dukes and princes are all shown making preparation for meeting defeat or victory. The King's speech to his troops before battle on St. Crispin's Day is famous for its evocation of a brotherhood in arms, but Shakespeare has placed it in a context full of ironies and challenging contrasts. The picture of two nations at war is full of deeply felt individual responses: a boy comes to realize that his masters are cowards; a herald is almost at a loss for words; a common soldier has to justify his heart before his king. Just before the conclusion, the King woos the French princess; she knows almost no English, and so he is forced to plead on the merits only of his simplest words, a kiss, and the plain fact of himself and his "heart." There is no doubt that Kate marries Henry because he has won a battle and peace is necessary, but Shakespeare has developed the comedy and earnestness of their wooing so that the need for human trust and acceptance is also evident. This play is presented by a chorus, which speaks in terms of heroism, pride, excitement, fear, and national glory. But at the end, when the King prays that the oaths of marriage and peace may "well kept and prosperous be," the chorus speaks for the last time, reminding the audience that England was to be plunged into civil war during the reign of Henry V's son. The last of a great series of history plays thus concludes with a reminder that no man's story can bring lasting success.

The Roman plays. *Julius Caesar.* After the last group of English history plays, Shakespeare chose to write about Julius Caesar, who held particular fascination for the Elizabethans. He was soldier, scholar, and politician (Francis Bacon held him in special regard for the universality of his genius); he had been killed by his greatest friend (Shakespeare alluded to the "bastard hand" of Brutus in *2 Henry VI*); and he was seen as the first Roman to perceive and, in part, to achieve the benefits of a monarchial state. His biography had appeared in Sir Thomas North's translation, via a French version, of Plutarch's *Parallel Lives,* published as *The Lives of the noble Grecians and Romanes* in 1579, which Shakespeare certainly read. To all of this, Shakespeare's response was surprising: Caesar appears in three scenes and then is murdered, before the play is half finished. But a variety of characters respond to and reflect upon the central fact of the great man. This is the dramatic strategy of an ironist, or of a writer who wishes to question human behaviour and to observe interactions and consequences. In fact, Caesar influences the whole play, for he appears after his death as a bloodstained corpse and as a ghost before battle. Both Brutus and Cassius die conscious of Caesar and even speak to him as if he were present. And then his heir takes command, to "part the glories" of what is for him a "happy day."

The Elizabethans' fascination with the figure of Julius Caesar

In other ways *Julius Caesar* is shaped differently from the histories and tragedies that precede it, as if in manner as in subject matter Shakespeare was making decisive changes. The scene moves only from Rome to the battlefield, and with this new setting language becomes more restrained, firmer and sharper. Extensive descriptive images are few, and single words such as "Roman," "honour," "love," "friend," and proper names are repeated as if to enforce contrasts and ironies. In performance this sharp verbal edge, linked with commanding performances and the various excitements of debate, conspiracy, private crises, political eloquence, mob violence, supernatural portents, personal antagonisms, battle, and deaths, holds attention. The play has popular appeal and intellectual fascination.

For six or seven years Shakespeare did not return to a Roman theme, but, after completing *Macbeth* and *King Lear,* he again used Plutarch as a source for two more Roman plays, both tragedies that seem as much concerned to depict the broad context of history as to present tragic heroes.

Antony and Cleopatra. The language of *Antony and Cleopatra* is sensuous, imaginative, and vigorous. "*Feliciter audax* ["happily bold"] is the motto for its style comparatively with his other works," said the poet Samuel Taylor Coleridge. Almost every character seems to talk of kingdoms and to envision heroic deeds: Dolabella, the Roman soldier, says that his "love makes religion to obey" Cleopatra in her last imprisonment; Antony's servant is called Eros, who kills himself before his "great chief"; his soldiers have seen his eyes "glow like plated Mars"; his enemies say that, even in defeat, he "continues still a Jove." Octavius knows, as he closes for the kill, that great issues are at stake. Yet, while the issues are thus enlarged (or inflated), the protagonists do not reveal themselves to an audience as they do in *Hamlet, Othello, Lear,* or *Macbeth.* Antony has soliloquies only in defeat, and then he addresses the sun or fortune, false hearts or his queen, rather than seeking to hammer out his thoughts or to explore his own response. In the last scene, however, the focus concentrates intensely on a single character, when Cleopatra, prepared for death in robe and crown, believing in immortality, and hearing the dead Antony mock "the luck of Caesar," seems indeed to be transfigured:

The tragic intensity of Cleopatra's death scene

> . . . Husband, I come:
> Now to that name my courage prove my title!
> I am fire, and air; my other elements
> I give to baser life. . . .
>
> (Act IV, scene 2, 278 ff.)

Coriolanus. The hero of *Coriolanus* has still fewer soliloquies: one in rhyme as he arrives, a renegade in Antium, and another of a few sentences when he stands alone in the marketplace waiting for the citizens to express their choice of him for consul. Through many guises, the audience sees the same man: as a young nobleman in peacetime, as a soldier going to battle, as bloodstained fighter and then victor, as candidate for consul in the "napless garment of humility," as a banished renegade, and then as leader of the Volscians, enemies of Rome.

In this play Shakespeare's customary contrasts and ironies, which lead an audience to discover meanings for themselves, are replaced by repetitions within the single narrative line: there are three Forum scenes, four family scenes, a succession of fights, four scenes of mob violence, and continual attempts to argue with Coriolanus and deflect him from his chosen course. The language is sometimes elaborate, but does not have the poetic richness of *Antony and Cleopatra;* images are compact, sharply effective. Those moments when the audience is drawn most intently into the drama are strangely silent or understated. The citizens "steal away" instead of volunteering to fight for their country; their tribunes stay behind to organize their own responses. When the banished Coriolanus returns at the head of an opposing army, he says little to Menenius, the trusted family friend and politician, or to Volumnia, his mother, who have come to plead for Rome. His mother's argument is long and sustained, and for more than 50 lines he listens silent, until his resolution is broken from within: then, as a stage direction in the original edition testifies, he "holds her by the hand, silent." In his own words, he has "obeyed instinct" and betrayed his dependence; he cannot

> stand
> As if a man were author of himself
> And knew no other kin.
>
> (Act V, scene 3, 35 ff.)

His desire for revenge is defeated, and the army retreats. Volumnia is hailed as "patronness and life of Rome," but she is silent while the drums, trumpets, and voices greet her. Coriolanus is seen only once more, in the enemy city where he is accused of treachery and is assassinated in the kind of mob violence he has previously withstood. So *Coriolanus* finishes with the audience observing a hero helpless to prevent his own death and with patterns of political, social, and personal behaviour repeated without hope of change. Nowhere has Shakespeare shown an aspect so severe as in the silent moments of this Roman tragedy, during which the actor is at a loss for words.

The "great," or "middle," comedies. The comedies written between 1596 and 1602 have much in common and are as well considered together as individually. With the exception of *The Merry Wives of Windsor,* all are set in some "imaginary" country. Whether called Illyria, Messina, Venice and Belmont, Athens, or the Forest of Arden, the sun shines as the dramatist wills. A lioness, snakes, magic caskets, fairy spells, identical twins, disguise of sex, the sudden conversion of a tyrannous duke or the defeat offstage of a treacherous brother can all change the course of the plot and bring the characters to a conclusion in which almost all are happy and just deserts are found. Lovers are young and witty and almost always rich. The action concerns wooing; and its conclusion is marriage, beyond which the audience is scarcely concerned. Whether Shakespeare's source was an Italian novel (*The Merchant of Venice* and *Much Ado About Nothing*), an English pastoral tale (*As You Like It*), an Italian comedy (the Malvolio story in *Twelfth Night*), or something of his own invention (probably *A Midsummer Night's Dream,* and parts of each), always in his hands story and sentiments are instinct with idealism and capable of magic transformations. *The Merry Wives of Windsor* differs from the other comedies in that it is set not in an imaginary country but in Windsor and the rural life of Shakespeare's own day. Fantasy occurs at the end, however, when the characters enter a land of make-believe around the folk fertility symbol of Herne, the Hunter's oak in the forest; and, as they leave to "laugh this sport o'er by a country fire," quarrels are forgotten. The more overtly fantastic plays, in their turn, contain observations of ordinary and (usually) country life.

