The Solar System

The solar system consists of the Sun and all matter under the gravitational control of the Sun in its 225,000,000-year period of revolution around its galaxy. Any body not having sufficient velocity to escape from the Sun remains in a closed path (orbit) around it and is a part of its system.

This article surveys the structure and general characteristics of the solar system as a whole and summarizes the key theories concerning its origin. It also describes the components of the solar system and their properties.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 131, 133, 211, 212, and 213. (Ed.)

The article is divided into the following sections:

Table 1: Comparative Data for Solar System Bodies

	mass (Earth = 1)*	equatorial Earth radius (Earth = 1)†	mean density (g/cm^3)	rotation period‡ (h = hours, d = days) mean solar	sidereal	inclination of axis	mean distance from Sun (a.u.)§	orbital eccentricity	orbital inclination	number of known satellites

*The mass of Earth is 5.9733×10^{24} kilograms. †The equatorial radius of Earth is 6,378.136±1 kilometres. ‡The mean solar day is the length of the day as measured by the average motion of the Sun, the clock day of Earth. The sidereal period is that required for a 360° rotation relative to the stars. Only if a planet did not move relative to the Sun could the sidereal and mean solar days be exactly equal, although for the outer planets, where the orbital motion is very slow, the differences are extremely small. §One astronomical unit (a.u.) is the average distance of Earth from the Sun, or 149,598,000 kilometres. ‖ Largest of the known asteroids.

Plan of the solar system. More than 99 percent of the mass of the solar system is in the Sun, whose mass is 1.989×10^{30} kilograms (4.385×10^{30} pounds)—333,000 times that of the Earth. The Sun is a gas (predominantly hydrogen) throughout its nearly 700,000-kilometre (435,000-mile) radius because it is heated by continuous nuclear fusion of the hydrogen in its core, where temperatures are near 15,000,000 K (27,000,000° F). As a result, the visible surface of the Sun has a temperature of about 5,780 K and continuously radiates a power of 3.85×10^{26} watts into space. Earth intercepts less than half of one-billionth of that power, but it is sufficient to make Earth a warm, habitable planet.

Of the remaining mass in the solar system more than 99 percent is found in the nine known planets, and more than 90 percent in Jupiter and Saturn alone. Most of the planets follow nearly circular paths around the Sun, with most of the circles nearly in the same plane. Only Mercury and Pluto, the innermost and outermost planets, and also the smallest, have orbital eccentricities greater than 0.2 and inclinations greater than 5°. (Eccentricity measures the amount by which an orbit departs from circularity, being zero for a circle and one for a parabola. Inclination is the angle between the plane of a planet's orbit and that of Earth's orbit.) These and other basic figures for all of the planets are given in Table 1.

Terrestrial and giant planets

The planets can be divided physically into two groups—an inner group of small, rocky, high-density bodies (Mercury, Venus, Earth, and Mars), called the terrestrial planets, and an outer group of large, gassy, low-density objects (Jupiter, Saturn, Uranus, and Neptune), called the giant planets. This leaves Pluto as a curious anomaly—small, icy, of low density, and in its makeup more like a satellite than a planet. The giant planets have occasionally been called the major planets, but the latter term is best applied to all nine planets in juxtaposition to the minor planets, or asteroids. Discussion of a possible 10th planet is heard from time to time. Searches have been conducted, within 30° of the plane of the planets, that would have found any object brighter than about one-tenth the brightness of Pluto. There are very small variations from prediction in the orbits of Uranus and Neptune that could be caused by another planet, but the evidence is not strong.

Planetary surfaces. *The inner planets.* The inner planets are bodies made of refractory materials. They are composed of outer shells of silicates with inner metallic cores, yet their surfaces show differing morphologies because of the vastly different surface environments that evolved over their 4,500,000,000-year histories. Despite similar gross compositions, the inner planets differ in their volatile inventories—*i.e.,* substances such as carbon dioxide (CO_2) and water (H_2O). The relatively slight differences have given Mercury a hellishly hot, crater-pocked surface; have turned the surface of Venus into a gaseous, suffocating inferno; have given Mars a history of megafloods and Arctic-like permafrost; and have allowed Earth's surface to be mainly oceans of liquid water.

The outer planets. Among the outer planets the gas giants—Jupiter, Saturn, Uranus, and Neptune—do not have accessible surfaces. Their rocky cores are submerged beneath massive atmospheres. Pluto is so small and distant that it is equally unknown.

Planetary atmospheres. Atmospheres are the parts of planets and other solar system bodies that are mostly gaseous. Mercury, nearest the Sun, has no appreciable atmosphere. Venus, Earth, and Mars have thin atmospheric layers surrounding the solid portions composing the bulk of their masses. Jupiter, Saturn, Uranus, and Neptune have atmospheres that are so substantial that no detection of solid surfaces had been made by the mid-1980s, though theoretical models predict solid cores deep in their interiors. A thin atmosphere of methane (CH_4) has been detected above Pluto's surface.

Surface temperatures and pressures

For the inner planets with atmospheres, their increasing distance from the Sun results in a progressive drop of surface temperatures and is partially the cause of a like drop in surface atmospheric pressures. Venus' surface temperature is about 730 K and its surface pressure 90 atmospheres (*i.e.,* 90 times the pressure at Earth's sea level). The Earth's average surface temperature is about 289 K. Mars has an average surface temperature of 218 K and an average surface pressure of 0.007 atmosphere. The atmospheric temperatures of Earth and Mars vary with changes in season.

The temperature differences among the giant planets are due to differences in solar heating and to the amount of energy coming independently from the planetary interiors. At the level where the total pressure is equal to one atmosphere, the temperature of Jupiter is about 166 K, and that of Saturn is approximately 91 K. Uranus and Neptune are both roughly 72 K at the same pressure level. The temperatures of both Jupiter and Saturn are known to change with position on the planet and with season. The surface temperature of Pluto is estimated at 55 K, and its surface pressure is at least 0.0001 atmosphere.

Chemical composition

The chemical composition of the atmospheres of Venus and Mars are similar. The atmosphere of Venus is 96 percent CO_2 and 3.5 percent molecular nitrogen (N_2); Mars is 95 percent CO_2 and 2.7 percent N_2 with another 1.6 percent argon (Ar). In contrast, Earth's atmosphere is 77 percent N_2, 21 percent molecular oxygen (O_2), 1 percent H_2O, and 0.93 percent Ar. The remainder of the composition of each atmosphere is shared by several species of chemicals. For Venus the most abundant of these are sulfur dioxide (SO_2), H_2O, Ar, and carbon monoxide (CO); for Earth they are CO_2, neon (Ne), and helium (He); and for Mars they are O_2, CO, and H_2O.

The bulk of the outer-planet atmospheres is molecular hydrogen (H_2), with mixtures of smaller amounts of helium. Jupiter is known to be about 89 percent H_2 and 11 percent He, with minor abundances of CH_4 and ammonia (NH_3). Measurements of Saturn show 94 percent H_2 and 6 percent He, but the He content is expected to be greater in the interior of the planet; its atmosphere contains minor and trace chemicals similar to those of Jupiter. Methane is estimated to make up 0.2 to 4 percent of the total volumes of the atmospheres of Uranus and Neptune, which are otherwise mostly H_2 and He. The only known constituent of the atmosphere of Pluto is CH_4.

All of the atmospheres contain some liquid droplets and solid particles in suspension. In the case of Venus, concentrations of sulfuric acid (H_2SO_4) droplets form the bright clouds that blanket the planet. In ultraviolet light, markings are recognizable that show winds with speeds up to 100 metres per second (about 224 miles per hour). Earth's atmosphere is usually 50 percent covered by liquid water and ice clouds, often clustered in storm patterns. Clouds of water vapour and carbon dioxide are sometimes visible in the Martian atmosphere, which is filled with dust carried aloft from the surface by strong winds.

Visible clouds

The visible clouds of the giant planets generally form bands that surround the planets and are parallel to their equators. Jupiter's bands are the most striking in colour and duration; they are accompanied by smaller regions of local clouds, one of the most observed and longest lasting of which is the Great Red Spot. Saturn's clouds are more subdued in colour and contrast than those of Jupiter. The uppermost clouds of Jupiter and Saturn are probably NH_3 ice particles; at deeper levels clouds of ammonium hydrogen sulfide (NH_4HS) and H_2O may exist. The colours of the clouds may be due mostly to the presence of elemental sulfur or complex hydrocarbon molecules. Cloud patterns have been detected in the atmospheres of Uranus and Neptune; above NH_3 clouds there may be CH_4 ice clouds in the atmospheres of both planets. The absorption of visible red light by gaseous CH_4 above the cloud tops makes both Uranus and Neptune appear bluish green.

Satellites. A satellite is a body in orbit around a planet or other body that, in turn, is in orbit around the Sun or, in principle, another star. When a satellite reaches half the size of the planet it circles, as seems to be the case with Pluto and its satellite, Charon, the system might better be called a double planet. At the other extreme, the planetary rings around Jupiter, Saturn, and Uranus are made up of innumerable tiny satellites, typically a few metres in diameter in the main rings of Saturn and probably much smaller in Jupiter's rings.

The number of verified satellites in the solar system in the late 1980s was at least 57. Their diversity in size, morphology, and composition is at least as great as that among the planets themselves. In size they range from Jupiter's Ganymede and Saturn's Titan—which are larger than the planet Mercury—to tiny, irregular bodies such as Mars's Deimos. As might be expected, the inner planets have silicate satellites. The Moon has a composition very much like that of Earth's own upper layers, mostly iron–magnesium silicates, but has no water. Phobos and Deimos, the small satellites of Mars, have predominantly silicate compositions; they are probably captured asteroids.

Jovian satellites

The satellites of Jupiter present a somewhat more complex situation. Of the planet's Galilean satellites, Io, which is mainly silicate, has been well differentiated—since it shows no spectral signature of water—and is the most geologically active body in the solar system. Io is being constantly pushed and pulled, as it orbits close to Jupiter, by the gravity fields of Jupiter and of Europa, the next satellite out. Europa is also mostly silicate but exhibits the spectral signature of water ice and is very bright. Ganymede has substantially more water than the inner two Galilean satellites and exhibits huge, rifted icy plates that, earlier in its history, were probably mobile over a plastic or partially molten water interior. Callisto has even more water than Ganymede and a relatively stable crust with little mobility over geologic time. Amalthea, a small inner satellite, could well be a captured asteroid and is probably mainly silicate in composition. The outer satellites of Jupiter are all small. Some are in retrograde orbits and may be captured minor planets or condensed remnants of a circum-Jovian cloud.

Except for Titan, the major satellites of Saturn have bulk densities within 40 percent of water, and that substance is undoubtedly a major constituent of all of them. The remarkable trait common to the major Saturnian satellites is that they appear to have had episodes of geological activity, indicating internal heat sources with mobilization of surface materials. How such small icy bodies (all less than 750 kilometres in radius), with little silicate material to generate internal heat through radioactive decay, could exhibit episodes of geological activity is still a mystery.

Titan is the only satellite to possess a substantial atmosphere. Clouds of liquid methane droplets and other unidentified chemicals obscure its surface and give it a reddish orange colour. It is possible that methane plays a role on Titan much like that of water on Earth, with liquid methane seas and solid methane polar caps. Liquid hydrocarbons probably rain down from the upper atmosphere, producing a tarlike layer 100 metres thick.

The major satellites of Uranus, except for Umbriel, are similar to the largest moons of Saturn. They too are icy objects with small amounts of rocky material whose topography bears the effects of internal activity. For example, subsidence features such as fault scarps and trenches are found on Miranda and Ariel, while dark lavalike material covers the floors of various craters on Oberon.

Neptune's largest satellite, Triton, has a variegated surface. A large part of its equatorial region consists of valley-like depressions and polygonal ridge structures. Present, too, are broad plains covered by what is thought to be "lava" flows composed of water ice mixed with methane and possibly ammonia rather than of rock material. Some of these icy flows are extremely old and pitted by numerous impact craters. Plains covered by fresher-looking ice lavas have almost no such craters.

Other components of the solar system. *Asteroids.* The innumerable bodies orbiting the Sun—other than the nine major planets and their satellites—that can in principle be studied individually are asteroids and comets. During the 19th century it seemed there were many operational criteria uniquely defining each class of objects. An asteroid was defined as a small planet without obvious atmosphere in a nearly circular orbit between Mars and Jupiter. A comet was defined as an enormous volume of dust and extremely low-density gas emitted from something in an extremely elongated orbit. Today, only the evolution of a large quantity of gas remains as an observational distinction unique to comets. (See below *Asteroids.*)

Ceres

The first asteroid was discovered in 1801 and named Ceres. Ceres proved to be in a nearly circular orbit 2.77 astronomical units (a.u.) from the Sun, and modern observations give its diameter as 940 kilometres, the largest of the asteroids. (One astronomical unit is the average distance of Earth from the Sun, or 149,598,000 kilometres.) Once an asteroid has a well-determined orbit, it is given a number and a name. By the late 1980s there were about 3,500 numbered asteroids, more than 95 percent of them fitting the original criteria. Statistical studies indicate that in addition to Ceres there are more than 1,000,000 asteroids between Mars and Jupiter with a diameter greater than one kilometre, but the total mass of all these is roughly equal to that of Ceres, and the total mass of all "main-belt" asteroids, including Ceres, is certainly less than a thousandth of Earth.

Most asteroids are small objects of irregular shape. They show properties similar to the Moon—probably cratered and overlain with rocky, dusty debris. Certain differences in colorimetric properties of the asteroids suggest different compositional classes. Those of the C-class, with very low albedo (surface reflective power), are similar to carbonaceous chondrite meteorites, which are brittle, dark bodies with fine opaque material throughout and with hydrated (water-rich) mineral phases. Those of the S-class are thought to be similar to stony-iron meteorites in composition. Another, rarer group is the M-class, which is probably similar to nickel–iron meteorites.

The 5 percent of asteroids that, because of their orbits, do not fit the classic criteria include the Amor-class objects, which come nearer to the Sun than the perihelion distance of Mars (1.38 a.u.); the Apollo-class objects, which come nearer the Sun than Earth's mean distance (1 a.u.); and the Aten-class objects, whose average distance from the Sun is less than Earth's. There are at least 1,000 Trojan minor planets in the same orbit as Jupiter, but preceding or following it by roughly 60°. In 1977 a body a few hundred kilometres in diameter was discovered in an orbit extending inside Saturn's (to 8.5 a.u.) and outward nearly to that of Uranus (to 18.9 a.u.); it has been named Chiron.

Trojan minor planets

Comets. Comets are believed to be "snowballs" of frozen gases and dust a few hundred metres to a few tens of kilometres in diameter. They move in very elongated orbits, and only when they approach near enough to the Sun for the ices to begin vaporizing rapidly do they become obvious and clearly identifiable. Yet the very process that makes them visible destroys them. After 1,000 passages near the Sun, there should be little left except, possibly, a small inert core. A typical short-period comet makes a revolution in 10 years or less, giving it a total lifetime of less than 10,000 years. A large body, especially Jupiter, can make major alterations (perturbations) in the orbit of any comet passing near it, sometimes shortening the period of revolution, sometimes lengthening it. Statistical studies of this process and others affecting cometary orbits and lifetimes indicate that the total number of comets in existence may be as many as 3×10^{12}. Their combined mass would be nearly two Earth masses.

Meteoroids and interplanetary medium. Any body too small to be studied individually and moving in or through the solar system is called a meteoroid. Upon impact with an atmosphere it becomes a meteor. If some part survives and reaches the surface, it is a meteorite.

The smallest asteroids that have been studied individually are a few near one kilometre in diameter that have approached close to Earth, in some cases barely more than the distance of the Moon. There is also direct evidence of meteoroids in the solar system. Meteorites weighing from a few grams up to more than 50 metric tons (55 short tons) and roughly $3 \times 3 \times 1$ metres in size have been found after impact on Earth. Craters, such as Arizona's Meteor Crater, give evidence of yet larger impacts. Every clear night, meteors ("shooting stars") are visible streaking across the sky, most of them particles only a few millimetres in diameter that burn up from atmospheric friction without ever reaching the ground.

The interplanetary medium contains even lighter components than meteoroids, namely individual molecules, atoms, ions, and electrons from many sources. Most neutral molecules and atoms lost from comets or planets are rapidly ionized by solar ultraviolet radiation. The Sun itself is the largest source of interplanetary charged particles, which escape from the solar chromosphere. This "solar wind" has sufficient velocity to escape from the solar system, so although it is always present as a component of the interplanetary medium, individual ions, protons, and electrons are not in closed paths around the Sun.

Solar wind

Theories of origin. It is generally thought that the solar system evolved from a nebular cloud associated with the proto-Sun. As that rotating cloud cooled and condensed, it formed a disk in which compositional and thermal gradients evolved. That early nebular differentiation is reflected in the systematic change in planetary composition, physical properties, correlated surface morphological properties, and composition of planetary atmospheres from the Sun outward through the solar system. The inner planets are silicate and metal-rich, while proportionately more and more volatiles such as water and methane are incorporated in planets and satellites that presumably had a cooler formation environment. The Jupiter system is an interesting analogue to the entire solar system from the standpoint of composition and physical properties—of the Galilean satellites, Io is the closest, and it has the highest density and the least water, while Callisto is the farthest from Jupiter and possesses the most water. Nearly all of the planets and satellites in the solar system whose surfaces have been observed retain evidence of the torrential meteoritic bombardment that accompanied the final states of accretion.

Increasing evidence suggests that most of the original gases in the inner solar system were blown away during its early history. All the lighter gases, such as molecular hydrogen and helium, exist only in the colder and gravitationally more powerful giant planets. The atmospheres of Venus, Earth, and Mars are considered to have evolved substantially over the course of time by extrusion of materials from their interiors in tectonic processes and volcanism. The differences between them are probably due to the effect of different amounts of sunlight and also to the extent to which their interiors were heated. The abundance of O_2 on Earth is almost certainly due to the presence of photosynthetic life, which converts CO_2 to O_2. The massive gravity of Jupiter probably allowed it to retain the same chemical constituents that existed at its distance from the Sun in the early solar nebula. This should also be true to some extent for the other giant planets, and their compositions and those of comets should provide the best clues to the distribution of chemicals in the outer solar system at the time of its formation.

(R.L.Ne./G.S.O./D.C.P./Ed.)

THE SUN

The dominant body of the solar system, the Sun is the Earth's nearest star, eight light-minutes (149,598,000 kilometres) away from it. It is a typical star, approximately midway between the largest and the smallest and the brightest and the faintest stars known. On the basis of its temperature and radius (see below) it is called a G2 type dwarf star.

Energy source

The Sun's energy comes from the conversion of hydrogen to helium at a temperature of about 15,000,000 K, deep in its core where pressures are many thousand million (10^9) times that of the Earth's atmosphere at sea level and the density is 150 times that of water. The energy released in the core by nuclear processes slowly works its way to the surface, where it is radiated into space. The enormous energy output, of which the Earth intercepts only one part in 2,200,000,000, has been sufficiently constant over geologic time spans of hundreds of millions of years for complex life-forms, governed by cycles of day and night, by seasons, or by tides, to develop.

The visible surface of the Sun is the photosphere (Figure 1, top). Above it a layer 5,000 kilometres thick constitutes the inner atmosphere, or chromosphere, while above this lies the exceedingly tenuous high-temperature corona, which extends to the Earth and beyond. The Sun has a magnetic field; it rotates; it generates energy in its core. The outflow of energy from the deep interior through the surface and the surface manifestations of the magnetic field and solar rotation combine to make a complex and fascinating picture of solar phenomena that can be observed in great detail.

History of solar observations

For centuries the Sun was worshipped as a deity and was, therefore, not often the subject of physical study. Anaxagoras, the 5th-century-BC philosopher of Athens, supposed a great meteorite, which fell at Aegospotami in the daytime about 467 BC, to have come from the Sun, and he concluded that the Sun was a mass of red-hot iron larger than the Peloponnesus. With the invention of the telescope, Galileo Galilei, Johannes Fabricius, Christoph Scheiner, and Thomas Harriot almost simultaneously (1610–11) discovered sunspots (Figure 1), but it was the genius of Galileo that recognized their true nature as solar phenomena. Two centuries later, a German amateur astronomer, Samuel Heinrich Schwabe (1843), having diligently observed the Sun for 33 years, announced that the average number of spots varies cyclically with a period of about 10 years. In 1852 the cyclic period was found to be 11.2 years and the possibility of there being still another period of 80 years was recognized. In 1858 it was noted that the sunspots of a new cycle appear at latitudes of ±30° and, as the cycle progresses, the spots break out closer to the Sun's equator so that the last spots of the cycle appear at about ±8°.

Establishment of the first magnetic observatory

A German mathematician and astronomer, Carl Friedrich Gauss, established the first magnetic observatory in 1834 at Göttingen. Others soon followed. Small daily magnetic changes were shown to be related to the sunspot cycle in 1857. In 1904 intense magnetic storms were found to be associated with the passage of large sunspot groups over the central meridian.

Many important advances in solar astronomy have resulted from the construction of new telescopes and ancillary instrumentation of great sophistication. The physical and chemical nature of sunspots became known only after the development of the spectroscope. In 1870 dark bands were discovered in the spectrum of light radiated from sunspots, indicating the presence of molecular compounds; furthermore, it was postulated that the widening and splitting of some lines and the complete reversal of some dark lines to bright ones were caused by gaseous eruptions in the neighbourhood of sunspots—now called flares. The outflow of gases from the cooler dark centre of the spot (the umbra) to the edge of the penumbra, or outer part, at a speed of two kilometres per second was discovered spectroscopically in 1909. A reverse flow, inward, toward the centre of the spot, for the gases at the highest levels of the atmosphere above it, was found in 1913. The invention of the spectroheliograph by the U.S. astronomer George Ellery Hale in 1891 made possible the examination of the Sun in hydrogen light, calcium light, and the light radiated by ions or atoms of other elements, bringing out a wealth of detail in the chromosphere. In 1908 Hale looked for splitting and polarization of some atomic lines (the Zeeman effect) in spot spectra, but it required the large solar tower telescopes and pit spectrograph designed and constructed by Hale at Mount Wilson Observatory, California, to prove the magnetic character of sunspots. Between 1914 and 1924 Hale developed the laws of alternating sunspot polarity (see below). Although he also attempted to measure the Sun's general magnetic field, reliable measures were achieved only after the invention of the photoelectric magnetograph in 1948.

Table 2: Data for the Sun

Distance	149,600,000 km 92,957,000 mi
Mean angular diameter	31′59.3″
Diameter	1,392,000 km (864,950 mi) (109.3 times the Earth's diameter)
Surface area	6.087 × 10^{12} km^2 (2.35 × 10^{12} sq mi) (12,000 times the Earth's area)
Volume	1.412 × 10^{18} km^3 (3.387 × 10^{17} cu mi) (1,306,000 times the Earth's volume)
Mass	1.99 × 10^{30} kilograms (2.19 × 10^{27} tons) (333,400 times the Earth's mass)
Mean density	1.41, *i.e.*, less than 1½ times that of water
Escape velocity to infinity from the Sun's surface	618 km per sec (384 mi per second)
Effective temperature	5,740° K
Total energy output	3.86 × 10^{33} ergs per second
Radiation from the Sun's surface	6.35 × 10^{10} ergs/cm^2/sec
Brightness at the centre of the disk	8.23 × 10^5 lamberts
Candlepower	3.17 × 10^{27} candles
Light flux	141,400 lux, at the Earth's mean distance, outside the atmosphere 103,000 lux, the average illumination from the Sun at the zenith
Period of rotation	
Equator	26.9 days (synodical)
Sunspot zone (16° N)	27.3 days (synodical)
Pole	31.1 days (synodical)
The Sun's interior	
Density	150 gm/cm^3
Temperature	15,000,000° K*
Pressure	4 × 10^{17} dynes/cm^2 (4 × 10^{11} atmospheres)
The Sun as a star	
Spectral type	G2
Colour index	Mpg-Mpv = +0.45
Visual magnitude	Mpv = −26.86
Absolute visual magnitude	Mpv = +4.71
Velocity in space relative to nearby stars	19.4 km per sec in the direction of Lyra (Vega). The motion of the local stars of which the Sun is a member is about the galactic centre with a velocity of 220 km per sec

*Different calculations give results from 13,000,000°–25,000,000°.

Joseph von Fraunhofer, a German physicist with greatly improved spectroscopes of his own construction, had visually found and mapped many (574) dark lines in the solar spectrum; to the strongest of these he assigned letters—*e.g.,* A, a, B, C, D—that are still used to identify the lines. The physical significance of the dark lines was explained by another German physicist, Gustav Robert Kirchhoff, in 1859. Kirchhoff conceived the idea of a hot Sun surrounded by cooler layers of vapour, which he called the reversing layers, in which the dark lines were supposed to have been formed. By comparison of laboratory spectra with the solar spectrum, the presence of eight elements in the Sun was later established. Henry Augustus Rowland, a U.S. physicist, published in 1897 a 12-metre photographic map of the solar spectrum that was of the highest quality and that allowed for the presence of 39 chemical elements in the Sun. Rowland's map extended to the ultraviolet limit caused by terrestrial ozone. This limit has only recently been surpassed by observations from space; now the spectrum has been mapped from the visible to less than one angstrom (10^{-10} metre). Toward red, the solar spectrum was recorded to 53,000 angstroms in 1888. Today, with new detectors, the limit is set only by terrestrial water vapour bands that obscure the infrared spectrum beyond 25 micrometres (25×10^{-6} metre). The complete spectrum can be observed only from very high altitudes, above the water-vapour absorption and the ozone absorption.

Attempts to measure the Sun's temperature. The determination of the Sun's temperature has been one of the most difficult problems in solar astronomy. The English astronomer Sir John Herschel at the Cape of Good Hope and Claude-Servais-Mathias Pouillet in France (1837) observed that the vertical rays of the Sun, if totally absorbed, would raise the temperature of a layer of water 1.8 centimetres deep by 1° C per minute. The measurement is in principle easy, but atmospheric absorption has been the uncertain factor. The problem was solved in 1881 and again in 1904, when it was shown that extrapolations must be made for solar radiation of different wavelengths, to determine what the intensity of each would be if there were no intervening air; and the values for all wavelengths must then be summed. A value of 1.96 calories per square centimetre per minute was obtained for the solar constant (the flux of total radiation received outside the Earth's atmosphere per unit area at mean Earth–Sun distance), that only recently has been improved by observations from balloons and high-flying aircraft. Early estimates of the Sun's temperature ranged from 1,461° C to 10,000,000° C. Transforming the solar constant into the energy radiated by the Sun and thence into its effective temperature was impossible until the law that connects the temperature of a surface with the amount of heat radiated per second—the Stefan-Boltzmann law—was established about 1880.

The Moon, with its opaque disk of almost exactly the same apparent size as the Sun, and with a sharply defined edge, has been valuable to the solar astronomer at times of solar eclipse. In the Middle Ages, prominences on the Sun (see Figure 2) that became visible during eclipses were thought to be part of the Moon's atmosphere, mirages, clouds, or holes in the Moon. During an eclipse of

July 1860, which crossed Spain, prominences were successfully photographed, and, by observing the motion of the Moon across them, it was demonstrated that these were solar. During an eclipse of August 1868, observers in India and in England, struck by the brilliance of the prominences, independently showed that they might be seen in broad daylight simply by opening the slit of a spectroscope and aiming it just outside the brilliant disk of the Sun's photosphere. The invention (1930) of the coronagraph made it possible for the first time to study the corona without an eclipse from high-altitude stations and on a nearly continuous basis. With a modified instrument, the K-coronameter (1950), which uses photoelectric detection, it became possible to view the corona through hazy skies at sea level, and measurements at very clear sites were greatly extended, to large distances from the limb of the Sun.

Coronal spectrum

The mysterious coronal spectrum—at first attributed to the mythical element coronium—was discovered in 1941 to be made up of the so-called forbidden lines of highly ionized atoms of iron, nickel, and other elements. The lines are described as forbidden because they are almost impossible to produce in the laboratory.

Detection of radio waves. Radio waves from the Sun were first detected in 1942 on British radar sets. It was suggested that the bursts of radio energy were associated with an active sunspot visible on the surface of the Sun and, in particular, with the large solar flare of February 28. In the same year, a weak background radio emission, or noise, was detected from the "quiet" Sun; *i.e.,* the Sun observed when sunspots and related phenomena are at a minimum. The science of radio astronomy has since become a large and important field of solar research.

The modern concept of energy generation in the Sun's interior follows from Sir Arthur Stanley Eddington's suggestion that only through nuclear processes could sufficient energy be produced to have sustained the output of energy from the Sun throughout the known lifetime of the solar system. More details were provided in 1937 and 1938 when the energy production from nuclear reactions, capable of transforming hydrogen to helium, were calculated. Later experimental and theoretical work has given improved values for all the reactions considered possible for energy production.

The quiet Sun

PHOTOSPHERE

The visible luminous surface of the Sun is the photosphere or light sphere. When carefully examined through a telescope, it is seen to have a mottled appearance called granulation (Figure 3); the most conspicuous objects to be seen, however, are sunspots which form and dissipate and partake in the solar rotation. The photosphere radiates most of the Sun's energy; it comprises a thin but rather opaque layer approximately 400 kilometres thick, the temperature of which varies from 10,000 K at the bottom to 4,200 K at the top. A typical density in the photosphere is around 10^{-3} gram per cubic centimetre, about $^{1}/_{1,000}$ that of air at sea level.

Granulation. About 4,000,000 granules, each one the top of a hot cloud of gas, cover the surface of the Sun. Because of their small size—300 to 1,450 kilometres—they can be seen and photographed from the ground only when the Earth's atmosphere is steady and free of turbulence. Excellent photographs have been made with telescopes carried by balloons to heights of 20 kilometres.

Characteristics of a granule

The best of these show that granules are irregular, often polygonal, and that each is surrounded by a narrow, relatively dark, lane. They last about seven to 10 minutes. A typical bright granule starts as a small grain the diameter of which grows to about 1,500 kilometres before it divides into several parts that spread and fade. Each granule rises with a speed of about 0.5 kilometre per second; as the energy radiates, the gas cools and descends rapidly in the dark intergranular lanes. A remarkable five-minute vertical oscillating motion of the granules was discovered in 1962. It has also been observed that after a bright granule forms, its upward movement sets the chromosphere into oscillation, which then continues for three to five periods after the disappearance of the exciting granule.

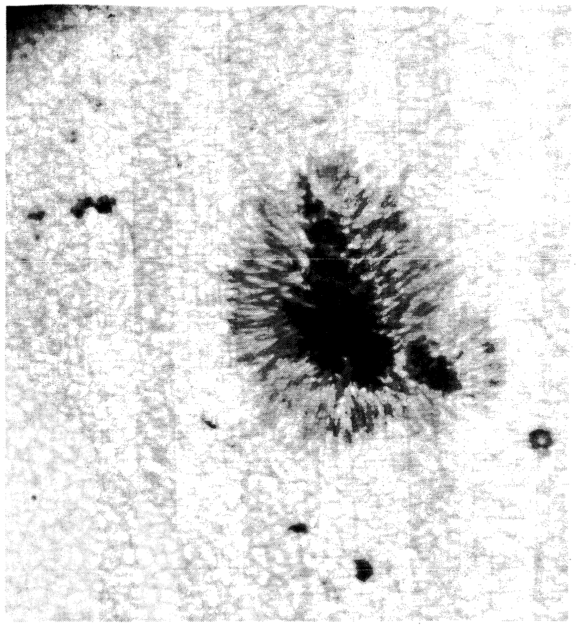

Figure 3: Granulation on the Sun showing a sunspot (centre right), which appears dark by contrast with the hotter regions surrounding it.

Limb darkening. The limb of the Sun (the visible edge) appears darker than the centre. The direct view downwards at the centre of the solar disk penetrates, on the average, into deeper, hotter layers of the photosphere; at the limb the higher, cooler layers are seen. Limb darkening (which exists for all stars) is due solely to a temperature gradient in the atmosphere, the deeper layers being hotter. Conversely, measures of the limb darkening lead to a determination of the temperature distribution with depth.

The Sun's temperature. The Sun emits energy over all wavelengths, from X-rays to radio waves. Approximately 40 percent of the emitted energy is in the visible portion of the spectrum, 50 percent is in the infrared, and the remainder is in the ultraviolet. Radiation escaping from the Sun's surface into space comes from different depths of the Sun's atmosphere, each with a different temperature. The boundary temperature is about 4,200 K, but the eye can see to depths where the temperature is 10,000 K; the Sun has, however, a well-defined effective temperature, namely, that of an equal sphere radiating a like amount of total energy in accordance with physical (blackbody) radiation laws. From the total energy radiated a temperature of about 5,700 K is found. Different (colour) temperatures are derived from different spectral regions. A colour temperature of 6,000 K fits the whole visible spectrum reasonably well.

Solar energy

It is not easy to describe the enormous output of solar energy. If the Sun were enveloped in a shell of ice 12 metres thick, it would thaw its way out in one minute of time. If an ice bridge three kilometres in diameter could be built, spanning the immense distance of 149,600,000 kilometres from Sun to Earth, and, if by some means, the whole of the Sun's radiation could be concentrated upon this ice bridge, in one second it would be water and in seven seconds more it would be dissipated into vapour. Though the energy received at the Earth's surface amounts to over 1,500,000 horsepower per square kilometre, to harness it effectively is difficult. To achieve high temperatures requires concentrators or large parabolic collectors, such as those used in solar furnaces.

The Sun's rotation and sphericity. Galileo gave the first proof of the Sun's rotation and shape. He noted the Sun's roundness and saw that the apparent motion of sunspots in parallel lines with diminished movement at the limbs could be explained if the spots were on the surface of a sphere rotating from east to west. Modern spectrographic observations of the Doppler shift (a change of wavelength with motion toward or away from the observer) of Fraunhofer lines show that the equator is rotating faster than the poles. Unlike some stars, which rotate rapidly and are strongly flattened oblate spheroids, the Sun is a slow rotator and is so nearly spherical that it is uncertain whether any flattening can be detected. A polar diameter 70 kilometres less than the equatorial diameter has been suggested by some observations. The ellipticity of the Sun has been of interest to scientists because the gravitational field of a nonspherical body affects planetary orbits in a way different from that of a sphere. It has been suggested that part of the perihelion advance (a gradual rotation of the point closest to the Sun, which is otherwise very satisfactorily explained by the theory of relativity) of Mercury's orbit could be explained in this manner.

The Fraunhofer spectrum. The solar spectrum, within the wavelength interval 2,950–10,000 angstroms, shows about 25,000 so-called Fraunhofer dark lines (see above *History of solar observations* and Figure 1, centre). The identification of elements in the Sun is still carried out by the classical method comparing the solar lines with lines observed in the laboratory for both wavelength and intensity. Care must be taken to distinguish between solar lines and lines produced by water vapour, oxygen, and other constituents of the Earth's atmosphere.

Element identification

About 73 percent of the lines have been identified; 63 elements and 11 molecules are recorded. Iron contributes the greatest number (5,458) of identified lines. There are 1,453 lines from chromium, 1,344 from titanium, 856 from nickel, 388 from zirconium, 1,572 from solar cyanogen, and 1,477 from terrestrial water. For many elements, however, only a few lines are observed, for example: two from beryllium, two from silver, six from platinum, one from gold. The majority of the unidentified lines are faint and probably due to molecules and to the faint lines of the abundant elements in the Sun.

Modern techniques of spectrum analysis make use of the most powerful spectrographs that can be built. This makes it possible to study each spectrum line in detail for position, shape, depth and width.

A Fraunhofer line has considerable width because of the turbulent motions of the solar gases and collisions caused by neighbouring atoms. The resulting line profile, measuring the intensity against wavelength (or frequency), is that of an inverted bell-shaped curve near the line centre with broad, shallow wings, which, for strong lines, may extend many angstroms from the line centre.

The Fraunhofer spectrum has been extended to include lines in the far ultraviolet from rocket observations above the Earth's atmosphere. Within the far ultraviolet region, in the interval 3,000–2,097 angstroms, 7,146 lines are observed. Below 2,100 angstroms, the intensity of the spectrum drops and by 1,500 angstroms the radiation comes from the chromosphere and the absorption spectrum has turned into an emission spectrum. This emission spectrum contains the strong resonance lines of the elements first identified from weaker subordinate lines in the visible spectrum. Also, higher stages of ionization for a given element are observed in the far ultraviolet emission spectrum.

The Sun's infrared spectrum is dissected by numerous terrestrial water vapour absorption bands. Thus, at ground level the solar spectrum must be observed in the "windows" between the bands. To observe the entire infrared spectrum of the Sun, it is necessary to use a vehicle such as a high-flying aircraft, a stratospheric balloon, or a space vehicle that can carry the infrared spectrometer above all, or most of, the Earth's absorbing atmosphere. In the wavelength interval 11,984–25,578 angstroms, 1,786 solar lines and 6,911 telluric lines—*i.e.,* lines caused by substances in Earth's atmosphere—have been listed. Silicon, iron, carbon, carbon monoxide, and titanium contribute most of the solar lines, while water vapour, carbon dioxide, methane, and isotopic bands of these molecules make up most of the telluric lines.

The chemical composition of the Sun. The proportions (abundances) of the elements in the Sun can be determined directly only for the surface layers, the so-called solar atmosphere. In the interior, the abundances of the elements may be different because the elements are transformed there at different rates by nuclear reactions. The chemical composition of the solar atmosphere is thought to be representative of the composition of the Sun at the time of its formation, before such alterations occurred. This initial composition is relevant to the study of the evolution of the Sun and the stars. The chemical composition of the solar atmosphere can be determined in various ways, which depend on the types of observation available.

Solar cosmic rays are emitted from active regions of the Sun. Abundances of the following light elements have been derived from analysis of solar cosmic rays: helium, beryllium jointly with boron, carbon, nitrogen, oxygen, fluorine, and neon. Since the heavier elements are difficult to separate by nuclear counting methods, their abundances are generally given for groups, such as phosphorus to scandium and titanium to nickel.

Coronal abundances

Abundances derived from observations of the solar emission lines that originate in the higher chromosphere and the corona are called coronal abundances. The coronal-emission spectrum may be analyzed in two different ways, depending on whether the observations were secured on the disk or above the limb of the Sun. The far-ultraviolet-emission lines observed on the disk of the Sun are produced by atoms in many different stages of ionization. Analyses have been carried out for the more abundant atoms, such as helium, carbon, nitrogen, oxygen, neon, sodium, magnesium, aluminum, silicon, phosphorus, sulfur, calcium, and iron. The emission lines in the interval 3,000–10,000 angstroms seen above the solar limb are a result of "forbidden" electron transitions within atoms; *i.e.,* transition almost impossible to obtain on Earth. Since the forbidden emission lines originate in the corona, and are thus extremely weak compared to the radiation from the body of the Sun, they can only be observed at the time of a total solar eclipse or by means of a coronagraph. The known forbidden emission lines are due to argon and calcium, and to atoms of the iron group, such as chromium, manganese, iron, cobalt, and nickel, all of them being highly ionized.

The most commonly used method of determining the abundance of elements in the solar atmosphere makes use of the solar absorption (Fraunhofer) spectrum, which extends from the near ultraviolet, through the visible, into the infrared wavelength regions. The majority of Fraunhofer lines are formed in the lowest layers of the solar atmosphere, that is, the photosphere and low chromosphere. The abundances derived from these lines are called photospheric abundances.

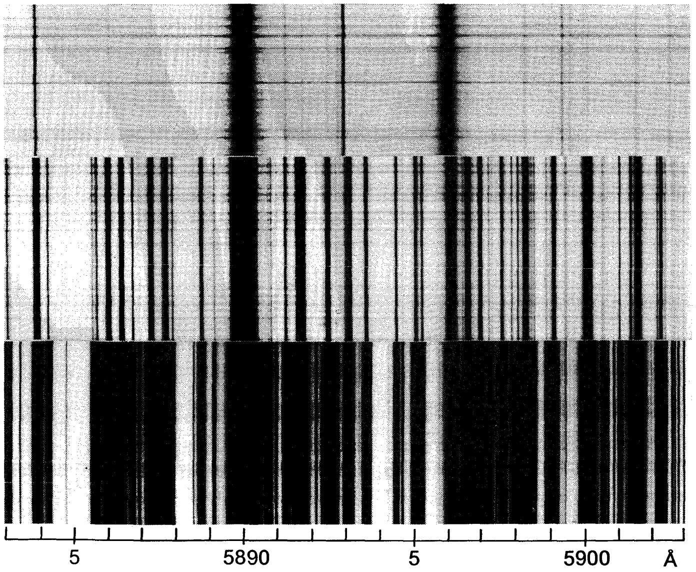

Figure 4: Sodium D lines observed at high Sun (top spectrum) and, through a greater amount of air, at low Sun (middle spectrum). The bottom spectrum shows water vapour bands for comparison. The strengthening of terrestrial water vapour lines at low Sun is most apparent.