The blend of fantasy and everyday experience in the comedies

Much Ado About Nothing is distinctive in many ways, for there is no obvious magic or disguise of sex. But many misunderstandings arise in a masked dance, and the play concludes with a pretended death and a simulated resurrection from behind yet another mask; moreover, the two main characters, Beatrice and Benedick, are transformed from within by what is called "Cupid, the only matchmaker."

In some ways these are intellectual plays. Each comedy has a multiple plot and moves from one set of characters to another, between whom Shakespeare invites his audience to seek connections and explanations. Despite very different classes of people (or immortals) in different strands of the narrative, the plays are unified by Shakespeare's idealistic vision and by an implicit judgment of human relationships, and all their characters are brought together—with certain significant exceptions—at, or near, the end.

The "outsider." The plays affirm truth, good order, and generosity, without any direct statement; they are shapely and complicated like a dance or like a game of chess. Yet at the general resolution all is not harmony: some characters are held back from full participation. At the end of *A Midsummer Night's Dream,* for example, the lovers' more callow comments on the rustics' play of *Pyramus and Thisbe* mark them as irresponsive to the imaginative world of Bottom and his fellows, who project themselves into their play's heroics almost without fear of failure; they are also distinct from the duke, Theseus, who says of the amateur performers:

> The best in this kind are but shadows: and the worst are no worse, if imagination amend them.

In *The Merchant of Venice,* most of the unresolved elements in the comedy are concentrated in the person of Shylock, a Jew who attempts to use justice to enforce a terrible, murderous revenge on Antonio, the Christian merchant, but is foiled by Portia, in disguise as a lawyer, who turns the tables on the Jew by a legal quibble and has him at the mercy of the court. This strange tale is realized with exceptionally credible detail: Shylock is a moneylender, like many in Shakespeare's London, and a Jew of pride and deep religious instincts; the Christians treat him with contempt and distrust, and, when one of them causes his daughter to elope and steal his money and jewels, he suffers with an intensity equalled only by that of his murderous hatred of all Christians. In a scene written in prose that gives at one time both histrionic power and sensitive, personal feeling, Shylock identifies his cause with basic human rights:

Shylock

> I am a Jew . . . Hath not a Jew eyes? hath not a Jew hands, organs, dimensions, senses, affections, passions? fed with the same food, hurt with the same weapons, subject to the same diseases, healed by the same means, warmed and cooled by the same winter and summer, as a Christian is? If you prick us, do we not bleed? if you tickle us, do we not laugh? if you poison us, do we not die? and if you wrong us, shall we not revenge?
>
> (Act III, scene 1, 50 ff.)

The happiness that follows the thwarting of his revenge, however, cannot be celebrated with full unison while there are reminders that he never reached "the beautiful mountain," Belmont.

In *As You Like It,* the melancholy character Jaques leaves the play before the concluding dances. He has seen, and voiced, the limitations of each of the pairs of lovers and is determined to hear more and learn more from the tyrant duke, so mysteriously converted to a "religious life." In *Twelfth Night,* Malvolio the steward is gulled by practical jokes that take advantage of his self-esteem; he is the last character to come onstage in the final scene, and he refuses reconciliation; he leaves after a noticeable silence with only these words: "I'll be revenged on the whole pack of you." This comedy has yet other "outsiders"; alone at the end, Feste the fool sings a strange song in which the whole of life is reduced to a melancholy tale sung by a knowing idiot. *Twelfth Night* is probably the last of the "great" comedies, and it is the saddest.

Wit and ambiguity. Incidental images, too, strike deep into the audience's remembrance of pain, fear, and suffering. In *Twelfth Night,* barren mountains, salt sea, and the smoke of war, storms, imprisonment, death, and madness are all invoked. When the king and queen of fairies quarrel in *A Midsummer Night's Dream,* Titania's speech evokes a world of chaos:

> The ox hath therefore stretched his yoke in vain,
> The plowman lost his sweat, and the green corn
> Hath rotted ere his youth attained a beard:
> The fold stands empty in the drowned field,
> And crows are fatted with the murrion flock . . .
>
> (Act II, scene 1, 81 ff.)

Yet the poetry also celebrates happiness and joy with a clearer note and quicker interplay of thought than had been achieved in English before. So, in *Twelfth Night,* from Orsino:

> Then let thy love be younger than thyself,
> Or thy affection cannot hold the bent:
> For women are as roses, whose fair flower,
> Being once displayed doth fall that very hour.

From Olivia:

> Cesario, by the roses of spring,
> By maidhood, honour, truth, and everything,
> I love thee so that, maugre all thy pride,
> Nor wit nor reason can my passion hide.

And from Viola:

> And all those sayings will I over-swear,
> And all those swearings keep as true in soul,
> As doth that orbed continent the fire
> That severs day from night.

The wit and ambiguity through which the apparent meanings are laced with further indications of love, yearning, sexuality, unrest, and happiness glance continuously through the dialogue, especially perhaps in *Much Ado About Nothing.* Often the disguise of identity or sex or else misunderstandings or intentional counterfeiting serve to accentuate the varying levels of consciousness expressed; moments of near unmasking, or of recognition, hold the attention firmly. Witty debates between lovers were not unfamiliar; they had held the stage more than 10 years earlier in John Lyly's fantastic comedies that had been played at court by very young child actors. But never before had sharpness of wit been so matched by gentleness or fineness of sentiment.

Perhaps the most extraordinary achievement of these comedies—which change in mood so rapidly, which are so funny and yet sometimes dangerous and sad, which deal both with fantasy and eloquence—is that the recurrent moments of lifelike feeling are so expressed in words or action that an audience shares in the very moment of discovery. Sometimes this is a second thought, as in Viola's

> I am all the daughters of my father's house,
> And all the brothers too . . . and yet I know not . . .

Sometimes it is a single phrase—Sir Andrew Aguecheek's "I was adored once too"—and on several climactic occasions it is held in a song, whether of happiness, sorrow or peace, or of the "good life":

> O mistress mine, where are you roaming?
> O, stay and hear, your true-love's coming,
>   That can sing both high and low.

The "fancy" of art and sentiment in the great comedies

The structure of these comedies can be explained, their stage devices and language analyzed; but essentially they remain on the wing, alive with the "fancy" of art and sentiment. Puck's epilogue to the *Dream* is often quoted as their characteristic note:

> If we shadows have offended,
> Think but this, and all is mended,
> That you have but slumbered here
> While these visions did appear . . .

But Rosalind's epilogue to *As You Like It* is also apposite:

> . . . I am not furnished like a beggar; therefore to
> beg will not become me: my way is to conjure you . . .