Photospheric abundances

The determination of photospheric abundances is based on a measurement of the intensity of the lines. With modern instruments a solar spectrum line can be recorded at very high resolution (Figure 4) and, consequently, the intensity distribution in the line (the line profile) can be obtained with very good precision. The line profile and the measurement of the total intensity absorbed by each line depend not only on the abundance and physical characteristics of the particular atom (or molecule) producing the line but also on the physical conditions (temperature, density) that prevail in the layers of line formation. Thus, in an analysis of the solar spectrum, both the physical state of the solar atmosphere and its chemical composition are determined at once.

In Table 3 the results of abundance determinations for the photospheric and the coronal abundances, both as determined in 1968, are shown. For the elements lithium, beryllium, boron, iron, lead, bismuth, thorium and uranium, more recent and more accurate photospheric abundance results are given here. The differences between photospheric and coronal abundances of certain elements are essentially due to the uncertainties in the abundance determinations, both from the Fraunhofer spectrum and the emission spectrum.

From Table 3 it can be seen that only a minute portion of the solar gas is made up of elements heavier than helium, that about 15 percent is helium, and that the bulk of the solar gas is constituted of hydrogen.

Table 3: Solar Abundances
(log Σ relative to log Σ = 12 for hydrogen)

CHROMOSPHERE

Temperature range

The relatively transparent chromospheric layers form a complex transition zone about 5,000 kilometres thick between the low-temperature photosphere and the high-temperature corona. The chromosphere temperature increases outward from about 4,500 to 1,000,000 K, whereas the density decreases rather rapidly from about 10^{12} particles per cubic centimetre at the base to about 10^{9} particles per cubic centimetre at the top. The chromosphere is a region of great activity, visible at the time of a solar eclipse as a bright-coloured arc from which the "flash spectrum" originates. The low chromosphere is a relatively homogeneous layer of gas, about 1,500 kilometres thick, from which emerges, geyser-like, a multitude of upward-moving jets called spicules. At about 8,000 kilometres the spicules stand apart as separate entities and it is thought that the hot coronal gas reaches down between them. The chromospheric gas is quite transparent to continuous radiation but opaque to light in the cores of strong Fraunhofer lines. As a result, if the Sun is viewed in the monochromatic light of a Fraunhofer line, its substance is visible. By selecting lines of different strengths the astronomer can choose the depth of observation; thus, the chromospheric layers can be figuratively peeled like an onion. Through equipment capable of isolating a spectrum line a fraction of an angstrom in width, the Sun presents a picture of fine and coarse strcutures (Figure 5). Much of the fine structure visible in the cores of metal lines is due to Doppler displacements from ascending and descending volumes of gas. The periodic character of this motion has been discussed in the section on granulation above. Photographs that are taken in the light of one particular wavelength, called the hydrogen-alpha line, show a very coarse mottling, which near the sunspots becomes more or less organized into filamentary whorls.

Flash spectrum. During a total solar eclipse there is a moment when the photosphere is just hidden by the Moon, leaving exposed the chromospheric layers, which appear as a thin, orange-red crescent along the edge of the Moon. The light from this crescent is found to have

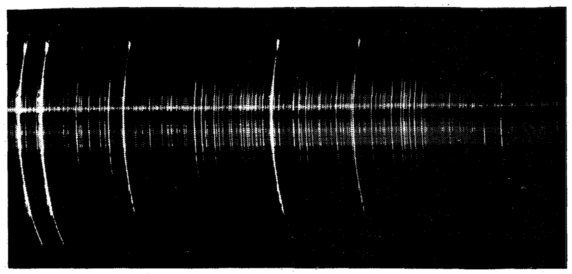

Figure 6: *Flash spectrum of the Sun in ultraviolet light.* The two bright spectral lines at left, showing prominence structure, are the H and K lines of ionized calcium. The bright line in the centre is a line of ionized titanium at 3,685Å. Frequency increases from left to right, wavelength from right to left. Obtained at the solar eclipse of February 1962 in New Guinea.

a bright-line spectrum, which, for a few seconds, "flashes" in and out of view as the Moon moves across the Sun's atmosphere, hence the name "flash spectrum" (Figure 6). The brightest lines and those which extend to the greatest heights are lines of hydrogen, helium, and calcium; when examined in detail the spectrum is nearly, but not quite, identical with the Fraunhofer spectrum, the differences reflecting the different physical state of the photospheric and chromospheric layers. Lower pressures and higher temperatures favour greater ionization and excitation. Characteristic flash spectra show an enhancement of high-excitation lines and the appearance of a great number of lines from singly ionized iron, titanium, nickel, chromium, and the rare earths.

Characteristics

Spicules. A 19th-century Italian astronomer, Angelo Secchi, described the chromospheric layers viewed at the limb as like a burning prairie. He had seen through his spectroscope a forest of superimposed jets, "the spicules," each lasting only a few minutes. Spicules appear as tiny, bright surges, less than 500 kilometres in diameter, moving upward with velocities of 20–30 kilometres per second to heights of 8,000 kilometres above the photospheric layers. They are often grouped in rosettes or brushlike shapes. They number about 100,000 and have an average lifetime of five to 15 minutes. On the basis of spectroscopic and radio studies, a spicule column is believed to have temperatures of 10,000 K in the core and 50,000 K on the surface. The denser core material emits lines of calcium and hydrogen and radio waves of millimetre and centimetre wavelengths. The hot sheath is the source of the far-ultraviolet emission of highly ionized atoms and of the lines of neutral and singly ionized helium.

Supergranulation. Spectroheliograms made, for example, with calcium light show a coarse pattern in addition to smaller mottles, which are due to a network of cells about 30,000 kilometres in diameter called supergranules. In these cells an expansion of material takes place from centre to edge with a speed of about 1/2 kilometre per second. These supergranules, which number about 5,000 at any time, have been identified as deep convection cells with a lifetime comparable to a day. It is observed that the flow of material from centre to edge tends to collect the majority of spicules on the cell boundaries and to sweep up the magnetic field domains so that the cellular pattern is visible on magnetic maps as well as on spectroheliograms.

CORONA

The corona is a luminous, high-temperature, rarefied gas envelope of the Sun. Close to the Sun it is about 1/1,000,000 as bright as the solar disk. Its brightness decreases rapidly with distance, so that at two solar radii the brightness is less than one percent of that of its innermost parts; hence, the feeble light is visible only at the time of a total eclipse or through a coronograph. The corona has a kinetic temperature of about 2,000,000 K out to several solar radii. Because of its high temperature it evaporates continuously, producing an outward flow of electrically charged particles called the solar wind, which extends beyond the vicinity of the Earth. The highly ionized coronal gas has a density of the order of 5×10^8 atoms per cubic centimetre at its base; the density decreases with height, diminishing by a factor of 2.7 approximately every 50,000 kilometres.

Form and structure. The corona owes its beauty to its form, which is made up of streamers, filaments and rays of pearly white light. Polar plumes, fanning out like iron filings about the poles of a magnet, suggest north and south magnetic poles for the Sun. At sunspot maximum the corona is globular in form with streamers in all directions, while the minimum phase is characterized by polar plumes and long equatorial streamers extending outward many solar radii.

The *F*-, *K*-, and *L*-coronas

Corona light has three components: the so-called *L*-, *K*-, and *F*-coronas. The *L*-corona, which contributes only about 1 percent of the coronal light, refers to the line spectrum emitted by the highly ionized atoms of the coronal gas, which in such a state is called a plasma. The light of the *K*-corona is caused by scattering of photospheric light by fast-moving free electrons near the Sun. The *K*-component is strongest in the inner corona where the electron density is highest. Since the electrons move at very great speeds (of the order of 6,000 kilometres per second), the photospheric Fraunhofer lines are here completely washed out by the scattering process and, consequently, the *K*-component reveals a continuous spectrum only. The *F*-component is caused by diffracted photospheric light from interplanetary dust particles. Its spectrum is that of the photosphere; *i.e.,* a continuous spectrum intersected by the Fraunhofer lines. The *F*-component is an extension of the zodiacal light into the region close to the Sun. The *L*-component and the *K*-component represent the true corona.

The corona may also be studied on radio heliograms, and on X-ray pictures made from above the Earth's atmosphere. The solar radio emission at wavelengths greater than one metre originates in the corona, and at the other end of the electromagnetic spectrum, any wavelength shorter than 200 angstroms can be emitted only by the corona. X-ray pictures show the regions of strongest coronal condensation. Comparison of observations over different parts of the electromagnetic spectrum show that the corona is very inhomogeneous and that its form, structure, and intensity change considerably with the level of activity on the surface of the Sun.

The quiet Sun emits radio waves. At metre wavelengths the emission comes from great heights where the electron density is less than 3×10^7 electrons per cubic centimetre—half a solar radius from the photosphere. At 10 metres, the corresponding height is 10 solar radii. Thus, the corona can be examined by the radio astronomer, layer by layer, in different radio wavelengths, just as the optical astronomer examines the chromosphere, layer by layer, with the spectroheliograph.

Physical properties. The most remarkable property of the corona is its high kinetic temperature, 1,500,000 to 2,500,000 K. This follows from many types of observation: (1) The coronal spectrum was shown in 1941 to be emitted by atoms of iron, nickel, calcium, and argon that had lost 10 to 14 electrons. Such a degree of ionization can come about only by collisional ionization by energetic electrons driven by high temperatures in a low-density gas. (2) The coronal emission lines are much broader than the Fraunhofer lines and if this is interpreted as Doppler broadening by random motion of the emitting atoms, a temperature of about 2,000,000 K is indicated. (3) The brightness of the Sun in radio wavelengths longer than 100 centimetres is about 1,000,000 K. (4) Finally, the density gradient of the electron gas has been shown to follow an exponential decrease with height and results in a temperature of 1,500,000 K.

It is generally believed that the energy source supplying the heating of the corona lies in the mass motions of granules and spicules in the photosphere and chromosphere. The interaction can take place by direct collision between the atoms of the spicule and those of the corona or by the transfer by shock waves (hydromagnetic, acoustic) of energy from below to the chromosphere and corona.

The solar wind. It was predicted in 1958 that the high temperature of the corona would cause some of it to boil off the Sun, and that the coronal particles would appear in the neighbourhood of the Earth as a solar wind moving with speeds of 300–1,000 kilometres per second. Though it had been suggested as early as 1951 that the behavior of certain comet tails could be explained by the interaction of a solar plasma from the Sun with the comet, not until satellites explored the space around the Earth was direct proof forthcoming. A space probe from the United States to Venus in 1962 established the wind's existence and showed that there is a steady stream of protons and electrons in the vicinity of the Earth with a density of about one to 10 particles per cubic centimetre and carrying with them an associated magnetic field ranging from two to 40 microgauss. Thus interplanetary space is filled with a fully ionized hot plasma of coronal origin. At solar minimum the average flow into space amounts to 10^{33} particles per second; this mass loss is thought to be supplied from below by the dissipation of spicules.

Particle density

A changing pattern of active regions covers the surface of the Sun and proceeding from each is a positive or negative magnetic field, which is carried by the plasma. Because of the Sun's rotation and the steady outflow of material, the magnetic field lines trace curves in space—Archimedean spirals in the equatorial plane.

The active Sun

The active Sun is characterized by the growth and decay of magnetic fields together with all the associated phenomena observed at many different levels of the solar atmosphere: sunspots with associated very bright areas called faculae, plages (other bright areas not necessarily associated with sunspots), flares, surges, prominences, coronal condensations, and the emission of radio, X-ray, and cosmic-ray bursts (see Figure 1 and below).

CENTRES OF ACTIVITY

A centre of activity is an area formed by the arrival from below of a localized strong magnetic field at the Sun's surface. Its description includes all of the transient interrelated phenomena listed above. A few centres of activity may live 200 days or more (eight to 10 solar rotations); most are short-lived, lasting one to two weeks.

Life history of a typical centre of activity

The life history of a typical centre of activity is given below. In the first few days a bipolar magnetic region (one showing both north and south magnetic polarity) develops, without spots, followed later by bright areas known as faculae and coronal extensions projecting from them. The coronagraph shows stable ray and arch structures about 150,000 kilometres long above the region. After two to three days the most important (spot) phase starts with the formation of a small spot and a rapid extension of the fine lineal elements—small prominences—in the neighbourhood of the spot. A second spot forms shortly afterward, followed by the formation of numerous small spots between the larger bipolar pair. A few flares and flare surges take place. After about ten days the group of spots reaches its maximum size. Each spot appears to be embedded in a large, complex penumbral region of converging filaments. Flare activity reaches its maximum along with the associated phenomena of solar radio bursts, enhanced X-ray emission, and, rarely, cosmic rays from superflares. By 27 days—one solar rotation—the activity has decayed and all spots except the preceding spot have disappeared. Flare activity is greatly reduced, but the bright facular areas (extremely bright areas associated with sunspots) continue to increase in size. Next, a stable prominence filament forms on the poleward side of the region, which, after the lapse of 50 days, cuts the facular region in half, separating regions with opposite magnetic polarity. The prominence filament now extends for 100,000 kilometres and is oriented more or less east and west, drawn out by the Sun's differential rotation. At about the 80th day, the facular area breaks up, but the filament continues to lengthen. After 100 days the faculae have disappeared completely and the prominence filament reaches its maximum length. In the succeeding days it shortens and drifts poleward where it still may have an identity after 150–250 days.

SUNSPOTS

Physical nature. In appearance a sunspot consists of two parts: a dark core, the umbra, surrounded by a filamentary border called the penumbra. Single spots comprise about 40 percent of the total. Normally, they are in complex groups exhibiting great variety of form and shape, often covered with brilliant "bridges," giving the impression of great turmoil. The smallest spots of a group are mere pores without penumbra, a few hundreds of kilometres in diameter, whereas the largest spots exceed by several times the diameter of the Earth. Large spot groups may extend over one-sixth of the diameter of the Sun and are easily visible to the naked eye at sunset when the Sun's intensity is much reduced. At the Sun's limb (visible edge) a large spot may appear as a slight depression in the Sun's surface.

Sunspots are dark only in contrast to the surrounding photosphere, for, in fact, they are brighter and hotter than molten tungsten. From their observed brightness a spot temperature of 3,800 K is obtained, as compared to 5,700 K for the photosphere. At spot temperatures, a number of chemical compounds are stable. The spectrum lines of many radicals and molecules, cyanogen, carbon monoxide and hydrides of nitrogen, carbon, oxygen, and magnesium, also known in the disk spectrum, strengthen greatly in the spot, indicating increased abundance; also lines of calcium, silicon and fluorine hydrides, and titanium and zirconium oxides show in the spectrum of a sunspot.

Magnetic property of sunspots

The predominant property of sunspots is their intense magnetic field. In general, the larger the spot, the stronger the magnetic field. A small spot typically has a field of about 500 gauss (a gauss is a unit of magnetic field strength), a large spot, 4,000 gauss. By comparison, Earth's natural magnetic field at the surface is somewhat less than one gauss, and the overall solar magnetic field is now believed to be about the same. In a simple spot the field is nearly axisymmetric; it has its maximum value at the centre of the umbra and decreases to a very small value at the outer edge of the penumbra. On the average, the lines of magnetic force stand vertical to the Sun's surface at the centre of the umbra but diverge outward so that at the edge of the penumbra the direction of the field has an inclination of about 70° to the vertical. An explanation of the relative coolness of sunspots must involve their associated magnetic fields. After the magnetic field is formed the region cools, presumably because convection, bringing energy from below—as exhibited by the surrounding granulation—is stopped. A balance is achieved when the gas pressure, the magnetic pressure, and the mass flow of material in and out of the spot are in equilibrium.

The sunspot cycle. That spots are not always equally numerous on the surface of the Sun is apparent to anyone who examines the Sun telescopically on every clear day. But it was not until 1851 that astronomers were able to find a regular periodicity of about 10 years. At sunspot minimum the Sun may remain spotless for weeks; at maximum several large groups containing dozens of spots are generally visible on its surface. Complete records of the Wolf sunspot numbers (named after the Swiss solar astronomer Rudolf Wolf, whose work on the behaviour of sunspots was fundamental) are known for the past 120 years. Monthly means have been established from 1749 and the epochs of maximum and minimum are known from the year 1610.

Sunspot numbers

Because of the wide fluctuations of the daily number of spots, the level of solar activity is generally expressed as a running mean of a month or a year. The average interval between maximum is 11.2 years but is quite variable, ranging from eight to 16 years. The ascent to maximum, which averages 5.2 years, is steeper than the decline. In addition to the 11-year cycle, a low-amplitude 80-year cycle is recognized, though observations have not yet extended over an interval long enough to define the long wave completely. Sunspot numbers show an 11-year period, but the true length of the cycle is 22 years, when account is taken of the alternation of the sign of spot magnetic fields. The leading spot of a bipolar group in the northern hemisphere has a magnetic polarity opposite that of the leader in the southern hemisphere; and the polarity of the leaders reverse at the beginning of each 11-

year cycle. Thus, the magnetic period of the Sun is twice the 11-year cycle.

The number of spots in each cycle is quite variable. Attempts have been made to fit the observed numbers by superposition of cycles, but, in general, these have failed to predict succeeding cycles. Others have tried to relate the sunspot cycle to planetary influence, particularly that of Jupiter, which revolves around the Sun in a period of 11.8 years. Apparently the true cause of sunspots is deeply seated in the Sun itself.

Each new cycle begins with the appearance of a few spots at about ±30° north and south latitude. Four years later in the cycle, at sunspot maximum, the zone of eruption is at ±15° latitude, while the last few spots of the cycle appear at ±8°. When the latitude of spots, without regard to size, is plotted as a function of time, a so-called butterfly diagram results. This shows that new spots of a new cycle can appear at high latitudes before the disappearance of low-latitude, old-cycle spots, and suggests each new cycle is in some ways independent of the old.

Magnetic field theories

Many of the known features of the sunspot cycle have been explained by a theory of magnetic-field amplification by solar differential rotation. Very much simplified, the theory postulates that the Sun's differential rotation slowly winds up the lines of magnetic force like string on a ball. These lines of force, called flux ropes, which are formed beneath the surface, become buoyant and tend to rise to the surface; thus, bipolar magnetic regions (sunspots) are formed where the flux rope loops through the surface. One worker has separated the field into three components and adopted an interior rotation faster than the exterior with a strong concentration of radial shear toward the equator. With suitable parameters, he was able to reproduce with remarkable exactitude all the phenomena connected with the solar cycle.

OTHER SOLAR PHENOMENA

Distribution

Faculae, or plages. Bright granulated structures, visible in white light, toward the Sun's limb, are called faculae. That they appear only near the limb and not at the centre of the disk means that the higher facular parts emit more radiation than the surrounding high photospheric layer and the lower parts emit less than the local photosphere. The temperature excess amounts to 250° C at the most.

Spectroheliograms of the active Sun reveal large, bright areas closely associated with the photospheric faculae. These chromospheric faculae, or plages, are the extension of the photospheric faculae into the chromosphere. Ultraviolet plages and X-ray plages are observed coming from the high chromosphere and corona. Radio plages are also observed in the centimetre and decimetre radio wavelengths.

Prominences, or filaments. Prominences are among the most beautiful of solar phenomena (see Figure 2). A typical fully developed quiescent prominence is a thin fish-tailed, or ribbon-like, gaseous structure standing above the Sun's surface; it may attain a size of 200,000 kilometres long, 40,000 kilometres high, and 6,000 kilometres thick. As seen on the disk, in hydrogen-alpha spectroheliograms, prominences appear as long, dark structures called filaments. At the Sun's limb projected against the dark sky they are seen as bright clouds composed of a myriad of fine threads. Generally, prominences are connected by appendages to the Sun's surface or rest upon it, but a few stand free. Like clouds, prominences take many fanciful forms. From their appearance and mode of formation they have been classified into the following types: active prominences, eruptive, sunspot, tornado, quiescent, and coronal prominences.

Time-lapse motion pictures reveal the intricate motions of prominences. Thus viewed, they show at least two active groups of the first type: prominences that appear as great funnels with downward-curving streamers feeding knots of material from the prominence into a nearby active area; and the spectacular arched prominences in which material condenses from the corona and moves down along each arm, often for several days, into a spot region. Quiescent hedgerow-type prominences are carried in, and are supported against the pull of gravity by, a trough of magnetic field lines; they separate regions of opposite magnetic polarity on the Sun's surface and may last for months. The large-scale structure of such quiescent prominences is fairly constant, but the fine structure shows much motion, generally downward. On occasion, a nearby solar flare may trigger great activity in the prominence such that it either flows downward into an active region and disappears, or that a portion of it may erupt from the surface of the Sun with velocities of 200–500 kilometres per second. Strangely, the activity appears not to destroy the magnetic-field configuration, for there is a tendency for the prominence to reappear a few days later, phoenix-like, in its former place and form.

Spectroscopy reveals the physical conditions in prominences. There are both hot and cold prominences. Cold prominences with kinetic temperatures of 8,000 to 10,000 K show sharp spectral lines: the Balmer lines of hydrogen, H and K of calcium, and a number of lines of ionized and neutral metals. Active prominences, loops and surges, with temperatures up to 100,000 K show lines broadened by thermal motions of the atoms; the metal lines are weak and ionized helium lines appear.

Flares. In plage areas, sudden and distinct brightenings occur from time to time. These brightenings, called flares, last from a few minutes for small ones, up to several hours for very large ones. Solar flares are among the most violent and dramatic events that occur on the Sun, yet, with few exceptions, they cannot be seen in white light and may well go unnoticed. They are easily seen, however, in the red light of hydrogen and they produce a number of effects observable at the Earth that make them of considerable importance.

Flares are classified by area and brightness on a scale of increasing importance, from −1 to +3, the latter group comprising only 1 percent of the total. As seen in hydrogen light, a typical large flare starts as a brightening of a pre-existing filamentary structure in the neighbourhood of a sunspot. The rise to maximum brightness is sudden, taking place in two to five minutes, with a rapid spreading of the flare area, the brightest parts of which are often elongated. The flare lasts about one hour longer during which a bifurcation and separation of the luminous ribbon and subsequent fading of the flare take place. Frequently, after the onset of a flare, a surge of gas is ejected with a velocity of perhaps 100 kilometres per second. A great flare can create an expanding magnetohydrodynamic wave, a complex effect involving both magnetic and hydrodynamic forces, propagating through the corona. Its passage is seen by the successive activation of disk filaments as it spreads over the surface with velocities of 1,000 kilometres per second and for distances of over 500,000 kilometres.

Geophysical phenomena

Many geophysical phenomena are caused by radiation and particle emission from flares. For example, simultaneous with the observed flare there is often a fade-out of shortwave-radio communication caused by a flash X-ray penetrating to the ionosphere of the Earth and greatly increasing its ionization and absorption. Plasma clouds from the flare region moving out at 2,000 kilometres per second produce auroras and geomagnetic storms a day or so later. Cosmic-ray particles from very large flares have been observed to penetrate to ground level. In the polar regions, measurements of cosmic-radio noise show a marked decrease, caused by bombardment of the upper atmosphere by high-energy protons from the flare.

Observations of the X-ray spectrum during a flare detect a great increase in the emission at the shorter X-ray wavelengths down to below 10 angstroms. This reveals the existence of localized regions with temperatures of the order of 25,000,000 K and more. The formation of such regions is explained as being due to thermal electrons heated by accelerated electrons, which, in turn, are responsible for the microwave emission connected with flares. Usually the enhanced X-ray emission caused by the flare phenomenon appears after the emission at radio frequencies, but the X-ray emission lasts much longer and decays more slowly than the microwave emissions.

In addition to the above-mentioned flare-associated X-ray emission (so-called quasi-thermal due to the heating of localized regions), bursts of very short wavelength (hard)

X-ray and radio phenomena

nonthermal X-rays may occur which are observed in the range between about one and 10 angstroms. They may last from a couple of seconds up to two minutes. Since the energies of these bursts are of the order of 10^4–10^6 electron volts, some of their electrons must be moving with velocities of between 60,000 to about 300,000 kilometres per second. Consequently, the bursts are felt to be due to bremsstrahlung radiation (that emitted by decelerating electrons) or to synchrotron radiation, produced by electrons accelerating in a curved path. The hard X-ray bursts are correlated with various types of radio bursts which also are produced by the acceleration of particles to high speeds. There is, however, not always a one-to-one correspondence between X-ray and radio emission in a flare or any other flare phenomenon.

The interaction of high-energy electrons, protons, and nuclei in the solar atmosphere may also produce gamma rays in a flare region. A few major flares have been observed to eject gamma-ray bursts with energies up to one million electron volts (*i.e.,* the energy that would be gained by an electron in moving through a potential energy difference of 1,000,000 volts). Like X-ray bursts, gamma-ray bursts are short-lived phenomena; their duration, being of the order of a few seconds to a minute, depends on the time the high-energy particles are trapped in the solar plasma.

The radio phenomena associated with a large flare are numerous and complex; different events appear at different frequencies and different times. During the flash phase of a large flare, a stream of high-energy electrons moving with one-third of the speed of light are ejected from the flare into the corona to generate waves moving at speeds faster than the speed of light in the plasma called Cherenkov plasma waves and fast-drift radio bursts, that is, bursts of radiation at rapidly changing radio wavelengths. These are observed in the frequency range 600 to 20 megacycles per second. In five to 10 minutes other fast electrons are trapped in the magnetic field and their oscillation, possibly between magnetic-mirror points, produces a broadband burst over areas of about one-quarter of the Sun's disk. Electrons accelerated downward from the ejection area of the flare plunge into the chromosphere creating X-rays and microwave bursts. In addition to the high-speed electrons, the flare explosively ejects a dense plasma cloud at a velocity of 1,000 kilometres per second. This cloud may interact with the corona at supersonic velocities to form shock waves and radio bursts. The magnetic field embedded in this plasma moving out from the Sun holds electrons moving at a high fraction of the speed of light, which emit synchrotron radiation that can be followed with radio telescopes as a moving burst. From deep in the flare site microwave emissions continue, generated by synchrotron and bremsstrahlung processes (see above). Continuous radio emission continues for hours at metre wavelengths.

Energy released by a flare

The physical causes of flares are still unknown, though it is believed that the energy released by a flare (about 10^{32} ergs in a large flare) must come from the intense magnetic or electric fields associated with the solar active regions. It has been estimated that the energy released by a single flare would be enough to provide electric power for the whole world for 1,000,000 to 100,000,000 years at the current rate of use, depending upon the size of the flare.

Coronal condensations. The corona is far from uniform. Coronal condensations occur over centres of activity. They dominate the scene in X-ray photographs of the Sun and can be observed with radio telescopes. The condensations are shaped in the forms of rays, brushes, loops, or arches, and are often associated with hot prominences. They vary rapidly in brightness (a factor of 2 in two hours is not uncommon) but may remain stable in form for quite some time; in fact, over a large, highly developed spot group or centre of activity, a condensation may remain visible for several months. At the time of a flare the structure of a condensation may suddenly undergo change and show great activity; arch streamers, for example, may expand outward with velocities of 500 kilometres per second. In a coronal condensation, the electron temperature approaches 5,000,000 K and the particle density is five to 10 times greater than that of the surrounding quiet corona. At radio frequencies coronal condensations manifest themselves by enhancement of the radio emission in centimetre and decimetre wavelengths. By far, the greatest enhancement, about 80 times greater than in the quiet corona, can be observed in the X-ray region, in which the emission is proportional to the square of the electron density.

The Sun's general magnetic field. The existence of a weak polar magnetic field for the Sun has long been assumed. The measurement of small magnetic fields by the Zeeman effect is exceedingly difficult; hence, it need not be surprising that, although early measurements of polar photospheric fields gave values of 20–50 gauss, modern measurements have indicated much smaller values, of the order of one gauss, roughly the same as the natural magnetic field at the surface of the Earth. How the observed photospheric field is related to the internal field is not known. The field observed in the photosphere in the polar regions is not the dipole field but results from the slow migration and expansion of magnetic remanents from centres of activity in the sunspot zones to the polar regions. Furthermore, the irregular or random eruption of magnetic flux in the spot zones is eventually reflected in the polar fields and explains why the Sun has, on occasion, had a magnetic south pole simultaneously at both north and south poles and why there is often a lack of perfect symmetry between the two hemispheres. Figure 7 shows a continuous plot of the photospheric magnetic field.

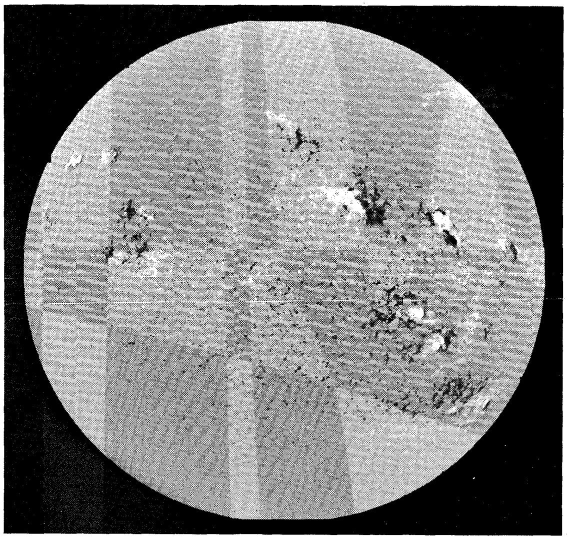

Figure 7: *Photospheric magnetic fields on the Sun.*
The dark and light areas correspond to positive and negative (north and south) polarities. The bipolar nature of most regions is indicated. The figure shows a computer-generated photograph or map built up of direct photoelectric scans covering the entire visible surface.

The solar interior: energy generation and evolution of the Sun

The internal structure of the Sun is determined by its chemical composition, by its mass, and by its previous history. Today, with the development of large, fast computers, theoretical solutions to equations governing the structure of the Sun can be found in a few minutes and the evolutionary track showing the changes in the structure and compositions followed for billions of years.

The development of a mathematical model of the Sun would require that the chemical composition be known throughout its mass, and this is not known. Hence, a sequence of models must be computed and compared to the true Sun. It has been suggested that the flux of neutrinos from the hydrogen-burning fusion reactions in the Sun's interior (see below) may allow direct observations of conditions in the Sun's core, and investigators have set up detectors to capture the neutrinos. The results so far indicate that the central temperature of the Sun is less than 20,000,000 K, but results have not yet fixed the chemical composition.

Energy output

The Sun radiates 3.86×10^{33} ergs of energy every second (from energy = mass times velocity of light squared, $e = mc^2$; this corresponds to a mass loss of 4,700,000 tons per second or 1×10^{-11} solar mass per year). Nuclear reactions are the only possible means that can produce such a great amount of energy. In the hot, dense core of the Sun, within about one-tenth of a solar radius of the centre, nuclear fusions liberate the energy that is emitted millions of years later at the surface of the Sun. The most important fusion process in the Sun is the so-called proton–proton reaction or hydrogen-burning. The fusion of two hydrogen atoms, the nuclei of which are called protons, produces a deuterium atom and releases a positron and a neutrino.

Nuclear reactions

The neutrino escapes with the velocity of light and the positron quickly collides with an electron, whereby they annihilate each other, producing a very high-energy photon of radiation, called a gamma ray. The collision of the deuterium atom with another proton produces an atom of the light helium isotope of atomic mass 3, called helium-3, and the emission of another gamma ray. Eventually, two helium-3 atoms collide and in doing so, produce an ordinary stable helium atom of atomic mass 4 and release two protons and a gamma ray. In total, two electrons and six protons are used up in the production of one stable helium atom; two new protons are rebuilt and two neutrinos and five gamma rays are released in the process, which provide the energy radiated away at the solar surface. About 5 percent of the energy is carried away by the neutrinos (see ATOMS).

The Sun is presently in a state of equilibrium with a balance between its total energy production and its luminosity. The evolution of the Sun has been considered by many theoreticians. The U.S. astrophysicist Icko Iben sees a million years as having been taken for the mass of gas that is now the Sun to evolve from a wholly convective state to a body with a radiative core. The radiative core then grows to encompass nearly all the Sun's mass. After 10^7 years the brightness reaches a minimum and then increases. At 2.3×10^7 years nuclear burning begins. At 2.6×10^7 years a convective core appears and the Sun begins to take on a form much like its present one at 3.7×10^7 years. As the conversion of carbon to nitrogen proceeds to burn carbon rapidly, the convective core is replaced by the condition of radiative equilibrium, in which the amount of energy received is everywhere exactly passed on throughout the mass. In 4.5×10^9 years the brightness increased to the present solar value. At its present stage the Sun consists of about 60 percent hydrogen by weight. After about 6×10^9 years a slight change in mass and luminosity may be recognizable. During the past 4.5×10^9 years, that is, since the formation of the Earth's crust, the Sun has virtually remained unchanged.

Future evolution

The future evolution of the Sun is expected to be similar to that of other normal stars. Eventually all hydrogen will be burned up and nuclear reactions involving helium and heavier atoms will take over. This will change the chemical composition of the Sun; as a result, the Sun will increase in size and luminosity and thus turn into a red giant star. Computations on evolutionary models predict that in a few times 10^9 years the Sun will reach the red giant stage. Finally, when all nuclear energy sources are used up, the Sun will reach its last evolutionary stage, that is, it will become a white dwarf, a star of small radius. Its radius will be about 100 times smaller than it is now. Its internal temperature and its luminosity will gradually decrease on a time scale of 10^9 years and, eventually, the Sun will become a black dwarf, a very dense, nonluminous object of degenerate matter. The total lifetime of the Sun is estimated to be some 10^{10} years. (A.K.P./E.A.M.)

THE MAJOR PLANETS AND THEIR SATELLITES

As previously noted, the known major planets in order of increasing distance from the Sun are Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune, and Pluto (see Figure 8). The terrestrial planets are Mercury, Venus, Earth, and Mars; the giant planets are Jupiter, Saturn, Uranus, and Neptune. Pluto, the outermost, is believed to be less than one-third the size of Earth, and its orbit crosses the orbit of Neptune. There are reasons for believing that Pluto may once have been a satellite of Neptune that escaped from its gravitational control. The terrestrial planets are of about the same size and mass as the Earth and are of high density, between about three and six times that of water. The giant planets have from 15 to 318 times the volume of Earth but have only about 20 percent the density of the terrestrial planets. Saturn is so light that an average piece of it, if available, would float in water. The high density of the terrestrial planets is attributed to their large metallic content. The giant planets are believed to consist mostly of the lightest elements, hydrogen and helium. They are thought, however, to have a small solid core of iron and silicates.

The inner or terrestrial planets

The Earth and Venus have been described as sister planets because their sizes, masses, and densities are roughly the same. Both have extensive atmospheres, but the composition of these are not the same. Venus has no moon. It is difficult to take the comparison further owing to observational difficulties caused by the extensive cloud cover on Venus. Surface relief and the existence of various landforms such as mountains, volcanoes, craters, and rift valleys have been discovered by radar. Oceans cannot exist on Venus because of the high surface temperature of about 730 K.

Mars, though smaller than Earth, has some similarities, and more extensive photographic coverage in the 1970s revealed the presence of many features on Mars that may have similar origins to those of their counterparts on Earth. Results from space probes sent to Mars and from radar studies have allowed some direct comparisons between planetary details. Many Martian features indicate ancient fluvial erosion, widespread volcanism, and extensive tectonics. Large areas resembling groups of calderas and craters have been photographed. Further, rifts and cracks in long double and single nearly straight lines and areas of intersecting sets of parallel rift systems have been found on Mars. All these can be matched on Earth. Many large height differences (up to several kilometres) have been found to exist on Mars.

Many Martian craters have counterparts on the Moon, which also shows large-scale systems of apparently tectonic lineaments (rills, raised ridges in intersecting sets of parallel systems).

The giant planets

Detailed knowledge of two of the outer planets and cross comparisons of data became possible during the 1980s. The U.S. Voyager 1 and 2 probes passed close to Jupiter in 1979 and then flew by Saturn in the early 1980s, transmitting scientific measurements and high-resolution photographs of both planets.

As pointed out earlier, a satellite is defined as a body that revolves around a planet. It is thus distinguished from a planet by its motion rather than by any physical property. All of the planets except Mercury and Venus are known to have satellites. Some satellites are only a few kilometres in diameter, as in the case of the two tiny moons of Mars and the outer satellites of Jupiter. A few satellites are about the size of Mercury and Mars, as in the case of satellites Ganymede and Callisto of Jupiter, Titan of Saturn, and Triton of Neptune, each of which is about 5,600 kilometres in diameter.

The characteristics of each of the planets and their principal satellites are described below. Considerable attention is given to the Earth's moon to accommodate the wealth of data collected by spaceflights and manned explorations of the lunar surface. (D.G.R./Ed.)

Mercury

Mercury, designated ☿ in astronomy, is the planet closest to the Sun, revolving around it at an average distance

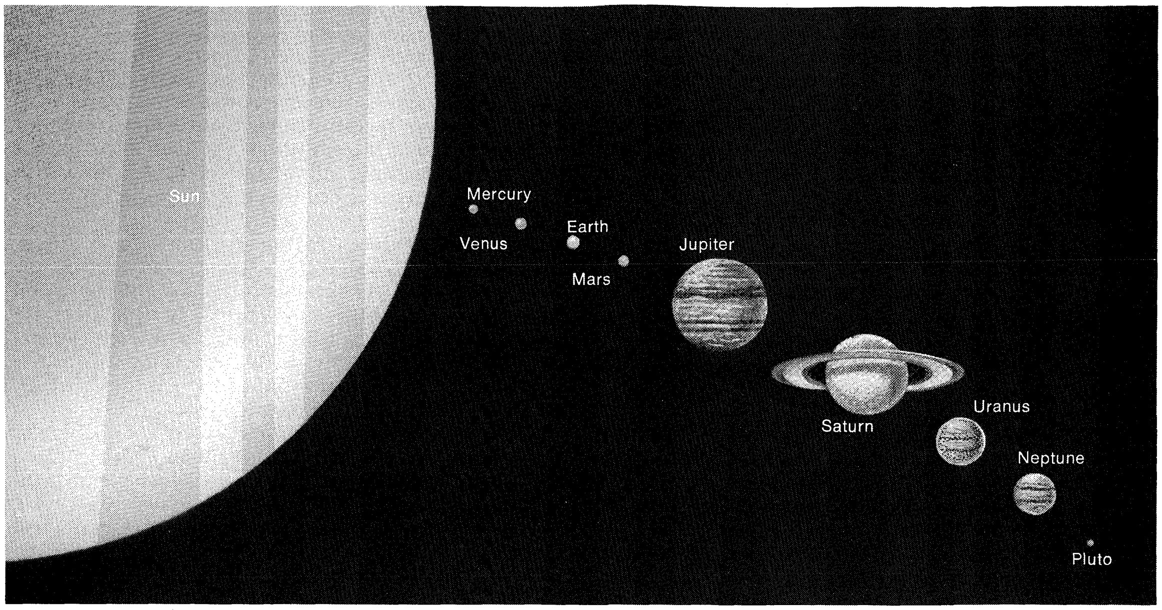

Figure 8: Relative sizes of the planets, arranged in order outward from the Sun (but not according to their respective distances from one another).

of 58,000,000 kilometres (about 2/5 the distance between the Sun and Earth). Mercury's orbit is inside the orbit of Earth, and this creates two important astronomical effects. First, Mercury is never more than 27°45′ of angle away from the Sun and is thus seen with the naked eye only as a "morning" star just before sunrise or an "evening" star just after sunset. Telescopic observations of Mercury are further complicated by mist, haze, and other materials in Earth's atmosphere that scatter and absorb light from Mercury, thereby greatly reducing its visibility. Second, Mercury exhibits phases much like the Moon: when it lies nearly between Earth and the Sun (inferior conjunction), it appears as a thin crescent; when it is at its greatest separation (or elongation) from the Sun, the apparent disk is half-illuminated; and when it is on the opposite side of the Sun from Earth (superior conjunction), its fully illuminated surface is visible. Since these changes in phase occur because of the motion of Mercury in its orbit, its apparent size also varies with the phase. It is largest at inferior conjunction (about 10″ of arc, or 1/180 the apparent size of the Moon) and smallest at superior conjunction (about 4 1/2″ of arc, or 1/380 the apparent size of the Moon).

Phases

Mercury was known to be a planet in Sumerian times, some 5,000 years ago. In classical Greece it was called Apollo when it appeared as a morning star and Hermes, for the Greek equivalent of the Roman god Mercury, when it appeared as an evening star. Hermes was the swift messenger of the gods, and the planet's name is thus a reference to its rapid motions relative to the other objects in the sky.