The great tragedies. It is a usual and reasonable opinion that Shakespeare's greatness is nowhere more visible than in the series of tragedies—*Hamlet, Othello, King Lear,* and *Macbeth. Julius Caesar,* which was written before these, and *Antony and Cleopatra* and *Coriolanus,* which were written after, have many links with the four. But, because of their rather strict relationship with the historical materials, they are best dealt with in a group by themselves. *Timon of Athens,* probably written after the above-named seven plays, shows signs of having been unfinished or abandoned by Shakespeare. It has its own splendours but has rarely been considered equal in achievement to the other tragedies of Shakespeare's maturity.

Hamlet. Judged by its reception by the civilized world, *Hamlet* must be regarded as Shakespeare's most successful play. It has unceasing theatrical vitality, and the character of Hamlet himself has become a figure of literary mythology. Yet *King Lear* became for a time the fashionable play in 20th-century criticism, with many critics arguing that in *Hamlet* Shakespeare did not make a psychologically consistent play out of a plot that retained much of the crudity of an earlier kind of "revenge" drama—that he was trying to transform a barbaric "revenge" hero into a subtle Renaissance prince but did not succeed.

Even if this opinion has become unacceptable, it nevertheless taught critics to look for elements other than psychological consistency. In particular, it is worth concentrating not on Elizabethan attitudes toward revenge but on Shakespeare's artistic balance in presenting the play's moral problems. It is likely that an artist will make his work more interesting if he leaves a dilemma morally ambiguous rather than explicit. The revenge situation in *Hamlet,* moreover, is one charged with emotional excitement as well as moral interest. Simply put, the good man (Hamlet) is weak, and the bad man (Claudius) is strong. The good man has suffered a deep injury from the bad man, and he cannot obtain justice because justice is in the hand of the strong bad man. Therefore the weak good man must go around and around in order to achieve a kind of natural justice; and the audience watches in suspense while the weak good man by subtlety attacks and gets his own back upon the strong bad man and the strong bad man spends his time evading the weak good man. Hamlet is given a formidable opponent: Claudius is a hypocrite, but he is a successful one. He achieves his desired effect on everybody. His hypocrisy is that of a skilled politician. He is not dramatically shown as being in any way unworthy of his station—he upholds his part with dignity. He is a "smiling villain" and is not exposed until the final catastrophe. The jealous Hamlet heaps abuse upon him, but Shakespeare makes Claudius the murderer self-controlled. Thus, theatrically, the situation is much more exciting.

Against this powerful opponent is pitted Hamlet, the witty intellectual. He shares his wit with the audience (and a few favoured characters such as Horatio), who thus share his superiority over most other personages in the play. His first words are a punning aside to the audience, and his first reply to the King is a cryptic retort. His sardonic witticisms are unforgettable ("The funeral baked meats/ Did coldly furnish forth the marriage tables"; and "More honoured in the breach than the observance"). Hamlet is an actor in many parts of the play. The range of language in the roles he affects shows that his mimetic powers are considerable. He is skillful in putting on "an antic disposition" and gives a very funny performance in talking to Polonius. He condescends to talk the silly bawdry of Rosencrantz and Guildenstern. He can mimic Osric's style to perfection. He quarrels with Laertes beside Ophelia's grave in a display of verbosity that exceeds the modesty of nature in much the same way as does that of Laertes.

Hamlet himself as an actor

Besides Claudius, set off against Hamlet is Polonius. He is wrong in his judgments, one after another, and this leads to the audience's rejection of his political and human values. In all circumstances he seems slightly ridiculous—a foil for Claudius as he is for Hamlet. His astuteness suffers by comparison with that of the King. His philosophical view of life is hollow compared with Hamlet's. Hamlet has as many general maxims as Polonius; but his seem to be the product of a far more refined sensibility and of an ability to respond truthfully to experience. It is these qualities in the somewhat enigmatic characterization of Hamlet that have won him the fascinated admiration of the world.

Othello. Trusting to false appearances and allowing one's reason to be guided by one's passions had been a theme of many of Shakespeare's comedies. In *Othello* he showed that the consequences of so doing can be tragic rather than comic. Shakespeare adapted the story from an Italian model. His principal innovation consisted in developing the character of Iago, the villain, whose motives are represented as complex and ambiguous. Clearly Shakespeare was keenly interested in a villain who could successfully preserve an appearance of honesty; the bad as well as the good can be "the lords and owners of their faces" (Sonnet 94). Iago is made a plausible villain by being so interesting. He is an actor who enjoys playing his role of "honesty." Shakespeare makes him take the audience into his confidence at every stage of his plotting, and, as a consequence, they have a kind of non-moral participation in his villainy.

The pure and deep love between Desdemona and Othello is stressed from the beginning. Again and again the moral and intellectual stature of Othello is elevated by Shakespeare. He quells tumults in the streets with a few words; he bears himself with dignity before the Venetian council, defending himself compellingly from bitter accusations by Brabantio and accepting his military burden with quiet confidence. Even Iago, in the opening scene of the play, grudgingly admits the dependence of the Venetians on his valour. After his terrible murder of Desdemona, Othello's contrition is agonizing enough to swing the sympathies of the audience back to him.

King Lear. For Shakespeare's contemporaries, Lear, king of Britain, was thought to have been a historical monarch. For Shakespeare, however, although he gave the play something of a chronicle structure, the interest lay not in political events but in the personal character of the King. The main theme of the play is put into the mouth of the evil Regan, speaking to the pitiful Gloucester:

> O sir, to wilful men
> The injuries that they themselves procure
> Must be their schoolmasters.
>
> (Act II, scene 4, 301)

The various stages of Lear's spiritual progress (a kind of "conversion") are carefully marked. He learns the value of patience and the worth of "unaccommodated man." He begins to realize his own faults as a king and almost understands his failure as a father. He begins to feel for the "poor naked wretches" and confesses, "O I have ta'en too little care of this." His initial instability of mind, almost a predisposition to madness, is shown from the beginning. His terrible rages and curses, first upon Cordelia and later upon Goneril and Regan, and his ranting and tyrannical language all foreshadow his breakdown. His faithful counsellor is plain with him: "Be Kent unmannerly/When Lear is mad"; and his daughters shrewdly judge him: "he hath ever but slenderly known himself." He is painfully conscious of approaching madness, but gradually the bombast of his sanity gives place to a remarkable kind of eloquence, flowing easily and never incoherent. His "ravings" are intelligible to the audience, however perturbing they may seem to the other characters on the stage. They express a point of view that, had he understood it earlier, would have saved him from many errors of judgment. The mode of speech of the mad King contrasts strongly with the

Lear's predisposition to madness

congenital inconsequentiality of his fool and the assumed madness of Edgar as "Poor Tom."

King Lear has a distinct underplot, a separable story of the fortunes of Gloucester—another father suffering from "filial ingratitude" and from his false judgment of the characters of his children. This underplot is introduced in the opening scene, in some detail, as if it were of as much importance as the main plot. The stages by which Gloucester similarly learns by suffering are clearly indicated. He begins by being the cheerful sinner, but gradually his sense of pity and duty become stronger, and he reveals himself to Edmund: "If I die for it (as no less is threatened me), the King my master must be relieved." This revelation of his good intentions to the treacherous Edmund leads directly to his downfall and to his being blinded.

Two of the "good" characters, Edgar and Albany, also grow in moral stature and strength in the course of the play. At first, Edgar seems rather ineffectual, quite unable to cope with the villainy of his half brother Edmund; but eventually he emerges as a strong character, confirmed by suffering and by compassion; able to fight and overcome Edmund in the ordeal at arms; and eventually, as one of the survivors, he is entrusted, along with Albany, with the future of the kingdom. Albany, too, is gradually built up, from being the weak husband of Goneril to being the spokesman of virtue and justice, with an authority able to cope with the force of Edmund's malignant energy.

Yet the representatives of goodness and of hope in *King Lear* do not emerge dynamically, and it has been difficult for champions of Shakespeare's moral and religious orthodoxy to combat the pessimism and nihilism that most readers experience when reading the play—precisely the qualities that have made it a favourite in the 20th century.

The historical basis of *Macbeth*

Macbeth. Macbeth is the only play of Shakespeare's that seems, to a large extent, to be related to the contemporary historical situation. It was intended to interest the new monarch, James VI of Scotland, who became James I of England. This was a matter of professional importance; for Shakespeare's company of actors had been taken over by the King on his accession, entitled to wear the royal livery as his retainers (as they did when they walked in the procession at his coronation). But more important than the flattering of the King was the way *Macbeth* satisfied public interest. For its subject was regicide, commonly regarded as the supreme crime. And the public had been profoundly moved by an attempted regicide in November 1605—the famous "Gunpowder Plot"—which the English people, even after three and a half centuries, have still not forgotten. The reign of Macbeth, king of Scotland, belonged, for Shakespeare and his audiences, to Scottish history of many centuries past. But the play of *Macbeth,* both in its treatment of the events of the story and in its details, was devised by Shakespeare with a very clear consciousness of the mood of his own times.

It is the first task of criticism to interpret the success of *Macbeth,* to explain how Shakespeare transformed a crude and horrible story of murderous ambition into a satisfying imaginative vision of good and evil. There are two principal artistic methods by which he effected this transformation. First, he made his play highly poetical; it is audacious in style, relying upon concentrated, brilliant brevity of phrase. So great is the imaginative verbal vigour that some critics, sensitive to poetry but unsympathetic to the theatre, have almost forgotten that *Macbeth* is a play and have encouraged readers to treat it rather as a poem. Second, Shakespeare has consistently humanized the two murderers, so that they almost become sympathetic—and, by making them husband and wife, their human relationship is as interesting as their motives for evil actions. This humanizing process is the key to Shakespeare's success in the play. His control of the reactions of an audience is an achievement of theatrical art, not of intellectual or moral subtlety.

Timon of Athens. Timon of Athens is yet another of Shakespeare's experiments—the exploration of a new kind of tragic form. Certain usual elements of Shakespearean tragedy are reduced in importance or eliminated from the structure of the play: the story, or "plot," is simple and lacks development. There is no maturing of characters—the only change is the single one of Timon, who moves from a fixed character of universal generosity to one of universal hatred. In the first half of the play, there is a consistent effort to build up a world around Timon in terms of which his behaviour can be judged. As he perceives characters and situations unrealistically and responds to them disproportionately, it becomes clear that his is a dream world. Into that world—as the audience watches, with some pain—reality intrudes. The second half of the play, however, is simply a series of interviews between Timon and his visitors, seemingly arranged solely to bring them under his curses; Timon's frenzied vituperation of his fellowmen becomes almost unbroken monotone. Eventually Timon rages himself to death, leaving Alcibiades to lament his death and punish his enemies.

Of the various explanations put forward for the uneven quality of the writing in *Timon of Athens* (collaboration; incomplete revision; completion by an inferior dramatist), much the most probable is that this is Shakespeare's rough draft of a play. It certainly has close analogies with the great plays of the few years to which its composition belongs (iterative words and iterative imagery, ironic preparation and anticipation, "chorus" statements by disinterested observers, plot and subplot parallel, both complementary and contrasted). If it is a rough draft, then it presents a unique opportunity of getting close to Shakespeare's method of writing. It would prove that he put structure before composition; that he went straight ahead drafting the structure of a play, unifying it by means of theme, imagery, and ironic preparation, and paying less attention to prose-verse form and to the characterization of minor personages. It would indicate that his pen wrote speeches quickly, not wasting much time at first about verse form, putting down the gist of what the character had to say, sometimes with imagery that came to him on the spur of the moment, incorporating lines or half lines of blank verse and even occasionally rhymed couplets—all to be "worked up" later. Nor, by judging the play "unfinished," are its worth and importance diminished: certain parts may be roughly written, but the imaginative conception has a wholeness that imperfect composition does not obscure.

Timon of Athens and Shakespeare's working method

The "dark" comedies. Before the death of Queen Elizabeth I in 1603 the country was ill at ease: the House of Commons became more outspoken about monopolies and royal prerogative; uncertainty about the succession to the throne made the future unsettled. In 1603 the Plague again struck London, closing the theatres. In 1604 Shakespeare's patron, the Earl of Southampton, was arrested on charges of treason; he was subsequently released, but such scares did not betoken confidence in the new reign. About Shakespeare's private reaction to these events there can be only speculation, but three of the five plays usually assigned to these years have become known as "dark" comedies for their distempered vision of the world.

Troilus and Cressida. Troilus and Cressida may never have been performed in Shakespeare's lifetime, and it fits no single category. Based on Homer (as translated by George Chapman) and on 15th-century accounts of the Trojan War by John Lydgate and William Caxton, it explores the causes of strife between and within the Greek and Trojan armies and might well have been a history play of a newly questioning and ironic kind. But Shakespeare was also influenced by Geoffrey Chaucer's love poem, *Troilus and Criseyde,* and for the first time portrayed sexual encounters outside the expectation of marriage. Cressida desires Troilus (and later Diomedes) with physical as well as idealistic longing; she considers love frankly as a chase and acts on the principle

That she was never yet that ever knew
Love got so sweet as when desire did sue.

As in Shakespeare's earlier comedies, these lovers are contrasted with others—but with a difference, for they are set beside the shallow and jaded routine of Helen's life with Paris and the assembled Trojans, and beside the jealous humours of Achilles, lounging in his tent with Patroclus. Into Cressida's last scene, when she begs Diomedes to come to her tent, Shakespeare has further introduced three lookers-on who comment directly: the enslaved Troilus watching with the politically wily Ulysses and, at another corner of the stage, Thersites. The audience cannot identify simply with any one of the five characters but, instead, must take note of each varying discord.

Thersites' revulsion from the pursuit of honour and love

In his ubiquitous commentary, Thersites, perhaps the most notable single invention in the play, expresses revulsion against the pursuit of both honour and love. When the lovers have left the stage he has the last word:

> Would I could meet that rogue Diomed! I would croak
> like a raven; I would bode, I would bode. . . . Lechery,
> lechery! Still wars and lechery! Nothing else holds
> fashion. A burning devil take them!

He proclaims Agamemnon "both ass and ox"; Ajax he would scratch from head to foot, to make the "loathsomest scab in Greece"; and as Menelaus and Paris fight in the last battle, he sees them as "bull" and "dog," cuckold and cuckold maker—and then he saves his own life by cowardice. Yet he is not the only commentator in the play. Priam sits on his throne, between his disputing sons; Ulysses arouses Achilles by praising Ajax; and Cassandra cries out from a supernatural certainty of doom. Pandarus describes the handsome warriors as food for love and hurries forward to take prurient pleasure in Cressida's excitement.

Pandarus also speaks the epilogue, and something of the play's irony may be gauged by contrasting his weak and broken appearance as he speaks the last words with that of Prologue, who, dressed in armour, had announced the scene of Troy, the "princes orgulous," and all the brave and massy consequences of war. No history play by Shakespeare had run such a gamut from the heroic to the petty and familiar. Although the earlier comedies sometimes start with tyrannies and loss, they all conclude with a dance or, at their least hopeful, with a procession offstage until a "golden time convents." Nor could this play be called a tragedy, for, despite the death of Hector and the loss of all Troilus' hopes beyond those of hatred and revenge, there is no scope in the last disordered and inglorious battle for the intensity of tragedy. The stature of every character has been progressively diminished.