BASIC ASTRONOMICAL DATA

Mercury's orbit. While orbits of the planets around the Sun are nearly circular, that of Mercury is more elliptical than usual. At its closest approach (perihelion), Mercury is only 46,000,000 kilometres from the Sun, while its greatest distance (aphelion) approaches 70,000,000 kilometres. The eccentricity of this orbital ellipse is 0.206. Mercury orbits the Sun in 88 Earth days at an average speed of 48 kilometres per second, allowing it to overtake and pass Earth every 116 Earth days (synodic period).

Mercury has played an important role in the development and testing of theories of the nature of gravity because its elliptical, inclined orbit—its orbit is 7°004′ out of a plane defined by the total mass of the Sun plus the planets—is perturbed by the gravitational pull of the Sun and the other planets. This small motion (about 10′ of arc per century) has been known for nearly 200 years, and in fact all but about 40″ of arc (about 7 percent) could be explained by the theory of gravity proposed by Newton. This discrepancy was, however, too large to ignore, and explanations were proposed, usually invoking as yet undiscovered planets. In 1915 Albert Einstein showed that his general theory of relativity, which included a treatment of gravity, could explain the small discrepancy. Thus, the motion of Mercury's orbit has been considered an important observational verification of Einstein's theory. Mercury has also been used in additional tests of relativity because radar signals that are bounced off its surface when it is at superior conjunction must pass close to the Sun. The general theory of relativity predicts that such electromagnetic signals, moving in the warped space caused by the immense gravity of the Sun, will follow a slightly different path and take a slightly different time to traverse that space than they would if the Sun were not there at all. By comparing such signals as a function of the position of Mercury with respect to the Sun, a second important confirmation of the general theory of relativity has been acquired.

Models of the composition and evolution of the dust and gas cloud from which the Sun and planets are believed to have accumulated are based on presumptions of the temperature and pressure of the cloud; the composition of a planet at a given distance from the Sun is crucially dependent on these presumptions. Many cosmochemists rely on observations of the density or surface composition of the planets for clues to verify their assumptions. Mercury, being the closest planet to the Sun, is an important "end-member" in these models.

Surface temperatures and seasons. Because of its proximity to the Sun, the surface of Mercury can get extremely hot. High temperatures at "noon" may reach 675 K, while the "pre-dawn" lowest temperatures are 100 K. Thus, portions of Mercury's surface experience temperature variations approaching 575 K.

Seasons on Earth arise from variations in the amount of sunlight reaching its surface. These variations are caused by the tilt of Earth's equator with respect to its orbital plane. Mercury's equator is almost exactly in its orbital plane (its spin axis inclination is nearly zero), and thus Mercury does not have seasons as does Earth. Because of its elliptical orbit and a peculiarity of its rotational period (see below), however, certain longitudes experience cyclical variations in temperatures on a "yearly" as well as on a "diurnal" basis.

Mass, radius, and density. Mercury is about 4,878 kilometres in diameter, smaller than any other planet with the possible exception of Pluto. Mercury is only a bit larger than the Moon and is comparable in size to the largest satellites of Jupiter (Ganymede and Callisto), Sat-

Escape velocity

urn (Titan), and Neptune (Triton). Its mass, measured by the gravitational perturbation of the path of the Mariner 10 spacecraft during close flybys in 1974 and 1975, is 3.30×10^{26} grams, about $^{1}/_{18}$ of the mass of Earth. Escape velocity, that speed needed to escape from a planet's gravitational field, is about 4.25 kilometres per second (compared with 11.2 kilometres per second for Earth). The mean density of Mercury, calculated from its mass and radius, is about 5.44 grams per cubic centimetre, nearly the same as that of Earth (5.5 grams per cubic centimetre). Earth, however, being much more massive than Mercury, owes some of its high density to gravitational compression. Thus, the smaller Mercury must owe its high density to a greater abundance of a naturally denser material, such as iron. Much of Earth's high-density material resides in its core. Mercury probably has a core as well, and it probably is relatively larger than Earth's core. This abundance of high-density material is a constraint on the models of planetary formation. (See Table 4.)

Table 4: Planetary Data for Mercury

Average distance from Sun	58,000,000 km (36,000,000 mi)
Eccentricity of orbit	0.206
Inclination of orbit to invariable plane of solar system	7°004′
Sidereal period of revolution (orbital period = year)	87.9694 Earth days
Rotation period	58.6461 Earth days (= 2/3 of orbital period)
Mean synodic period	116 Earth days
Mean orbital velocity	48 km/sec (30 mi/sec)
Inclination of equator to orbit	<3° (probably 0°)
Mass	3.30×10^{26} gm (0.055 × mass of Earth)
Diameter	4,878 ± 2 km (3,032 mi) (0.38 × diameter of Earth)
Density	5.44 gm/cm^3
Gravitational acceleration	370 cm/sec^2 (0.38 × Earth's gravity)
Satellites	none

Rotation rate. The rates at which planets spin on their axes (rotation rates) have traditionally been determined by visual astronomical observations. Features on a planet are watched as they move across the apparent disk, and a period of rotation is derived from the time they take to traverse the disk. Problems arise with this technique if the features are clouds in a planet's atmosphere, or if the planet is small and its surface features are poorly distinguishable because of intrinsically low contrast, poorly defined margins, or atmospheric conditions at the observatory that cause blurring.

Mercury is so difficult to see from Earth that its rotation rate has been the subject of study for more than 200 years. Initial observations suggested to astronomers in the early 19th century a period of 24 hours, essentially identical to Earth's. This was shown to be erroneous in the late 19th century, when it was concluded that Mercury rotated once every 88 Earth days, exactly equal to its year. This implied that Mercury was in synchronous rotation (always keeping one face toward the Sun), much as the Moon is in synchronous rotation with respect to Earth. Both visual and photographic studies for almost 80 years thereafter seemed to support this view. In the early 1960s, however, observations at radio wavelengths indicated a different story. The amount of radio wavelength energy emitted by a planet is dependent on the temperature of the planet, and observations indicated that the temperature of the "dark side" of Mercury (that side presumed to always face away from the Sun) was much higher than it should have been for a planet in synchronous rotation. Later scientists were able to bounce radar signals off Mercury. These signals showed the effect of a shift in frequency characteristic of moving bodies (the Doppler effect). This effect, familiar as the cause of the change in the pitch of automobile horns as they approach and recede, showed that Mercury's rotation rate was about 59, not 88, Earth days.

Determinations using photographs relayed by the Mariner 10 spacecraft (launched in 1973) led to a much more precise measurement. Mercury rotates once every 58.6461 Earth days, exactly two-thirds of the orbital period of 87.9694 Earth days. This observation confirms theoretical studies, developed after the radio wavelength observations, that suggested that Mercury was in a 3:2 spin-orbit tidal resonance—that is, that tides raised on Mercury by the Sun had forced it into a condition that caused it to rotate three times on its axis in the same time it took to revolve around the Sun twice.

The two-thirds spin orbit

The 3:2 spin-orbit coupling combines with Mercury's eccentric orbit to create very unusual temperature effects. First, although it rotates on its axis once every 59 Earth days, one rotation does not bring the Sun back to the same part of the sky, because during that time Mercury has moved partway around the Sun. A solar day on Mercury (for example, from one sunrise to another, or one noon to another) is 176 Earth days, and equal to two Mercurian years. The eccentricity causes the apparent angular size of the Sun to vary by nearly 50 percent (from 1.1° at aphelion to 1.7° at perihelion, compared to 0.5° as viewed from Earth). Thus, sunlight at perihelion is more than twice as intense as at aphelion. The two longitudes that experience noontime illumination when Mercury is at perihelion are therefore much hotter than the two longitudes that experience noontime illumination at aphelion. The intersections of the equator with these longitudes can be called "poles." Mercury has two "hot" poles, two "warm" poles, and of course, north and south poles defined by the spin axis.

Sunrise and sunset from Mercury

These relationships would create unusual "days" to an observer. At a hot pole a small Sun would rise rapidly, increase in size and decrease in speed as it climbed toward the zenith, actually stop and reverse its course, stop again, and then proceed toward the opposite horizon, decreasing in size while increasing in speed until it set 88 Earth days after it had risen. The stars would be moving through the sky three times as fast as the Sun, and stars that rose with the Sun would set and rise again before the Sun set. An observer at a warm pole would see a large Sun slowly rise, stop, and sink below the horizon, and then rise again, shrinking in size and increasing in speed as it rose toward the zenith. It would then increase in size and slow its pace as it approached the horizon, where it would set, rise again briefly, and finally set again.

ATMOSPHERE AND MAGNETIC FIELD

Tenuous atmosphere

Mercury's low escape velocity and high surface temperatures do not permit it to retain a significant atmosphere. Its total atmospheric pressure, determined by experiments during the Mariner 10 spacecraft mission, is about 2×10^{-9} millibar, or $^{1}/_{500,000,000,000}$ that of Earth, as low as many vacuums created in terrestrial laboratories. The composition of this very tenuous atmosphere is principally hydrogen, helium, and neon, with upper limits placed on the presence of heavier, but much less abundant, gases such as argon, carbon dioxide, krypton, and xenon. Those actually detected may come from the release of primordial gases from deep within the planet, or, more likely, from material flung off the Sun by activity in its high-temperature atmosphere (the solar wind). The abundance of helium is compatible with either a solar wind source or a release of helium from rocks containing the radioactive elements uranium and thorium. Surface features on Mercury show no evidence of atmospheric interaction—no sand dunes, streaks of sand or dust, wind etching of surface forms, or similar phenomena. Because many of Mercury's surface features are very old, it has been concluded that Mercury has not had an appreciable atmosphere since it formed, probably 4,500,000,000 years ago.

Mercury has a small but important magnetic field, with a strength of about 1 percent that of Earth and a moment about 6×10^{-4} that of Earth (Figure 9). This field sets Mercury apart from the Moon, Venus, and probably Mars, which do not display such fields. Mercury's magnetic field can be modelled as a dipole with its axis more or less aligned with the spin axis, thus making the resemblance to Earth even closer. The origin of the magnetic field is unknown but of great scientific importance because it may help to understand the origin and nature of Earth's field and also the evolution of Mercury's interior. Theoretical studies suggest that Earth's magnetic field is actively

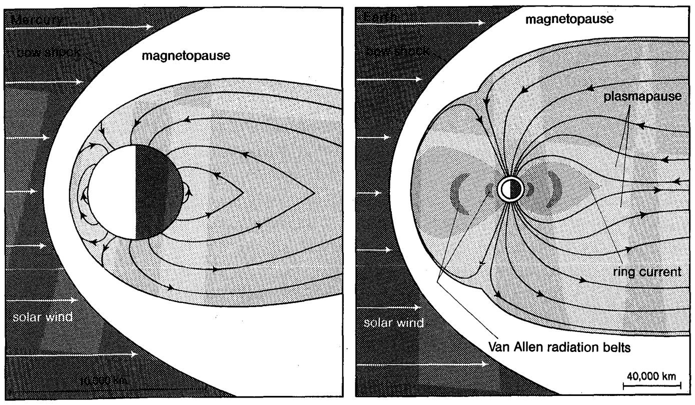

Figure 9: Comparison of the magnetic fields of Mercury and Earth. Mercury's field is very similar to Earth's, but smaller.

generated by the motion of hot, electrically conductive materials in its core (a magnetohydrodynamical dynamo). If Mercury's field is similarly created, then Mercury's interior is still hot and active, even though little evidence of this is seen on its surface. Alternatively, Mercury's magnetic field may be a remnant of an earlier epoch, when a dynamo was active and capable of magnetizing rocks that could retain the imprint of the ancient field after the dynamo waned. A third alternative is that the field is not indigenous to Mercury, but rather is induced by the immensely stronger solar magnetic field. It appears that such induction cannot create today a field as strong and steady as that observed, but in the distant past, when the Sun's field may have been even stronger, it may have been able to induce a sufficiently large field in Mercury to create a remnant field preserved in magnetized rocks.

THE SURFACE

Surface properties. The surface properties of Mercury (the composition of its rocky material and its small-scale structure) can be only inferred from optical and thermal- and radio-wavelength observations. Because such techniques have been applied to the Moon and Earth, as well as to samples of lunar and terrestrial rocks and soils, observations of Mercury can be compared to known materials and its properties more accurately inferred.

Similarities to the Moon's surface

The reflection of sunlight off Mercury's surface as viewed from different angles suggests a surface layer with a rough texture, composed of fine, dark grains of rock. Temperature measurements at different wavelengths in the infrared and microwave portion of the spectrum, and at different viewing angles, support this interpretation. Multispectral observations at visible and near visible infrared wavelengths indicate a general similarity to mature lunar soils, with a subtle absorption of radiation at about one micrometre wavelength (visible light extends from about 0.4 to 0.7 micrometre) suggesting about as much iron-rich material as is found in the lunar highlands (about 5 percent ferrous oxide by weight).

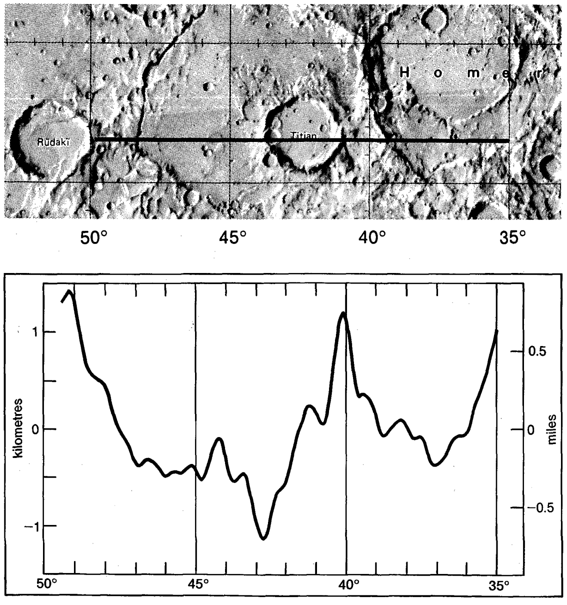

Figure 10: Earth-based topographic profile along the line indicated on the map shows large craters to be between one and two kilometres deep.

Earth-based radar observations show a rough topography much like that of the Moon, including depressions with raised rims and blocky surfaces that clearly portray their impact origin (Figure 10). These observations, acquired before the Mariner spacecraft mission, were the first indication of lunar-like surface features, as well as surface physical properties and composition.

Spacecraft observations contribute additional information on physical and compositional properties of the Mercurian surface. The darkest features on Mercury are not as dark as the darkest features on the Moon, but the overall brightness (albedo) of many Mercurian surfaces is comparable to that of the heavily cratered, relatively bright lunar highlands, which reflect about 15 percent of the sunlight striking them. The brightest areas seen on Mercury are found in the floors of a few unusual craters, where as much as 50 percent of the incident sunlight is reflected. The average brightness of Mercurian surfaces suggests a composition deficient in titanium- and iron-bearing minerals such as are found in the lunar maria (low-lying dark areas), and perhaps more like the calcium-bearing minerals of the lunar highlands. The few extremely bright crater floors require compositions or surface textures unlike any seen on the Moon.

The Mercurian regolith

Thermal infrared observations from Mariner 10 show results similar to Earth-based studies; namely, that the Mercurian surface is covered by a layer of fine silicate dust and sand at least tens of centimetres thick. Such a regolith, or rock mantle, is also found on the Moon, where it is formed by the repeated pulverizing of the surface rocks by the impact of microscopic particles moving through space at many tens of kilometres per second. Infrared observations also show, however, areas of compacted soil or boulders or bedrock, indicating a few places of thin regolith or fresh, unweathered surfaces.

Observed features. Mercury is a difficult planet to observe from Earth, and this led to several erroneous conclusions about it. Such observations could at best attempt to resolve features several hundreds of kilometres across, but usually this was not possible and only regions 1,000 kilometres on a side could be seen. It was not until the Mariner 10 spacecraft flew past Mercury that high-resolution views of its surface were obtained (Figure 11) and surface features unambiguously described. At their best resolution the Mariner 10 photographic data are nearly 5,000 times better than Earth-based views.

Six types of features are seen on the Mercurian surface: impact-generated craters, usually named for men and women who have made contributions to the arts and humanities; scarps, named for ships used in exploration on Earth; ridges and valleys, named for astronomers and radio observatories, respectively; plains, named for the planet or god Mercury in various languages; and mountains, usually the rims of extremely large craters, named for the nearest plains.

Impact craters. Impact craters are the most abundant landform on Mercury, an attribute shared with many other solid bodies in the solar system. Craters come in many sizes and shapes, though they usually appear nearly circular. They are studied intensively for two reasons. First, their abundances and variations in size as seen on several planets permit investigation of similarities and differences between planets. Second, the number of craters on a given surface is most likely an indication of that surface's age—the older the surface, the more craters that have formed on it.

The craters on Mercury are very much like those on the Moon. The smallest visible craters are about one to two kilometres across; they are bowl-shaped, with raised rims

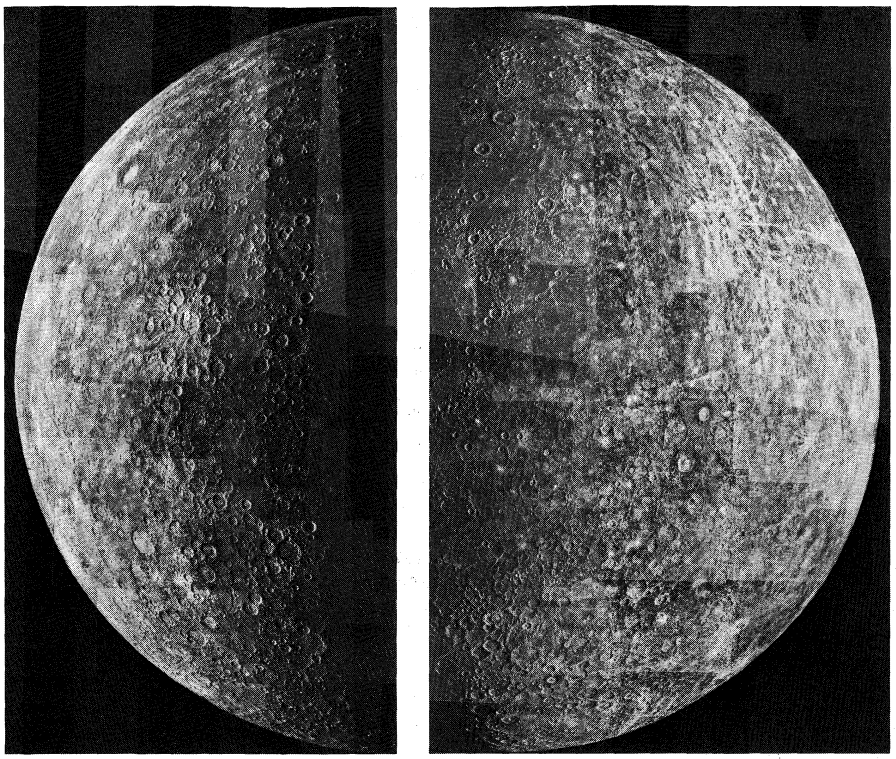

Figure 11: Two mosaic views of Mercury, each about one-half in shadow. The view on the left, taken as Mariner 10 approached Mercury, shows impact craters, intercrater plains, scarps, and hilly and lineated terrain. The view on the right, taken after Mariner 10 had flown past Mercury, shows the enormous Caloris impact basin, smooth plains, bright rays associated with very fresh craters, and many older craters.

By courtesy of the Jet Propulsion Laboratory/National Aeronautics and Space Administration

and blankets of ejecta surrounding these rims and thinning rapidly away from the crater. Slightly larger craters, about 10 kilometres in diameter, begin to show interior complexities (slumping, terraced walls, central mounds or peaks, and flat floors), along with more extensive ejecta blankets. Secondary craters, formed by large blocks ejected by an impact, form chains and clusters beyond the zone of continuous blanketing. The largest craters often have a ring of isolated or continuous peaks inside and concentric to their rim.

Influence of gravity

Subtle variations in the morphology of fresh craters may show the influence of gravity and material properties on impact phenomena. One dramatic influence of gravity on the cratering process is its effect on ejecta. Mercury's gravity is 2.3 times greater than that of the Moon, and this permits ejecta to reach only 65 percent of the distance it would reach on the Moon. By studying craters of the same size on the two bodies, it can be shown that the amount ejected is roughly the same, so the restriction of Mercurian ejecta causes a higher concentration of secondary craters nearer the crater and an increase in the thickness of the continuous ejecta blanket. These restrictions also reduce the effect on Mercury of proximity erosion, in which ejecta from one crater lands on and covers or degrades an adjacent crater.

The number of craters on various surfaces on Mercury also shows remarkable similarities to lunar cratering. The age of some lunar surfaces is known because Apollo and Luna space missions brought to Earth samples of rocks that have been dated by radioactive age-dating techniques. Although it is not certain that the same number of craters were formed at the same rate on Mercury as on the Moon, their histories have probably not been widely different. Thus, Mercurian surfaces are thought to be very old—perhaps 3,000,000,000–4,000,000,000 years old. Variations in the details of the number of craters at different sizes, and differences in these from comparable variations in the lunar craters, suggest a more complex picture, combining variations in the number of crater-forming impacts (reflecting different sources of interplanetary debris) and variations in crater preservation after formation (reflecting planetary processes such as global melting and volcanism).

Escarpments. Among the unique features of the surface of Mercury are enormous escarpments up to hundreds of kilometres in length and as much as three kilometres high. Many of these scarps cut through surfaces and topographic features (Figure 12), while in other areas they are themselves covered. These relationships permit both the relative age and possible origins of the scarps to be studied. The morphology of the scarps and their transectional relationships show that most occur along steep, nearly vertical faults. By close inspection of several craters cut by scarps, it appears that portions of these craters have been shoved on top of other parts (Figure 12). Thus, the scarps are inferred to have formed by compression. The number and length of scarps imply a shrinking of the surface area of Mercury by about 0.1 percent, or a decrease in the planet's radius of between one and two kilometres.

The shrinking of Mercury

The orientation of the scarps and other linear features further constrains the mechanisms of global crustal fracturing and movement (tectonic deformation). These suggest that tidal stresses induced in Mercury by the Sun (probably those that established the spin-orbit resonance) deformed the crust in a specific manner, depending on latitude, and that concurrent or subsequent to this tidal deformation the interior of Mercury cooled, causing the planet to shrink. Most scarps are relatively old; a few small, young scarps probably formed later by local deformation (associated with, for example, impact cratering or volcanism) and usually follow the trends established in the crust by the earlier global deformation.

Ridges and valleys. Three types of ridges are found on Mercury. Relatively narrow, discontinuous ridges are usually found radial to extremely large impact craters (called basins) and are often accompanied by intervening valleys; they represent impact-induced radial faulting and radial deposition and grooving during ejecta emplacement. Many well-defined ridges are found in areas of smooth, relatively lightly cratered flat surfaces (smooth plains) and probably were formed through local adjustment of the underlying rock to the weight of the plains-forming material. Finally, large ridges (up to several hundred kilometres long), found

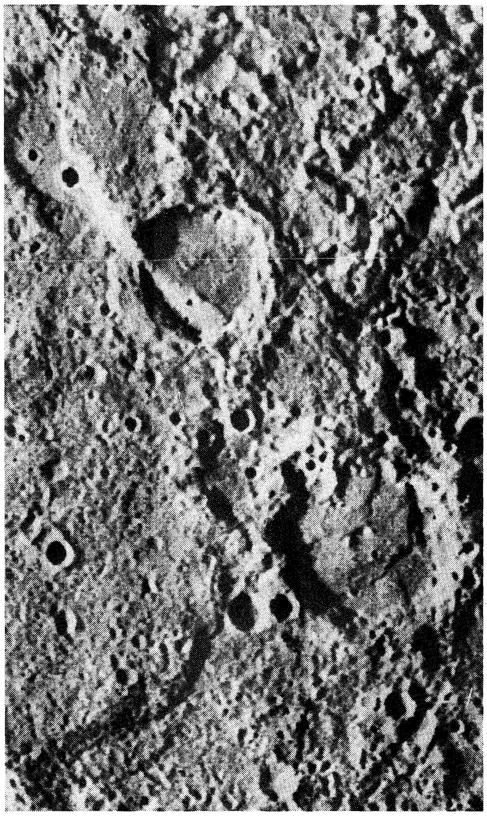

Figure 12: The Vostok scarp cuts two craters, as seen in the upper left portion of this Mariner 10 photograph. The lower of the two craters is called Guido d'Arezzo and is 65 kilometres across. The upper right portion of the crater appears to be thrust over the lower left.

By courtesy of the Jet Propulsion Laboratory/National Aeronautics and Space Administration

in the most heavily cratered areas and in the moderately cratered zones between these areas, follow trends similar to scarps and are inferred to be sources of volcanic material erupted early in Mercurian history.

Valleys are relatively rare on Mercury. They were formed mostly in association with impact craters, either as an integrated chain of secondary craters, as radially grooved ejecta, or as radially faulted, uplifted bedrock. A few valleys may also have formed as fault-bounded depressions (grabens) of tectonic origin.

Plains. Plains, or relatively flat or smoothly undulating surfaces, are ubiquitous on Mercury and the other planets. They represent a canvas on which other landforms develop. The covering or destruction of a rough topography and the creation of a smoother surface is called resurfacing, and plains are evidence of this process. There are at least three ways that planets are resurfaced, and all three may have had a role in creating Mercurian plains. One mechanism is to reduce the strength of the crust to retain high relief by raising its temperature and, over millions of years, allowing the mountains to sink and craters to rise. A second mechanism involves the horizontal flow of material along surface topographic gradients, eventually collecting in low areas and filling up to higher levels, as more volume is added. Lava flows behave in this manner. The third mechanism is for fragmented material to be deposited on a surface from above, first mantling and eventually covering the rough topography. Blanketing by impact crater ejecta and volcanic ash are examples of this mechanism.

Mountains. Mercury can be said to be mountainous only to the extent that the largest impact craters create zones of blocks of rock that are regionally extensive and of great local relief. The mountain-building processes common on Earth (involving the collision of large regional plates of Earth's crust moving under the influence of internal heat) do not occur on Mercury. The mountains on Mercury are mostly the exaggerated rims and rim deposits of very large craters.

The physiography of the planet. The features described above combine in regional and global patterns to establish physiographic provinces that reflect the geological evolution of Mercury (Figure 11). Three principal types of terrain are found globally, and a few others are found only in certain regions. The three global types are heavily cratered terrain, intercrater plains, and smooth plains; and the regional terrains include those associated with an enormous crater called the Caloris Basin and an area of highly disrupted hills and depressions that occurs on the other side of the planet, exactly opposite Caloris.

Heavily cratered terrain. The term heavily cratered terrain is applied to areas of closely grouped and overlapping craters with diameters greater than about 30 kilometres (Figure 11). The small distances between craters inhibit the detection of ejecta blankets and fields of secondary craters about individuals within the group. Many of the craters appear degraded (*i.e.,* they have smoother walls, more rounded rims, and are pocked by additional small craters) when compared to more isolated, fresher looking craters. This degradation probably reflects in part their greater age and in part the effectiveness of erosion and deposition by ejecta from adjacent craters (proximity erosion). The interiors of many craters in heavily cratered terrain are occupied by relatively smooth plains.

Degradation of craters

Intercrater and smooth plains. Intercrater plains, the term applied to the less cratered zones between the areas of heavily cratered terrain, are the most widespread physiographic unit on Mercury. They may be relatively smooth or have a low, irregular, undulating relief. They are characteristically covered by many small craters (mostly less than 10 kilometres in diameter), thought to be secondary craters but which cannot be traced back to a specific primary source. The time relationships between the formation of heavily cratered terrain and intercrater plains are difficult to discern. In some areas secondary craters and ejecta from craters clustered in an area of heavily cratered terrain can be traced out onto intercrater plains. Thus, in these areas the plains are older than the cratered terrain. In other areas, however, the clustered craters do not have discernible secondary craters or ejecta, and the relative ages are thus indeterminate. In still other areas ejecta relations indicate that the craters came after the plains, yet under close stereoscopic scrutiny the intercrater plains areas are seen to be themselves clusters of subtle, circular depressions of low relief. It appears from all of these cases that heavily cratered terrain and intercrater plains were formed during the same interval, although the rate of formation of plains appears to have differed from the rate of production of craters.

Smooth plains are relatively deficient in craters and are often found inside young, large craters. They are thus considered to be among the youngest features on Mercury. The largest observed occurrence of smooth plains fills and surrounds the Caloris Basin. Ridges and scarps are abundant on smooth plains. The plains resemble the lunar maria in pattern, location of occurrence, surface texture, and crater population, but they do not differ in albedo and colour from their surroundings, as do the maria.

The mechanisms by which the intercrater and smooth plains were produced are of great importance because their age differences permit investigation of the evolution in time of the resurfacing on Mercury. Initial thoughts were that both plains were formed by volcanic flows, and that the lesser abundance of younger, smooth plains indicated that Mercury was initially hot and volcanically active but had cooled as it lost its primordial heat and become less active with time. An opposing view suggested that both kinds of plains were formed by enormous amounts of ejecta derived from craters, that the greater abundance of older intercrater plains was the result of the large number of impacts occurring early in Mercurian history, and that the smooth plains represented the ejecta from the last, great impacts, such as that which formed the Caloris Basin. An additional view suggested that the areas of intercrater plains, seen to be subdued depressions, were in fact craters degraded by the inability of a warm crust to support their relief (the result of crustal plasticity). It now seems likely that all three mechanisms operated on Mercury. Although scientists still debate the relative proportions, it is most likely that volcanism is responsible for most of the resurfacing, with crustal plasticity responsible for early shaping of most of the heavily cratered regions into intercrater plains between areas of heavily cratered terrain. That most smooth plains were produced by volcanic activity rather than by impact ejecta is suggested by the areal restriction of ejecta owing to gravitational effects, the absence of specific source craters, the wide range in the areas of smooth plains compared to the areas of craters in sites where they occur together, and the occurrence of plains inside craters without additional, exterior craters as sources. Some impact ejecta effects are seen, however, notably in proximity erosion, and plains formed by such ballistic processes may be locally important.

Evidence of volcanism

The Caloris Basin. The Caloris Basin—so named because it lies on the longitude of one of the hot (Latin: *calor*) poles—is about 1,300 kilometres in diameter (Figure 13). The interior of Caloris is occupied by smooth plains that are extensively ridged and fractured in a crudely radial and concentric pattern. The largest ridges are a few hundred kilometres long, about three kilometres wide, and less than 300 metres high. Fractures are comparable in size, and may be flat-floored. Some resemble the fault-bounded depressions that are called grabens. Where they cross, the fractures transect the ridges. Two terrains surround the Caloris Basin—the basin rim and basin ejecta terrains. The basin rim consists of a ring of irregular mountains, up to two kilometres high, bounded on the interior by a relatively steep escarpment and on the outside by a smaller, inward-facing scarp. The intervening 100 to 150 kilometres consists of mountain blocks up to 50 kilometres square, with plains within the depressions between blocks. Beyond the rim is a zone of linear, radial ridges and valleys (see above). These ridges and valleys are embayed and partially filled by two types of plains, some smooth and some with many knobs and hills only a few tenths of a kilometre across. These plains may represent basin ejecta or volcanic material, but their relationship to the large structures of the Caloris Basin indicate that they formed after, though not necessarily long after, the basin.

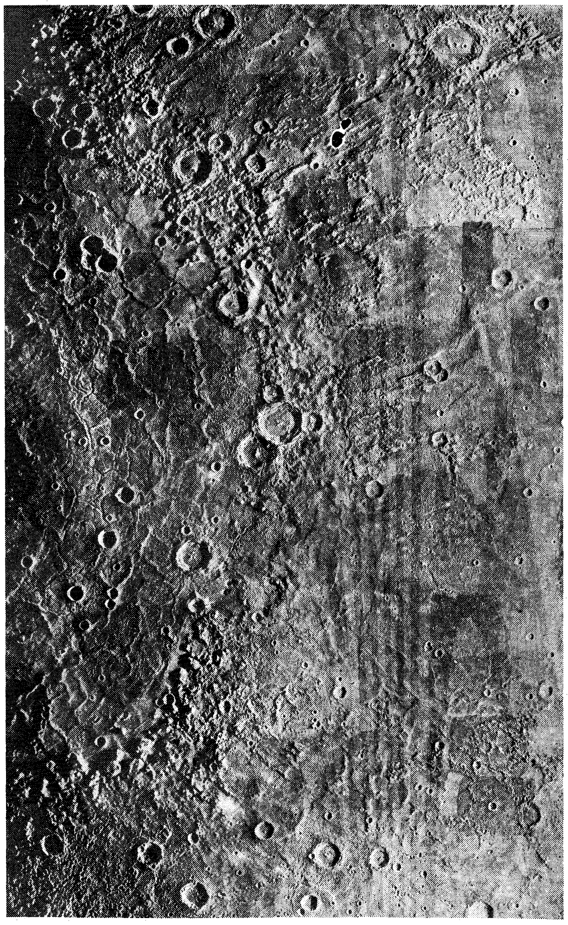

Figure 13: The Caloris Basin, as seen in a mosaic of Mariner 10 photographs.

Region opposite Caloris. Antipodal to Caloris is an extensive area of hills and depressions termed hilly and lineated terrain (Figure 14). The hills are 5 to 10 kilometres wide and up to 1.5 kilometres high, and they have crudely polygonal outlines. Crater rims have been disrupted into hills and fractures by the process that created the terrain. Some of these craters have smooth floors that have not been disrupted, suggesting a later infilling of smooth plains material. The location of this terrain exactly opposite the Caloris Basin, and the similarity in part to features seen antipodal to some lunar basins, suggests to most investigators that some link exists, either by ejecta travelling preferentially halfway around the planet or by the focussing of seismic energy. The second alternative has come to be most favoured.

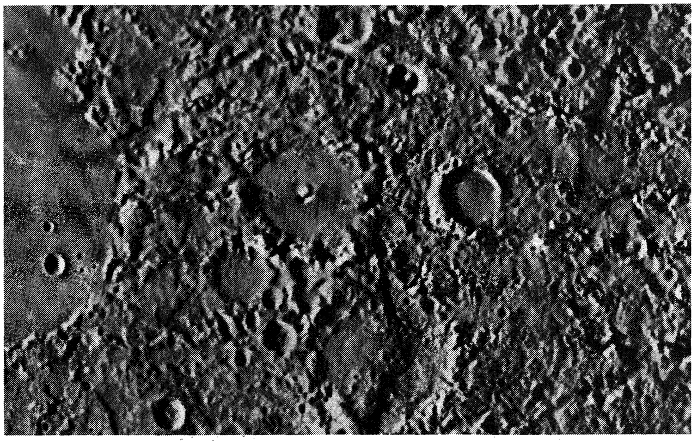

Figure 14: Hilly and lineated terrain antipodal to the Caloris Basin. The area is about 400 kilometres across.

GEOLOGICAL HISTORY

The geological evolution of Mercury can be divided into five stages: initial formation (accretion) and segregation of materials (differentiation); early thermal and dynamical evolution; decreasing bombardment and planetary cooling; reduced crater and plains formation; and relative quiescence.

Mercury, like the other planets, is believed to have formed from materials within a gas and dust cloud associated with the early Sun. This cloud (the solar nebula) condensed to form solid materials, and through processes of gas drag and gravitational interaction eventually formed small bodies that collided to form the planets. Because of its proximity to the Sun, Mercury was probably made of materials stable at relatively high temperatures. It was also probably spinning faster than it is today, because as it accumulated mass it also accumulated spin (angular momentum), much as an ice skater speeds up by drawing in his arms. Sometime during or shortly after this process of accretion, Mercury's interior materials segregated to form an outer shell of iron-poor silicates and an inner zone of iron. Though there is no direct evidence of this differentiation, the high density of Mercury cannot be reconciled with its silicate outer surface without a core of iron or nickel–iron. Mercury probably has an outer zone, perhaps 500 kilometres thick, of silicates much like the lunar highlands, over an iron core amounting to 75 to 85 percent of the radius and 50 percent of the volume of the planet. At its formation this core was probably liquid, but it now may not be.

Early evolution of Mercury

The early evolution of Mercury was next dominated by its early thermal history, the dynamical evolution of its spin and orbit, and the intense bombardment of its surface by interplanetary debris. Little direct evidence of this period is preserved on Mercury, although the end results are clear. The gravitational energy released by core formation would have greatly heated Mercury if it were not already hot. Craters formed by continuing accretion of the few bodies left near Mercury would surely be destroyed or highly degraded as the surface lost its capacity to support relief (crustal plasticity) and as volcanism occurred. Such processes probably created the intercrater plains, and the preserved heavily cratered terrains represent those areas formed late in this epoch, when both crater destruction and plains-forming volcanism were already waning. During this entire period, however, Mercury was being affected by solar tides, slowed in its spin, and distorted in shape. These distortions were preserved in the cooling upper silicate layer as fractures that guided volcanic extrusions and crater excavation.

Toward the end of the period of heavy bombardment, not only had the silicate shell cooled, but most likely the core had begun to solidify as well. This caused the planet to shrink slightly, creating the large scarps. In order for the core to "freeze," however, even more heat had to be deposited at the interface between the iron core and silicate shell. This may have provided material for smooth-plains-forming volcanism. The end of this period was marked by the enormous Caloris impact.

The seismic energy and fracturing of the crust that attended the Caloris impact permitted a final surge of plains formation, one occurring after the cratering had fallen off to a very low and nearly constant rate. Response of the surface to the weight of these plains caused fractures and ridges to develop, usually along patterns inherited from earlier deformation. Finally, Mercury's interior was sufficiently cool that volcanic activity ceased altogether. With the exception of occasional impacts, little else has occurred there that is visible in spacecraft images or discernible in Earth-based telescopic observations of composition and physical properties.

As inferred from relative crater abundances on the different cratered and plains surfaces, from theoretical models of heat generation and loss, and from dynamical models of spin evolution—and by analogy to lunar evolution known from radioactive age dating of samples—most of this sequence occurred relatively early in Mercury's history. If accretion occurred 4,500,000,000 years ago, core formation and despinning probably was complete by 4,300,000,000 years ago, the crust was rigid and volcanism on the wane by 4,100,000,000 years ago, and the surface and interior were essentially quiescent for well over 3,500,000,000 years. Thus, despite an active early life, Mercury is now, like the Moon, probably a dead world. (M.C.Ma.)

Venus

The second planet from the Sun, Venus is, after the Moon, the brightest natural object in the night sky of the Earth. Venus, symbol ♀ in astronomy, revolves about the Sun in a nearly circular orbit (eccentricity 0.007), which is inclined to the ecliptic plane (the plane in which the combined centre of gravity of the Earth and Moon revolves around the Sun) by 3° 24′. It is the planet that comes closest to the Earth, being less than 42,000,000 kilometres away at inferior conjunction (when Venus is between the Earth and the Sun). At superior conjunction (when Venus lies almost behind the Sun), the disk of Venus is fully illuminated as seen from the Earth; it is then about 256,000,000 kilometres from the Earth. Its mean distance from the Sun is 107,500,000 kilometres (Table 5).

BASIC ASTRONOMICAL DATA

Venus' orbit. As it revolves around the Sun, Venus undergoes phase changes similar to those of the Moon. Its sidereal period (the time needed to complete one revolution around the Sun) is 225 Earth days, but its synodic period (the time in which it goes through one cycle of phases) is 584 Earth days. Galileo's historic early observation of the gibbous phase of Venus (seen with more than half but not all of the apparent disk illuminated) gave decisive evidence against the Ptolemaic, or geocentric, theory of the arrangement of the planets. It also solved a problem of the heliocentric theory; Venus is not much brighter when it is nearest the Earth, because we then see only a thin crescent. When it is farther away we see a larger fraction of the illuminated hemisphere. Galileo cautiously announced his observation in an anagram in Latin, then the international language of science. A rearrangement of the letters of Galileo's message gives *Cynthiae figuras aemulatur mater amorum,* or "The mother of Love [*i.e.,* Venus] imitates the form of Cynthia [*i.e.,* the phases of the Moon]."