All's Well That Ends Well; Measure for Measure. The other two comedies of 1601–04, are less completely original. Both *All's Well That Ends Well* and *Measure for Measure* centre on stories of love that lead to marriage, and both end with complicated denouements superintended by a benevolent king or duke. The fantasy of the earlier comedies, however, is largely missing, and, although there are clowns, they haunt brothels or a prison, or they "love as an old man loves money, with no stomach." Subplots are about cowardice in battle or fornication. Only *Measure for Measure* has a song, and that "pleases" the woe of Mariana deserted by her unworthy Angelo.

The intensity of the "dark" comedies

Perhaps the most important element in both comedies is a new intensity. In *All's Well,* Helena's soliloquies of frustrated love and, sometimes, the brevity of her speech reveal her inner struggles; and a few words from her graceless husband indicate his new loss of assurance. In *Measure for Measure,* Isabella pleading for her brother's life and defending her chastity or the Duke disguised as a friar persuading Claudio to disdain life both carry their arguments fiercely and finely; and Angelo is shown twice in soliloquy, tempted to what he knows is evil by Isabella, who he knows is good:

> When I would pray and think, I think and pray
> To several subjects. . . .
>
> (Act II, scene 4, 1 ff.)

In this comedy the intensity of much of the dialogue, the overt religious and legal concerns, and the variety of plot and subplot in Shakespeare's earlier manner all combine to make a searching, unsettling, and, in the opinion of most judges, precarious play, a comedy that reaches its general conclusion only with difficulty, with adroitness, compromise, or dramatic necessity.

Although such issues are present in *All's Well,* they are more in the background, and Shakespeare ostensibly considers other themes—inherited virtue opposed to virtue achieved by oneself, the wisdom of age over and against the impressionability of youth, and the need for each man to make his own choice, even if wrongly.

Only during the 20th century have the three "dark" comedies been frequently performed in anything like Shakespeare's texts, an indication that their questioning, satiric, intense, and shifting comedy could not please earlier audiences.

The late plays. *Pericles, Cymbeline, The Winter's Tale, The Tempest,* and *Henry VIII,* written between 1608 and 1612, are commonly known as Shakespeare's "late plays," or his "last plays," and sometimes, with reference to their tragicomic form, they are called his "romances." Works written by an author in his 40s hardly deserve to be classified as "late" in any critical sense, yet these plays are often discussed as if they had been written by a venerable old author, tottering on the edge of a well-earned grave. On the contrary, Shakespeare must have believed that plenty of writing years lay before him, and indeed the theatrical effectiveness and experimental nature of *Cymbeline, The Winter's Tale,* and *The Tempest* in particular make them very unlike the fatigued work of a writer about to break his staff and drown his book.

One of the common characteristics of these plays is that, although they portray a wide range of tragic or pathetic emotions, events move toward a resolution of difficulties in which reconciliations and reunions are prominent. They differ from earlier comedies in their structural emphasis on a renewal of hope that comes from penitence and forgiveness, together with a faith in the younger generation, who by love will heal or obliterate the wounds inflicted in the past.

There is also an extravagance of story and an unreality of motivation, both prompting the use of the label "romances." From *Coriolanus,* the most austere of his tragedies, Shakespeare turned immediately to *Pericles,* a fantastically episodic play set in a vaguely pre-Christian world. He no longer saw antiquity through the eyes of a historian like Plutarch but through the bright fictions of the imitators of late Greek romances, Heliodorus and Achilles Tatius. In *The Winter's Tale,* for instance, where events are determined by the god Apollo from his oracle on the island of Delphos, the kingdoms of Bohemia and Sicilia nevertheless contain Warwickshire country festivals and conycatchers; and Queen Hermione boldy asserts: "The Emperor of Russia was my father."

Some critics have attributed this change in theatrical manner to Shakespeare's boredom with everything except poetry; others have pointed to a revival of interest in romantic tragicomedy (in *Phylaster,* by Beaumont and Fletcher, many characteristics of Shakespeare's latest plays are discernible, but the precise date of this play is questioned, and thus it is difficult to decide whether the fashion was set by Beaumont and Fletcher with their play or by Shakespeare with *Pericles*). It is at least likely, however, that Shakespeare himself was the pioneer and originator of a new style. The King's Men took over the Blackfriars Theatre in 1608. It was a more expensive theatre, and it has reasonably been conjectured that its facilities influenced Shakespeare to produce a new kind of play for a sophisticated audience more responsive to imaginative experiment in drama.

The stylistic maturity of the second half of *Pericles*

Pericles. The first scenes of *Pericles* are often feeble in expression, frequently unsyntactical, and sometimes scarcely intelligible. The second half is splendidly written, in Shakespeare's mature style. It is now generally supposed that the inadequate parts of the play are due to its being a reconstruction of the text from the actors' imperfect memories. For the second half of the play, either the printer had a manuscript of good quality or the actors' memories were more accurate. Ben Jonson called it "a mouldy tale." Certainly it was a very old one. There was a Greek prose fiction on the story, which survives in a Latin translation. Versions of it are found in many European languages. John Gower, Chaucer's friend and contemporary, had included the story in his poem *Confessio amantis,* and there were two separate prose renderings in Shakespeare's time.

Cymbeline. The main theme of *Cymbeline*—Posthumus' wager on the chastity of his wife, Imogen—Shakespeare derived from a story in Boccaccio's *Decameron.* But he put this Italianate intrigue into a setting that, for his audience, was authentic. Cymbeline, king of Britain, and his two sons, Guiderius and Arviragus, who succeeded him, were, for Shakespeare's audience, historical monarchs. The play is carefully set in the pre-Christian Roman world. The Romans who invade Britain are recognizably derived from the same kind of exploration of the antique world that had produced *Julius Caesar, Antony and Cleopatra,* and *Coriolanus.*

Shakespeare shows great dramatic skill in weaving together many different elements of plot, period, and place. The open-air scenes in Wales, Iachimo's concealment in a trunk in Imogen's bedchamber, the supposed deaths of Posthumus and of Imogen disguised as Fidele, the battle between the Britons and Romans, the vision of the eagle-borne Jupiter—all these in preparation for the amazing complications of the final scene of the play, where (it has been calculated) there are 24 distinct "revelations" in 455 lines.

The Winter's Tale. In *The Winter's Tale* Shakespeare's audacity had increased. He introduced a similar combination of heterogeneous civilizations. But he also abandoned a unity of development in the story: he made a break of 16 years in the middle of the play, introducing the figure of Time to persuade the audience to accept the rapid shift of dramatic time. Shakespeare similarly challenged their confidence by the pathos of the deaths of the little boy Mamillius and, seemingly, of his mother Hermione, followed by the repentance of her jealous husband Leontes. He also allows Antigonus, a most attractive character, to be eaten by a bear. Shakespeare clearly intended the audience to become involved only at certain moments of the play, by intensifying particular episodes without allowing emotional commitment to the whole plot. Three times his characters use the phrase "like an old tale," as if they were themselves commenting on its incredibility. What might have been the most moving scene or series of scenes in this group of plays—the revelation of Perdita's true birth—is related only at second hand by a number of anonymous gentlemen. Presumably, Shakespeare did not wish to anticipate or reduce the theatrical effect of the final scene, in which the "statue" of Hermione comes to life. Or perhaps, having already shown a similar scene of recognition of father and long-lost daughter in *Pericles,* he did not wish to repeat himself.