Table 5: Planetary Data for Venus

Mean distance from Sun	107,500,000 kilometres 67,200,000 miles
Eccentricity of orbit	0.007
Inclination of orbit to ecliptic plane	3° 24′
Sidereal period of revolution (year)	225 Earth days
Rotation period	−243.0 ± 0.1 Earth days
Mean synodic period	584 Earth days
Mean orbital velocity	about 21.8 miles (35 kilometres) per second
Inclination of equator to orbit	very small
Mass (Earth = 1)	0.81
Diameter (atmosphere not included)	12,103 ± 0.2 kilometres
Density	about 5.1 grams per cubic centimetre
Satellites	none known
Acceleration due to gravity (Earth = 1)	0.904
Atmospheric composition	0.96 CO_2, 0.035 N_2, 0.0002 H_2O; trace quantities of CO, O_2, SO_2, HCl, and other gases
Surface atmospheric pressure (Earth = 1 bar)	94 ± 1 bars
Mean surface temperature	735 ± 5 K
Mean visible cloud temperature	230 ± 10 K

Venus as morning or evening star

In middle latitudes Venus can rise or set more than three hours before or after the Sun. When seen in the western sky as the evening star, it was called Hesperus by the Greeks, and when visible in the east as the morning star it was called Phosphorus. Probably as early as 3100 BC it was associated with the goddess of love.

Gross characteristics. At superior conjunction, when it is farthest from the Earth and beyond the Sun, the angular diameter of Venus is about 10 seconds of arc; but at inferior conjunction, when the Earth and Venus are practically in line with the Sun and on the same side of it, it exceeds 60 seconds. The mean radius of the solid body of Venus is 6,051.5 ± 0.2 kilometres, compared to 6,371 kilometres for the Earth; and its mass, as determined by its gravitational influence on other astronomical bodies and on such spacecraft as Mariner 5, is about 0.81 that of the Earth.

The acceleration due to gravity on the surface of Venus is about 90 percent that on Earth. For these reasons Venus has been thought of as "Earth's sister planet." Recent information, however, indicates that this phrase is not altogether appropriate.

Retrograde rotation

Period of rotation. Since, from the vantage point of the Earth, Venus is completely covered by clouds, it is not possible to determine its period of rotation by optical examination of its surface features. From observations of faint and evanescent markings in the clouds, various observers have deduced periods of rotation ranging from 24 hours to 225 Earth days. The development of radar astronomy, however, has provided more precise information. The period of rotation can be determined by measuring the Doppler effect at the limbs of the planet—that is, the increase or decrease in the frequency of a radar wave after reflection from the approaching or receding limbs, or edges. Individual surface features that reflect radar as they move across the planet's rotating disk are now known also, and these can be followed and a period of rotation determined. Accordingly, it is known from the work of R.F. Jurgens and others that the planet rotates in 243.0 ± 0.1 Earth days in a retrograde sense; *i.e.,* in a direction contrary to that of the motion of the other planets. The retrograde rotation of Venus is quite remarkable. With the marginal exception of Uranus, whose rotational axis is nearly in the plane of the ecliptic, all the other planets in the solar system rotate in a direct sense; that is, if the solar system is viewed from above (to the north), where the planets appear to revolve around the Sun in a counterclockwise direction, then all the planets except Venus and Uranus will also rotate about their axes in a counterclockwise direction. Venus, however, rotates clock-wise, in the direction opposite to its revolution. Radar and passive radio determination of the position of the axis of rotation show it to be very nearly perpendicular to the plane of its orbit. Another remarkable fact about the rotation of Venus is that with a rotation period of nearly 243.16 days, a value close to the observed period, Venus presents the same face to the Earth at every inferior conjunction. The questions as to why Venus should be rotating "backward" and why it should be influenced by the presence of the Earth are unsolved celestial mechanical problems connected with the origins and early histories of the planets. One suggestion is that Venus has a pronounced bulge or lumpiness in its equatorial plane, which permits the Earth's gravitational force to exert a tidal couple on Venus. Another suggestion is that the Earth's gravitational influence operates not only on the solid body of Venus but also on its massive atmosphere (see below).

EARLY SCIENTIFIC VIEWS

Perhaps the earliest scientific speculation on the environment of Venus was that of Christiaan Huygens, who, in the 17th century, engaged in prolonged scrutiny of Venus with one of the earliest astronomical telescopes: "I have often wonder'd that when I have view'd Venus . . . she always appeared to me all-over equally lucid, that I can't say I observed so much as one Spot in her . . . is not all that Light we see reflected from an Atmosphere surrounding Venus?"

The appearance of Venus during transit, as it passed in front of the Sun in the year 1761, suggested to Mikhail Vasilyevich Lomonosov that Venus has an atmosphere at least as dense as the Earth's. The visible face of the planet shows, in the experience of almost all visual observers, an unbroken appearance, which suggested to many a very thick cloud layer. By analogy with the Earth, such clouds were imagined to be composed of water. But the Earth is about 50 percent cloud covered and Venus is about 100 percent cloud covered. The idea then evolved that Venus was a wetter place than the Earth, suggesting in 1918 to Svante August Arrhenius that "everything on Venus is dripping wet . . . a very great part of the surface of Venus is no doubt covered with swamps . . . the constantly uniform climatic conditions which exist everywhere result in an entire absence of adaptation to changing exterior conditions. Only low forms of life are therefore represented, mostly no doubt, belonging to the vegetable kingdom; and the organisms are nearly of the same kind all over the planet."

If the clouds were composed of water, it should be possible to detect water vapour above the clouds by spectroscopic means. An unsuccessful attempt to make such a water vapour detection by Charles Edward St. John and Seth Barnes Nicholson in the 1920s led them to deduce instead a dry desert planet with clouds made of dust stirred up from the surface by winds. Subsequent speculation about Venus proposed a surface covered with carbonated water or with petroleum-like hydrocarbons. More definitive information is now available about the surface conditions on Venus (see below).

THE CLOUDS

The clouds of Venus have a high reflectivity. At some visible and near-infrared wavelengths, they reflect 85 percent or more of the sunlight falling on them. The clouds are not perfectly white but exhibit a pale lemon-yellow hue, due to the presence of some material that absorbs blue light. Although they are featureless when viewed in visible light, when photographed using ultraviolet wavelengths the clouds display variable, low-contrast features (see Figure 15). When the reflectivity at all wavelengths is considered, it is possible to calculate the clouds' effective temperature, *i.e.*, the temperature at which they radiate back to space the same amount of energy that they absorb from the Sun. This temperature is about 230 K, exactly the value given by direct infrared measurements of the clouds by William Sinton and John Strong, among others.

During the 1970s, temperatures within the clouds of Venus were directly sensed by Soviet and U.S. space probes in their descent through the planet's atmosphere. The U.S. Pioneer Venus mission of 1978 sent four probes into widely separated regions of the planet. These probes measured the detailed structure of temperature within the clouds and found that the temperature of 230 K occurred about 70 kilometres above the planet's surface—where the cloud tops were observed to be by other probe experiments—thereby confirming the temperatures estimated from reflectivity data.

The cloud layers

The Soviet Venera probes and the U.S. Pioneer Venus probes and orbiter also determined many of the physical and chemical characteristics of the clouds, as well as their altitudes and depths. The clouds are in three closely spaced layers between about 46 and 70 kilometres above the

Table 6: Composition of the Atmosphere of Venus

gas	mixing ratio	gas	mixing ratio
CO_2	0.96	He	10 ppm
N_2	.035	Ne	10 ppm
H_2O	<.001	Kr	<0.2 ppm
Ar	70 ppm	COS	<2 ppm
SO_2	600 ppm*	HCl	0.4 ppm
CO	20 ppm	HF	0.01 ppm
O_2	40 ppm		

*At cloud base.

surface. Outside of these layers, the atmosphere is almost free of particles, except for a haze of tiny particles about 0.002 millimetre in diameter that extends a few kilometres below and about 20 kilometres above the main clouds.

The clouds completely envelop Venus from the equator to the poles, and from the dayside to the nightside. Moreover, they are generally similar at all locations except that the overlying haze is deeper and more dense near the poles. The dense and ubiquitous cloud cover has very important consequences; it is one of two factors responsible for the exceedingly high temperatures in the deep atmosphere of Venus near the planet's surface. The clouds are termed "optically thick," which means that they are opaque. Very little of the light that is incident on their upper surface ultimately emerges from the lower surface. This fact notwithstanding, there is enough light at ground level to permit photography, as demonstrated by the Venera 9 and 10 landers.

Three distinct families of cloud particles have been identified. Their chemical compositions are very different from that of Earth's clouds, which are largely liquid water and water ice. That the major material of Venus' clouds is concentrated (80 percent) sulfuric acid, H_2SO_4, was confirmed by in situ observations of sulfur dioxide and sulfur trioxide vapours from the evaporation of cloud droplets. (Their composition had been originally inferred from the optical properties of the liquid droplets as measured from Earth.) The larger acid droplets have a representative diameter of 0.008 millimetre. The haze also is mainly sulfuric acid. Another type of particle is up to 0.030 millimetre long; as measured by the Pioneer Venus particle-size spectrometer, this type of particle may be a tiny, solid crystal, probably in the form of a thin plate structure. The composition of these particles is not as well determined, but it may be a metallic chloride, perhaps iron chloride ($FeCl_3$), that was boiled out of the hot planetary surface and diffused up to higher and cooler altitudes, there condensing into crystals. The water vapour in Venus' atmosphere appears to be limited to that which is in equilibrium with the sulfuric acid droplets, which have a high affinity for water and scavenge it from the atmosphere.

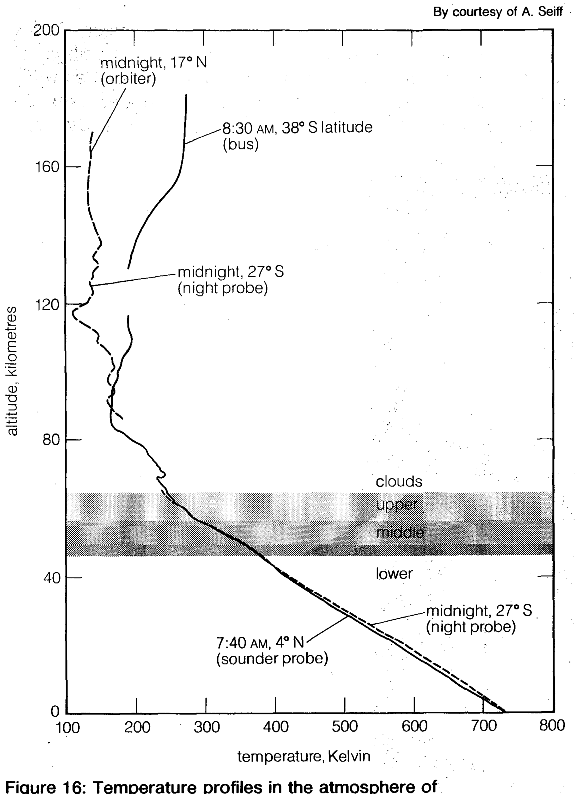

Figure 16: Temperature profiles in the atmosphere of Venus measured in 1978 by the Pioneer Venus mission. Below 100 kilometres, the atmospheric temperatures are amazingly uniform from day to night and over latitudes up to 60°. Above 100 kilometres, the night side becomes much cooler than the day and is not far above the condensation temperature of CO_2.

THE ATMOSPHERE

Carbon dioxide

Composition. The Venera 11 and 12 and Pioneer Venus probes of 1978 each carried two instruments to measure composition of the atmosphere. They directly measured nitrogen (N_2), which, at 3.5 percent, is a minor constituent of the atmosphere, and carbon dioxide (CO_2), which, at more than 96 percent, comprises the bulk of the atmosphere. (Although the percentage of nitrogen is small, its total amount in the massive atmosphere of Venus is equivalent to four times the nitrogen present in the Earth's atmosphere, where it is the major constituent.) Oxygen (O_2), the second most abundant gas on Earth, is a trace constituent of Venus' atmosphere and about one-fifth as plentiful as it is on Earth. Other gases detected by the sensitive instruments on the entry probes are present in trace quantities (see Table 6).

Water vapour measurements by different techniques have produced somewhat varied results but lie in the range of 0.1 to 0.5 percent, depending on altitude. The highest value was obtained a few kilometres below the sulfuric acid cloud, and the lowest values were recorded near the planet's surface. Above the clouds, the atmosphere is exceedingly dry because temperatures there are below the freezing point of water. If there were 0.1 percent of water throughout the atmosphere, and if the water were condensed into liquid on the surface, it would form a layer 10 centimetres deep over the entire planet. (Of course, liquid water cannot exist on the surface at the high temperatures found there.) Compared to the quantities of water in the Earth's vast oceans, the amount found on Venus is negligible. Investigators have proposed two possible explanations for the lack of water. The first states that Venus was formed with lesser amounts of volatile materials, including water, because of its position nearer the Sun, where temperatures during the formation of the planets were high. According to the second theory, Venus originally had much larger quantities of water; this water was vaporized by high surface temperatures and then dissociated into hydrogen and oxygen by sunlight at upper levels, the hydrogen escaping into space and the oxygen diffusing downward and reacting chemically.

Sulfur dioxide

The sulfur dioxide content of the atmosphere varies with altitude. It is greatest near the cloud base, where the cloud droplets vaporize and decompose into water and sulfur oxides, which are then carried upward where lower temperatures permit them to recombine and condense into droplets that grow to the maximum size found in the middle cloud. The droplets then settle to lower altitudes, where they vaporize and repeat the process. This cycle is somewhat analogous to the water-vapour condensation cycles in cloud formation on the Earth.

Hydrochloric and hydrofluoric acid vapours, measured spectroscopically from the Earth, are present above the clouds in trace amounts that may offer additional evidence of chlorides in the large particles of the clouds.

An important finding of the Pioneer Venus mass analyzers was that the ratio of abundance on Venus of the isotopes argon-36 to argon-40 is 300 times greater than it is on the Earth. This implies a significant difference in the chemistry of planetary formation because of Venus' location nearer the Sun.

Structure. Temperatures in the lower atmosphere of Venus increase continually from the cloud tops to the surface, where it is a very hot 735 K (see Figure 16). This is well above the melting temperatures of lead and tin, and above the boiling point of mercury (although it has not been detected, mercury could exist as a trace constituent vapour in the deep atmosphere). The first indications of high atmospheric temperatures on Venus came in 1956 from Earth-based measurements of intense microwave radiation. Interpretation of this radiation was at first varied, including explanations other than high temperatures. Spacecraft measurements, beginning with Venera 5 and 6 in 1969, however, have shown conclusively that the deep atmosphere is indeed very hot.

Temperature structure of the atmosphere was measured with great precision by the Pioneer Venus probes. They found remarkably similar temperature profiles at the four probe sites, at latitudes from the equator to 60°, and from the morning sector to the midnight meridian (see Figure 16). Temperature differences at a given altitude were much smaller than they are at such widely different locations on Earth. This is understood to be a consequence of the great thermal inertia of the massive deep atmosphere, coupled with a rapid east-to-west wind that moves the atmosphere at higher levels rapidly around the planet. This motion tends to equalize temperatures on the nightside and dayside.

High atmospheric pressures

High temperatures are accompanied by equally impressive pressures, about 94 atmospheres at the planet's mean surface. This pressure signifies a huge mass of gas, principally carbon dioxide, in the atmosphere. The mass ratio of Venus' atmosphere to Earth's atmosphere is the ratio of surface pressures divided by the ratio of gravitational accelerations, or $94/0.904 = 104$. To find a pressure on Earth equal to the pressure at the surface of Venus, it is necessary to descend into the oceans to a depth of one kilometre.

Earth-like conditions in the atmosphere of Venus are found in the clouds. For example, at 50 kilometres altitude above the planet's surface, the pressure is one atmosphere and the temperature is 350 K. Temperatures comfortable for human beings, around 295 K, are found near the top of the middle cloud at about 55 kilometres altitude, where the pressure is about half an atmosphere.

The thermosphere

Above the clouds, temperatures of the atmosphere continue to decrease to a minimum level of about 165 K in the Venus stratosphere. A nearly isothermal (constant temperature) region then extends from about 85 to 110 kilometres. Above this level lies the Venus thermosphere, the region of heating by absorption of very shortwave ultraviolet radiation from the Sun. On Earth, the thermosphere attains temperatures of 1,000 to 1,500 K. Venus is surprisingly different. Because its principal gas is carbon dioxide, an efficient radiator, it re-emits the absorbed energy at infrared wavelengths, so that the peak midday temperature in the thermosphere is about 300 K, or about room temperature on Earth. On the nightside, where solar heating is absent, the temperature drops to as low as 130 K, not far above the solidification point of carbon dioxide at these altitudes. Reasons for the cold nightside upper atmosphere are not yet understood in full detail.

Evolution. It is interesting to consider the interrelated questions of how the atmosphere of Venus evolved to its present state; why it is so different from the atmosphere of Venus' "sister planet," Earth; and why the deep atmosphere of Venus is so hot. It is believed by most astronomers that the planet's massive carbon dioxide atmosphere was released from carbonate rocks under the action of high temperatures. Conversely, the maintenance of high temperatures depends on the mass of the atmosphere and the presence of large quantities of carbon dioxide gas, which, in the "greenhouse effect," absorb and trap heat radiated up from below. Hence, an evolutionary progression is suggested in which pressure and temperature each act to increase the other over a long time period comparable to the age of the solar system.

The conspicuous external difference between the Earth and Venus is that Venus is 0.72 times closer to the Sun. This implies that 1.91 times as much solar energy is received by Venus and, for equal reflectivity, also implies surface temperatures greater by about 345 K. At the present time, the reflectivity of Venus' clouds is very high—such that 80 percent of the Sun's energy is reflected back into space—and Venus therefore absorbs less energy from the Sun than does the Earth. Before the cloud cover formed, however, Venus was probably about 345 K warmer than the Earth is now. Whether this comparatively small difference in temperature was enough to set in motion the chain of events that led to the current massive atmosphere of Venus is uncertain. It is interesting, however, that Venus, Earth, and Mars exhibit a progression in which the amount of atmosphere decreases as the distance from the Sun increases.

The greenhouse effect

It does seem clear that the present high temperatures in Venus' deep atmosphere are the result of the radiative equilibrium usually termed the greenhouse effect. The small amount of solar heat that penetrates to the deep atmosphere is conserved by the high infrared absorption of the carbon dioxide atmosphere; water vapour and the clouds and haze particles close the transparent "windows" in the carbon dioxide spectrum through which heat could escape. There is an analogue to the greenhouse effect in everyday experience on Earth—the warming that accompanies a cloudy night sky, when the clouds trap the Earth's radiant heat and send it back down, and the association between clear skies and cold nights. More precisely, a radiative balance occurs at every level when the amount of downward-directed solar radiation that is absorbed is equal to the amount of infrared radiation that is emitted upward. When local temperatures satisfy this balance, the atmospheric temperature is maintained. Radiative balance calculations using the data on chemical composition, haze particles, clouds, and water vapour as measured by the Pioneer Venus and Venera space probe experiments can generate a temperature profile that closely corresponds with the temperatures directly measured by the probes.

Atmospheric circulation and winds. Another method by which heat can move upward in the atmosphere is by convection, in which warm gas rises from below and cool gas descends to a nearby location. The Pioneer Venus temperature data showed that convection occurs far less generally on Venus than had been supposed. In fact, only a shallow layer two or three kilometres in depth in the clouds and another layer between 20 and 30 kilometres from the surface overturn in the way the Earth's atmosphere overturns beneath cumulus clouds. A third convective layer may exist near the surface. The remainder of the atmosphere, including one deep layer from 28 to 52 kilometres from the surface, is stable; *i.e.,* it carries heat upward only by radiation and not by motion of the atmosphere.

The four-day circulation

There are, however, general motions of the atmosphere of global scale, in which the main winds blow from east to west at velocities near the cloud tops of about 100 metres per second. These winds, which transport the clouds and circle the planet in about four days, are commonly referred to as the four-day circulation. This circulation was discovered by observation of a four-day repetition of patterns in the clouds that are visible in ultraviolet photographs. The first such photographs, taken through telescopes from Earth, only dimly show the clouds' features, but many such photographs taken from the Mariner 10 and Pioneer Venus spacecraft show the patterns more clearly (see Figure 15). The rapid rotation of the atmosphere at cloud altitudes efficiently transports solar heat from the dayside, where it is absorbed, to the nightside, so that, below 100 kilometres, temperature differences from day to night are no greater than a few degrees Celsius. Because the winds are ultimately driven by solar heat absorption (which occurs mainly in and above the clouds), it is not surprising to find the highest wind velocities in and just above the clouds. Below the clouds, wind velocities decrease progressively and steadily to a final level of one or two metres per second near the surface.

There are also relatively low-velocity north–south winds in the clouds. These winds perform the important function of transporting solar heat from the equatorial region toward the poles and returning the cold polar air to the equatorial region, where it is warmed. In the case of Venus, the vigorous equatorial–polar pattern of circulation is located in the clouds, whereas on Earth such circulation patterns are driven by surface heating and begin at the surface. The north–south winds of Venus limit latitudinal

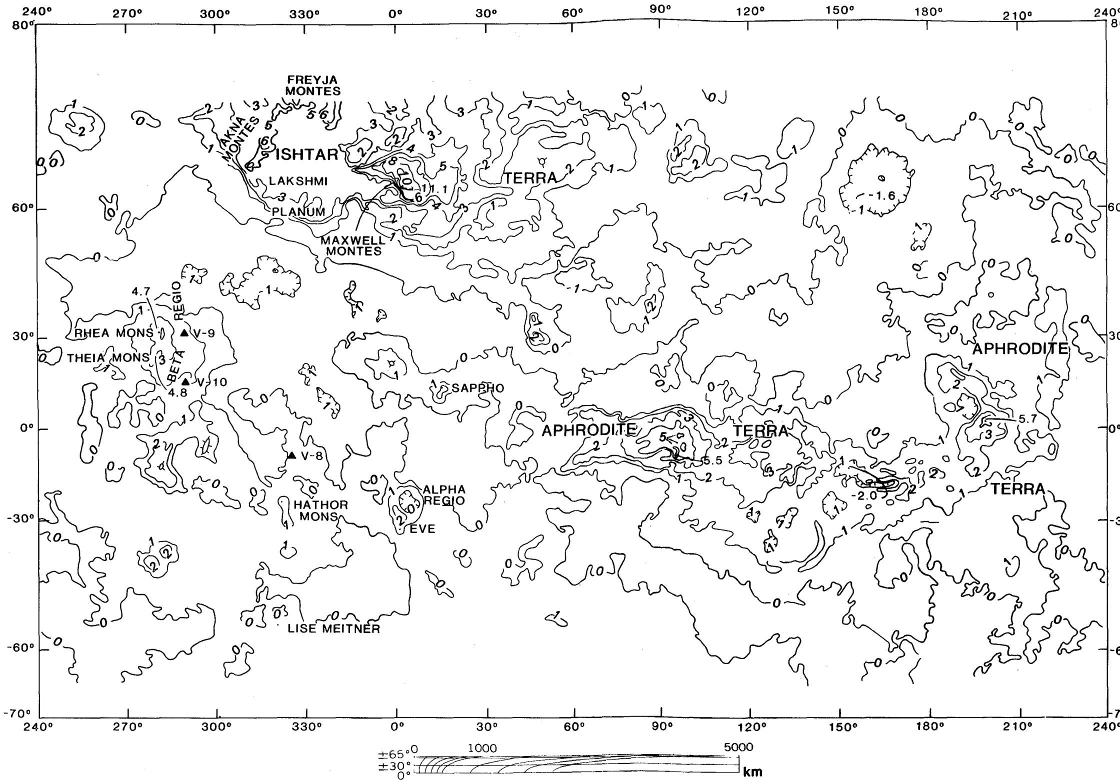

Figure 17: Surface contour map of the planet Venus, compiled in June 1980. Contour lines are described at intervals of 0.5 and 1 kilometre.

By courtesy of H. Masursky, U.S. Geological Survey, Ames Research Center, NASA; Massachusetts Institute of Technology

temperature differences, just as the four-day circulation limits the day-night differences. It is believed that other north-south circulation patterns that efficiently distribute heat from equator to the poles are present in Venus' deep atmosphere, possibly supplemented by large-scale horizontal eddies that are similar to cyclones on Earth.

THE SURFACE

Topographical features. Although clouds continually enshroud Venus and shield its surface from telescopic observation, the planet's surface has been examined by the longer waves of radio telescopes and of the Pioneer Venus radar altimeter. A radar map of almost the entire surface has been produced, showing the elevations of the surface; the presence of mountains, volcanoes, highlands (continents), and lowlands; large circular features similar to impact craters; and rift-valley features, one of which is 9,000 kilometres long, that are similar to the comparably immense Valles Marineris on Mars. The range of surface elevation extends from a high peak 11 kilometres above the mean planetary radius (6,051.5 kilometres) to low points 3.5 kilometres below the mean surface. The acceleration of gravity at the mean surface of Venus is 8.869 metres per second per second, or 0.90 times that on Earth.

Radar also measured the roughness of the terrain and found that the mountains are rough (signifying large rocks, steep surfaces, and rapid change in slope), while the plains are relatively smooth. Venera 9 and 10, after landing on the surface, returned pictures of their surroundings. The field around the Venera 9 landing spot is strewn with large rocks, while that around the Venera 10 landing appears to be dominated by an immense boulder outcropping, approximately flush with the surrounding surface. Venera 8 measured the composition of surface materials and found them to be granite-like in a region where the planetary crust was undisturbed. Venera 9 and 10 found basaltic composition in a region near Beta Regio, which is believed to be volcanic and to have experienced lava flows that left materials on the surface similar to those around volcanoes on Earth and the Moon.

Surface conditions. A human being standing on the surface of Venus during the daytime, if he could survive, would notice that the high clouds admit some scattered sunlight to the surface, much as do clouds on a heavily overcast day on Earth. The time from one sunrise to the next would be equivalent to about 118 Earth days. Because of the extremely high surface pressures on Venus, light from the bright side of the planet would be refracted through the lower atmosphere around toward the dark side, and some scattered light would be available even at night. The refraction effect is so strong in such a dense atmosphere that during the daytime it would be possible to see beyond the true horizon, and as a level surface on Venus would, for the same reason appear concave, the viewer would seem to be in a depression that remained around him, no matter how far he moved across it.

Effects of refraction on Venus

Radar and microwave observations imply that the surface of Venus is granular on a large scale, suggesting a rock-strewn surface. Dust storms may occur because of the high atmospheric density, even with the low velocities found near the surface. Erosion by windblown dust could modify the terrain features on Venus. Such erosion, however, does not affect the large-scale surface features seen on radar maps of the planet. In addition to apparent mountain ranges, large circular features that may be of impact origin and others analogous to the lunar maria have been detected by radar techniques. Fine dust should tend to accumulate in the lowlands, and many of the large craters may be filled in with dust.

The surface temperatures are so high that liquid water is excluded everywhere. In shadows, objects probably could be seen to glow by their own red heat. Temperatures everywhere on Venus are much too high to permit terrestrial forms of life. The temperatures are, in fact, so high that most organic molecules would denature rapidly.

The existence of some forms of life, however, for example in the vicinity of the clouds, is not impossible, although at the present time it can only be conjectured.

Astonishingly hot, with an oppressively dense atmosphere containing corrosive gases, with a surface glowing dimly by its own red heat and characterized by bizarre optical refraction effects, Venus (curiously identified in ancient literature with Lucifer) seems very much like the classical view of hell. (C.Sn./A.S./Ed.)

MAGNETIC FIELD, IONOSPHERE, AND SOLAR WIND INTERACTION

Lack of a magnetic field

The earliest spacecraft to fly by Venus, Mariner 2 and 5 and Venera 4, found no measurable intensity in the planet's magnetic field. Data from the Pioneer Venus orbiter place the strength of the magnetic field at less than 0.00001 gauss. The data do not, in fact, find any real evidence for an intrinsic magnetic field; *i.e.,* one associated with the solid planet. There are very weak fields associated with the ionosphere and with the solar wind that are generally less than 0.001 times the strength of the Earth's surface magnetic field. The absence of a planetary magnetic field on Venus is consistent with the internal dynamo theory of field generation, which ascribes the existence of planetary magnetic fields to internal current systems driven by planet rotation, generally similar to electric generators. Since Venus rotates slowly, once in 243 days, its dynamo is weak.

The ionosphere of Venus, as on other planets, is created primarily by the absorption of solar shortwave (extreme ultraviolet) radiation. On Venus, the impact of solar wind protons and electrons on neutral molecules in the upper atmosphere may also contribute. The absorbed energy can result in an electron escaping from the molecule, leaving a positively charged ion and a free electron. Because of Venus' proximity to the Sun, these processes occur somewhat more frequently than on more distant planets. The number of free electrons in Venus' ionosphere, however, is fairly typical of that found in the ionospheres of other planets out to Jupiter—about 100,000 to 300,000 per cubic centimetre, depending on distance from the subsolar point and on altitude. The number of ions per cubic centimetre increases with decreasing altitude down to 160 kilometres above the surface, but theory indicates that it should peak at about 130 kilometres. The major ions are O_2^+ and CO_2^+. The density of ions and electrons is much lower on the nightside than on the dayside, generally less than 10,000 per cubic centimetre. The upper limit of ionosphere, called the ionopause, is sharply defined, but it is variable from about 300 kilometres altitude on the dayside to about 1,000 kilometres on the nightside. The dayside boundary is imposed by magnetic pressure from the solar wind that impinges on the upper atmosphere.

Bow shock wave

Venus—like Earth, Mars, Jupiter, and Saturn—is enveloped by a bow shock wave, which forms in the supersonic flow of the solar wind about the planet. Because Venus lacks a magnetic field, its bow wave stands closer to the planet, only about one-third of the planet radius away at the subsolar point. This is because the solar-wind particles are reflected directly by the ionosphere, rather than by the planetary magnetic field, which extends much farther out in space for Earth, Jupiter, and Saturn. The

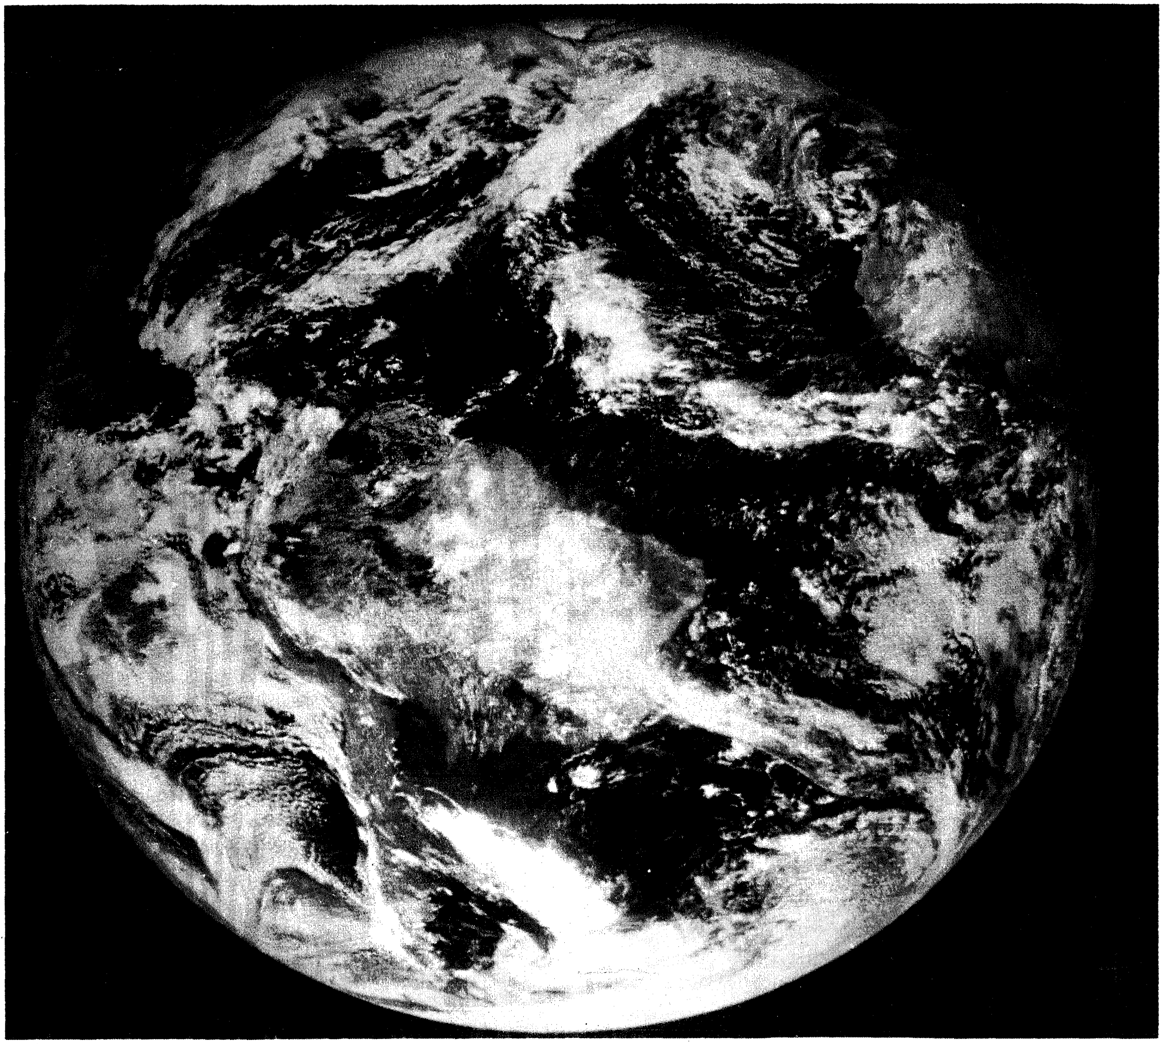

Figure 18: *The Earth from 35,900 kilometres in space.*
The National Aeronautics and Space Administration's ATS III satellite transmitted this colour photograph to a ground station at Rosman, North Carolina. It was received at 10:30 AM EST on November 10, 1967, from its on-station position at 47° west longitude on the Equator over Brazil. Four continents (portions of North and South America, Africa, and Europe and the Greenland ice cap) can readily be seen, while the Antarctic continent is blanketed under cloud cover. Major weather over the central United States, stretching from the Great Lakes to Mexico, represents a cold front moving eastward. A tropical storm (bottom centre) with a cold front extending into Argentina can be seen.

bow shock wave is basically similar to the wave formed about projectiles and rockets in supersonic flight. In fact, a sphere fired from a gun at a Mach number of 2 or 3 has a shock wave closely similar in appearance to the bow wave surrounding Venus. (A.S.)

Earth

Comparison with other planets

The Earth, symbol ⊕ in astronomy, is the third planet in distance outward from the Sun. Many consider the Earth–Moon system to be a unique double planet because the Moon is much larger in comparison with its primary, the Earth, than most other planetary satellites. In the more usual view, the Earth has a single natural satellite, the Moon. Like some other planets of the solar system, the Earth has radiation belts, an ionosphere (part of the atmosphere containing electrically charged particles, or ions), an atmosphere, and a lithosphere, or crust (outer surface); beneath the crust, the deep interior is divided into layers called the mantle and the inner and outer core (see Figure 19). Much more is known about details of the Earth's structure and composition than about those of the other planets because of its accessibility. The Earth has, however, been much changed and differentiated locally because of its active and turbulent history, and, thus, care is needed in making interpretations. Processes such as volcanism, mountain building, and seafloor spreading are still going on.

The curvature of the Earth can be demonstrated from ground level in many simple ways—for example, by measurements of Eratosthenes of Cyrene in antiquity (see below). Photographs from rockets in the 1950s clearly showed the curvature of the edge of the Earth (at the horizon), as did later photographs taken from the space vehicle Gemini 4. In the 1960s, for the first time, the Earth was photographed from sufficient distance to show it as a planet, more beautifully coloured and more varied than any other. (See Figure 18.) In this picture, cloud patterns show clearly the scale of atmospheric circulation. Below the clouds, the oceans appear blue, and the outlines of continents can be seen. The Earth's oceans are probably unique among the planets because of the small range of temperatures and pressures within which water exists as a liquid.

Like other planets, the Earth is approximately a sphere. It spins on its axis (the line joining the points at the surface called the North Pole and South Pole) once a day relative to the Sun. This is equivalent to once in about 23 hours 56 minutes 4 seconds relative to the stars (the sidereal day). The sidereal day is shorter than the solar day (24 hours 3 minutes 57 seconds) because the Earth, revolving at the same time about the Sun, must rotate farther, after completing the sidereal day, before the solar day is completed.

This section presents an overview of the Earth as a whole, ignoring the details of its surface features, the oceans, and the atmosphere. Those topics are treated in the articles CONTINENTAL LANDFORMS; OCEANS; and ATMOSPHERE. For additional information on the Earth's interior, surface configuration, physical properties, and chemical composition, see EARTH, THE and CHEMICAL ELEMENTS. The history of the Earth is summarized in the article GEOCHRONOLOGY, and the origin and nature of the Earth's major surface features are treated in GEOMORPHIC PROCESSES; RIVERS; and PLATE TECTONICS.

BASIC PLANETARY DATA

Figure of the Earth. The radius from the centre to the poles is not quite the same as that from the centre to a point on the Equator (see Table 7), but the concept of the Earth as a sphere is a good approximation. The distance a traveller has to proceed northward in order to make the elevation of the Pole Star increase by one degree is the length of one degree of latitude. The length of a degree of latitude depends slightly on the latitude at which it is measured. This dependence indicates that there is a deviation of the Earth from spherical shape. Sir Isaac Newton was the first to demonstrate that the centrifugal force of the Earth's rotation would tend to make the Earth bulge out at the Equator, giving it the shape of an oblate spheroid (the surface formed by an ellipse when it is rotated about its short axis). Such a surface is flatter near the pole than near the Equator, and one degree of latitude is therefore longer in high latitudes than it is in low ones. Gravity also varies over the Earth's surface, primarily with latitude, being somewhat higher by about 0.5 percent at the poles than at the Equator.

Table 7: Earth Data

Equatorial radius	6,378.136±1 km (3,963.374 mi)
Polar radius	6,356.784 km (3,949.921 mi)
Mean radius	6,371 km (3,959 mi)
Flattening	1/298.257
Eccentricity	0.017
Circumference, equatorial	40,075.51 km (24,902.45 mi)
M (mass)	5.976×10^{27} g
V (volume)	1.083×10^{27} cu cm
Mean density (*M/V*)	5.517 g per cu cm
Mass ratios: Sun to Earth to Moon	333,400 : 1 : 0.01228
Mean distance from Sun	1.496×10^{8} km (92,900,000 mi)
Earth's speed in its orbit	29.8 km/sec (18.5 mi/sec)
Revolution around Sun	365.25 days
Rotation	23 hr 56 min 4.09 sec
Area	5.096×10^{8} sq km (197,000,000 sq mi)
Land	1.48×10^{8} sq km (57,000,000 sq mi; 29% of Earth)
Highest point	8,848 m (29,028 ft; Mt. Everest)
Lowest point	−11,034 m (−36,201 ft; Marianas Trench)
Lowest point on land	−397 m (−1,302 ft; Dead Sea)

Factors in the changing length of the day

Rotation and precession. Because the Earth revolves around the Sun in 365.25 days, the sidereal day (the exact length of which is 23 hours, 56 minutes, 4.099 seconds of mean solar time) is shorter than the conventional mean solar day by about one part in 365. Astronomical observations show that the Earth is not an ideal timekeeper. The length of the day is subject to certain tiny changes. The most important are (1) a gradual slowing down of the Earth's rotation—*i.e.,* lengthening of the day; (2) small annual or seasonal variations; (3) small irregular variations. The magnitude of the gradual slowing down found from ancient astronomical observations, especially from ancient eclipses and from the more accurate astronomical data available since about 1600, amounts to an aggregated time change of about 30 seconds per century. If this phenomenon is assumed to have existed throughout the Earth's lifetime, the Earth must once have rotated much more rapidly than it does now. The cause of the slowing down has not been established with complete certainty, but most probably it is due to the effect of tidal friction in the oceans. The loss of angular momentum (that is, momentum acquired through rotation) by the Earth is compensated by that gained by the Moon's orbit, which then moves farther away from Earth. The seasonal fluctuations in the length of the day are tiny, on the order of some thousandths of a second per year; they can be explained by changes in the size of the polar ice caps and changes in atmospheric circulation. The irregular changes are equally tiny and can apparently be traced to motions in the Earth's core.

Lacking any external influences, the direction of the Earth's axis of rotation in space would remain the same for all time. Gravitational forces of other members of the solar system, in particular the Moon and the Sun, however, influence the Earth. Because the Earth is flattened, the Moon's gravity tends to tilt the Earth's axis, so that it becomes perpendicular to the Moon's orbit, and to a lesser extent the same is true for the Sun. A spinning body, such as the Earth or a gyroscope, subject to such a force will not, however, yield to it, but the axis of rotation will precess—*i.e.,* move around the surface of a cone in space. This motion of the Earth's axis is known as the precession of the equinoxes (times of equal day and night in spring and autumn). It was discovered by the astronomer Hipparchus in 120 BC and first theoretically explained by Sir Isaac Newton in the 17th century. Precession implies that the pole is not always in the same place among the constellations but moves about; for instance, 12,000 years hence it will coincide with the star Vega. The length of one period of the precession is 26,000 years. The precession makes the Sun's orbit in the heavens (the ecliptic) and its intersection with the celestial equator (the equinoctial points) move in such a direction as always to meet the Sun, at a rate of 50.26″ per year. This change amounts to about 29° since Hipparchus' time; hence the ancient Greek's description of the Sun's yearly path across the constellations no longer fits. The force tending to alter the tilt of the axis is not constant; when the Sun or Moon is crossing the Equator, for instance, it has no effect. The path of the pole is therefore not exactly a circle but contains a superimposed smaller oscillation, the nutation, with a period of 18.6 years and an amplitude of 9.2 seconds of arc. The Chandler wobble, another gyroscopic effect of extremely small amplitude and a period of 436 days, is accompanied by a slight deformation of the Earth's body. The solid body of the Earth undergoes a slight daily tidal deformation caused by the gravitational action of the Moon and Sun, about 25 centimetres at most.

The Chandler wobble

Numerical data. Some quantities relating to the Earth are known with a precision exceeding one part in 1,000,000. Others are known only to within a much lower error limit, and those derived from the latter have corresponding uncertainties. The one most important quantity of the former type is the constant of universal gravitation, $G = 6.67259 \times 10^{-11}$ m^3 kg^{-1} s^{-2}. The numbers with many digits given in Table 7 might someday have to undergo revision in the last one or two decimal places, but they are internationally agreed upon as the most likely values.

STRUCTURE OF THE INTERIOR

Data from seismic waves. Two phenomena provide information about the deeper layers of the Earth's interior: seismic waves generated by earthquakes and, to a lesser degree, the Earth's magnetic field. There are two main types of seismic waves, the P-waves (primary, because they travel fastest) and the S-waves (secondary, because they travel more slowly and, hence, arrive later at the station than the P-waves). The P-waves are compressional (longitudinal) in nature, whereas the S-waves are shear (transverse) waves. The existence of two types of waves greatly increases the amount of information about the Earth's interior.

Types of seismic waves

The most conspicuous feature of the Earth's interior is the existence of a sharp boundary at which reflection and refraction occur and which encloses the part known as the core; it represents an extremely well-defined discontinuity. The mean radius of the core (ignoring flattening) is 3,470 kilometres, or nearly 55 percent of the Earth's radius. The most outstanding feature of the core is that it never transmits S-waves. Because the failure to transmit transverse waves is a distinctive characteristic of liquids, it is generally accepted that the core material is in a liquid state, probably mainly of molten iron. Existence of the core was first quantitatively established in 1913. Later studies have shown an additional boundary, somewhat diffuse, which encloses the so-called inner core. Its radius, not precisely known, is about 1,300 kilometres. Evidence indicates that the inner core is solid iron (solidified under extreme pressures).

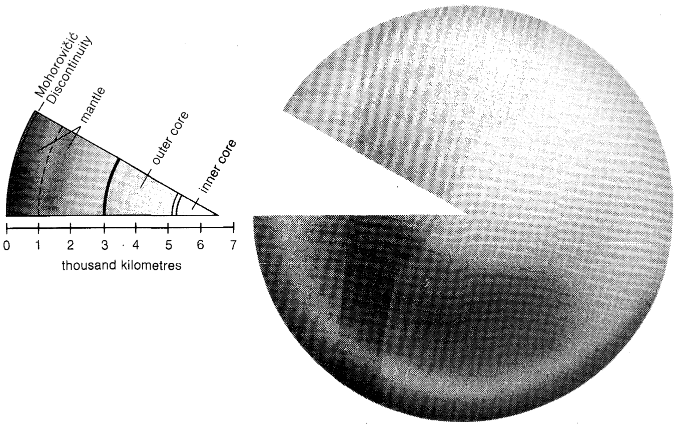

Figure 19: Main layers of the Earth.

Seismic velocities, density, pressure. In the mantle and the core a progressive stiffening of the material with increasing pressure makes the velocity of seismic waves increase at greater depths. The density distribution cannot be uniquely determined from such data, but certain rather restrictive conditions are imposed on it thereby. A further condition results from a knowledge of the moment of inertia of the Earth about its axis, known with great accuracy from a combination of astronomical and geodetic observations. The moment of inertia about an axis through the centre of a homogeneous sphere, for which *m* is the total mass and *a* is the radius, is 0.4 ma^2. Observations show that the moment of inertia of the Earth is 0.334 ma^2, which indicates a rather pronounced increase of density toward the central parts.

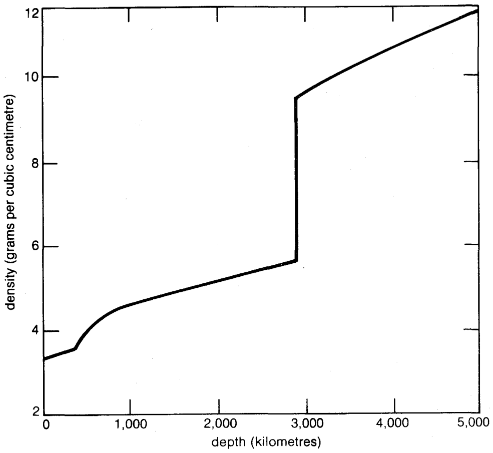

Figure 20: Known density distribution in the Earth down to the limit of the inner core.

The pressure inside the Earth rises rather regularly with increasing depth. In the mantle the rise is at a rate of about 470 atmospheres per kilometre (one atmosphere of pressure equals 14.7 pounds per square inch). The pressure at the boundary of the core is 1,370,000 atmospheres; at the centre of the Earth it is 3,700,000 atmospheres. The strength of gravity is also a function of the depth; it clearly must vanish at the centre. Gravity is remarkably constant throughout the mantle, to within 1 or 2 percent; but, beginning at about the boundary of the core, it decreases steadily to zero.

ORIGIN, COMPOSITION, AND AGE

Formation of the Earth. Astronomers have speculated about the origin of the solar system ever since it was suggested in the 18th century that the stars and planets arose from the condensation of vast gaseous masses filling cosmic space. The formation of the Sun may have occurred much earlier than that of the planets. It is now generally accepted that the planetary system developed out of a disk-shaped mass of gas surrounding the Sun. The original cosmic matter consisted mainly of hydrogen (and some helium), and most of these gaseous components must have been lost to space early from the disk. The less volatile matter condensed, mainly as silicates and metallic iron, these being the prime constituents of present-day meteorites as well as of the interior of the Earth. At the time the gas escaped, the solid matter probably consisted of bodies much smaller than the present planets, because the larger bodies would hold on to a gaseous envelope by gravitation, at least to some of the gases heavier than hydrogen. Most probably, the original solid components were dust grains.

Origin of the planetary system

While this picture is crude and speculative in its details, it brings out one crucial point common to all modern theories as distinct from the views held in the 19th century: the original matter from which the planets condensed must have been relatively cold. The temperature in this primary lens-shaped body of gas and dust was probably quite low, because it should readily have been cooled by radiation that could escape in a direction perpendicular to the plane of the disk. When dust congregated to form the Earth, gravitational energy was released and could be transformed into heat, but it is not known what fraction was available for actual heating, because this amount depends critically on the speed of aggregation. If the aggregation was slow, most heat should have escaped by radiation, and this is the most likely case.

Chemical composition. The composition of the Earth's crust can be investigated directly by quantitative chemical analysis of samplings from many rocks. The pioneer in this field was Victor M. Goldschmidt, who in the early decades of the 20th century undertook the painstaking task of determining the average proportions of the chemical elements in the Earth's crust. To appreciate the significance of the results it is necessary to compare them with what is known about the chemical composition of cosmic objects other than the Earth. Among the objects that fall upon the Earth from outer space are meteorites. Meteorites are generally considered to be fragments of a larger solar system body or bodies. Many chemical analyses of meteorites have been made. Next, quantitative determinations of the relative proportions of the chemical elements can be made for the Sun by spectroscopic methods. Finally, though with greater limitations, the same can be done for other stars.

One conclusion long drawn from the vast mass of observations is that the gross chemical composition of matter in the universe is relatively uniform. There might be small variations from one star to the next, but the impression of overall uniformity is strong. Scientists are thus led to think of a definite gross composition of primordial matter from which the Earth and the other planets were formed. The figures given below for the relative proportions (known as cosmic abundances) of the most important elements are from a classical compilation by H. Suess and Harold C. Urey (1956). Since the abundances are only relative, they are expressed as the numbers of atoms existing per one atom of a reference substance. The latter is taken to be the element silicon, since rocks consist largely of compounds of silicon. These abundances are as follows:

hydrogen	40,000.0	aluminum	0.09
helium	3,100.0	silicon	1.00
carbon	3.5	phosphorus	0.01
nitrogen	6.6	sulfur	0.37
oxygen	21.5	argon	0.15
neon	8.6	calcium	0.05
sodium	0.04	iron	0.60
magnesium	0.91	nickel	0.03

Remarkably enough, only six of the remaining elements have abundances that lie between 0.001 and 0.0001; all other elements are so rare that they exist only in minutest traces on the cosmic scale.

Location of concentrations of elements in the Earth's layers

On the whole, the lighter compounds are more concentrated in the crust, including oxides and more complex compounds of sodium, magnesium, aluminum, and calcium that form many important constituents of common rocks. Geologists are able to discriminate between rocks of the surface layers and others that have been pushed up from lower layers and should therefore resemble more closely the chemical composition of the Earth's mantle. On the basis of such data it is commonly believed that the Earth's mantle consists primarily of certain compounds (silicates) containing oxygen combined with silicon, magnesium, and iron, three of the most common nonvolatile elements. Sulfur most probably exists in the interior of the Earth in the form of iron sulfide. Geochemical evidence, however, indicates that sulfur is far less abundant on the Earth than the overall cosmic abundance figure given above.

Composition of the core

It has long been held that the Earth's core is composed of iron. Iron is by far the heaviest of the common nonvolatile elements; hence, it would tend to sink toward the more central parts of the Earth. Recent studies indicate, however, that, while the inner core consists of solid iron in pure form, the outer core is probably composed of molten iron alloy. Profiles of seismic-wave velocities and densities through the core strongly suggest the presence of certain contaminants or alloying elements such as oxygen and sulfur. The cosmic abundances of these particular elements, along with other geochemical considerations, all tend to point to the occurrence of iron oxides and sulfides in the outer core.

Radioactive age determinations. Geologists early arrived at minimum figures of well over 100,000,000 years for the main part of geological history. The discovery of radioactive decay around 1900 provided an entirely new and much more reliable method for dating events in the Earth's history. Radioactivity consists of the transformation of one species of atomic nucleus into another. In the case of naturally radioactive substances, this transformation occurs spontaneously, and no chemical or physical condition of the environment has any effect on the rate of radioactive decay. In any given interval of time a fixed fraction of the atoms of the mother substance decays into atoms of the daughter substance. Radioactive decay, therefore, furnishes a natural and trustworthy type of clock wherewith to measure the distant past. Only the most long-lived of radioactive substances are useful for dating earlier periods in the history of the Earth.

The age of the Earth

Attempts have been made to estimate the total age of the Earth under certain plausible assumptions, using data on the relative proportions of lead isotopes in very old rocks and in meteorites. The age arrived at is about 4,500,000,000 years, a figure now well established and believed to be accurate to within a very small percentage of possible error.

MAGNETISM AND TEMPERATURE

Characteristics of the Earth's magnetic field

Earth's magnetic field. The Earth's magnetic field has two outstanding characteristics. The first is its irregularity, as seen for instance in the variation of the magnetic declination from place to place, the overall pattern of which is quite complicated. The second is its gradual change in time, a phenomenon well-known to all navigators because the declination of the needle changes continuously. Magnetic maps indicating the declination are seriously in error after a few years and must be redrawn periodically from new observations. This change is known as the secular variation of the Earth's magnetic field. If a variation of 10′ per year continues over, say, 60 years, it corresponds to the considerable change of 10° in declination. The pattern of change is, however, itself variable.

These rapid changes make it clear that the field does not originate in the solid mantle. The magnetic field is caused by electric currents that flow in the fluid, metallic outer core. The secular variation indicates that the fluid of the outer core is in motion. This motion carries the electric currents about and thus produces the variation of the field observed at the Earth's surface. The details of this variation, rather irregular, may be interpreted as representing so many large-scale eddies in the fluid. From the secular magnetic variation may be obtained a value for the average speed of the fluid iron: 0.03 centimetre per second or about 10 kilometres per year. Further development of these ideas leads to the conclusion that the fluid motion not only modifies the electric currents but also can produce and maintain them. This process resembles closely the one that takes place in a rotating generator of electric currents as found in power stations, in which current is produced by the motion of metallic wires past each other. In the core, streams of molten metal are the equivalent of the moving wires. This explanation of the Earth's magnetic field, known as the dynamo theory, has become accepted generally.

Rock magnetism. When a lava melt is solidified in a magnetic field and the field is removed later, the solid rock retains a slight amount of so-called remanent magnetism along the direction in which the original magnetic force pointed. The remanent magnetism is due to small grains of magnetic material (iron oxide) embedded in the rock. It becomes possible to infer from this the direction of the Earth's magnetic field at the time an ancient lava flow occurred. Similarly, sandstones have been shown to retain a small remanent magnetization along the direction of the field in which the material was deposited. The study of rock magnetism has been systematically developed, giving information about the character of the magnetic field at earlier times in the Earth's history. There seems to be little doubt that, during the last 500,000,000 years or so that are accessible to detailed geological study, the Earth has had a magnetic field similar to its present one.

Past magnetic reversals

Work on rock magnetism has shown, surprisingly, that apparently the magnetic field has reversed its polarity many times, perhaps hundreds of times during the past history of the Earth—that is, the magnetic south pole became the north pole, and conversely. A detailed explanation of this phenomenon is lacking; it can be said merely that its occurrence is conceivable in terms of the dynamo theory, because a self-excited generator can produce electric current in one direction as well as in the other, depending on its starting conditions. This phenomenon is also seen in some stars.

Temperature and heat transport. There is no direct way of determining the temperature distribution inside the Earth, but it is well-known that the temperature rises in the lower levels of deep mines. The rate at which heat is delivered to the surface is given by the rate at which the temperature rises (the thermal gradient), multiplied by the thermal conductivity, which is a characteristic constant of the material. Thus, by measuring the two last-named quantities, the heat flowing out of the Earth can be determined. The results of heat-flow measurements on the ocean bottom indicate that, even where the oceans are very deep, the heat flow is comparable to that flowing out on the continents. The average thermal gradient in the outermost layers of the Earth is about 25°–30° C per kilometre of depth. The average heat flow near the surface of the Earth is about 1.2×10^{-6} calories per square centimetre per second.

Assuming, say, average thermal gradients of 14° per kilometre at some greater depth, the temperature at a depth of 300 kilometres would be about 4,200° C, far above the melting point of any silicate, even at the pressures prevailing at such depth. Hence the temperature must level off; that is, the thermal gradient must radically diminish even at moderate depths inside the Earth. It long has been concluded that most of the heat flowing out of the Earth is produced by radioactivity (mostly from the decay of the uranium and thorium families) and that the radioactive material must now be strongly concentrated in the top layers of the Earth.

Source of heat

It was long believed that most of the radioactive material is in the crust, and because the crust is thick under the continents but thin or almost absent under the oceans, this occurrence would mean that most of the heat flow would occur in continental areas. Heat-flow measurements on the ocean bottom have shown that this view is wrong; it is now usually assumed that heat, especially under the oceans, is also transported by mechanical, convective motions.

In the deeper layers of the Earth it is necessary to rely largely on guesswork, but any assumed distribution is subject to certain conditions. It must remain below the melting point of the simple silicates throughout the mantle, it must be above the melting point of iron in the outer core, and if the inner core consists again of iron the temperature must rise to the melting point of iron at the boundary of the inner core and exceed it inside the latter. The best way to obtain the temperature inside the Earth is, therefore, to estimate the increase of melting point with increasing pressure. The existing estimates of the temperature in the Earth's interior tend toward relatively low values, perhaps in the neighbourhood of 3,000° C at the boundary of the core and near 4,000° C at the centre of the Earth. These estimates, however, may be in error by many hundreds of degrees.

ORIGIN OF THE SURFACE FEATURES

The surface of the Earth shows a remarkable degree of irregular structure. The surface levels cluster around two preferred heights: (1) sea level—most of the areas of the continents and of the offshore continental shelves lie near it—and (2) ocean bottoms, with an average depth of about five kilometres. Levels between these are rare. Another remarkable regularity has to do with the asymmetrical distribution of land and water masses. If a diameter is drawn arbitrarily across the Earth's centre, in more than 90 percent of all cases, one end is on land, the other on the sea. The fact that conclusive explanations, going beyond mere speculation, of such simple regularities cannot be given is indicative of lack of understanding of most of the basic physical and chemical processes that have shaped the surface of the Earth into its present form.

Isostasy. The crust considered as a load on the mantle is less dense; it is specifically lighter than the substratum. Such a load will sink only to a depth at which it is floating freely with respect to vertical displacements; it resembles an iceberg floating in the water with the larger part submerged beneath the surface. According to the principle of isostasy there is a tendency toward vertical equilibrium of the crust. Quantitatively speaking, the total mass encountered on going from the surface down toward the Earth's centre tends to be the same for any point of the surface. Where there is a mountain there seems to be more mass, but isostasy indicates that there must be a deficiency of mass farther down; the mountain has a root consisting of matter less dense than the matter lying under lowlands and the oceans. The root is bigger than the mountain itself; the lighter material extends down to about six times the mean elevation of the mountain.

This idea of isostatic (vertical) compensation was first developed on the basis of gravity observations. If ideal isostatic balance prevailed, gravity would be the same over the oceans and continents (apart from variation with geographical latitude). Actually, most mountainous elevations and most oceanic depths are fairly well compensated isostatically. Deviations, known as gravity anomalies, occur in the regions in which active mountain building occurs, such as the Pacific island areas (*e.g.,* the Japanese islands). Volcanic activity is concentrated in these same regions, as are earthquakes. Many earthquakes originate fairly near the Earth's surface, but in active regions earthquakes are observed to originate at depths down to 700 kilometres. Thus the upper mantle seems to participate to at least this depth in mountain-building.

Volcanism and earthquakes

Deformation of the crust: mountain building. Four agencies have been held responsible for mountain building, either individually or jointly, though it is probable that several (especially the last three) have been acting together.

Principal agencies of orogeny

1. *Contraction*—The Earth resembles a shrunken apple, the mountains and valleys being likened to the wrinkles of its skin. This is the oldest hypothesis, but since the discovery of radioactive heating of the Earth it has been difficult to believe that the Earth has shrunk appreciably in geological times.

2. *Convection*—If the mantle were a viscous fluid heated from below, convective upwelling would occur at a slow rate. If the thermal conditions are right, there must certainly be a tendency toward convection, though the mantle is a plastic solid and not a viscous fluid, and this might make actual patterns look quite different from those of a fluid.

3. *Phase change*—A change in the crystalline structure of minerals, which may occur as a result of either temperature or pressure changes is a phase change. Much evidence shows that at high pressures certain more compact forms of minerals that do not exist at the surface of the Earth are stable. It has been claimed that the Mohorovičić Discontinuity at the bottom of the crust represents such a phase change. Temperature might rise by radioactive heating and this rise could shift the discontinuity downward. Temperature falls again and the discontinuity rises if the heat is carried off by volcanism and other agencies. The tendency toward isostatic equilibrium might then produce fairly large vertical displacements.

4. *Accretion*—Because at increasing depths in the Earth the temperature first rises rapidly and then more slowly, the silicates of the mantle might be closer to melting at a depth of a few hundred kilometres than elsewhere. If melting occurs locally, the material will separate into its lighter components on top and its heavier below. Lighter material might gradually make its way through the overlying layers to the top, and in this manner the amount of crustal material can grow. Volcanism appears to be a process of this kind. The continental blocks of the crust may thus have only gradually accumulated through ge-

ological ages. Strong evidence exists that the ocean and the atmosphere are secondary products of accretion—that is, they have been slowly formed in the course of the Earth's history from material coming out of the rocks.

A more definitive theory of mountain building arose in the 1960s and 1970s. The discovery of the extent and nature of the Earth's mid-oceanic ridges and the fact that seafloor materials became older along paths normal to the ridges led to the concept of seafloor spreading—that new ocean floor is generated by the upwelling of the mantle along the ridge crests, that it subsequently moves laterally away from the ridges and toward the continents, and that it is eventually subducted or dragged downward back into the mantle along continental margins. These processes are thought to result in both continental drift and mountain building and are further discussed in the articles EARTH, THE; and PLATE TECTONICS.

(W.M.E./Ed.)

The Moon

The Moon, designated ☾ in astronomy, is a natural satellite of the Earth, but it is sometimes described as a planet because it is larger than most known natural planetary satellites and, because of its size, has many of the properties of a small planet such as Mercury. The Moon, like the Earth and the other terrestrial planets, has a solid body, nearly spherical in shape. The Moon's radius is about 1,738 kilometres, only 0.2725 that of the equatorial radius of the Earth; this difference, with the fact that the Moon's mass is only $^1/_{81.3}$ of the Earth's mass, is largely responsible for the difference between the atmospheres of the two bodies. The escape velocity of a particle from the surface of the Moon is about 0.213 that from the Earth, and, if past temperature conditions were much like present ones, the gas molecules and atoms of any early lunar atmosphere would have escaped in a time that is short when compared with the Moon's lifetime.

The Moon's mean density is about 3.34 grams per cubic centimetre, close to the density of the Earth's mantle; but studies of rocks returned from the Moon's surface indicate that the Moon's interior composition is not the same as that of the Earth's mantle and that in the Moon there is only a very small (possibly no) core. Many of the rock samples retrieved from the large, relatively smooth, dark areas of the face of the Moon called the maria are best described as basalts, but they are quite uncharacteristic of any known terrestrial rock or meteorite. They are about the colour of graphite—charcoal gray.

The whole Moon reflects less than one-tenth of the light that falls on it. The low reflecting power of the Moon had been known for a long time from estimates of its overall albedo. "Albedo" is a Latin word meaning "whiteness." While it is relatively easy to measure the relative brightness, or reflecting power (normal albedo), of flat surfaces illuminated and viewed normally in the laboratory, it is more difficult to assess the overall albedo of a spherical planet. The brightness of the Moon varies through its phases because of the roughness of its surface and the resulting variable amount of shadow. The Full Moon, when the Sun, Earth, and Moon are in the same line, is 10 times as bright as the Moon at First Quarter, the position of the satellite when it has completed one-quarter of its orbit around the Earth. When three-quarters of the orbit is completed, the Moon is said to be in the Last Quarter.

Variable brightness

(G.Fi.)

THE MOTION OF THE MOON

The apparent motion of the Moon. The lunar orbit is nearly circular, but it is more accurately described as an ellipse with the Earth at one focus, its eccentricity being about 0.0549. As seen from the Sun, however, the Moon sweeps out a sinuous concave path because its elliptic geocentric motion is superimposed on the elliptical orbit motion of the centre of gravity of the Earth–Moon system about the Sun.

The month. The Moon's motion around the Earth may be judged by reference to the Sun, the stars, the Earth's equator, or the Earth's orbit. To an Earth-bound observer, it is the fastest moving permanent natural object in the sky, making a complete circuit of the Earth with respect to the stellar background in only 27.322 days. This is the sidereal month.

By the time the Moon has completed one revolution of the Earth relative to the stars, the Earth–Moon system has itself moved through 7.5 percent of its orbit about the Sun. This causes the time between successive Full Moons or successive New Moons (called syzygies) to be longer than a sidereal month. This period of the lunar phases of 29.531 days is called the synodic, or lunar, month. The synodic month is determined by using the Earth–Sun direction as a reference.

If the orbital plane of the Moon were in the ecliptic (the plane of the Earth's orbit around the Sun), there would be a lunar eclipse at every Full Moon and a solar eclipse at every New Moon. Eclipses do not happen so frequently, however, because the lunar orbit is inclined to the ecliptic by 5°.15. The points at which the Moon crosses the ecliptic into the northern and southern celestial hemispheres are called the ascending and descending nodes, respectively. The interval between successive crossings of a given node, called the draconic, or nodical, month, is 27.212 days; the term draconic refers to the dragon that the ancients believed swallowed the Moon and Sun to cause eclipses. The draconic month differs from the sidereal month because the nodes regress (move opposite to the orbital motion), completing a full revolution every 18.6 years. This regression is caused principally by the gravitational pull of the Earth's equatorial bulge. The cycle of lunar and solar eclipses repeats every 18.6 years, a period that is sometimes called the saros.

Distance from the Earth

The mean distance between the Earth and the Moon is 384,400 kilometres, but, because of the ellipticity of the lunar orbit, the actual distance varies about 11 percent, between 363,000 and 406,000 kilometres. At its closest approach to the Earth, a satellite is said to be at perigee, and it is at apogee at its most distant separation; the time interval between successive perigee passages by the Moon of 27.555 days is called the anomalistic month.

Viewed from the celestial north pole, the Moon's geocentric orbital motion, the Earth–Moon's heliocentric motion, and the axial rotations of both Earth and Moon are all counterclockwise. Because the Earth spins west to east in a time that is short compared to the month, the Moon, like the Sun and the stars, appears to rise in the east and set in the west, even though its true motion relative to the celestial north pole is from west to east. Because of its orbital motion, the Moon rises, on the average, about 50 minutes later each day.

Optical librations. Galileo discovered that the Moon always turns the same face to the Earth. This means that the Moon rotates on its axis with exactly the same period as its orbital motion, a common feature among natural satellites. While its axial rotation is nearly uniform, the orbital speed of the Moon varies by 11 percent—the same amount of variation as in the Earth–Moon distance. The Moon moves faster near perigee and slower near apogee, with an average speed of 1.02 kilometres per second. Thus, from the Earth, the Moon seems to oscillate as the orbital speed loses or gains on the constant rotation. This causes features in the region of the limb, the visible edge of the Moon, to slip alternately into and out of view. A patient observer on Earth can eventually see about 57 percent of the total lunar surface. These apparent oscillations of the Moon are known as optical librations and can amount to Moon-centred angular displacements of 8° in longitude and 6°.8 in latitude. The laws governing such oscillations were discovered empirically by Gian Domenico Cassini in 1693.

The actual motion of the Moon. The mathematical treatment of the Moon's actual geocentric motion is called the lunar theory. Customary astronomical terminology distinguishes between an analytic procedure, called a theory of general perturbations, and a numerical method, called a theory of special perturbations. Because of the Moon's nearness to Earth and of its rapid angular motion, the lunar theory has long played a major role in formulating and testing dynamical theory.

Pre-Newtonian history. In ancient times, the Moon's phenomena were of great religious importance. Thus, considerable attention was paid to its motions; and the observations made were of an exactitude unsought in recording terrestrial phenomena. The Babylonians devised numerical methods for predicting eclipses and heliacal risings. The Greek astronomer Hipparchus in the 2nd century BC discovered the eccentricity of the lunar orbit, the motions of perigee and node, and the inclination of the orbital plane to the ecliptic. He explained the motion as being uniform in a circular orbit with the Earth placed eccentrically, and this was adequate to represent the observations then available. The numerical values of the parameters were derived from eclipse observations, some dating to Chaldean times. Although his results were superior to previous attempts, the restriction to eclipse data led Hipparchus to an incorrect value of eccentricity, through inability to distinguish the major inequality (departure from uniform motion, true value 6°.29), due to eccentricity, from the greatest solar perturbation. The latter inequality, called evection (1°.27), was discovered by the Greek astronomer Ptolemy in the 2nd century AD. Little significant improvement in the knowledge of the lunar motion was secured until the 16th-century Danish astronomer Tycho Brahe discovered the other great inequality caused by solar attraction, called the variation. This phenomenon, whose amplitude is 0°.66, vanishes when the Moon is new, full, or in quadrature. The physical explanation of these effects required the discovery of universal gravitation.

The discoveries of Hipparchus

Analytic theory. The analytic treatment of the lunar motion is carried out in two stages. In what is termed the "main problem," it is assumed that the Sun, Earth, and Moon behave as point masses and that the barycentre, or centre of gravity, of the Earth–Moon system describes a fixed ellipse around the Sun. After the solution of this problem, the remaining effects are introduced as small corrections to the main solution. These effects include the gravitational attractions of the planets acting on both the Earth and Moon, the forces caused by the irregular shapes of the Earth and Moon, corrections because of the use of a non-inertial coordinate system, and relativistic corrections.

The solution of the main problem gives the coordinates as harmonic series in which the arguments are linear combinations of the time-variant angles l, l', F, and D. The periods of revolution of l, F, and D are the anomalistic, draconic, and synodic months. That for l' is the anomalistic year in the Earth's heliocentric motion. The series coefficients are power series in these parameters: e ($= 0.055$) the eccentricity and γ ($= 0.045$) the sine of half the inclination of the lunar orbit; m ($= 0.075$) the ratio of average angular speeds of Earth and Moon; a ($= 0.0025$) the ratio of average geocentric distances of Moon and Sun; and e' ($= 0.017$) the eccentricity of Earth's orbit. The values of these parameters are determined from observation. The perturbations developed in the second stage of the analysis introduce the planetary orbit periods and the motion of the Moon's node into the arguments, as well as secular effects that grow without bound with time.

Isaac Newton based his theory of gravitation largely on the comparison of the motion of the Moon with that of bodies falling freely near Earth. He succeeded in proving that the principal periodic inequalities, as well as the motions of node and perigee, were caused by solar attraction. He deduced many new inequalities not previously known, but his motion of perigee was only about half the observed value; this disparity was later reduced to about 8 percent. Newton's theory was published in geometrical form in his *Principia,* but the method of fluxions (developed later into the integral calculus) was probably used in the actual derivation. No substantial advance was made beyond Newton's work until the mid-18th century, when the lunar motion was studied by many mathematicians.

Outstanding lunar theories were those obtained in the 19th century by Peter Andreas Hansen, Charles Eugène Delaunay, and George William Hill and Ernest William Brown. Hansen's theory was the most nearly numerical of the analytic theories, and it was of greater accuracy than any other before Brown; it was used worldwide from 1862 to 1922. Corrections by Simon Newcomb were applied after 1883. Hansen's work has served as the basis for orbit computations for artificial satellites.

The most complete algebraic development of the lunar theory until the present time was that of Delaunay. It was never adequate for comparison with observations, but it has been valuable in theoretical studies, the extension of other lunar theories, and the analysis of the orbits of natural satellites of other planets.

Hill developed methods that allowed the achievement of results of given accuracy with much reduced labour. These methods have been effective in studies of the general problem of three bodies (see MECHANICS) as well as in the practical solution of the lunar problem. The two principal features were (1) the introduction of the value of m from the outset to avoid convergence difficulties and (2) the use of a rectangular coordinate system rotating at the mean angular rate of the Moon. Hill's elegant method for determining the motion of perigee was later applied by John Couch Adams to the motion of the node. Based largely on Hill's work, Brown then developed the lunar theory that has been generally used to compute the coordinates of the Moon since 1923, although it was still necessary to replace the theoretical motions of node and perigee with the observed values, as the former were unsatisfactory.

Brown's series contain about 1,500 terms, five times as many as in Hansen's theory. Reduced to tables, it filled 650 quarto pages, and one man working alone with a desk calculator could extract the coordinates just fast enough to keep up with the real Moon. The electronic computer relieved this burden by permitting, since 1952, the direct calculation of the series. At the same time, corrections were introduced to compensate for the variations in the Earth's rotation rate and for the effect of tidal friction.

Brown's theory remained adequate for even the most precise astronomical uses for nearly half a century, and was still used for national almanacs in 1981. During the 1960s, the technologies of space exploration and radio astronomy, however, introduced the need for an enormous improvement in both the accuracy and internal coherence of the theory. At the same time, the rapid development of electronic computer systems for algebraic manipulation brought a resurgence of interest in the construction of analytic theories. The powerful new mathematical technique of Lie series, applied by computer, has permitted a return to the purely algebraic approach abandoned after Delaunay. Of the efforts to produce radically new theories, none had been sufficiently completed for general use by 1981. Along with the lunar coordinates, some of these efforts provide the necessary functions for correcting the lunar orbit parameters, an important innovation.

Numerical lunar theory. Although strictly numerical orbit theories have long been constructed for some solar system objects, this was impractical for the lunar motion before the development of the electronic computer. The nearest approach to a special theory was the attempt by Sir George Biddell Airy in 1883. He was unsuccessful and the idea was abandoned.

Space exploration required more accurate lunar positions than could be obtained from extant analytic theories; the solution was to compute the ephemerides by numerical integration of the equations of lunar orbital motion. This technique had been used for several decades for planetary orbits, but its application to the lunar problem was more difficult because of the Moon's high angular speed and the accuracy with which small perturbations can be observed. Numerical ephemerides first came into general use in 1969 and are now widely used for the most exacting applications, such as spacecraft navigation, lunar laser ranging, and radio interferometry. The method of special perturbations has the advantages of arbitrarily high internal precision and simultaneous inclusion of all desired perturbing forces in one basic calculation. Since both laser and radio observations can detect motions of a few centimetres, the calculations must account for such effects as planetary attractions, the Earth's oblateness, lunar libration, tidal friction in the Earth, and very complicated relativistic effects. The coupling between orbital and lunar rotation is now observable, so simultaneous numerical integration of these two motions is more commonplace.

Use of numerical ephemerides

The major disadvantage of the numerical approach is the uncorrectibility of a special theory; improvements to the parameter values require a completely new integration.

Cassini's laws for lunar rotation

The rotation of the Moon. Cassini's laws for the rotation of the Moon go beyond the fact of synchronous spin. They state, in addition, that the equator of the Moon is inclined by about 1°.5 to the ecliptic (6°.7 to the lunar orbit), and that the rotation axis always lies in a plane perpendicular to the line of nodes of the lunar orbit on the ecliptic. Thus, the axis precesses in space with the same period of 18.6 years as the nodes. The synchronism and the axial precession are evidence of a gravitational resonance in which the Earth controls the Moon's spin. The apparent monthly oscillations that result are due primarily to the parallax of an Earth-bound observer. The Moon does oscillate in its rotation, but these wobbles, called librations, are so small as to be undetectable except by precise observation.

Physical librations. The Moon is not spherically symmetric (see below, *The mass and gravity of the Moon*). The gravitational attraction of the Earth on the excess mass in the irregularities of the Moon's shape produces torques that influence rotation. Even the Cassini motion is caused by a bulge on the Moon along the principal axis pointed in the mean direction to Earth. The Earth's pull tends to bring its satellite back into line following any movement (caused by variations in the Moon's orbital speed) away from the true Earth direction. Consequently, the actual rotation forced by gravitational attractions includes a complex pattern of small motions that can exceed 100 arc seconds in selenocentric (Moon-centred) rotation. These motions are called physical librations. Since they arise entirely from gravitational action, they can be calculated from mathematical theory, following principles laid down by Sir Isaac Newton and Leonhard Euler. Such theories have only arisen in the past century, owing to the difficulties of observation; they are now constructed both by analytic methods and by numerical integration, similarly as (and sometimes simultaneously with) the lunar orbit theories.

Free librations. The lunar surface shows evidence of many impacts by external bodies, both large and small. In any such impact, much of the energy of the impacting object is transmitted to the Moon. Some of that energy produces yet another rotational motion, a type of Eulerian oscillation that, in specific reference to the Moon, is called free libration. The mathematical theory of rotating bodies specifies that these free librations will occur at only three frequencies, the periods of which are predictable from the physical properties of the Moon. Since these librations depend on the size and direction of the impacting object, however, their amplitudes cannot be predicted and can be determined only from observation. Once stimulated by an impact, the free librations gradually disappear by internal friction, and so are expected to be very small. The first claim of detection of a free libration was made in 1967, but this now seems spurious; modern data appear to show a free libration in longitude, but it cannot be larger than a selenocentric rotation of 2 arc seconds, 0.01 arc second as seen from the Earth.

Interpretation of small irregularities in the motion. The lunar motion provided Newton with the key to universal gravitation, and it has remained for three centuries one of the most difficult and fruitful practical problems in celestial mechanics. In conjunction with new methods of observation of unprecedented accuracy, recent work has confirmed the classical value of tidal friction, given evidence of a dense lunar core, determined the location and motion of the equinox, invalidated the Brans-Dicke scalar-tensor relativity theory, suggested a weakening of gravity, and improved knowledge of the shape, mass, and gravity field of the Moon. In the 1970s, the accuracy of the theories of both the orbit and rotation of the Moon was improved by a factor of nearly 100.

Such discoveries were made possible by the analysis of small irregularities in the observed motion of the Moon. For each observation, the mathematical theory is used to compute the place at which the Moon (or, more correctly, the observed point on the Moon) should have been if all aspects of the theory were correct. When this computation is compared with the observation, there remains a small difference, called a residual. When residuals from many observations are compared, systematic patterns appear that are clues to errors or omissions in the mathematical theory. Each contributing phenomenon (*e.g.,* mass, gravity, or observer's location) has a characteristic "signature" in the residuals. Improvement of the mathematical theory, or the discovery of new phenomena, is then derived from an analysis of the residuals to recognize and explain various signatures, many of which are present in the same data. It is essentially a problem in mathematical decoding. For example, in the 19th century, gravitational theory could not explain all of the motion of the Moon then observed. At first, this failure was thought to be due to a deficiency in the orbit theory. It was later shown to be caused, however, by previously unknown fluctuations in the Earth's rate of rotation. These fluctuations affect the apparent motion of all celestial objects, but the magnitude of the effect is proportional to the object's orbital speed, and so it was first discovered in the lunar motion. From 1954 to 1976, observations of the Moon were used to refine the determination of time from the rotation of Earth; more precise refinements are now achieved by the use of atomic clocks.

Using new techniques of occultations, radio interferometry and laser ranging, much finer details of the lunar orbit and rotation are now observable than was formerly possible. Such data are, in fact, so precise that it is no longer feasible to consider the orbital and rotational motions of the Moon as unrelated subjects.

An occultation is the disappearance or reappearance of a star from the view of an Earth-based observer as the Moon passes in front of it. In a normal occultation, there is one disappearance and one reappearance in a given event. In a grazing occultation, however, the edge of the Moon's disk passes in front of the star so that the star disappears behind each of a series of lunar mountains and reappears in each of the valleys between them. In both cases, measurements of the lunar surface can be made; these measurements can be accurate within a few metres at the Moon, but their further refinement is limited by the Moon's topography. Occultations have been used primarily to study the shape of the Moon and the long-term evolution of its orbit, including the effects of both tidal friction and the possible weakening of gravity.

Very long baseline (radio) interferometry (VLBI) is used to determine the direction of a celestial source of radio waves. It measures the parallax effect of two simultaneous observations of radio waves by Earth-based stations separated by large distances. The Moon is not a natural source of radio waves, and so radio transmitters were landed on the Moon by various spacecraft to send such radio signals back to Earth. Another technique of lunar observation is that of lunar laser ranging (LLR), which provides measurements of the Moon's distance from Earth. Like VLBI, LLR required the placement of man-made devices—in this case, passive reflectors, or mirrors—on the lunar surface. In LLR, a short light-pulse is emitted through an Earth-based telescope to the Moon, where it is reflected from one of the mirrors back to Earth, where the light travel-time is measured. Although LLR observations have been made at several places, more than 95 percent of them have been made at McDonald Observatory, where an LLR program has been in operation since the landing of Apollo 11 on the Moon in 1969.

Both VLBI and LLR provide data on the position of the Moon that is accurate within a few centimetres. Using these techniques, important discoveries have been made since 1969. In the question of gravitational theory, for example, the lunar motion continues in its important role; new data have shown the so-called Nordtvedt effect, a violation of the principle of equivalence, to be essentially zero, thereby eliminating the Brans-Dicke-Jordan theories of relativity as serious alternatives to Einstein's general relativity theory. No convincing evidence has yet been found for a variation of the gravitational constant, a variation required by some theories of relativity. In other results, terrestrial tidal friction has been found to affect the lunar

Nordtvedt effect

longitude by an acceleration of −24 arc seconds per century per century, a value consistent with that discerned by Sir Harold Spencer-Jones in 1938, but only half that believed to be correct in 1970. The principal moment of inertia of the Moon as now measured indicates a significant increase of density toward the Moon's centre, which suggests the existence of a small metallic core. Finally, measurements of free libration are consistent with, but do not prove, the hypothesis that the Giordano Bruno crater was formed on the lunar surface by a meteorite impact witnessed from Earth in AD 1178.