Ingredients in the plot of *The Tempest*

The Tempest. *The Tempest* shows even greater excellence in the variety of its ingredients. There is story enough, including two assassination plots. There is a group of quickly differentiated characters; there is elaborate dancing and singing; there is an inset entertainment, a marriage masque performed by the goddesses Iris, Ceres, and Juno; there is a theatrical "quaint device," the introduction and vanishing of a banquet; there is a tender love affair; there are marvellous comic turns. Yet a mood of seriousness is felt throughout the play; questions about freedom, about the instinct for revenge, and the conflicting claims of generosity are being asked; there is a sense of subtle seriousness when Prospero speaks his cryptic epilogue as an actor appealing for the good opinion of his audience.

Most of the action of the plot has taken place in the past; only the climax of reconciliation and the events immediately leading up to it are represented. But, although the "unity of time" is almost preserved, the amount of mental progress, the number of mental events, is large. The newcomers to Prospero's island grope their way toward repentance; the Prince finds his way to true love, after his previous tentative explorations; and Miranda awakens to womanhood. Caliban, the subhuman creature, rebels and then comes to learn the error of his ways; Ariel, the supernatural sprite, finds the means of regaining his freedom. Prospero resumes his political authority as duke and pardons all.

The play has a most interesting double focus, geographically speaking. Openly it is a story of Naples and Milan, a world of usurpations, tributes, homages, and political marriages that is familiar in Jacobean tragedy. At the same time the contemporary excitement of the New World permeates the play—a world of Indians and the plantations of the colonies, of the wonders and terrors and credulities of a newly discovered land. A lesser dramatist would surely have set his play far away in the west of the Atlantic to take advantage of this contemporary excitement. Perhaps with a surer theatrical instinct, Shakespeare offered his audience a familiar Italianate fictional world, which then became shot through with glimpses of the New World, too exciting to be fictional.

Henry VIII. *Henry VIII* is a play that has offered many difficulties to criticism. It has had a long and interesting stage history, but, from the mid-19th century, judgment has been confused by doubts about Shakespeare's sole authorship of the play, for many scenes and splendid speeches are written in a style very close to that of John Fletcher (see below *Collaborative and attributed plays*). The best of recent criticism, however, is inclined to restrict itself to consideration of the play as it stands. Although a story of English history, it differs from the "histories" that Shakespeare had written earlier, during the reign of Queen Elizabeth I. It is more episodic—more of a pageant and a series of loosely connected crises—than a skillfully plotted drama. It has a different sort of unity: three tragic episodes involving the deaths of Buckingham, Wolsey, and Queen Katharine led to the prophecy of a new age. For Anne Boleyn's infant, whose christening closes the play, inspires Thomas Cranmer, archbishop of Canterbury, to a marvelous speech about the glories of her future reign as the first Elizabeth. Thus *Henry VIII,* in spite of many differences, resembles Shakespeare's other late plays in its emphasis on the way in which past tragic events lead to reconciliation and to hope for the new generation.

The search for "other hands" in Shakespeare

Collaborative and attributed plays. The busy competition of Elizabethan theatre encouraged collaboration between authors and was almost the rule in some companies. Naturally, therefore, scholars have sought "other hands" in Shakespeare's plays, but, following the magisterial arguments of the distinguished scholar Sir Edmund Chambers, critical opinion has held that each play in the Folio edition of 1623 is substantially Shakespeare's. The possibility remains that parts of the earliest plays, especially *1 Henry VI* and *The Taming of the Shrew,* may derive from earlier plays by other hands. Stronger than this, however, are arguments that parts of *Henry VIII* were written by John Fletcher, who from 1608 onward wrote frequently for the King's Men. Fletcher's name has been linked with Shakespeare's elsewhere, most notably in the play *The Two Noble Kinsmen,* published as their joint work in 1634. Internal evidence of style and structure suggests that Shakespeare planned the whole work and wrote Act I; that then a need for haste arose and Fletcher took over responsiblity for Acts II, III and IV, leaving Shakespeare to complete Act V. Some such story could account for a curious lack of cohesion in the writing and also for the closeness of the theme to interests apparent in Shakespeare's latest plays.

In his own lifetime and in later ages, several plays were attributed to Shakespeare (often with no justification at all). In his own handwriting, however, are 147 lines of a scene in *The Booke of Sir Thomas More,* a play written in about 1595 by a group of five authors (probably including Thomas Dekker, Anthony Munday, and Henry Chettle) and then suppressed by the censor. The attempts of Sir Thomas to quell the anti-alien riots are linked in sentiment to Shylock episodes from *The Merchant of Venice* and echo the plays of the 1590s in imagery and versification. Among the printed texts that have been ascribed to Shakespeare is the anonymous *Edward III* (1596); the stylistic evidence adduced for his authorship of an episode in which the King woos the Countess of Salisbury might, however, be the work of an imitator. Several plays were added to his works in the third edition of the Folio (1664): *Locrine* (1595), *Sir John Oldcastle* (1600), *Thomas Lord Cromwell* (1602), *The London Prodigal* (1605), *The Puritan* (1607), and *A Yorkshire Tragedy* (1608). None is now considered to be of his authorship. Other plays, too, were printed as Shakespeare's, indicating the extent of his prestige—a brand name that could sell even rotten fish. No other dramatist of his time was so misused.

SHAKESPEARE'S READING

With a few exceptions, Shakespeare did not invent the plots of his plays. Sometimes he used old stories (*Ham-*

Shakespeare's plots

let, Pericles). Sometimes he worked from the stories of comparatively recent Italian writers, such as Boccaccio—using both well-known stories (*Romeo and Juliet, Much Ado About Nothing*) and little-known ones (*Othello*). He used the popular prose fictions of his contemporaries in *As You Like It* and *The Winter's Tale.* In writing his historical plays, he drew largely from Plutarch's *Lives of the Noble Grecians and Romans* for the Roman plays and the chronicles of Edward Hall and Ralph Holinshed for the plays based upon English history. Some plays deal with rather remote and legendary history (*King Lear, Cymbeline, Macbeth*)—though it seemed more genuinely historical to Shakespeare's contemporaries than it does today. Earlier dramatists had occasionally used the same material (there were, for example, earlier plays called *The Famous Victories of Henry the fifth* and *King Leir*). But, because many plays of Shakespeare's time have been lost, it is impossible to be sure of the relation between an earlier, lost play and Shakespeare's surviving one: in the case of *Hamlet* it has been plausibly argued that an "old play," known to have existed, was merely an early version of Shakespeare's own.

Availability of literary contacts and accessibility of books

Shakespeare was probably too busy for prolonged study. He had to read what books he could, when he needed them. His enormous vocabulary could only be derived from a mind of great celerity, responding to the literary as well as the spoken language. It is not known what libraries were available to him. The Huguenot family of Mountjoys, with whom he lodged in London, presumably possessed French books. There was, moreover, a very interesting connection between Shakespeare and the book trade. For there survives the record of apprenticeship of one Richard Field, who published Shakespeare's two poems *Venus and Adonis* and *Lucrece,* describing him as the "son of Henry Field of Stratford-upon-Avon in the County of Warwick, tanner." When Henry Field the tanner died in 1592, John Shakespeare the glover was one of the three appointed to value his goods and chattels. Field's son, bound apprentice in 1579, was probably almost exactly the same age as Shakespeare. From 1587 he steadily established himself as a printer of serious literature—notably of Sir Thomas North's translation of Plutarch (1595, reprinted in 1603 and 1610). There is no direct evidence of any close friendship between Field and Shakespeare. But it cannot escape notice that one of the important printer-publishers in London at the time was an exact contemporary of Shakespeare at Stratford, that he can hardly have been other than a schoolfellow, that he was the son of a close associate of John Shakespeare, and that he published Shakespeare's first poems. Clearly, a considerable number of literary contacts were available to Shakespeare, and many books were accessible.

That Shakespeare's plays had "sources" was already apparent in his own time. An interesting contemporary description of a performance is to be found in the diary of a young lawyer of the Middle Temple, John Manningham, who kept a record of his experiences in 1602 and 1603. On February 2, 1602, he wrote:

> At our feast we had a play called *Twelfth Night, or What You Will,* much like *The Comedy of Errors,* or *Menaechmi* in Plautus, but most like and near to that in Italian called *Inganni.* . . .

The first collection of information about sources of Elizabethan plays was published in the 17th century—Gerard Langbaine's *Account of the English Dramatick Poets* (1691) briefly indicated where Shakespeare found materials for some plays. But, during the course of the 17th century, it came to be felt that Shakespeare was an outstandingly "natural" writer, whose intellectual background was of comparatively little significance: "he was naturally learn'd; he needed not the spectacles of books to read nature," said John Dryden in 1668. It was nevertheless obvious that the intellectual quality of Shakespeare's writings was high and revealed a remarkably perceptive mind. The Roman plays, in particular, gave evidence of careful reconstruction of the ancient world.

The first collection of source materials, arranged so that they could be read and closely compared with Shakespeare's plays, was made by Mrs. Charlotte Lennox in the 18th century. More complete collections appeared later, notably those of John Payne Collier (*Shakespeare's Library,* 1843; revised by W. Carew Hazlitt, 1875). These earlier collections have been superseded by one edited by Geoffrey Bullough as *Narrative and Dramatic Sources of Shakespeare* (7 vol., 1957–72).

It has become steadily more possible to see what was original in Shakespeare's dramatic art. He achieved compression and economy by the exclusion of undramatic material. He developed characters from brief suggestions in his source (Mercutio, Touchstone, Falstaff, Pandarus), and he developed entirely new characters (the Dromio brothers, Beatrice and Benedick, Sir Toby Belch, Malvolio, Paulina, Roderigo, Lear's fool). He rearranged the plot with a view to more effective contrasts of character, climaxes, and conclusions (*Macbeth, Othello, The Winter's Tale, As You Like It*). A wider philosophical outlook was introduced (*Hamlet, Coriolanus, All's Well That Ends Well, Troilus and Cressida*). And everywhere an intensification of the dialogue and an altogether higher level of imaginative writing together transformed the older work.

Acquaintance with the literary achievements of other writers

But, quite apart from evidence of the sources of his plays, it is not difficult to get a fair impression of Shakespeare as a reader, feeding his own imagination by a moderate acquaintance with the literary achievements of other men and of other ages. He quotes his contemporary Christopher Marlowe in *As You Like It.* He casually refers to the *Aethiopica* ("Ethiopian History") of Heliodorus (which had been translated by Thomas Underdown in 1569) in *Twelfth Night.* He read the translation of Ovid's *Metamorphoses* by Arthur Golding, which went through seven editions between 1567 and 1612. Chapman's vigorous translation of Homer's *Iliad* impressed him, though he used some of the material rather sardonically in *Troilus and Cressida.* He derived the ironical account of an ideal republic in *The Tempest* from one of Montaigne's essays. He read (in part, at least) Samuel Harsnett's *Declaration of egregious popish impostors* and remembered lively passages from it when he was writing *King Lear.* The beginning lines of one sonnet (106) indicate that he had read Edmund Spenser's poem *The Faerie Queene* or comparable romantic literature.

He was acutely aware of the varieties of poetic style that characterized the work of other authors. A brilliant little poem he composed for Prince Hamlet (Act II, scene 2, line 115) shows how ironically he perceived the qualities of poetry in the last years of the 16th century, when poets such as John Donne were writing love poems uniting astronomical and cosmogenic imagery with skepticism and moral paradoxes. The eight-syllable lines in an archaic mode written for the 14th-century poet John Gower in *Pericles* show his reading of that poet's *Confessio amantis.* The influence of the great figure of Sir Philip Sidney, whose *Arcadia* was first printed in 1590 and was widely read for generations, is frequently felt in Shakespeare's writings. Finally, the importance of the Bible for Shakespeare's style and range of allusion is not to be underestimated. His works show a pervasive familiarity with the passages appointed to be read in church on each Sunday throughout the year, and a large number of allusions to passages in Ecclesiasticus (Wisdom of Jesus the Son of Sirach) indicates a personal interest in one of the uncanonical books.

Understanding Shakespeare

SYMPATHETIC EXPLORATION OF THE TEXTS

On opening the works of Shakespeare, a reader can be held by a few lines of verse or a sentence or one complex, glittering, or telling word. Indeed, Shakespeare's supreme mastery of words and images, of sound, rhythm, metre, and texture, as well as the point, neatness, and lyricism of his lines, has enslaved countless people.

The next step in understanding, for most readers, is an appreciation of individual characters. Many of the early books on Shakespeare were about his "characters," and controversy about them still continues. Appreciation of the argument of the plays usually comes on insensibly, for Shakespeare is not a didactic playwright. But most persistent readers gain an increasing sense of a unity of inspiration, of an alert moral judgment and idealistic vision, both in the individual plays and in the works as a whole.

When the plays are seen in performance, they are further revealed in a new, three-dimensional, flesh and blood reality, which can grow in the minds of individual playgoers and readers as they become more experienced in response to the plays' many suggestions.

Shakespeare's direct appeal to readers

But, while various skills and learned guidance are needed for a developed understanding of Shakespeare, the directness of his appeal remains—the editors of the First Folio commended the plays to everyone "how odd soever your brains be, or your wisdoms." Perhaps most essentially, the plays will continually yield their secrets only to imaginative exploration.

CAUSES OF DIFFICULTY

Questions of authorship. The idea that Shakespeare's plays and poems were not actually written by William Shakespeare of Stratford has been the subject of many books and is widely regarded as at least an interesting possibility. The source of all doubts about the authorship of the plays lies in the disparity between the greatness of Shakespeare's literary achievement and his comparatively humble origin, the supposed inadequacy of his education, and the obscurity of his life. In Shakespeare's writings, people have claimed to discover a familiarity with languages and literature, with such subjects as law, history, politics, and geography, and with the manners and speech of courts, which they regard as inconceivable in a common player, the son of a provincial tradesman. This range of knowledge, it is said, is to be expected at that period only in a man of extensive education, one who was familiar with such royal and noble personages as figure largely in Shakespeare's plays. And the dearth of contemporary records has been regarded as incompatible with Shakespeare's eminence and as therefore suggestive of mystery. That none of his manuscripts has survived has been taken as evidence that they were destroyed to conceal the identity of their author.

The claims put forward for Bacon. The first suggestion that the author of Shakespeare's plays might be Francis Bacon, Viscount St. Albans, seems to have been made in the middle of the 19th century, inquiry at first centring on textual comparison between Bacon's known writings and the plays. A discovery was made that references to the Bible, the law, and the classics were given similar treatment in both canons. In the later 19th century a search was made for ciphered messages embedded in the dramatic texts. In *Love's Labour's Lost*, for example, it was found that the Latin word "honorificabilitudinitatibus" is an anagram of *Hi ludi F. Baconis nati tuiti orbi* ("These plays, the offspring of F. Bacon, are preserved for the world."). Professional cryptographers of the 20th century, however, examining all the Baconian ciphers, have rejected them as invalid, and interest in the Shakespeare–Bacon controversy has diminished.