THE MOON'S MASS AND GRAVITY FIELD

Until the era of space exploration, the mass and the gravity field of the Moon were only determinable by their effects on telescopic observations of the apparent motions of the Moon and stars. As late as 1965, the ratio, μ, of the Moon's mass to that of the Earth was calculable only to three figures, and knowledge of the lunar gravity field was so scant that a hollow Moon was still a mathematical, if not a physical, possibility. It was evident, however, that the Moon was of significantly lower density and of less spherical shape than the Earth. Knowledge of both the mass and the gravity field of the Moon was markedly improved by the spacecraft missions of the 1960s and '70s and by the use of radio interferometry and laser ranging techniques.

The mass of the Moon. The mass of a celestial object can be determined only from the gravitational effects of that object on others and can be expressed only in a ratio with respect to a "standard" celestial mass. In studies of the solar system, as in stellar astronomy, the standard mass used for such calculations is that of the Sun; a secondary standard mass, that of the Earth, is also used for the mass of the Moon. The total mass of the Earth–Moon system, in solar units, is best determined by comparing the geocentric orbit of the Moon with the heliocentric orbit of the Earth–Moon system, using Kepler's third law relating the orbital periods, distances, and masses of bodies in the solar system. Recent determinations from very long baseline interferometry (VLBI) and lunar laser ranging (LLR) calculations give a value of 328,900.5 for the mass ratio Sun: (Earth + Moon).

Results of VLBI and LLR

Accurate separation of the masses of the Earth and Moon requires an analysis of their gravitational influence on other nearby bodies, such as spacecraft leaving the Earth–Moon system for other planets. Roughly speaking, the Earth and Moon both describe elliptical paths about their common centre of gravity, or barycentre, and the ratio of the sizes of these ellipses is the inverse of the ratio of the Moon's mass to that of the Earth, or μ. (Since μ is about 1:81, the Earth's centre is about 4,700 kilometres from the barycentre, which is itself, therefore, always within the body of the Earth.) For distant objects, the gravitational influence of the Earth–Moon system is essentially that of a single planet of their combined mass. For a spacecraft beyond the Moon's orbit but not yet in the vicinity of Venus or Mars, however, the Earth and Moon each produce distinct effects that appear as monthly perturbations in the spacecraft's motion. Data of such perturbations have been obtained from all interplanetary spacecraft since Mariner 2 was launched in 1962; the resulting calculation of the value of the Moon/Earth mass ratio is $\mu = 1/81.3007 = 0.012300$. The Moon is thus only 1/26,410,940 the mass of the Sun.

By far the least accurate step in determining the mass of the Moon is the next, which requires the value of the mass of the Earth as measured in grams and relies on measurements of the Earth's surface gravity and radius. With a value for the Earth's mass of 5.977×10^{27} grams, the mass of the Moon is 7.352×10^{25} grams.

The gravity field of the Moon. A celestial object that is spherically symmetrical exerts a gravitational influence on other bodies that is equivalent to that of an infinitesimal point of the same mass. Any irregularities of shape, however, affect the gravitational field of such a body. Thus, to speak of the gravity field of a body is to discuss its departures from sphericity. A discussion of a gravity field can be conveniently separated into three categories: triaxiality, gravity harmonics, and local gravity anomalies.

Tri-axiality. Any body that is not a perfect sphere has an axis of greatest moment of inertia, *C*. This axis is usually that about which the body rotates, perpendicular to the body's equator. The axis of least moment of inertia, *A*, is usually in the equator. Perpendicular to both axes is the intermediate axis of inertia, *B*. These three axes are the parameters of any tri-axial body. In the case of the Earth, the Equator is virtually circular, so *A* and *B* are essentially equal, and the Equator bulges like a belt around the planet. The Moon, however, apparently never rotated fast enough to distribute its mass evenly in circumference and, consequently, it bulges in only one direction—along the Earth–Moon line. The differences of the principal moments of inertia of the Moon are not enormous, but they are important: $(B-A)/C = 0.00023$, $(C-A)/B = 0.000631$, $(C-B)/A = 0.00040$. These figures represent the ellipticities of the lunar equator, the polar section in the Earth–Moon direction, and the polar section normal to that direction, respectively.

The lunar tri-axiality was known and taken into account in the lunar orbit theories of the 19th century and the lunar rotation theories of the early 20th century. More detailed knowledge of the lunar gravity field was not to come until a spacecraft, Luna 10, was first sent into orbit around the Moon in 1966. The Moon is exceedingly lumpy, and the three-dimensional average given by the principal moments of inertia does not describe the gravity field accurately enough for present-day observations.

Gravity harmonics. In mathematical theories, it is the preferred practice to describe the gravity field of a body in spherical harmonic functions. In such a scheme, the non-spherical perturbing potential acting at an external point of distance, *r*, longitude, *l*, and latitude, *b* (all three being referred to the perturbing body's equator), is written as:

$$\Sigma\Sigma\ (1/r)^{\mathrm{n}}\, P_{\mathrm{nm}}(\sin b)\ (C_{\mathrm{nm}}\cos \mathrm{m}l + S_{\mathrm{nm}}\sin \mathrm{m}l)$$

where, in principle, the summations cover all values of $\mathrm{n} > 1$ and all non-negative values of $\mathrm{m} \leq \mathrm{n}$. In practice, the term $(1/r)^{\mathrm{n}}$ diminishes rapidly as n increases, so only a limited number of terms is required. The coefficients *C* and *S* are numerical quantities, called the gravity harmonic coefficients, that describe the shape of the gravity field; they can be determined only from observation. The principal moments of inertia are equivalent to the parameters C_{20}, C_{22}, and S_{22}. A description more detailed than tri-axiality requires a determination of the harmonic coefficients for $\mathrm{n} > 2$. Most of the values for $C_{3\mathrm{m}}$ and $S_{3\mathrm{m}}$ are obtained from LLR and VLBI observations by analysis of the residuals. More detailed structure of the harmonic field is only possible from analysis of the motion of artificial lunar satellites. A combination of LLR and lunar orbiter data has been used to determine the values of the gravity coefficients up to $\mathrm{n} = 5$.

Gravity harmonic coefficients

For most bodies, the values of *C* and *S* are expected to diminish significantly as n increases. For example, for the Earth (using units of 10^{-6}), $C_{20} = -1{,}083$, $C_{30} = -2.4$, and most of the remaining coefficients are negligible except for close artificial satellites. The irregularity of the Moon is illustrated by the corresponding values of its harmonic coefficients: $C_{20} = -202$, $C_{22} = +22$, $C_{30} = -12$, $C_{31} = +31$, $C_{32} = +5$, $S_{31} = +6$. Even some of the coefficients with $\mathrm{n} = 4$ and $\mathrm{n} = 5$ are significant at this level.

Local gravity anomalies. The Moon is the only body known for which the usual harmonic representation of the gravity field does not suffice for all purposes. Early analyses of tracking data from the first U.S. lunar satellite launched in 1966 produced unexplainable irregularities. The residuals showed curious oscillations that were reported by subsequent spacecraft, but not in any decipherable pattern, constituting a serious operational problem for two years. Attempts to solve the problem at first concentrated on improving and extending the set of harmonic coefficients. In 1968, it was shown that these effects were due to anomalous accelerations as the spacecraft passed over certain of the lunar maria, indicating unexpectedly large masses in those regions. It has since been shown that such concentrations of mass—popularly known as mascons—exist in all of the ringed maria. Though large enough to produce observable effects on the spacecraft, the mascons are too small to be represented by the harmonic coefficients.

In terms of the Moon's gravity field, Mare Orientale is unique. It looks rather like a giant target, complete with rings, as though a meteorite had splashed into a partly molten surface that solidified before the waves subsided. In fact, the local gravity field shows the same features, with alternating rings of excess gravity and gravity defect. This is one of the few cases on the Moon in which there is a clear-cut correspondence between the shape of the gravity field and the shape of the lunar surface.

(J.D.Mu.)

THE PHYSICAL NATURE OF THE MOON: SELENOLOGY

Observations from the Earth and from space vehicles. *Limits of resolution.* Lunar craters of the order of 100 metres in diameter may be seen from the Earth under the best conditions using moderately sized telescopes, and, because, in practice, resolution depends on the shape of an object and on its contrast with the surroundings, the same instruments can be used to view lunar lineaments (linear features), such as rilles, considerably smaller than 100 metres in width, provided they are many times longer than 100 metres. The best Earth-based photographs of the Moon show some (the sharpest) craters as small as 500 metres in diameter. Photographs from space vehicles have resolved details in some cases as small as a metre.

The first far-side pictures

The first camera was put into an orbit passing behind the Moon (October 1959) by the Soviet Union. Its useful photography was confined to some 70 percent of the Moon's averted hemisphere lit by a high Sun, and both the picture quality and the resolution were poor by the standards of Earth-based telescopic photography. Useful far-side photographs were obtained from another Soviet space vehicle, which completed the lunar far-side coverage in July 1965, and from a third, which provided higher resolution coverage of a limited portion of the far side. A number of ray craters (see below) were readily identifiable, but the most surprising observation was that most of the far side of the Moon contained no maria. Major crater chains, up to 1,000 kilometres long, were found.

Small-scale details. The photography from a series of vehicles designed to crash-land on the Moon and relay television pictures to Earth prior to crashing was not successful until July 1964, when a U.S. probe approached and crashed in a part of Mare Nubium; the area was renamed Mare Cognitum by the International Astronomical Union. For the first time, more and more small craters were seen as the vehicle effectively decreased the lunar-surface resolution to a limit of about 50 centimetres. Craters of various shapes, rock blocks, and ridges 100 to 1,000 times smaller than any that had been seen before were recorded during the last minutes of descent.

The Moon was found to be cratered more heavily than had been predicted, and the substantial excess of craters was attributed both to the mechanism of secondary cratering—that is, crater formation by objects ejected from a primary meteoric (or volcanic) cratering event—and to endogenic cratering—that is, crater formation by internal processes such as outgassing or collapse. A few dimple-shaped craters, probably the result of drainage of the Moon's veneer of fragmental rock into subsurface fractures, were discovered. Many more were later found in Mare Tranquillitatis and in the structure of Alphonsus, a crater 110 kilometres in diameter. None of these craters has the bowl- or saucer-shaped profile characteristic of a fresh, sharply sculptured (eumorphic) explosion crater or of an older, denuded (submorphic) explosion crater. On the other hand, the majority of the craters less than a kilometre in diameter could well be explosion craters produced either by high-speed impact or by violent outgassing (explosive volcanism).

Mare Cognitum is traversed by faint rays of lighter hued material. The lunar rays that emanate from many craters are generally thought to be composed of small craters and blocks of rock. A certain proportion of the craters set in rays may be secondary-impact craters. In one cluster of craters, chains (linear arrays) of both sharply sculptured and older craters trend in a given, narrow range of azimuth. It is not known whether the two types of crater were formed as respective secondaries when hard and soft material landed to produce craters at the same time and at the same distance from some primary crater; or if the eumorphic and submorphic craters were formed internally at widely different times, the latter being formed first and then undergoing denudation.

The lunar regolith

The principal erosive force on the Moon at the present time is probably that of meteoric impact. Primary meteoroids are increasingly the more numerous with diminution in size, so that micrometeoroids are probably the principal factor involved in the attrition of freshly formed surfaces on the Moon. The net direction of movement of material sprayed from a meteoric cratering event is downslope; and this downward migration of rock fragments tends to level the lunar terrain and to generate a ubiquitous veneer of particles that is variable in thickness from one locality to the next. This layer, known as the lunar regolith, is composed of fines, particles less than one centimetre and mostly much less than one millimetre in size, and of larger fragments of rock. The process of impact mixing of the lunar soil and the particles of the regolith is sometimes referred to as "impact gardening."

Some of the blocks of rock photographed on the Moon appear to be partially buried in the regolith, and a first estimate of the strength of the lunar-surface materials was made from considerations of the depth of penetration of these blocks and the distances they had been thrown. A bearing strength of about one kilogram per square centimetre found for this part of the Moon showed that it was strong enough to support a man clad in a spacesuit or any of the planned soft-landing craft. Following the first soft landing of a spacecraft, Luna 9, on the Moon, in February 1966, the Soviets determined the soil in Oceanus Procellarum to have a bearing strength of at least several kilograms per square centimetre.

It appears to have been confirmed that some of the small craters of the Moon are of internal origin, though it is still believed that the vast majority of these craters are of impact origin. Several chains of contiguous craters are generally thought to be secondary craters from Theophilus, a crater 85 kilometres in diameter, even though many of them run nearly parallel to tectonic lineaments such as linear ridges and troughs—a situation indicative, instead, of an endogenic origin of these craters. The blocks of rock, up to 100 metres in diameter, are commonly scattered in and around craters that were probably deep enough to cut through the friable regolith into cohesive bedrock. It has been argued that this bedrock would have been excavated and tossed, as blocks, from a crater during its formation.

The rilles

Many rilles (lunar trenches of lengths up to a few hundred kilometres and widths up to a few kilometres) have been photographed by space vehicles. Those recorded in Alphonsus are particularly interesting because of the intimate connection between the rilles in the floor of the crater and dark halo craters that lie in the rilles. Exceptionally dark deposits encircling these craters have tended to obliterate underlying relief and, locally, fill the rilles. The craters themselves are elongated along the axis of a rille and are without raised rims—characteristics that point to internal origins. The associated dark deposits were probably erupted as sprays of pyroclasts.

In the next phase of lunar exploration, closeup television photographs of the landing feet of a soft-landing vehicle in June 1966 (within a large ring structure, known as Flamsteed P, in Oceanus Procellarum) showed that the feet had penetrated a few centimetres into the ground and had disturbed the soil around them, giving it a darker appearance in the process. Stones and blocks of rock were found to vary considerably in appearance. Some appeared to be partly buried, their surfaces smoothed by erosion. Some appeared to have been put on the surface and to have remained in their original, angular configurations. Some had different shapes and numbers of pores (vesicularity) and different structure (layering and differential denudation) or, possibly, composition (tonal differences and the presence of inclusions).

Similar results were found from other probes soft-landed in Mare Tranquillitatis and in Sinus Medii in missions

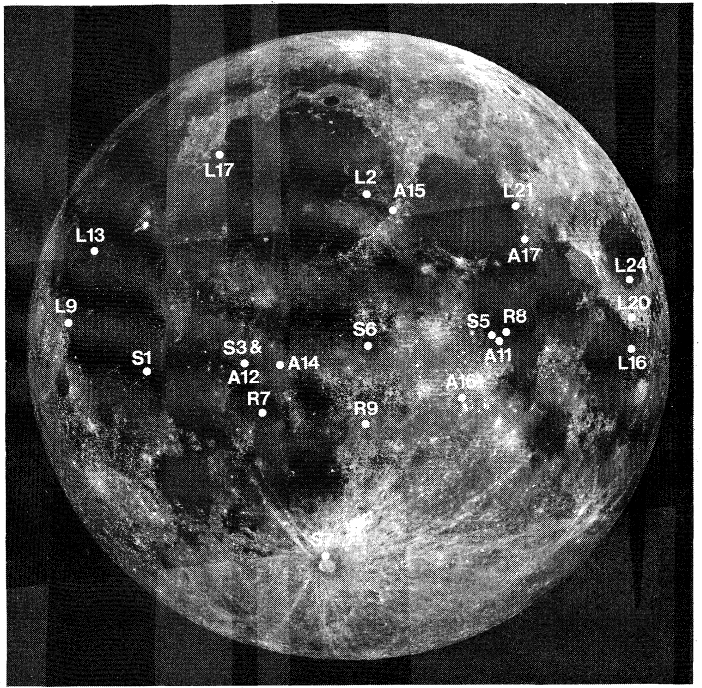

Figure 21: The side of the Moon visible from the Earth, photographed at Full Moon. The approximate points of landing are shown for selected U.S. and Soviet spacecraft on the Apollo (A), Ranger (R), Surveyor (S), and Luna (L) series. Three dark "seas," left to right, just above centre, are Mare Imbrium, Mare Serenitatis, and Mare Tranquillitatis. Tycho crater lies at bottom centre, just below landing site S7.

By courtesy of the Lunar and Planetary Laboratory, University of Arizona

meant to examine possible landing areas and analyze the soil. One mission was sent 42° south of the lunar equator to examine, for the first time, part of the Moon's highland domain. It landed (January 1968) successfully within what was, by comparison with the area of the highlands around Tycho, a fairly smooth area. The television cameras, however, showed the terrain to be strewn with many more blocks of rock per unit area than had been found in the maria. The most revealing discovery concerned the composition of the rocks; the percent weights of elements in rocks were estimated, and the landing area was found to be similar in composition to the mare samples, with the exception that the iron-group elements (mass numbers 47 to 65) were less abundant in the highlands.

Data on rock composition

The elemental composition of the rocks at three sites approached that of some terrestrial basalts (types of dark igneous rock). The tested areas of the Moon were compositionally unlike chondrites—the most common kind of meteorite—and analyses indicated that the Moon had been differentiated and heated. The theory that the Moon originated as a cold body and has never been heated suffered a serious blow, although the heating might have been the local result of major impacts. Later analyses of rocks returned to Earth provided further information on heating (see below).

Results from manned lunar landings. The first manned lunar landing was made in July 1969 in Mare Tranquillitatis. Some 22 kilograms of lunar rocks were collected and returned to Earth for study.

Later manned landings were in the Fra Mauro highlands of Oceanus Procellarum, between the Apennine Mountains and the Hadley Rille in Mare Imbrium, in the highlands near Descartes, and in the Taurus Mountains. Each landing added to the store of lunar rocks returned to Earth, and each crew left behind functioning observing instruments. A seismometer, a device commonly used to measure earthquakes, was included in each of the first five scientific packages of the manned landing missions.

Though the first seismometer failed after only a short operating time, the others worked simultaneously. In registering the vibrations generated by impacts and moonquakes, they have provided valuable information about the frequency with which meteoroids strike the Moon and also about the slight, relative movements of rocks along lunar faults or other slip surfaces. Other data revealed by instruments included the behaviour of lunar material at depth and the probable nature of the rocks at various depths and localities.

In addition to impacts by meteoroids, the Moon is subject to thousands of minor quakes each year. Most of them are triggered by the Earth's changing tidal pull, which, during each lunation, is greatest when the Moon is at its closest point to the Earth. Lunar seismic signals are characteristically different from any received at terrestrial seismic stations, the difference indicating that the Moon's rocks scatter and transfer energy much more efficiently than do Earth rocks. The reason is probably to be found in the dryness and the fractured or fragmental nature of the outer parts of the Moon. Lunar quakes originate from depths about halfway from the surface to the centre of the Moon; observations are consistent with the theory that there is some plasticity or melting of some of the rocks at these depths. Indeed, heat-flow measurements at two localities showed a thermal output of 0.03 watt per square metre—a value as high as one-half of the mean output of heat from the Earth.

Origin of lunar quakes

Missions have also landed a type of optical reflector on the Moon, capable of returning to Earth extremely accurately timed laser pulses for reception by large telescopes. (See above, *Interpretation of small irregularities in the motion.*) Other instruments left behind on the various manned landings provide continuing physical and geophysical data. Earlier measurements of the physical properties of the lunar environment using crash-landing and orbiting vehicles were supplemented or superseded by the results drawn from the later missions. (For sites of the impact or landing of significant lunar missions, see Figure 21 and Table 8.)

Table 8: Impact or Landing Sites of Successful Lunar Spacecraft

name and launch date	remarks
Luna 2 Sept. 12, 1959	first man-made craft to impact the Moon
Ranger 7 July 28, 1964	first craft to obtain high-resolution (one metre) television pictures
Ranger 8 Feb. 17, 1965	similar mission to Ranger 7
Ranger 9 March 21, 1965	similar mission to Ranger 7, but in highland region
Luna 9 Jan. 31, 1966	first craft to soft-land and relay panoramic and close-up pictures from lunar surface
Surveyor 1 May 30, 1966	first U.S. craft to soft-land and relay panoramic and close-up pictures from lunar surface
Luna 13 Dec. 21, 1966	similar to Luna 9, but also tested lunar soil hardness
Surveyor 3 April 17, 1967	similar to Surveyor 1, also first craft to dig trenches
Surveyor 5 Sept. 8, 1967	similar to Surveyor 1, also first craft to analyze lunar mare soil
Surveyor 6 Nov. 7, 1967	similar to Surveyor 5
Surveyor 7 Jan. 7, 1968	similar to Surveyor 5 and 3, first soft landing in highlands
Apollo 11 July 16, 1969	first manned landing (Mare Tranquillitatis)
Apollo 12 Nov. 14, 1969	first manned landing near an unmanned craft (Surveyor 3)
Luna 16 Sept. 12, 1970	first unmanned craft to return lunar soil to Earth
Luna 17 Nov. 10, 1970	first unmanned craft to deploy a roving vehicle (Lunakhod 1)
Apollo 14 Jan. 31, 1971	first manned landing in highland region (Fra Mauro)
Apollo 15 July 26, 1971	first manned landing to use roving vehicle (Hadley Rille)
Luna 20 Feb. 14, 1972	similar to Luna 16, but highlands sample instead of mare
Apollo 16 April 16, 1972	similar to Apollo 15, but in highland region (Descartes)
Apollo 17 Dec. 7, 1972	similar to Apollo 16, but sampled highland and adjacent valley
Luna 21 Jan. 8, 1973	similar to Luna 20, but landed in Le Monnier
Luna 24 Aug. 9, 1976	similar to Luna 20, but landed in Mare Crisium

Data from closeup photographs. Increasingly valuable photographs of the Moon were taken by the astronauts on succeeding missions, both from orbit and from the surface. Many of the rock samples were photographed in relation to their surroundings prior to removal from the Moon's surface, to assist in later interpretations (the broad setting from which a rock is drawn is important to an investigator in any comprehensive geological study).

The lunar photographs by no means record all possible bits of lunar surface, but vast amounts of unmeasured, unprocessed data are stored in existing photographs. From them, lunar craters have been measured for size, shape, and depth (from shadow measurements): crater counts have been used in estimates of the terrain roughness and in statistical studies bearing on the origin of the craters. The roughness of lunar rock blocks, estimated from photographs and returned samples, has been related to theories of denudation (wearing down) and aging. Lunar-surface processes, such as transport of the material and impact mixing, have been studied using photographs alone. Lava flows covering large areas of the maria have been detected and mapped using Earth-based infrared and ultraviolet photographs in combination with photographs taken from lunar orbit. The brightness contrasts displayed by different rock units have been measured from Full Moon photographs. Slopes have been assessed from shadows under different Sun angles. Topographic maps have been prepared. Texturally distinct geological units have been mapped and used to produce a lunar stratigraphic column of relative ages. Faults and other tectonic lineaments have been recognized on the photographs.

Porosity of topsoils

The photometric function. Scientists correctly reasoned, in the early 20th century, that the Moon's photometric function (changes in the intensity of scattered sunlight with different angles of illumination and reflection) proved that the lunar surface was far from smooth on a centimetric scale. The respective scattering properties of highland and mare material were deduced in 1956, when it was shown that the lunar surface in both the lunarite and the lunabase was extremely irregular and porous and that both types of terrain displayed essentially similar surface structure. Slight differences were observed in the way light was scattered by lunarite (highland) and lunabase (maria) material, and these differences indicated that, in general, there was a slightly greater roughness (more irregularities, or pores, per unit of surface) in the lunabase. In a more sophisticated analysis made in 1971, it was estimated that the porosity (fractional pore space) of the highland topsoil had an average value of 60 percent and that the mare topsoil averaged 80 percent. The measured values of the Moon's surface porosity at specific sites are not generally in conflict with these overall results.

The reason for the different structure in the uppermost centimetre or so of the lunarite and lunabase may be found in a study of the differential denudation or of the different histories of outgassing of the two types of terrain. Processes such as mass wastage—that is, downslope migration of material under gravity—may be expected to play a relatively important role in the highlands. Therefore, there may well be a tendency for craters and pores in the highlands to be smoothed over more quickly than corresponding features in the maria. On the other hand, the outgassing of the mare materials is believed to have occurred later than much of that in the highlands; and the initial porosity of the two types of material probably differed as well.

The packing of lunar fines

A special use of photometry is in the determination of the packing of lunar fines (small particles and dust). The acceleration caused by the Earth's gravity is six times that of the Moon at their respective surfaces, so that fines scooped from the Moon and transported to Earth will undergo an increase in their state of compaction. Agitation, severe during parts of the journey back to Earth, assists the process of compaction. The undisturbed fines and samples returned to Earth will scatter light in different ways, and it is possible, by rearranging the compacted fines into various states on Earth and comparing them with remote lunar observations, to deduce their approximate surface state before they left the Moon.

It is difficult to visually assess large-scale colour contrasts on the Moon from the Earth. A profitable investigation of lunar colour contrasts may be made from ultraviolet and infrared photographs. The technique is useful for surveying extensive areas of the Moon for differing rock units.

Certain parts of the Moon strongly absorb ultraviolet light. Such an absorption can be produced by traces of the element sulfur, for example. At the other end of the spectrum, lunar rocks display characteristic absorption bands in their infrared reflection spectra. One such prominent band, at a wavelength of about one micron, is due to the presence of iron in certain lunar materials.

Another instructive technique is that of plotting the photometrically determined colours of discrete patches of lunar terrain against their respective albedos and comparing the resulting colour-brightness diagram with others constructed for a wide range of terrestrial rocks prepared in widely different forms. It is found that blocks of terrestrial-type rock, or meteorites, cannot cover more than a small fraction of the lunar surface, although many rocks ground to powders and then irradiated with protons (to simulate the effect of particles from the Sun striking the Moon) have been found to approach the lunar domain of the colour-brightness diagram.

The lunar soil

Lunar polarization studies. A much more powerful optical method of studying the nature of the particles of lunar soil is that in which polarization curves are utilized. Polarization is a wave property of light, and different substances have different characteristic polarization curves. At a given lunar phase, the amount by which light from different parts of the Moon is polarized depends on the brightness of those parts: the brightest spots polarize no more than about 5 percent of the incident light, whereas the degree of polarization attains 20 percent or so for the darkest spots. These maxima were recorded at times close to those of the First and Last Quarters of the Moon. Most terrestrial rocks, whether solid or pulverized, polarize much more light than the Moon. The Full Moon polarizes no light, and practically no light is polarized when the Moon offers a very narrow, sunlit crescent. When the light intensity component in the Sun–Moon–Earth plane exceeds the corresponding component at right angles to this plane of diffusion, the maximum polarization in the visible (yellow light) is found to be − 1.2 percent for all parts of the Moon. The independence of the negative part of the polarization curve on the location on the Moon's near side indicates a fairly high degree of textural uniformity of this part of the lunar surface. Extensive laboratory experiments made with visual and photoelectric polarimeters, in attempts to narrow the choice of lunar surface models by careful comparison of laboratory and lunar polarimetric functions, have shown that the best match to the lunar soil at large is in dark, fine-grained basic to intermediate rocks.

Angle of inversion

In changing from positive to negative, the Moon's polarization passes through zero at a phase angle of about 23°, called the angle of inversion. The angle of inversion remains constant only when the behaviour of light of a particular wavelength is considered: the angle increases with wavelength (whereas the degree of polarization generally decreases as the light becomes redder). The maximum polarization, at a given wavelength, generally decreases as the particle size decreases. Reducing the grain size of a rock usually has the effect of increasing its albedo, and this, in turn, generally decreases its maximum degree of polarization.

It has been suggested that solar protons not only damage but also darken particles on the lunar surface. It is difficult to simulate all the appropriate aspects of the lunar environment in the laboratory, but it is clear that, if the solar wind were to darken fine particles derived from certain terrestrial rocks, their polarization functions could be made to approach or be rendered identical with those pertaining to the lunar fines.

Polarization studies of light-toned rocks brought from the Moon have shown that they either do not occur in large concentrations on the Moon's surface or they are generally covered with the fines responsible for the uniformity of the Moon's near-side polarization.

Infrared (heat) studies. Evidence of a widely dispersed layer of dustlike material on the Moon is given by measurements of infrared radiation from the Moon. The lag shown by temperature changes of the subsolar point during eclipse shows the very poor conductivity of the lunar surface in the eight- to 14-micrometre (one micrometre = 10^{-6} metre) waveband. Highlands and maria behave similarly, so the poorly conducting layer must cover most of the surface.

The poor surface conduction also produces differences in heat curves at different wavelengths. Measured at a microwave wavelength of 1.25 centimetres, the Moon's temperature attains a lower maximum than that determined by the eight- to 14-micrometre infrared measurements, and this lower maximum temperature occurs about 3.5 days later than the infrared maximum. The eight- to 14-micrometre radiation is from a surface layer only a millimetre or so thick, whereas the centimetre radiation comes from layers a few tens of centimetres beneath the surface. The Sun's heat generates the highest temperatures on the surface of the Moon, but deeper rocks are also warmed as the thermal wave penetrates and is attenuated in the poorly conducting regolith. Lunar radio emission derives from thermal energy finding its way to different levels in the Moon. Increasingly longer radio wavelengths have been used to observe the Moon at increasingly greater depths; but, although the average depth of the emitted waves increases with wavelength, the radiation at radio frequencies originates over a range of depths. In addition, the limit of angular resolution of a telescope increases with wavelength, so that, whereas the optical heat measurements may refer to a small patch of the Moon, the specific origin of the longer radio waves may be impossible to locate on the disk. At wavelengths above about 10 centimetres, no diurnal change in the intensity of received radiation has been observed. In these cases the upper layers of the Moon, which show strong diurnal temperature changes, are contributing a negligible fraction of the total radiation received.

Changes in temperature with depth

In principle, radio observations provide a means of estimating the variation of temperature with depth in the regolith and, thus, of investigating any internal heat source such as one that could be produced by widespread radioactive elements. The thermal conductivity at depth in the Moon, however, is not yet well-known, nor is it in the troublesome regolith, in particular, where the dependence of conductivity on temperature and depth is marked and thermal transport by radiation through incompletely specified vacuum pores contributes to the difficulties.

Theoretical models of the Moon's upper layers have been attempted, but it is not possible to derive the conductivity directly: density and specific heat must be determined first. Furthermore, the specific heat of lunar rock depends on its temperature: the specific heats of both a vesicular basalt sample and a sample of regolith from the Moon have been found to change smoothly from 0.06 calorie per gram per K at 90 K to 0.2 calorie per gram per K at 350 K. Such dependence on the prevailing temperature can change the thermal inertia of lunar surface materials by a factor of up to 2. A representative value of the thermal conductivity of the uppermost part of the regolith is about 2×10^{-5} watt per centimetre per K. Apollo measurements showed that, at depths of the order of one metre, this value was exceeded by a factor of 10.

The so-called hot spots

During optical infrared scans across the eclipsed Moon with a resolution of details of about 20 kilometres, numerous patches of terrain—mostly eumorphic craters—have been found to be significantly warmer than their surroundings. The most easily recognizable thermal anomalies (hot spots) were associated with bright-ray centres such as Tycho, Copernicus, and Aristarchus. These craters remained cooler than their surroundings during the lunar daytime, and the hot spots could be areas of higher than average thermal conductivity, permitting heat at depth to flow out during eclipse and be radiated to space more readily than from adjacent areas.

The night spectrum of Tycho, Copernicus, and Aristarchus, observed over the three- to 15-micrometre waveband, proved that the surface rocks of these craters emitted radiation from areas at widely different temperatures. Parts of the floors of two, Tycho (Figure 22) and Aristarchus, appear to be of ashy or regolith-type material, but other parts are probably volcanic domes apparently not covered by detritus or pyroclasts (substances fragmented by volcanic action). With geologically dissimilar rock units found in and around the craters, including lava flows with contorted surface ridging, such craters must be expected to generate cooling curves that are made up from several different cooling functions.

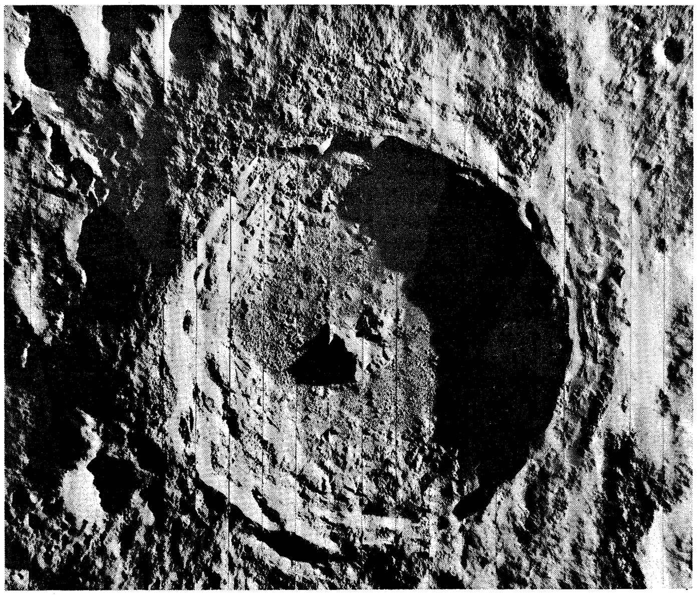

Figure 22: The lunar crater Tycho, in the lunar highlands. Picture obtained by the U.S. Lunar Orbiter 5.

By courtesy of National Aeronautics and Space Administration

The hottest craters are invariably the most sharply sculptured, freshest looking features. Large blocks of rock and characteristically rough terrain may be resolved around several of these craters, the hottest 20 of which have diameters from four to 16 kilometres in length.

There are relatively fewer hot spots per unit surface in the highlands than in the maria, and the number density of hot spots changes significantly from one mare to the next. The reasons are not well understood, though a tentative explanation may be offered in the case of Mare Tranquillitatis, which has an anomalously high number of hot spots per unit of its surface. First, there is a positive correlation between the number of eumorphic craters in the lunabase and the number of hot spots in the same area. Second, a study of the shape parameters of small, concentric craters suggests that at least the southern part of Mare Tranquillitatis has a thinner cover of regolith than most of the maria. It may be imagined that the sharpest eumorphic craters—which are almost certainly explosion craters—would be formed preferentially in areas of thin regolith, where the excavation of coherent bedrock could provide an abundance of ejected rock blocks.

Cold spots

A few cold spots have also been observed. Of the nine cold spots with the highest thermal gradients (those in excess of 5/7 K per second of arc), none is associated with a single, eumorphic crater.

Finally, there is the type of thermal anomaly in which a spot is observed to be hot during both eclipse and daytime conditions. Such a spot could be indicative of a source of internal heat.

Analysis of returned radar signals. For better understanding of the nature and origin of lunar thermal anomalies, more widely dispersed and improved estimates of the regolith thickness, layering, and conductivity are required. Analyses of radar signals returned from the Moon have proved of interest in this connection. The first part of a radar echo from the Moon returned to Earth derives from the central region of the Earth-pointing face. Later parts of the return signal come from rings of progressively increasing radii. Also, the lunar librational motions introduce frequency shifts in the return signals. As these effects are superimposed, it is possible to isolate the radar-reflection characteristics of two small patches on the Moon. Anomalously strong radar reflections were obtained in 1962 from Tycho and the corresponding area in the Moon's northern hemisphere. The latter had no topographic peculiarities, and it was concluded that Tycho was probably responsible for the anomaly: either the terrain in and around Tycho was much rougher than that in any other equal area of the Moon's near side, or the rocks of Tycho were much denser than those elsewhere. Since that time, photogeological studies of high-resolution pictures of the Tycho area have shown that it is indeed rough.

Radar has been used, further, to estimate the porosity of lunar-surface materials. On radar wavelengths of 10 to 100 centimetres, the effective dielectric constant (its ability to store electrical potential energy) of the lunar surface lies in the range of 1 to 2.7. To calculate its actual porosity, this can be compared with the assumed dielectric constant of its solid component. Returned fines have been used to estimate that the density of the solid rock is about three grams per cubic centimetre and that the corresponding dielectric constant at 450 megahertz is about 6. These figures, with a mean observed lunar dielectric constant of 1.6, show that the average porosity of the lunar surface layers may be more than 80 percent. The results compare favourably with those from Earth-based photometry, although the two methods refer to data from different areas and different effective depths.

Relative reflectivity

Radar studies of the relative reflectivity of small areas of the Moon's surface at 2.2 metres in wavelength involving the circumlunar satellite Explorer 35 show that, on average, the maria reflect approximately 30 percent more power than the highlands; and reflectivity structure was observed in the lunabase, a particularly high reflectivity being associated with a region near the crater Flamsteed. There appears to be a significant correlation among radar reflectivity, hot spots, and regolith thickness; both the radar reflectivity and the number density of hot spots increase as the thickness of regolith decreases. The effective (mean) dielectric constant of the lunar rocks (lunarite and lunabase together) down to depths of several tens of metres is about 3, slightly more than the mean value of the dielectric constant of layers nearer the surface measured on shorter wavelengths from the Earth. The porosity of the lunar rocks should decrease, on average, with depth as, in a fragmental, or granular, regolith, the weight of the overburden will cause increased packing as the depth increases. This would explain the observed increase of thermal conductivity with depth.

Gamma-ray spectroscopy

Physical experiments from orbiting spacecraft. Early physical experiments conducted by the Soviets from circumlunar orbits included a gamma-ray-spectroscopy experiment carried aboard the first artificial lunar satellite. Gamma rays are emitted by lunar radioactive elements, particularly potassium, uranium, and thorium, and the character of the emission can indicate whether the Moon has been chemically differentiated. Cosmic rays incident on the Moon induce a much higher intensity of gamma-ray emission than that deriving from natural radioactive decay in the lunar rocks. Nevertheless, Soviet scientists deduced that the surface rocks of the Moon were of the basaltic type and that a slightly greater intensity of gamma radiation derived from the maria.

Gamma-ray spectrometry from two Apollo modules in lunar orbit achieved further results. Not only were the maria found to be more radioactive than the highlands but the western mare units (*e.g.,* Oceanus Procellarum) were, in general, higher in the radioactive elements of uranium, thorium, and potassium than were the eastern maria. In general, the higher and the more light toned the lunar rocks, the less they exhibited radioactivity. The same modules also carried X-ray fluorescence spectrometers that were used to determine the ratios of aluminum

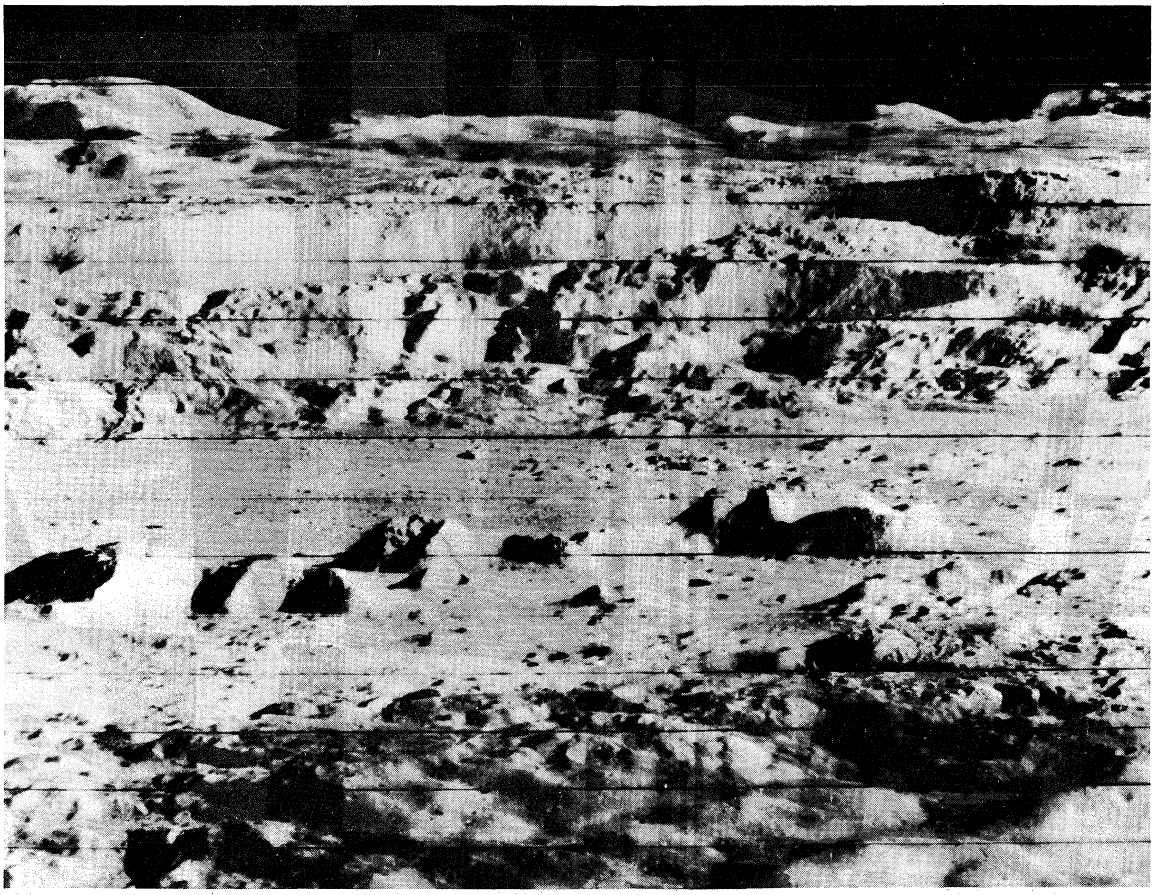

Figure 23: Crater Copernicus as photographed in November 1966 by Lunar Orbiter 2 from a height of 45.7 kilometres, looking due north from a position above the crater's southern rim. The mountains rising from the flat floor of the crater are about nearly 460 metres high; the 914-metre mountain Gay-Lussac, on the horizon, is part of the Carpathian range.

to silicon and magnesium to silicon. The lighter toned highland materials were found to be higher in aluminum and lower in magnesium than the dark-toned maria. All these results were consistent with the theory that the Moon had been chemically differentiated. Other U.S. experiments from orbit included gravity profiling—in which some of the mascons (see above), determined earlier, were evaluated in more detail and other, smaller mass concentrations were discovered—and heat flow measurements, in which hot spots and cold spots, similar to those discovered telescopically, were found.