Edward de Vere, earl of Oxford

Other candidates. A theory that the author of the plays was Edward de Vere, 17th earl of Oxford, receives some circumstantial support from the coincidence that Oxford's known poems apparently ceased just before Shakespeare's work began to appear. It is argued that Oxford assumed a pseudonym in order to protect his family from the social stigma then attached to the stage and also because extravagance had brought him into disrepute at court. Another candidate is William Stanley, 6th earl of Derby, who was keenly interested in the theatre and was patron of his own company of actors. Several poems, written in the 1580s and exhibiting signs of an immature Shakespearean style, cannot well have been written by Shakespeare himself. One of these is in Derby's handwriting, and three of them are signed "W.S." These initials are thought by some to have been a concealment for Derby's identity (for some such motives as were attributed to Oxford) and to have been later expanded into "William Shakespeare."

Christopher Marlowe

Shakespeare has also been identified with Christopher Marlowe, one theory even going so far as to assert that Marlowe was not killed in a tavern brawl in 1593 (the corpse of another being represented as his own) but was smuggled to France and thence to Italy where he continued to write in exile—his plays being fathered on Shakespeare, who was paid to keep silent.

The case for Shakespeare. In spite of recorded allusions to Shakespeare as the author of many plays in the canon, made by about 50 men during his lifetime, it is arguable that his greatness was not as clearly recognized in his own day as one might expect. But on the other hand, the difficulties are not so great as many disbelievers have held, and their proposals have all too often raised larger problems than they have resolved. Shakespeare's contemporaries, after all, wrote of him unequivocally as the author of the plays. Ben Jonson, who knew him well, contributed verses to the First Folio of 1623, where (as elsewhere) he criticizes and praises Shakespeare as the author. John Heminge and Henry Condell, fellow actors and theatre owners with Shakespeare, signed the dedication and a foreword to the First Folio and described their methods as editors. In his own day, therefore, he was accepted as the author of the plays. Throughout his lifetime, and for long after, no person is known to have questioned his authorship. In an age that loved gossip and mystery as much as any, it seems hardly conceivable that Jonson and Shakespeare's theatrical associates shared the secret of a gigantic literary hoax without a single leak or that they could have been imposed upon without suspicion. Unsupported assertions that the author of the plays was a man of great learning and that Shakespeare of Stratford was an illiterate rustic no longer carry weight, and only when a believer in Bacon or Oxford or Marlowe produces sound evidence will scholars pay close attention to it and to him.

Linguistic and historical problems. Since the days of Shakespeare, the English language has changed, and so have audiences, theatres, actors, and customary patterns of thought and feeling. Time has placed an ever-increasing cloud before the mirror he held up to life, and it is here that scholarship can help.

Problems are most obvious in single words. In the 20th century, "presently," for instance, does not mean "immediately," as it usually did for Shakespeare, or "will" mean "lust" or "rage" mean "folly" or "silly" denote "innocence" and "purity." In Shakespeare's day, words sounded different, too, so that "ably" could rhyme with "eye" or "tomb" with "dumb." Syntax was often different, and, far more difficult to define, so was response to metre and phrase. What sounds formal and stiff to a modern hearer might have sounded fresh and gay to an Elizabethan.

Ideas have changed, too, most obviously political ones. Shakespeare's contemporaries almost unanimously believed in authoritarian monarchy and recognized divine intervention in history. Most of them would have agreed that a man should be burned for ultimate religious heresies. It is the office of linguistic and historical scholarship to aid the understanding of the multitude of factors that have significantly affected the impressions made by Shakespeare's plays.

Textual and editorial problems. None of Shakespeare's plays has survived in his handwritten manuscript, and, in the printed texts of some plays, notably *King Lear* and *Richard III*, there are passages manifestly corrupt, with no clue to the words Shakespeare once wrote. Even if the printer received a good manuscript, small errors could still be introduced. Compositors were less than perfect; they often "regularized" the readings of their copy, altered punctuation because they lacked the necessary pieces of type, or made mistakes because they had to work too hurriedly. Even the correction of proof sheets in the printing house could further corrupt the text, since such correction was usually effected without reference to the author or to the manuscript copy; when both corrected and uncorrected states are still available, it is often the uncorrected version that is preferable. Correctors are undoubtedly responsible for many errors now impossible to right.

OVERCOMING SOME DIFFICULTIES

The contribution of textual criticism. The early editors of Shakespeare saw their task chiefly as one of correction and regularization of the faulty printing and imperfect texts of the original editions or their reprints. Many changes in the text of the quartos and folios that are now accepted derive from Nicholas Rowe (1709) and Alexander Pope (1723–25), but these editors also introduced many thousands of small changes that have since been rejected. Later in the 18th century, editors compiled collations of alternative and rejected readings. Samuel Johnson (1765), Edward Capell (1767–68), and Edmond Malone (1790) were notable pioneers. Their work reached its most comprehensive form in the Cambridge edition in nine volumes by W.G. Clark, J. Glover, and W.A. Wright, published in 1863–66. A famous one-volume Globe edition of 1864 was based on this Cambridge text.

The "New Variorum Edition"

Each major editor had added to the great number of annotations on textual problems and on linguistic and historical difficulties, and in 1871 was published the first of a series of large volumes, one or two for each play, called "A New Variorum Edition," which aimed at bringing all previous textual scholarship together. The series remains incomplete, but A.W. Pollard published his *Shakespeare Folios and Quartos* in 1909 and, together with R.B. McKerrow, Sir Walter Greg, and Charles Sisson, began a concerted study of the manuscript plays surviving from Elizabethan theatres and the practice of Elizabethan printers. Their work was summed up in Greg's study *The Shakespeare First Folio* (1955) and Fredson Bowers' *On Editing Shakespeare and the Elizabethan Dramatists* (1955). By this time a new phase of bibliographic and textual inquiry had begun, and Bowers, with Alice Walker, Charlton Hinman, and others, began studying the minutiae of each substantive early edition. Computers will analyze the huge mass of their detailed information and make available the full results of their investigations. Also, individual compositors who set in type the early editions are being identified, and already something of their work habits and habitual errors is known. Processes of correction in the Elizabethan printing houses are also being studied more intensively. Before the end of the 20th century, a new edition of Shakespeare may appear in which a multitude of small errors have been removed. But even then, nothing will compensate for the loss of Shakespeare's manuscripts, and numerous important readings and details of presentation will still have to be supplied by educated guesses.

Historical, linguistic, and dramatic studies. Since the end of the 19th century, many other problems that hinder the understanding of Shakespeare's texts have been at least partly overcome thanks to extensive investigation into, for example, his syntax, vocabulary, and word usage—especially with regard to other Elizabethan and Jacobean literature. Such technical works, as well as studies of current theories of composition (the use of rhetoric, metaphor, and simile), have provided material for critical analysis, as have works that examine the ideas and life-style of Shakespeare's contemporaries. An increasingly large proportion of research is devoted to an investigation of contemporary literary and dramatic conventions.

LITERARY CRITICISM

Literary critics and the theatre. Shakespeare criticism must take into account the certainty that Shakespeare intended his plays to be acted, that he was the professional playwright of a repertory company, that the success of a play in performance by his company was what determined his income, and that during his lifetime he apparently made no effort (or perhaps was too busy) to gain a "literary" reputation from his plays. Yet, his contemporaries had no doubt about his literary eminence. Heminge and Condell, his fellow players, and Ben Jonson, his fellow playwright, commended the great Folio of 1623 to "the great variety of readers."

The tension between the critics and the theatre