TYPES OF LUNAR FEATURES

Lunar craters. The ubiquitous nearly circular features on the Moon have all come to be called craters; the traditional terms "ring plain" and "walled plain" describe, respectively, round and irregular lunar features with walls encompassing relatively smooth, level floors.

Forms of craters

Lunar craters, in the broad sense, may be classified, first, on the basis of their form. Many intermediate-sized craters, in particular, display mountain blocks or hills near their centres. The inner (and, to a smaller extent, the outer) walls of many craters are terraced, or benched.

Although in a lunar photograph (see Figure 21) the majority of the lips of crater rims (walls) appear to be approximately circular, it is common to find that, in detail, the actual shapes better approximate some polygon or an ellipse. A number of lunar craters have ellipticities greater than 30 percent. Some of the so-called craters have a spiral inner ringwall lower than the outer; there are craters with eccentrically placed inner craters and plateau craters that seem to have been filled with dark material.

Bowl-shaped craters with parts of the floor darker than the inner slopes are common among lunar craters less than 20 kilometres in diameter. They may be as much as three kilometres deep, with inner slopes of up to 50° and outer rims sloping at up to 20° near the lip. The shallowest "saucer" craters have the surfaces of their rims inclined to the horizontal at no more than a few degrees. Crater pits are those without raised rims. Funnel- or dimple-shaped crater pits with convex inner walls near their lips have been discovered in photographs.

Ray and dark-halo craters

A crater may be classified also by the neighbouring craters or other features that appear to be associated with it. Thus, craters such as Tycho (Figures 21 and 22), Aristarchus, Copernicus (Figure 23), and Kepler are known as ray craters, being major centres of subradial systems of bright rays that are now known to consist of numerous small, bright craters and blocks of light-toned rock. The rays of Tycho are up to 1,900 kilometres long. A number of kilometre-sized craters are known as dark-halo craters; these have associated dark-toned rings or halos around them that may be pyroclastic (volcanic) deposits. Other craters are associated with subradial linear formations that are distinct from rays and others again with adjacent positive elements of terrain known as deltoids. Dome-top craters are conspicuous because each occupies the summit of a broad, topographic swelling. Small craters often seen on the summits of hills or mountain peaks may form a class of their own (summit craters). It is common to find a high number of craters on ridges in the maria or centred in the crests of crater walls; such craters have been referred to as parasitic or ringwall craters. A crater that is one member of a linear progression, or chain, of craters may be described as a chain crater, particularly if other members of the progression are of a common and distinct morphological type. Other mutually similar craters form arcuate chains. Consanguineous craters with strong morphological similarities may be numbered among the members of a chain, but they are commonly found in close pairs also. The walls of interlocking craters may pass across one another without interruption. Finally, rille craters are those single or chained craters that are set in and form part of the lunar rilles, which are trenchlike features. A rille crater may be circular or markedly elliptical and may be the centre of a dark halo.

Height measurements

Height measurements form an essential element in the construction of a profile of a lunar feature. In principle, the height (h) of a lunar mountain peak above the lunar ground where the tip of the mountain's shadow, of some length (l), lies is determined by simple geometry provided the mountain is near the centre of the Moon's disk or measured on a photograph taken vertically. Taking the elevation of the Sun over the mountain as θ degrees, the height h of the mountain is calculated with the formula $h = l \tan \theta$; the angle θ can be obtained from regularly published tables. For mountains not viewed under these conditions, a more general formula for h is used.

The near side of the Moon has been surveyed fairly intensively, but, until recently, methods employed to measure the Moon's overall shape, or figure, have been complex and laborious. Unlike the Earth, with its oceans, the Moon has no natural datum from which to measure altitudes. The physical librations (see above) show that the Moon cannot be both spherical and homogeneous. An accurate evaluation of the Moon's figure has become important in discussions of the origin of its surface features as well as in discussions of its internal constitution.

Apollo laser altimetry, used in computing circumlunar orbits, showed that particular belts around the Moon, close to its equator, averaged a few kilometres lower than a reference circle on the Moon's near side and a few kilometres higher than that circle on the Moon's far side. In other words, there are several large, topographically low, maria on the near side of the Moon, while the far side is dominated by highlands. Individual mountains attain heights of up to four or five kilometres above their bases, and this is also the order of depth of the deepest lunar craters, commonly measured from the rim crest of the enclosing ramparts, which are in some cases more than 200 kilometres in diameter.

Smaller craters are progressively less deep: whereas the deepest and largest craters of the Moon have a depth-to-diameter ratio of only 0.08, lunar craters with a diameter of 10 kilometres may have a depth-to-diameter ratio of 0.15. The latter, however, are the eumorphic (sharply defined) craters; and all craters with a 10-kilometre diameter, taken together, show a wide spread in the depth–diameter ratio. The tendency in the case of eumorphic lunar craters is for the depth-to-diameter ratio to increase as the size of a crater diminishes, a generalization known as Ebert's rule.

Placement of craters

The deepest and largest craters of the lunar near side are concentrated in the central meridional belt of the Moon's southern hemisphere. The deepest craters tend not to be near the maria. The encircling walls of the oldest craters have slumped into the craters or have been cut across by faults or graben; the craters themselves have been overlapped and partially obliterated by smaller craters formed later. In addition, the topography of large craters is often softer than that of many of the sharply sculptured, more recent craters, presumably because of changes resulting from denudation.

Dense cratering is found in the lunar highlands, and many of the older craters are difficult to observe. About four times as many craters between 10 and 50 kilometres in diameter are found per unit area of the near-side highlands as in the same unit area of the average mare. Standard statistical methods applied to lunar-crater data have shown that the lunar craters are not distributed across the surface in the random fashion that would be expected if they resulted from meteoric impact.

The maria abut on the highland domains, and mare materials are found in craters with breached walls on the peripheral zones of maria. Dating of lunar rocks by the rubidium-strontium isotope method has established that the mare lavas are younger than the highlands, and it is clear that late phases of mare lava outpourings could blanket craters and thereby render their overall distribution non-random. The maria themselves differ in age, as stratigraphic maps and dated rocks show. There are, even in a single mare, distinct geological units (such as individual lava flows), each with its own characteristic population of craters.

An attempt by statistical methods to distinguish between impact (including secondary-impact) craters and endogenic craters in the lunar maria has been made. The ratio of internally formed craters probably varies from one unit to the next, and, of the craters with diameters between 50

metres and hundreds of metres, it is not uncommon for up to half to be arrayed with the trends of known tectonic lineaments (internally formed linear features). Such craters are probably of internal origin.

Lunar lineaments. *Mare ridges.* Lunar lineaments (linear features) are of many different types. Mare ridges (Figure 24) are numerous in the maria and may be much longer than the brighter highland-type or lunaritic ridges. Mare ridges are also found in dark-floored craters and, rarely, may be traced beyond a mare into highland-type material. In transverse profile they consist, typically, of broad, low rises sloping at only a degree or so for 10 or more kilometres and capped by slightly steeper, relatively narrow ridges. Typically, the major mare ridges rise to an altitude of about 200 metres above the surrounding country. They lack continuity and are broken, offset, or arranged *en echelon.* The higher, narrower parts of the ridges show a strong tendency to be in short sections, or segments. While the overall trend of these ridges in a subcircular mare is generally aligned with the curved border of radially more distant mountains, the directions of the mare-ridge lineaments often follow other preferential directions. Like the lunaritic ridges, they may also belong to families of ridges that trend over much of the lunar surface in set ranges of azimuth—a fact that labels many of them as tectonic in origin.

Tectonic origin

The lunar grid system. Other lineaments, such as linear graben (depressed regions between faults), crater chains, rilles, and faults, together with the ridge network, form the lunar grid system. Near the centre of the Moon's nearside face the principal trends of the grid system are at about 45° to the central meridian. Interference between these dominant directions and other directions of lineaments that are subradial to certain of the maria, notably Mare Imbrium, makes recognition of the Moon-wide topographic pattern difficult. Many of the mare ridges have probably been built up by extrusion of basic lavas from fractures. Others may have been the result of the intrusion of lavas. Because of their tendency to form an overall grid pattern, many of the fractures must have been produced by uniformly acting crustal stresses of tectonic origin.

Regional lineaments subradially oriented (*i.e.,* somewhat offset from a radial direction) with respect to Mare Imbrium and Mare Orientale are easy to locate; fewer ridge lineaments are associated with Mare Nectaris and Mare Humorum. Such regional fracture or fault systems extend into and are modified by the older terrain around the mare. The circular mare sites on the Moon are at present thought to have been blasted out by gigantic impacts, and the basins so created later filled with lavas from inside the Moon. Much faulting and possibly the extrusion of lavas in the regions surrounding each mare basin would be generated in such major events. Fractures in a previously unstressed homogeneous medium will be radial and tangential at some distance from an explosion site. The systematic deviations of the mare lineament systems from these directions in association with the more general grid system suggest influence from preexisting fractures or weaknesses in the lunar crust.

Similar patterns are found around certain large craters, and these may be detected most readily in mare material. Around the crater Aristillus, bundles of lineaments, rather than a set of precisely radial ridges and troughs, are found. Only the central, longest lineament of each bundle is radial to the crater, while the other members are progressively offset from the radial direction. The central lineament of a bundle tends to be aligned with one of the principal directions of the grid system. The ultimate explanation of these minor sets of subradial lineaments is expected to be analogous to that pertaining to the maria.

Where the grid system abuts on the larger craters, northeast- and northwest-trending ridges commonly intersect and sometimes pass inside the northern or southern ringwalls. Well-developed nests of crisscrossing ridges found in such localities have been called lattice patterns. A quite different feature, called a deltoid, also commonly occurs outside the northern or southern walls of certain craters. Deltoids are raised elements of the lunar terrain in the form of a delta, or of a gothic arch, the base of which abuts on the rim of a crater.

Of the subcircular maria, some tend to be polygonal. As in the case of the polygonal craters, the shape might be the result of crustal weaknesses existing before the mare was formed. The peripheries of other areas of lunabase (dark, mare-type material), including some maria, are irregular. Maria also contain features known as rilles (German *Rille:* "trench," "groove," "channel"; Latin *rima,* a term used principally on official maps), which are, however, found also in the lunabase generally, in certain of the larger craters, and in the lunarite (brighter, highland-type material).

Normal rilles

Rilles. The normal rille is a linear or broadly arcuate trench without raised rims (except when it cuts through higher ground) and with gently insloping walls. The largest rilles are five kilometres wide, a few hundreds of kilometres long, and several hundreds of metres deep. The floors of normal rilles are relatively level (unless they are so narrow that fallen rocks and dust from the opposing walls meet in the bottom) or are humped or strewn longitudinally with blocks. They slice through the mountainous walls of some craters and traverse the lunarite for great distances. They tend to occur in parallel families, in arcuate paths generally just within the mountain ranges or hills that border maria or the larger craters, and to run in preferential directions suggestive of lines of probable crustal weakness and tectonic control. Some are arranged *en echelon,* a characteristic of strike-slip faults on Earth.

Single or contiguous craters without raised rims define parts of the walls and floors of some normal rilles; such rilles have sometimes been termed crater rilles. The craters appear to be of the collapse type, with flattish floors. Lunaritic ridges traverse some normal rilles (such as the Ariadaeus and Hesiodus rilles) and appear to have sagged or subsided into the rilles. Such ridges seem to be older than the rilles that they cross without a break. These observations suggest that normal rilles are not partially filled fissures, but are graben, or collapse features, and are probably controlled by underlying fractures or faults. In many instances, normal rilles run into or connect with other normal rilles at sharp angles and with faults, chains of craters, or mare ridges, again suggesting that the rilles in question are controlled by tectonic fractures.

Sinuous rilles

Examination of space photographs stimulated much discussion of another type of lunar rille—the sinuous rille. The direction of some parts of sinuous rilles, like normal rilles, appears to be controlled by tectonic lines of weakness. Other parts have features resembling meanders in a terrestrial river. The superficial resemblance to dry rivercourses—particularly to those cut by rivers draining inland into desert areas—led to a revival of interest in the possibility of water on the Moon. But later theoretical work using detailed measurements of the geometrical parameters of sinuous rilles lent weight to another hypothesis—that these rilles were shaped by the flow of lavas. Many of the sinuous rilles have one end marked by an elongated crater that would be a probable source of lava, and many degenerate into a chain of craters that are commonly elliptical and have their longest axes set along the probable courses of underlying lava tubes. In a few cases, smaller sinuous rilles meander along the floors of larger ones, such as Schröter's Valley. Several sinuous rilles have distributaries or reentrant loops, both of which are common in terrestrial lava channels.

Like normal rilles, sinuous rilles tend to concentrate around the borders of the circular maria or at the junctions of lunabase and lunarite. Exceptionally strong concentrations of sinuous rilles are found in the densely domed region near the crater Marius and also around the crater Aristarchus. Thus, sinuous rilles show a preference to regions that have been assessed from other evidence as showing volcanic characteristics.

Lunar faults

Opposite sides of a few stretches in some normal and sinuous rilles are observed to be at different levels. In principle, a rille may form by the collapse of a weakly cohesive regolith into an open fracture. Faulting is initiated when there is relative movement between the two blocks that define the fracture. The displacement of a fault may remain constant, or there may be continuing or intermittent movement. The direction of displacement may be steeply inclined to the horizontal (normal, or dip-slip, fault); steeply inclined to the vertical (thrust fault); or lateral (strike-slip, wrench, or transcurrent fault). Faults on the Earth and Moon may show a combination of these idealized directions of displacement. On the Moon, however, no thrust fault has yet been recognized. The term "wrinkle ridge," a synonym for "mare ridge," is suggestive of compression or thrusting, but there is little or no real evidence that any of the mare ridges (Figure 24) are compressional features.

Some rilles are directly associated with probable dip-slip faults. The characteristic *en echelon* pattern of strike-slip faults is reflected in other rilles, in segments of wrinkle ridges, and in lunaritic ridge systems. More than one major strike-slip fault appears to have offset blocks of the lunar Caucasus Mountains; and there are a host of probable minor strike-slip faults on the Moon, one of the most notable being the fault that has displaced the walls of the crater Capella and of another two craters further to the south. Strike-slip faults are perhaps of more importance on the Moon than the better known dip-slip faults, such as the inappropriately named Straight Wall. Major faults, dissecting large areas of lunarite, have been recognized. These "selenofaults" measure hundreds, rather than tens, of kilometres in length.

Bright rays. The bright rays that diverge from craters such as Tycho (Figures 21 and 22) are thought by some to be fracture controlled, but the majority of lunar geologists believe the rays to be the result of ejecta of secondary particles from a primary impact site. One of the strongest arguments for the impact origin of rays is that they look like splash marks. The particles that formed the end of the longest ray of Tycho must have been ejected from Tycho at a velocity of at least 1.4 kilometres per second if the ejection hypothesis is correct. The velocity of escape of a particle from the lunar surface is 2.4 kilometres per second, so potential ray-forming particles would not escape from the Moon. The evidence from closeup photographs is that more than the average number of craters are in unit areas crossed by rays; and evidence gathered by astronauts points to there being a complement of bright-toned rock blocks in a ray-strewn zone.

Contour maps

Lunar mountains. Systematic estimates of the altitudes of lunar mountains were first made in the 18th century. The most comprehensive program of lunar height measurement ever attempted was started in 1959 by the United States Air Force's Aeronautical Chart and Information Center. The results of this concerted program, in which many thousands of lunar photographs were taken at different Earth-based observatories, are incorporated in lunar near-side charts prepared by the Aeronautical Chart and Information Center. Charts of the whole surface of the Moon, compiled using space probe data when appropriate, include the spot heights of mountains. A number of detailed contour maps are based on accurate measurements of high-quality, controlled photographs taken from lunar orbit, and laser positional measurements.

The classical program of heliometer observations of the angular separation of points on the Moon, made in the 19th and early 20th centuries, is of fundamental importance in the present understanding of the lunar figure and physical libration. The time-consuming reductions involved the computation of the distances between Mösting A (a crater near the centre of the Moon's disk) and many control points scattered over the Moon's near side and, finally, solution for constants characterizing the librations.

Transient lunar phenomena. Ever since serious telescopic observation of the Moon began, astronomers have reported mistlike phenomena or temporary obscuration of detail in specific patches of the Moon. In 1966 a significant positive correlation was found between the times of more than 100 observations of transient lunar phenomena made between 1749 and 1963 and the distance of the Moon from the Earth. The majority of phenomena occurred close to the time of the Moon's perigee or apogee passages. The indication was that the Earth's tidal forces on the Moon's solid crust had contributed to the cause of the transient lunar phenomena, although the phenomena themselves may be manifestations of seismic (moonquake) or seismically triggered volcanic activity or merely caused by dust either blown out from the regolith and dispersed by cold gases escaping from cracks in the Moon or set in motion by seismic activity. Similar periodicities in some types of seismic signal from observing stations planted on the Moon show that lunar seismicity occurs most commonly within a day or so of perigee and of apogee, and this suggests that the majority of the transient lunar phenomena are connected with some kind of seismic activity.

Other kinds of lunar change have been suggested. Perhaps the most frequently discussed case of a possible permanent or long-term change of topography is that of the crater Linné, which may be located on many photographs as a whitish patch in Mare Serenitatis and appears on the best photographs as a crater about 1.5 kilometres in size,

centred in a bright halo. It cannot be concluded from the evidence available that the area has suffered any morphological change.

Observed eruptions

In 1958, a Soviet astronomer, N.A. Kozyrev, claimed to have detected a reddish cloud of volcanic ash, followed by an efflux of gas lasting for at least half an hour, from the vicinity of the central mountain block of the crater Alphonsus. He recorded a lunar emission band having its maximum intensity at 4,737 angstroms and gradually fading toward the violet end of the spectrum. This and other bands, he proposed, had their origin in carbon molecules. Some volcanoes on Earth emit carbonic gases. In 1959 Kozyrev again obtained an unusual spectrogram of Alphonsus and maintained that the central block of the crater had given birth to an eruption of lava at a temperature exceeding 1,270° C. Although these observations and interpretations have not been universally accepted, the reports did stimulate interest among other professional astronomers in a Moon long considered to be dead and changed only by impacts.

Notable reddish glows on the crests of ridges in the Aristarchus region were observed in 1963 at the Lowell Observatory. A month later, similar observations of the Aristarchus region were reported at two observatories. At this time, coloured patches persisting for more than an hour seem to have been authenticated.

THEORIES OF ORIGIN OF THE SURFACE FEATURES

In the early 17th century the lunar craters were thought to be endogenic; that is, of internal origin. The first part of the 19th century saw truly under way the argument that most craters could have been caused by the impacts of external bodies or by volcanism. Theories that could not be classified as either volcanic or meteoric (impact) have also been proposed; but lunar craters are now generally thought to include impact craters of all sizes, large impact craters modified by volcanism, and endogenic craters, mainly less than one kilometre in diameter.

Gas-bubble theory

Volcanic theory. One of the earliest hypotheses of the formation of the lunar craters was the so-called gas-bubble theory of Robert Hooke, who proposed in 1655 that they were formed by the collapse of huge bubbles of gas; the discharge of gas is a vital part of the volcanic process. On Earth, such bubbles that occur in fluidized mud, as at La Solfatara, Italy, commonly measure centimetres or decimetres in diameter, increasing in size with the viscosity of the containing medium and the gas pressure. In Iceland there are hollow domes of lava measuring metres in diameter; on the Moon the low gravity and lack of atmosphere could lead to significantly larger domes. In a later theory that was more attractive as far as the larger lunar craters were concerned, the starting point was thought to be a conventional eruptive centre such as might have given rise to a cone volcano of the Vesuvius type. According to this theory, volcanic materials would have been ejected from the central orifice in a symmetrical fountain and would have landed to construct, layer on layer, a roughly circular ringwall. Sometimes, dying activity would build up a central eminence; in other cases, the floor of a crater would be flooded by dark lavas.

Comparison of lunar features with terrestrial ones

Volcanoes on Earth generally produce domes, or cratered cones, rather than rimmed depressions. There are many tuff or lava and tuff rings of kilometre size in terrestrial volcanic fields, however; for example, in Iceland, Hawaii, Arizona, and Mexico, where central collapse or engulfment of materials tends to leave landforms resembling many of the lunar craters.

Both the bubble hypothesis and the volcanic-fountain theory were argued without any appreciation of the physical or geological principles involved. More competent geological arguments for lunar volcanism and caldera collapse were proferred in 1944 by Josiah Edward Spurr, who developed a theory that the larger lunar craters were volcanic collapse structures (calderas); he developed a classification of craters and described in detail the different modes of origin of different classes of crater. More importantly, he was the first to recognize the uniformity and extent of the overall structural pattern in the Moon's crust and to name it "the lunar grid system." Spurr's analyses were closely tied to his meticulous photogeological analyses of the lunar craters. Calderas may have developed during an intensive phase of lunar outgassing, while many of the low-walled ring formations on the Moon marked the positions of ring fractures from which lavas had been erupted in the precaldera phase of lunar crater formation.

Impact theory. The impact hypothesis was formulated comparatively late. Few people had seen a large meteoroid fall on Earth, though many had witnessed terrestrial volcanic eruptions, and there was practically no evidence for live, meteoric cratering events on the face of the Moon. Even the geologist who had been one of the first to argue convincingly (in 1893) for impact craters had disputed the impact origin of the world's best authenticated meteoritic crater, in Arizona. Until recent years, few craters on Earth had been described as of probable impact origin; many structures on Earth now regarded as impact craters had been termed cryptovolcanic craters by geologists. The predominantly circular shape of lunar craters was thought to be impossible to produce by impact, except from relatively rare, vertical impacts. It is now believed that a nearly circular crater would be blasted out of the lunar rocks by a large meteorite arriving at a high speed even if the angle of approach to the Moon's surface were far from the vertical.

This, essentially, is the basis of the modern impact theory. A vast array of statistical data on both terrestrial and lunar craters was collected, compared, and analyzed by Ralph Baldwin, who developed a thesis on the assumption that the great majority of the lunar craters were of impact origin, and who argued for the cataclysmic formation of Mare Imbrium following a major collision between a large object and the Moon that resulted in a gigantic explosion. Later, it was reasoned that the nearly circular maria, all the large craters, and the majority of the small ones were impact scars and that later lavas, flooding impact basins such as that of Mare Imbrium, flowed further afield than the confines of the basins and created the irregular maria. Later impact theories differed considerably from Baldwin's in some details.

Impact velocities

The velocities of interplanetary meteoroids in the vicinity of the Moon are commonly of the order of tens of kilometres per second. Because, in such a meteoric-impact process, the energy is transformed and released very rapidly, little of the initial kinetic energy is converted into heat, and the rocks in the floor of a crater are not likely to be melted to any appreciable extent. A longer period of time for the impact is needed to give the Moon rocks time to absorb more of the heat that would otherwise be dissipated in other ways.

A ring 1,000 kilometres in diameter (such as Mare Imbrium; Figure 21) could be formed by impact of a high-velocity meteoroid of less than one-tenth of that diameter or with a larger, lower velocity object. Asteroids, for instance, would collide with the Moon at relative velocities around six kilometres per second. Objects circling the Earth in a ring at about the Moon's distance could collide with the Moon at velocities as low as the velocity of escape from the Moon's surface, 2.4 kilometres per second.

Evidence against large-scale melting

H.C. Urey developed an argument based on the concepts that the Moon was nonspherical and that it had a nonequilibrium shape (even allowing for the Earth's tidal effects) and a peculiar mass distribution. The most important irregularity in the Moon's distribution of mass was found in the excess mass in or around the axis directed toward the Earth. Support of the excess mass in the Moon's Earthward-pointing axis implied considerable mechanical strength. If the Moon had undergone any appreciable melting phase in the past, it would have had insufficient strength in its deep interior to support the supposed bulge. This was regarded by some scientists as an indication that the Moon could never have been melted to any significant extent. The mare lavas would have been derived from the impacts themselves, and, hence, the impacting bodies must have been large, low-velocity objects. The observed asymmetric pattern of radial grooves and ridges beyond the periphery of Mare Imbrium could be generated by splashlike ejecta following an oblique, low-velocity collision, whereas a high-velocity collision at a similar angle of impact would produce an ejecta pattern essentially symmetrical about the explosion centre. It is to be pointed out, however, that one prediction of this theory was that the Moon had not undergone widespread igneous differentiation, whereas such differentiation is now known to have occurred.

Modern views on the origin of the craters have been much influenced by Baldwin's statistical work. He showed that the ratio of the depth to the diameter of terrestrial shell, bomb, and meteoric craters and of the craters of the Moon could all be fitted on smooth curves showing logarithmic plots of the ratio against the diameters of the craters. Terrestrial calderas (collapsed volcanic structures) also fit the depth-to-diameter curves of Baldwin. Further studies extended Baldwin's data, relating the ratios of rim widths of lunar craters to their diameters to those for volcanic craters and calderas on Earth; the six calderas studied had much wider rims than lunar craters of the same diameter (1–10 kilometres), though this may be because of underestimations of the lunar rims.

The shape of plots of the logarithm of cumulative number of craters larger than a certain diameter against the logarithm of that diameter has been said to be evidence for impact origin of the craters; probable amounts of meteoric debris in the solar system would collide with the Moon to produce craters giving a similar statistical result; that is, the numbers of lunar craters of various diameters seem to be relative to the numbers of meteoric bodies of various sizes, in space, available to produce the craters. Others, however, found that a high proportion of craters less than one kilometre in diameter were not impact craters and that their proportion varied with position.

Existence of both impact and volcanic features

There is now no real doubt that both impact and volcanic features exist on the Moon. Many details and some major problems remain to be solved. The origin of the circular maria, as has been suggested, may be that basins were created by impacts and were later flooded by lavas from within the Moon. The same argument may apply to many of the larger craters; following an explosive cratering event, the terrain beneath the excavated material will be fractured and will tend to adjust upward, while the extra mass deposited in the form of ringwalls will tend to adjust downward. Through the friction, gravitational energy will be dissipated under the crater as heat. This heat might be sufficient to melt the underlying rocks, which would then have access to the surface through fractures. The volcanic floor of Tycho (Figure 22)—and possibly its central peaks (which might also have been formed by impact)—may have been produced in this way. For Mare Orientale, there is much to be said for an explosive origin, since, for one thing, many characteristics of the surrounding terrain may be so explained. Other maria may be predominantly lava-filled calderas of igneous origin. The maria differ in age and were not all formed in one short-lived catastrophe.

(G.Fi.)

THE ORIGIN AND EVOLUTION OF THE MOON

The evolution of the Moon's orbit. The Moon is gradually changing its orbit because of a continual increase in its angular momentum. This increase, in turn, is due largely to the Moon's own effect in raising tides on the Earth. The action of both lunar and solar tides causes an energy loss through internal friction, transforming mechanical energy into heat; most of the dissipation of energy is thought to occur in shallow seas, principally the Bering Strait. The immediate effect of tidal friction is a slowing of the Earth's rate of rotation; the length of a terrestrial day, as determined by observation, is increasing by about 2×10^{-3} seconds of time per century.

As its spin slows, the Earth loses angular momentum. The total angular momentum of the Earth–Moon system, however, must remain nearly constant (there is a small increase from the Sun's tidal action), and the lunar orbit must acquire that which is lost by Earth's rotation. This is accomplished by the gravitational action of the solid Earth tide, exerting a force in the direction of the Moon's orbital motion. According to Kepler's laws, this must cause the Moon to move ever farther from the Earth, while the Moon's orbital angular speed decreases. Because it amounts only to a few centimetres per year, the Moon's recession had not been observed directly by the early 1980s, although it is expected that laser ranging observations will soon detect it. "Tidal acceleration" was first measured by Sir Harold Spencer-Jones in 1938; his value of −22 arc seconds per century^2 differs by only 10 to 15 percent from values obtained with the most modern techniques; much higher values have been published on the basis of erroneous analyses, however. Precise determination of the tidal effect is complicated by the possibility, required by some theories of relativity, that the gravitational "constant" is changing with time; if true, this would cause an acceleration that is distinguishable from the tidal acceleration only with difficulty.

When discussing changes in the Moon's orbit, it is important to bear in mind that the hour is a defined quantity and therefore constant, and that the year can be considered as having been essentially constant since the formation of the Earth, or shortly thereafter. The day, however, did not always have 24 hours, nor was the synodic month always 1/12.4 of a year. Astronomical observation, as all human activity, has taken place in a miniscule fraction of the history of the Earth, and there is no direct evidence of how the decelerations of the Earth and Moon proceeded in the distant past. Some scientists have interpreted the growth rings of tidal life forms (such as mollusks, corals, and stromatolites) as evidence that both the day and the month have lengthened since the Paleozoic Era. They estimate that, 400,000,000 years ago, the day was only 22 hours long and there were a bit more than 13 months in a year; these estimates give an average rate of slowing that is near to presently measured values. According to these data, the Moon appears to have been at a distance of 30 Earth radii, only half its present distance, about 2×10^9 years ago, with 34 months per year and 10 hours per day.

Simple mathematical calculations of the lunar orbit into the distant past, assuming the Earth's frictional response to be constant, lead to the conclusion that the Moon would have been at a distance of only 2.8 Earth radii 2,000,000,000 years ago, a distance that is closer than that of communications satellites; the day would have been only 5 hours and the month only 6.5 hours in length. Such calculations are doubtful because they are contradicted by geological evidence, they assume a constancy in the Earth's rheological properties that is physically unrealistic, and they include an unreliable time-scale. In 1982 D.J. Webb employed an idealized hemispherical ocean for a mathematical model in which the Earth's frictional response increased rapidly as its rotation decreased. In any case, it is reasonable to assume that the Moon was much closer to the Earth in the geologically distant past, and this fact has given rise to several theories of the origin of the Moon.

Dynamical theories of lunar origin. The physical mechanism for tidal evolution was recognized around 1880 by Sir George Darwin. There followed three fundamentally different hypotheses of how the Moon was formed. Plausible qualitative arguments have been advanced for each one, but each has major physical and/or geochemical flaws, and the problem remains unsolved.

Terrestrial fission. Sir George Darwin proposed the simplest possible extrapolation of tidal friction, that the Earth was formed as a rapidly spinning fluid spheroid that became rotationally unstable because of solar tides and then broke in two, the smaller piece receding from the larger ever since because of tides between the two. Harold Jeffreys showed in 1930 that such instability was not likely, and the theory was little considered for three decades. Because the density of the Moon is about that of the Earth's outer layer, or mantle, it was proposed in the 1960s that the Moon was ejected from the solid Earth, leaving the vast depression known as the Pacific Ocean basin. This theory was proved untenable by recent dating that shows the lunar surface to be nearly as old as the Earth's and the ocean floor to be much younger. A number of more recent variations on the fission theory have appeared, but the ejection mechanism is always unclear, and none of these theories can account for the present obliquity of the lunar orbit.

Untenability of the fission theory

Circumterrestrial coagulation. A theory of the Moon's origin from a "circumterrestrial swarm"—a respectable extension of the condensation theory of the origin of the solar system—was proposed in 1950. According to this theory, bits of dust, meteorites, and larger bodies are to have come together to form the primitive Earth and a swarm of debris; the remaining matter was then to have precipitated to form the Moon. Differing densities were explained by differential precipitation, the heavier metallic content of the "swarm" going into the Earth, leaving mostly silicates for the Moon. Variations on this idea include a "many Moon" theory, in which the circumterrestrial debris coagulated into several Moon-sized objects, some of which are accreted onto Earth and only one surviving the hazards of coexistence. Dynamical problems with such theories include the accumulation of the Moon's present angular momentum, the obliquity of its orbit, and the accumulation of two planets instead of one. Present gravitational theory suggests that the formation of one large object will sweep up all loose debris, blocking the possible formation of other large bodies in the vicinity.

"Many Moon" theory

Orbital capture. Sir George Darwin calculated the lunar orbit backward in time to a point at which it was extremely close to the Earth; he then took an intellectual leap to the fission hypothesis. In 1955, Horst Gerstenkorn continued Darwin's calculations. According to his result, the Moon did not come from the Earth, but from the distant reaches of the solar system, and it was captured into its present orbit during a chance close approach toward the Earth. The assumptions made in Gerstenkorn's calculations were physically implausible; they have since been replaced by improved models in which the major unknown factor is the dynamic and viscous response of the Earth to such an encounter. Extreme disruption and melting is implied, so the encounter would have happened very early in the history of the solar system, before the formation of the lunar maria some 4,000,000,000 years ago. According to the assumptions made in the calculations, the event can be located at any time in the distant past, and the Moon can be made to come from almost any direction, with either a direct or retrograde initial orbit. If a retrograde orbit is assumed, the action of the tides would cause the inclination of the orbit to flip over the Earth's poles, bringing the Moon into its present direct orbit. The most serious objection to this theory is the requirement that such a massive object as the Moon come from elsewhere in the solar system and pass within a few radii of the Earth. It has been said that the only dynamical objection to capture is its improbability. (J.D.Mu.)

Evidence from the composition and physical properties of the Moon. *Chemical analysis of lunar samples.* The first orbital measurements of the broad composition of the rocks covering the Moon's surface served to confirm the speculations of photogeologists, who had argued for the presence of basic rocks, such as the mare basalts.

By courtesy of National Aeronautics and Space Administration

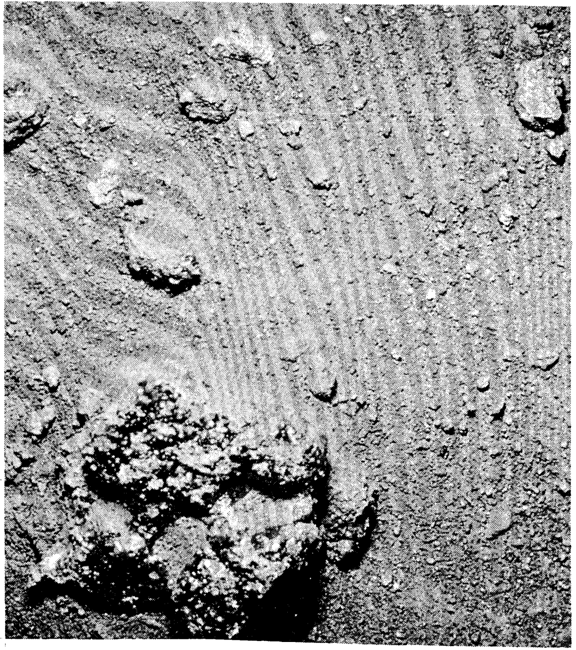

Figure 26: Closeup of a lunar rock taken during the Apollo 12 EVA on the lunar surface. The image scale is half actual size.

Detailed and more accurate measurements of the compositions of lunar samples were made *in situ,* in Mare Tranquillitatis, in Sinus Medii, and on the edge of a flow unit in the highlands near Tycho beginning in 1967. The findings indicated compositions close to those of some basalts on Earth, but there were differences between the highland analyses, on the one hand, and the earlier analyses in two patches of the lunabase. In the highland site, undisturbed lunar soil, disturbed soil, and a small rock block were analyzed separately. The rock block had a chemical composition that closely paralleled that of the undisturbed soil except for the elements magnesium and iron, which were slightly less abundant in the rock, and aluminum, which was slightly more abundant. Taken as a whole, the results indicate that the Tycho flow unit is compositionally similar to anorthosite, a granular igneous rock on the Earth.

These results led many authors to suggest that the lunar highlands in general were higher in aluminum and calcium and lower in the iron-group elements (those with mass numbers between about 47 and 65) than the maria. More iron in the maria could contribute to their generally darker tones and could also contribute to the higher rock density of the mare units.

Chemical differentiation

By 1968, scientists were beginning to appreciate the fact that the Moon had more in common with the Earth than many of them had previously been prepared to accept. It appeared that the Moon had suffered some degree of chemical differentiation and that its face presented not only physiographic domains but also true geological domains (the highlands and the lunabase) that differed in density. Furthermore, if these areas were to be established as separate geological domains, it would be clear that the Moon had been differentiated and heated. The evidence for the mare–highland rock contrast, however, was slender. First, it was based on only one analysis in the highlands. Second, the rocks analyzed were not necessarily typical highland material. Magnetic experiments indicated that the lunar samples were of basalt with little (about 1 percent by volume) or no addition of meteoric nickel–iron. This level of iron is less than would be expected if meteoroids were the only agent responsible for breaking up and gardening the lunar rocks.

The first samples of Moon rock to be returned to the Earth for exhaustive study were collected in Mare Tranquillitatis in July 1969. Since that time, rocks from Oceanus Procellarum, Mare Fecunditatis, the Fra Mauro highlands (Figure 26), Hadley Rille, the highlands near Mare Crisium, the southern highlands (near Descartes), and the Taurus Mountains have been returned to the Earth and have been analyzed.

All the rocks are volcanic basalts, except for small meteoric, anorthositic, and glassy components in the surface debris. The coherent, basaltic rocks subdivide into those of vesicular, crystalline type and breccias (consisting of compacted regolith materials), although the breccias and regolith contain fractions of meteoric nickel–iron, anorthosite, and glass, and, among themselves, glass particles show a range of composition that includes that of basalt.

Evidence that meteoroids have been an important factor in shaping the Moon is found in the layering of returned core samples and in the shocked minerals present in the returned rocks. The compositional similarity between the anorthosites and the rocks of the Tycho highlands pointed to the anorthosites and some of the shocked materials found in the mare regions having been ejected from the highlands; following later missions, the highlands were found to consist of anorthositic gabbros, including anorthosites, norites, and troctolites—the so-called ANT suite of differentiated rocks—as well as numerous surface breccias. The glasses that have undergone selective volatilization and that range widely in overall composition have probably derived from the melting of materials at a variety of impact sites. Certain glass globules of more uniform composition may be volcanic in origin.

Density at different depths

The astronomically determined mean density of the Moon as a whole is 3.34 grams per cubic centimetre, and the mean density of the basalts returned from the Moon's surface has a similar value. Yet the Moon cannot be composed of these mare basalts all the way through, since, at the pressures existing at moderate depths in the Moon, such materials would suffer a phase change and transform to eclogite, which has a density of 3.7 grams per cubic centimetre. One hypothesis is that the lunar highlands are composed of anorthosites of density between 2.8 and 2.9 grams per cubic centimetre, and certainly the bulk of the Moon's outer parts must be of rock with lower density than basalt. Yet, by comparison with the average chondrite (the most common meteorite), the returned lunar basalts are, in general, enriched in silicates and oxides and depleted in iron-group elements, and this is again consistent with the theory that the Moon has undergone general magmatic differentiation that might have led to the formation of a nickel–iron core. Dynamical considerations limit the mass of iron in any lunar core to 6 percent of the Moon's mass, so that the core, if it exists, must be very small compared to that of the Earth.

Differences in the abundances of the elements are observed at different lunar sites. Some differences could be related to crystal fractionation in near-surface melts. If the final products of fractionation had neared the lunar surface, the residual liquid rocks might have crystallized as granites; and a few such fragments have been reported. In the rocks from Mare Tranquillitatis, titanium (occurring principally as ilmenite, $FeTiO_3$) was found to be much more abundant than in either chondrites or most terrestrial rocks. Evidently, the lavas in Mare Tranquillitatis contain more titanium because they were extruded at a stage of fractionation in which certain elements, including titanium, were enriched in the melt.

The principal minerals of which the outer layers of the Moon are composed appear to be pyroxene, plagioclase, and olivine, all of which are common on the Earth. One of the most striking differences between the Earth and the Moon is the Moon's enrichment in refractory elements and its depletion in volatile materials. In particular, water—common elsewhere in the solar system—is essentially absent from the Moon in either free or combined form. The analysis of returned samples led to the discovery of a few lunar minerals that had not been found on the Earth: the first was named Armalcolite for the astronauts Neil Armstrong, Edwin Aldrin, and Michael Collins.

Rocks collected from the Fra Mauro site were the first found to be high (with reference to rocks from other parts of the Moon) in basalts enriched in potassium, rare-earth elements, and phosphorus. The element europium was found to be less enriched than most other rare earths in the mare lavas. Later, it was confirmed that europium was more prevalent than many other rare earths in the highland rocks. Together with the evidence for the divalent state of most of the lunar europium, this argues for past lunar magmatic processes occurring on a large scale in a chemically reducing environment. Indeed, it is the comparative abundance of elements, rather than of minerals, that distinguishes the Moon rocks from those of the Earth (or from chondrites) and identifies the Moon as a special object with its own geochemical evolution.

Origin of mare lavas

Formation of the maria and highlands. The geological evidence for magmatic differentiation, partial melting, and crystal fractionation seems to rule against the theory that the mare lavas were generated by impact; rather, it seems that they came from deep within the Moon. Furthermore, the lavas were extruded at widely different times. Standard rock-dating methods showed that, broadly speaking, the crystalline rocks from the maria solidified at different times lying in the interval 2×10^9 years to 4×10^9 years ago. At the present time, certain radioisotopes of the elements potassium, uranium, and thorium are, together, the most important source of radioactive heating in the Moon. Calculations relating to the heat flow through, and net heating of, the Moon have been conducted for plausible compositional models of the Moon, and it is likely that the mare lavas derived from magmas heated by this kind of radioactivity, since the thermal models show that the Moon would probably have reached its state of maximum heat content at about 2×10^9 years ago. The extent of the melting would depend on the initial temperature of the Moon, but the period of maximum heat would appear to approach, or coincide with, the outpourings of the mare lavas. There are many examples of major lava flows in the maria, the most notable in Mare Imbrium.

By contrast, most of the samples from the lunar highlands appear to have solidified 4.6×10^9 years ago. The Moon's highlands are almost certainly much older than any of the Earth's rocks. Although these ages confirmed the view of lunar stratigraphers that the lighter toned highlands were overlain by the mare lavas, the fact that the highland suite of rocks was now observed to be differentiated posed the interesting problem of the source of the heat that led to their melting and very early differentiation. If the Moon were formed by accumulation, the gravitational energy of the accumulation would provide an early source of low-level heating. A more promising source, however, may be found in the decay of short-lived radionuclides, such as aluminum-26. In principle, an early interplanetary magnetic field might be capable of heating the Moon by an inductive process. Finally, the presently observed secular acceleration of the Moon and the general tectonic (grid) system of fractures observed on the Moon's surface appear to require that the Moon was once much closer to the Earth during its early evolution; and the dissipation of tidal energy in the Moon would provide yet another way of heating it. Whatever the solution to this problem of the formation of the lunar highlands, there seems to be a record of lunar magmatic processes in operation long before any processes that can be deduced directly by terrestrial geological studies. Possibly this early heating phase, and its associated volcanism, was of some relevance in the loss of volatiles from the Moon; but an alternative theory is that the volatiles were lost before the Moon accumulated as a single object. The crater counts in distinct geological units suggest that parts of Tycho and Aristarchus are considerably younger than the surrounding materials, so there may be a dispersion of ages in highland material as well as in mare material.

Remanent magnetization

Magnetism. Remanent magnetization has been found in lunar crystalline-rock samples. Further studies of the specimens have raised questions about the origin of that magnetization. Rocks may have been magnetized as a result of electrical discharges in the primitive solar system or by the early field of the Earth when the Earth–Moon distance was small. There is some evidence, however, that the early magnetizing field was associated with the dynamo effect of a hot lunar core. Evidence drawn from surface instruments has been combined with that derived from other sources to deduce the bulk electrical conductivity and temperature profile of the lunar rocks at different depths. Although the electrical conductivity of rocks has a low value near the surface of the Moon, it increases to a depth of the order of 200 kilometres. A mantle with the conductivity of basalts and a core with the conductivity of olivine-like materials would be consistent with these observations. The precise temperature of the core is not yet decided; the core's temperature must be related, for example, to the initial temperature of accumulation of the Moon and to the extent and rate of redistribution of radioactive elements in the upper layers of the Moon. The elemental abundances of the stony meteorites and of the rocks of the Earth seem to be much the same, but they differ from the overall abundances of elements on the Moon. (G.Fi.)

Mars

Mars, symbol ♂ in astronomy, is the fourth planet in order of distance from the Sun and seventh in order of diminishing size and mass. It completes its orbit about the Sun once in 687 Earth days and spins on its axis with a period only 37 minutes longer than a terrestrial day; it has become common to refer to a Martian solar day as a sol. Orbital data for Mars are listed in Table 9; physical parameters in Table 11.

Mars is named for the Roman god of war. This astrological association of the planet with destructive forces can be traced back as far as 3,000 years ago to Babylonian astronomer-astrologers, who named the planet Nergal for their god of death and pestilence. The early Greeks named the planet Ares, for their god of battle; the planet's two satellites, Phobos (Fear) and Deimos (Terror), were named for two of the sons of Ares and Aphrodite.

HISTORY OF OBSERVATION

Work of Johannes Kepler

Mars was an enigma to ancient astronomers, who were bewildered by its apparently capricious motion, sometimes direct, sometimes retrograde, across the sky. Johannes Kepler solved this problem in 1609. Using Tycho Brahe's superior naked-eye observations of the planet, he was able to deduce empirically its laws of motion and so pave the way for the modern gravitational theory of the solar system. Kepler found that the orbit of Mars was an ellipse along which the planet moved with non-uniform, but predictable, motion. He was able to demonstrate why the planet's motion had confounded earlier astronomers who had based their theories on the older Ptolemaic idea of hierarchies of circular orbits. In the words of Kepler: ". . . Mars alone enables us to penetrate the secrets of astronomy which otherwise would remain hidden from us."

Early visual observations. The earliest telescopic observations of Mars in which the disk of the planet was seen were those of Galileo Galilei, who, in 1610, noted that the planet did not appear to be perfectly round. In 1636, Francesco Fontana produced the earliest drawings that show markings on the disk of the planet. Some of these drawings show Mars in the gibbous phase, *i.e.,* with more than half the visible disk illuminated. Unfortunately, the markings drawn by Fontana bear no resemblance to the planetary details now known, and Christiaan Huygens is credited with the first accurate drawings of surface markings. In 1659, Huygens made a drawing of the planet showing a major dark marking on the planet now known as Syrtis Major. Polar caps on the planet were first noted by Giovanni Domenico Cassini around 1666.

The accomplishments of visual observers were many. The tenuous Martian atmosphere was first noted by Sir William Herschel, who also measured the tilt of the planet's rotation axis and first discussed the seasons of Mars. The rotation of the planet was discovered by Huygens in 1659 and measured by Cassini in 1666. Cassini found the rotation period to be 24 hours and 40 minutes, which is in error by only three minutes. The moons of Mars were also discovered visually, by Asaph Hall in 1877.

Visual observations accumulated a rich compendium of meteorological and seasonal phenomena that occur on Mars, such as numerous cloud phenomena (yellow, blue, white, and gray clouds), the waxing and waning of the polar caps, seasonal changes in the colour and extent of the dark areas, a "wave of darkening" in the markings that sweeps across the planet in phase with the melting of the polar caps, and a green haze and bright transient spots. But the explanation of most of the phenomena had to await the scientific exploration of Mars by spacecraft.

Space probes. In the interval 1960–80, space missions to Mars were the major objective of the U.S. and Soviet programs for the exploration of the solar system. In an extended scientific program consisting of six missions, U.S. spacecraft successfully flew by the planet (Mariners 4, 6, and 7), orbited the planet (Mariner 9 and Viking 1 and 2), and placed lander modules on the planet (Viking 1 and 2). Three Soviet probes (Mars 2, 3, and 5) also investigated the planet, two of them reaching its surface. Before orbiting the planet, on November 27, 1971, Mars 2 placed into the Martian atmosphere a capsule bearing the Soviet coat of arms that may or may not have reached the surface. Mars 3 was the first spacecraft to soft-land an instrumented capsule on the planet on December 2, 1971; landing during a planet-wide dust storm, the device returned data for approximately 20 seconds. The Mars 5 mission entered orbit about the planet in February 1974 and returned important data that are believed by Soviet scientists to demonstrate a very weak magnetic field on Mars. The Mariner 9 and Viking missions played a major role in the development of planetary science during 1970–80. Much of the discussion in this section is based on the results of these missions.

Mariner 9 was placed in orbit about Mars in November 1971 and operated until October 1972. It returned a wide variety of spectroscopic, radio propagation, and imaging data. Some 7,329 pictures covering 70 percent of the surface demonstrate a history of widespread volcanism, ancient fluvial erosion, and extensive tectonics. The largest known volcano in the solar system, which is possibly still active, has a summit that rises 27 kilometres above the mean surface of Mars.

The Viking missions

The central theme of the Viking missions was the search for extraterrestrial life, Mars being the most likely place. No signs of biological activity were found, but the various instruments on the four spacecraft (two orbiters and two landers) returned an enormous wealth of detailed knowledge concerning Martian geology, meteorology, and aeronomy that encompasses a wide range of Martian environments and seasons. Vikings 1 and 2 were placed into

orbit during June and August 1976, respectively. Lander modules descended to the surface from the orbiters after suitable sites had been determined. Viking 1 landed in the region of Chryse Planitia (22° N, 48° W) on July 20, 1976, and Viking 2 landed in Utopia Planitia (48° N, 226° W) on September 3, 1976. All of the spacecraft operated far beyond expectations, with the last pictures from the Viking 1 orbiter being transmitted on August 7, 1980, more than four years after its arrival at Mars. The Viking 2 orbiter ceased to operate in July 1978. The Viking 1 lander was still operational in 1981; it was programmed to operate on a severely limited basis until early 1990.

Martian maps. The first known map of Mars was produced in 1830 by Wilhelm Beer and Johann H. von Mädler. The earliest system of longitude and latitude, not too different from that in use today, was defined by these pioneers. Better maps with the first systematic attempts to name the markings on the planet were produced by Richard A. Proctor (1867), Nathaniel E. Green (1877), and Camille Flammarion (1877). The nomenclature for the markings was based on the names of prominent scientists and observers of the planet such as William Herschel, William R. Dawes, Pierre-Simon Laplace, Wilhelm Beer, Dominique Arago, and Johann Schroter.

First modern map of Mars

Giovanni Schiaparelli produced what might be called the first modern astronomical map of Mars in 1877; and it contained the basis of the system of nomenclature still in use. The names on his map are in Latin and are formulated predominantly in terms of the ancient geography of the Mediterranean area. This map also showed, for the first time, indications of a system of canals, or channels, on the bright areas. Schiaparelli is usually credited with their first description, although the idea of canals on Mars may have originated 10 years earlier in the work of Angelo Secchi.

Since Schiaparelli's time, the map of Mars has been constantly improved, and hundreds of new details have been added to it. Moreover, photography has played an increasingly important role in this process. In 1958 the International Astronomical Union adopted a formal list of Martian place-names related to a map of Mars drawn by G. de Mottoni and based on a large number of photographs of the planet taken by Henri Camichel at the Pic du Midi Observatory (see Figure 27). The remarkable quality of Mottoni's map was borne out by comparison with pictures later returned from approaching spacecraft.

Until Mariner 9, maps of planets were of large-scale features distinguished by their albedo, or their ability to reflect light. The detailed observations made by the Mariner and Viking orbiters led to an explosion of the number and types of maps, the new maps presenting topography, geologic provinces, temperatures, craters, and so on. Figure 27 is a modern geologic map of Mars based on Mariner 9 data. The responsibility for producing high-quality maps from spacecraft data has been undertaken by the U.S. Geological Survey, and the responsibility for naming the plethora of features found on the surface of the planet has been taken by the International Astronomical Union. The names used in early maps are kept for features that can be identified telescopically, and Latin terms (Planitia, Tholus, Mons, etc.) are used to extend this nomenclature to the different types of geologic features that have been discovered. Craters whose diameters are between five and 100 kilometres in size are named for small towns and villages on Earth. The basic geodesic control net for a system of longitude and latitude on Mars is based on data from Mariner 9 and has the prime meridian defined by a small crater named Airey-O. This tiny crater is the Martian equivalent of Greenwich.

BASIC ASTRONOMICAL DATA

The orbit of Mars. Mars moves around the Sun at a mean distance approximately 1.52 times that of the Earth from the Sun. The relatively large eccentricity (0.0934) of its orbital ellipse brings Mars, at its closest approach, to within 206,600,000 kilometres of the Sun and, at its furthest distance, to 249,200,000 kilometres. Mars completes an orbit in roughly the time in which the Earth completes two, and, therefore, Mars spends most of its year far from the Earth in directions that are near the Sun. At its closest approach, Mars is less than 56,000,000 kilometres from the Earth, but it recedes to almost 400,000,000 kilometres; thus, it is not generally available for detailed telescopic observation.

Table 9: Orbital Elements of Mars*

Mean distance from Sun	227,941,963 km
Eccentricity	0.093387
Inclination	1.86641°
Mean longitude of node	49.4032°
Mean longitude of perihelion	335.6909°
Sidereal period	686.9804 mean solar days
Mean synodic period	779.94 mean solar days
Mean orbital velocity	24.1 km/sec

Most Earth-based observations of Mars are best made when the planet is at opposition; *i.e.,* when the planet is in the opposite direction in the sky to the Sun. In this position, the planet culminates near local midnight and is also close to the Earth. Successive oppositions occur at an interval of approximately two years and seven weeks; because this interval, called the synodic period, is not commensurate with the orbital period of Mars, an opposition may occur at any point in the Martian orbit. Oppositions near perihelion are called favourable, or perihelic, because the planet is then closest to both the Earth and the Sun and, therefore, is brighter and appears larger than usual. The largest angular size that the planet can attain is 25 seconds of arc. Oppositions that occur near aphelion are the least favourable, for the planet is then farther from the Earth (101,000,000 kilometres) and at its greatest distance from the Sun. During such oppositions, called aphelic, the planet is less bright and smaller than at the average opposition, and it may attain an angular diameter of only 14 seconds of arc.

Inclination of the orbital plane

Another factor that critically influences observations of Mars at opposition is that the orbital plane of Mars is inclined at an angle of 1.85° to the Earth's orbital plane. At Martian perihelion, Mars is well south of the Earth's orbital plane. Consequently, at favourable oppositions Mars is badly placed in the sky for observations in the Northern Hemisphere and is best observed from sites south of the Equator. The situation is reversed for aphelic oppositions.

The north pole of rotation of the planet is at present pointed in the direction of a sixth magnitude star best known by its *Bonner Durchmusterung* catalog number, BD 52°2880, which is located near the bright star Deneb in the constellation of Cygnus. BD 52°2880 is therefore the Martian "pole star" about which the apparent daily motion of the heavens takes place. As is the case of the Earth, the direction of the pole in the sky changes slowly, owing to gravitational torques exerted by the Sun on the planet's equatorial bulge. This precession causes the Martian pole to move along a small circle in the sky with a period of 97,000 Martian years.

The axis of rotation is not perpendicular to the orbital plane of the planet, but is inclined at an angle of 24.935°, and, as for the Earth, the tilt gives rise to the phenomenon of seasons on Mars. The Martian year consists of 668.6 Martian solar days, called sol. For 371 sol, or more than one-half of the Martian year, the Sun appears overhead at some northern latitude and it is spring and summer in the northern hemisphere. The orientation and eccentricity of the orbit, however, leads to an important characteristic of the seasons on Mars: they are quite uneven in length. The summer solstice, which separates spring from summer, occurs considerably later than the midtime between the times of passage through the spring and fall equinoxes. The southern summer is short and hot, while the northern summer is long and cool (see Table 10). These are important factors in understanding the seasonal behaviour of the polar caps (see *The polar caps,* below).

Mars is a small planet. Its equatorial radius is about half that of the Earth, and its mass only one-tenth the terrestrial value. It follows that Mars possesses four times less surface area than the Earth, and its gravity is reduced by a factor of nearly 3. To escape the gravitational pull of Mars, a velocity of only 5.022 kilometres per second

Table 10: Length of Season on Mars

Northern Hemisphere	Southern Hemisphere	Martian days (sol)
Spring	Fall	194
Summer	Winter	178
Fall	Spring	143
Winter	Summer	154

is required. Thus, a rocket need only supply to an object one-fifth of the energy that would be needed on Earth to free it from the gravitational attraction of the planet.

Shape of Mars

Mars is observed to be roughly spheroidal in shape. Early and extensive Earth-based observations indicated that the polar radius was about 40 kilometres less than the equatorial radius. These observations are now known to have systematically overestimated the equatorial radius as a result of a bias imposed on measurements by the Martian atmosphere. Radio occultation measurements and photographic observations from Mariner 9 showed that the actual amount of polar flattening is, in fact, much less, about 21 kilometres, and that the centre of figure is displaced from the centre of mass by about 2.5 kilometres toward the south.

General appearance. To the Earth-based telescopic observer, the Martian surface outside the polar caps is characterized by red-ochre-coloured bright areas on which dark markings are superimposed. In the past, the bright areas were usually referred to as deserts and the majority of large dark areas as maria (sing. mare; *i.e.,* oceans or seas). It is now absolutely certain that these dark areas are not, and in all probability never were, covered by expanses of water. Nor do they appear to be physically similar to the dark maria on the Moon. It therefore seems more reasonable to simply refer to dark and bright areas on the planet than to use the older terms.

The dark areas

Surface features. The most prominent dark areas of Mars occupy a band around the planet between 10° and 40° S. Their distribution is irregular, and the northern hemisphere has only two such major features, called Mare Acidalium and Syrtis Major. Dark markings cover about one-third of the total area of the planet's surface, and—according to the interpretation given to the photographs obtained from the Mariner 9 and Viking orbiters over a period of several Martian years—they originated with the interaction of atmospheric wind systems and surface topography. The dark regions of Mars, when viewed at high resolution, are covered with dark streaks and splotches that are associated with craters, ridges, hills, and other obstructions to the flow of local winds. The streaks are sometimes variable and are caused by the removal, from a darker surface material, of a layer of fine dust by atmospheric turbulence in the lee of obstructions. Some of the dark splotches seen in crater floors have been found to be vast fields of sand dunes.

One of the most remarkable facts about the dark areas discovered by telescopic observation is that they undergo both seasonal and long-term variations in size and colour. In the words of E.C. Slipher: "The markings are in a state of perpetual and bewildering fluctuation, the slower and more gradual ones partly through change in the illumination of the Martian air and partly through inherent change in the markings themselves." Charles F. Capen, an expert visual observer, has reported changes in the Trivium Charontis region. In the spring, the area is medium-dark gray with brown tints, olive drab with a darkening wave, later taking on intense black. In summer, the area stays black, but in fall the colour is dark gray and brown, turning to medium-dark gray with brown tints in the winter.

The reported colours of the dark features have been subject to considerable discussion, particularly because colour recognition is largely subjective. It has been questioned if the colours reported are accurate or are merely a reflection of physiological processes in the eye and mind of the observer. A straightforward answer is not entirely possible, but photoelectric spectrophotometry of the dark areas has shown that they are actually red, although less so than the bright areas of the planet.

The bright areas

The bright areas, which represent about 70 percent of the planet's surface, are also well endowed with subtle shadings and intricate features—the so-called Martian canals and oases. The explanation of these phenomena is now clear. The surface of Mars is largely covered by fine dust, which can be effectively transported by surface winds. The global pattern of this dust on the surface largely controls the pattern of albedo on the surface, and the basic pattern itself is set by reoccurring seasonal wind systems and their interaction with the local terrain.

The blue haze. Another phenomenon reported by many Martian observers from Earth-based photographs has been called the blue haze, or violet layer. A comparison of photographs taken through blue and red filters shows that the contrast of surface features is less in blue light. Slipher found, if the wavelength of the light was less than 4,600 angstroms, dark features on the surface were generally totally obscured. Occasional exceptions, called blue clearings, occur when the obscuration lifts for a short time and the visibility of the dark markings is reestablished. Many theories, none entirely satisfactory, have been devised to explain this phenomenon. Most presume that the blue haze is related to the presence of some scattering or absorbing agent in the Martian atmosphere, although others have considered the effect to be illusory. To investigate this phenomenon, some of the television pictures taken by the Mariner 6 and 7 spacecraft were exposed through a blue filter similar to those used in Earth-based telescopic studies of the blue haze. No evidence for any loss of contrast was found for real topographical features on the surface, but albedo markings did show a reduced contrast in the blue light. The blue haze is therefore a real phenomenon, and the explanation of its cause and variability is probably linked to the interplay of reflectance properties of intermixed bright and dark areas on the surface and of the large amounts of fine dust that are now known to be kept in suspension in the atmosphere.

The wave of darkening. Major seasonal changes occur on the planet and are closely associated with changes in the polar caps. The caps wax and wane, and corresponding periodic changes occur in the appearance of surface features. One of the more enigmatic sequences that take place is called the wave of darkening, first discussed in detail by Lowell in 1894. Near the edge of either polar cap, a general darkening of the surface markings appears in early spring as the cap begins to recede. The darkening then moves away from the receding polar cap and sweeps toward and crosses the equator in an indistinct band of heightened contrast, finally dissipating in the opposite hemisphere. The waves, one in each hemisphere, travel at an apparent speed of about 35 kilometres per day. Studies of the phenomenon were carried out by John H. Focas in 1962, using photometric techniques instead of subjective visual reports. While these waves have been well documented in observations from the Earth, all attempts by 1981 to study them from spacecraft had failed. No surface changes had been detected that could be associated with this phenomenon, and, if it is not illusory, it seems most likely to be some kind of atmospheric effect.

Dust storms. Frequently, and with some regularity, the surface features of Mars are obliterated completely as a result of atmospheric dust storms of planetary dimensions. While these events can apparently happen at any time, they occur more frequently when the planet is near perihelion. Observations from the Viking lander spacecraft, which experienced several such storms, have shown that these storms have a major effect on the structure of the Martian atmosphere. Perhaps the best known storm was that which occurred during the approach of the Mariner 9 spacecraft to the planet. The storm had begun several weeks before the arrival of the spacecraft, and it prevented photography and other measurements of the surface for the first few weeks of the mission.

STRUCTURE AND EVOLUTION OF THE MARTIAN INTERIOR

Knowledge of the interior of Mars and how it has evolved is of the broadest conceptual kind. Observations that bound these concepts include the relatively precise measurements

Density of Mars

by the Mariner and Viking missions of the planet's mean radius, its mass, and its moment of inertia. These known factors, together with hypotheses on the overall chemical composition of Mars, restrict the range of interior models to a surprising degree and show that the internal structure of the planet must be substantially different from that of the Earth or the Moon. The mean density of Mars, when corrected for internal pressure, is 3.75 g/cm^3 and is much lower than the corresponding value of 4.04 g/cm^3 of the Earth. Evidently the overall chemical composition of Mars is different from that of the Earth. Most likely Mars has a lower iron–nickel content or is enriched in lighter, more volatile elements.

Table 11: Physical Parameters of Mars

Equatorial radius	3,396.9 km
Polar radius	3,376.1 km
Geometric flattening	0.00612
Dynamical flattening	0.00525
Surface area	1.44 × 10^8 km^2
Volume	1.63 × 10^{11} km^3

The geometric and gravitational figure, or shape, of Mars places constraints on the internal distribution of density, its more spheroidal shape indicating a less centrally condensed object. Evidence of gravity anomalies, a range in topographic altitudes that is twice that found on the Earth, photogeological evidence of extensional stresses, and the fact that the mean geometric figure of the planet does not coincide with that of the gravitational field raises some doubt as to the veracity of the theory that is used to interpret observations of the planet's shape. It is thought, however, that any deviations that are present will have only a minor effect on the implications for internal structure.

Many interior models have been constructed based on the above facts. While they differ in many important details and assumptions, the general picture that emerges is of a planet that is differentiated into three well-defined zones—a dense core, a mantle, and a thin lithospheric veneer, or crust. The radius of the core is about 1,700 kilometres, with a density in the range of 5 to 8 g/cm^3 (depending on assumed composition), and the mantle extends to perhaps within 200 kilometres of the surface. The best estimates of the density of the mantle are in the range of 3.33 to 3.58 g/cm^3, substantially higher than mantle densities estimated for the Earth.

Experiments were conducted by the Viking landers and Mars spacecraft to examine the chemical composition of the crustal layers on Mars and, by Viking, to probe the interior seismically. Results of these experiments obtained by 1981, while of considerable interest regarding detailed phenomena, were not useful as a probe of the interior. The X-ray fluorescent spectrometer on Viking examined surface materials at both lander sites and found them to be remarkably similar, even though they were separated by a distance of 6,500 kilometres. The chemical nature of the Martian soil is unlike any rock type found on the Earth or known on the Moon and seems to be similar to a heavily weathered, hydrated clay. The Mars spacecraft found direct evidence for the occurrence of natural radionuclei of potassium, uranium, and thorium in the soil in similar proportions to those found in terrestrial soils; the energy released by these long-lived radioactive elements has probably determined the thermal evolution of Mars over most of geological time. Only one of the Viking seismometers was able to operate on the Martian surface, and so it was not possible to probe the structure of the deep interior by listening to the reverberations of Mars quakes from two stations, as has been done on the Moon. The Martian core is probably solid, since the planet appears to have no strong intrinsic magnetic field of global dimensions that is of the dynamo type.

The small amount of factual data regarding the evolu-

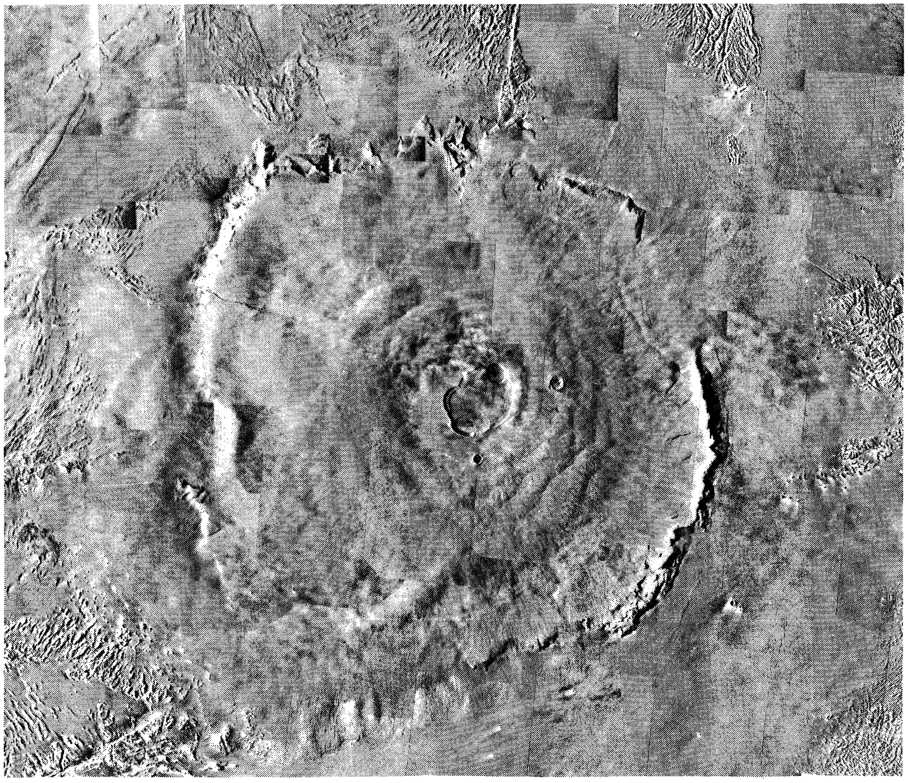

Figure 28: Viking photographs form a mosaic image of Olympus Mons looking directly into the top of the caldera. The circular escarpment, which borders the mountain, is at places as high as seven kilometres.

Evolution of the interior

tion of the Martian interior is primarily comprised of the geologic record of large-scale extensional stresses in the crust, the presence of volcanism (lava plains, volcanic domes), and the densities of impact craters (see below). It is thought that there were four identifiable stages in the evolution of the planet. The first was its accretion over a relatively short time scale. This was quickly followed by the second stage, the separation of the core and the formation of a veneer of crust on the otherwise hot planet. These first two stages are thought to have been completed in the first 1,000,000,000 years of the planet's existence. In the third stage, which occupied the next 2,000,000,000 years, strong heating throughout the body of the planet by long-lived radioactive elements in the interior governed the development of the basic physical and chemical structure of the mantle. This was accompanied by a considerable degassing of the interior and formation of early atmosphere, volcanism, and a general physical expansion of the planet. It was during this stage that the large-scale topography, volcanoes, and enormous chasms and channels found by Mariner 9 were formed. This activity probably stopped some 1,500,000,000 years ago, as the planet reached an equilibrium referred to as its mature state. The fourth stage of evolution is one of cooling and contraction as the interior energy sources become exhausted, and it is not known whether Mars is yet in this terminal stage.

CHARACTER OF THE SURFACE

The character of the Martian surface on linear scales below 100 kilometres was a matter of pure conjecture until the pictures of Mariners 4, 6, and 7 were returned to Earth in 1965 and 1969. But Mars did not reveal the true character of its surface until the Mariner 9 orbiter mission, which photographically surveyed more than 70 percent of the total surface of the planet at spatial resolutions between one and three kilometres. The Viking missions in 1976 then provided much of the detailed information that explains the forces and processes that have shaped the surface.

The early fly-by missions of the 1960s seemed to indicate a planet much like the Moon, a planet whose interior had been essentially inactive throughout its history and whose inhospitable surface was saturated by impact craters. Only glimpses of the presence of a "chaotic" terrain, characterized by irregular areas of jumbled short ridges and depressions, seemed to indicate exceptional surface modification processes. The reaction from many scientists at the time was that Mars was simply uninteresting.

Olympus Mons

Mariner 9 showed that this impression was quite inaccurate and simply the result of bad luck. In fact, a surface of widely varying character was revealed. Any possible relationship between the classical "canals" of Lowell and real surface features was immediately dispelled as an optical illusion resulting from the poor spatial resolution achievable by telescopes on Earth. Some of the classical "oases," such as Juventae Fons and Oxia Palus, were identified as large, dark-floored craters. Nix Olympica, discovered by Schiaparelli in 1879, was found to be a truly enormous and complex caldera at the summit of the largest volcanic mountain presently known in the solar system. This volcano, now called Olympus Mons, has 10 times the volume of the Earth's largest volcano, Mauna Kea, and, at an elevation of 27 kilometres, is three times the height of Mt. Everest. Olympus Mons covers a circular area some 550 kilometres in diameter and is skirted by an escarpment that in places rises as much as seven kilometres above the adjacent terrain.

The Mariner and Viking pictures show the surface to be composed of an almost innumerable variety of land forms, the origin of many of which was not yet understood in the mid-1980s. Many of the thousands of images and other scientific data taken by Viking still had not been studied in detail. Nevertheless, there are clear indications of planet-wide order in the location and variety of the primary terrain types.

Two regions of relief. Except for the polar regions, the character of the surface terrain divides the planet into two hemispheres. In the south, the surface is mostly one or two kilometres above the mean level and is heavily cratered. At low resolution, photographs of the surface are reminiscent of those of the lunar uplands or the planet Mercury, and the density of impact craters indicates a very old and primitive terrain. In the north, which is generally below the mean level, there are many craters, but the surface is chiefly characterized by widespread, relatively smooth plains. These plains were probably formed by widespread flooding of the original heavily cratered surface by molten lava from the interior in the third stage of the planet's development. This type of hemispheric dichotomy is not unique in the solar system and is present on the Moon and the Earth. The physical cause of the dichotomy may, however, be different in all three cases.

The boundary of the two regions is not parallel to the equator, but roughly follows a great circle inclined to it by about 50°. The boundary is broad and irregular and slopes downward toward the north. Along this interface, the terrain is both varied and at places unique. Here are found "fretted" terrain, "chaotic" terrain, large "channels," "knobby" terrain, and, in the region of Tharsis, a large area of relatively young volcanic and "grooved" terrain that is surmounted by four of the largest volcanic mountains in the solar system.

Types of craters

The southern craters. The southern cratered terrain appears to be extremely old. The number of very large craters implies an uncertain age of about 3,000,000,000–4,000,000,000 years, depending on the precise history of impact cratering events. There are several distinctive types of craters: large and flat-bottomed craters; smaller and fresh-looking bowl-shaped craters, as on the Moon; pedestal craters; and rampart craters. The last two types are unique to Mars, with rampart craters distinguished by smooth layers of ejecta that appear to have splattered from the crater, possibly because of the presence of a deep permafrost layer just below the surface and of groundwater below the permafrost. Pedestal craters are otherwise normal-looking craters that sit on elevated circular platforms. It is thought that these platforms may be debris from the original impact that was left intact as the rest of the surface was stripped away in severe erosional episodes. The largest recognizable impact feature on Mars is the Hellas basin, which is roughly 1,600 kilometres in diameter. Its floor, once erroneously thought to have a special featureless character, is the lowest topographic region on the planet, lying some four kilometres below the mean surface level.

The high spatial resolution of the Viking photography has yielded one further tantalizing feature characteristic of this ancient southern terrain: the pervasive presence of fine channels and gullies that strongly resemble networks of desert runoff channels. It is speculated that, because of the wide occurrence of these features and their similarity to runoff systems in terrestrial deserts, they were formed as a result of widespread rainfall in a primitive epoch in the history of the planet, when its atmosphere was much more massive than it is today.

Possible fluvial channels

The interface terrain. In fretted, chaotic, and knobby regions, the Martian surface has apparently undergone vigorous modification processes leading to the collapse of large areas, sometimes followed by erosional processes (*e.g.,* landslides, wind, outflow of subsurface water) and volcanic flooding with fluid lavas. Collapse in the case of chaotic terrain is thought, in one hypothesis, to be the result of the melting of a subsurface permafrost layer by volcanic activity. If the water was released rapidly and was in great enough quantity, it may have flowed away from the site, leaving chaotic terrain at the head of a fluvial channel. Such channels, some very large, are seen in the region near Chryse Planitia (the Viking 1 spacecraft landed at the end of such a channel). The channels often show sinuous scour lines that diverge around obstacles that have themselves been eroded into streamlined shapes. The hypothesis of fluvial (water) origin is, however, not entirely certain, since liquid water is not stable under the present conditions of the Martian surface, and the probability of a former climate more favourable for such processes is uncertain. Several alternative, but less satisfactory, hypotheses for the formation of the channels include the flow of highly fluid lava or of fluids other than water, or wind erosion.

The Tharsis region. The youngest surface on Mars is found in the region of Tharsis. The surface is a vast,

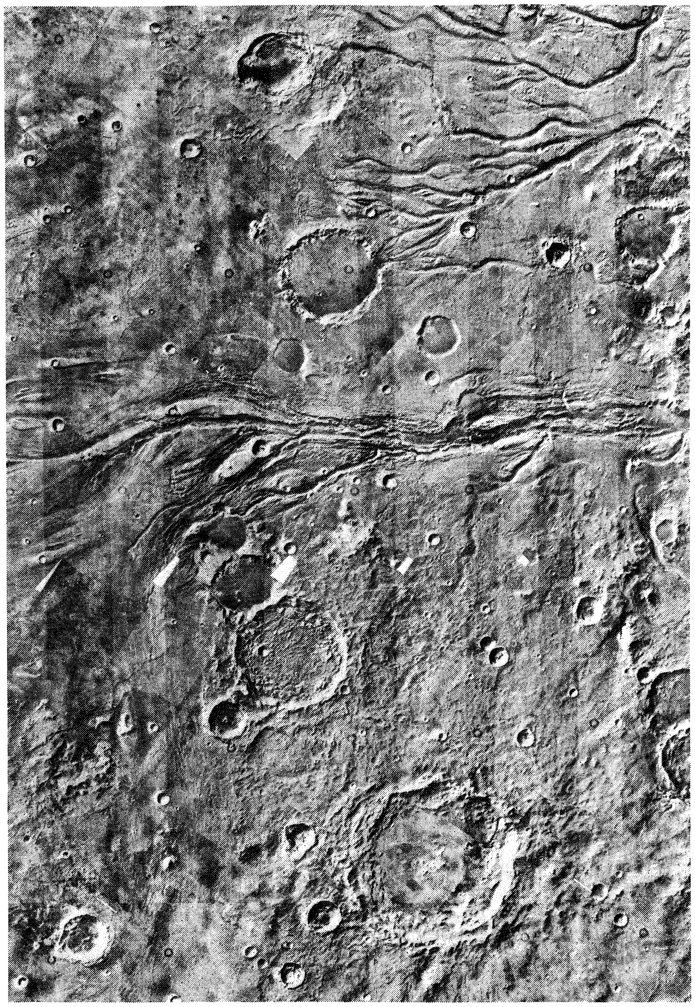

Figure 29: Viking photograph of the cratered terrain in Lunae Planum. The dry channels are thought to have been caused by a catastrophic flood during the early history of Mars.

domed, volcanic plain some 2,000 kilometres in extent. This Tharsis "bulge" is raised in excess of 10 kilometres above the mean surface level. Superimposed on it is a ridge formed of three massive volcanoes of the shield type: Arsia Mons, Pavonis Mons, and Ascraeus Mons. On the flanks of the bulge are Olympus Mons and the remnants of a much older volcanic mountain, Alba Patera. It is not possible to estimate accurately the age of these volcanoes, but, with the exception of Alba Patera, they could be less than 1,000,000,000 years old. The possibility of their being active today cannot be completely discounted. Martian volcanic features, in smaller and in different forms, are almost ubiquitous in the northern plains. Many other volcanic mountains have now been located on the planet, with concentrations in Elysium and in both polar regions.

Tharsis area's volcanoes

The flanks of the Tharsis bulge are also the site of a "grooved" terrain that is formed of largely parallel fractures radial to the centre of the bulge. Some of these fractures are very large and complex; the largest, Valles Marineris, is a canyon system that runs roughly east–west near longitude 70° west and some 10° south of the equator. Its length of 4,500 kilometres stretches almost a quarter of the way around the planet, and, with a maximum width of roughly 600 kilometres and depth of seven kilometres, it is comparable in dimensions to the East African Rift Valley. The walls of its canyons are very steep and show ample evidence of large landslides. The walls have receded in many places to form a complex pattern of tributary valleys in the surrounding plains. Flat-topped mesas found in the bottom of the canyon have been interpreted by some scientists as evidence for past flooding and sedimentation in the floor of the valley.

Topography. Early visual observers of the planet concluded that high mountain ranges similar to the Himalayas or the Alps were not present on Mars. Early estimates suggested that, if mountains existed with altitudes higher than 8.4 kilometres, they would have been detected as irregularities at the terminator. The calculations evidently did not apply to the gently sloping volcanic shields that have now been found on the planet and that rise to such enormous altitudes. The evidence against folded mountain building from the Mariner and Viking photographs also seems clear, for there are no signs of the compressional folding that arises as a result of plate tectonics. There is, however, plenty of evidence for topographic relief on the surface of the planet on the continental scale. Elevation differences of as much as 30 kilometres are known to exist over scales of thousands of kilometres. These differences in elevation, while large, nevertheless imply gentle slopes.

History of topographic studies of Mars

The history of the search for large-scale topographic relief is fascinating and has an ironic twist. In a sense, the search for large elevation differences grew out of the controversy over the nature of the dark areas and the possible presence of life. The proponents of the "vegetation" theory of the dark areas considered them to be low lying and hence warmer and moist, and therefore more conducive to life. The temperatures of the dark areas are indeed a few degrees warmer than those of the surrounding bright areas, but the opponents of the above hypothesis preferred to attribute the temperatures of the dark areas and their curious ability to change their appearance on a seasonal basis to inorganic causes. The fact that they are warmer is simply a result of their being darker, which is just another way of saying that they absorb more energy from the Sun. Their apparent ability to change their appearance was presumed to be the result of their being elevated regions and of the transport and deposition of small dust particles by the prevailing winds.

In 1965 it was noticed that white clouds that tended to form and remain stationary over certain bright areas were aligned with the boundaries of adjacent dark areas. These clouds were thought of as lee clouds formed in the prevailing wind as it crossed the dark areas and that the latter must therefore be high ridges. Further circumstantial evidence came from radar observations. Surface regions with high radar reflectivity were found to be correlated with dark areas, although they were not actually coincident with the dark areas, but were always somewhat displaced in longitude. The conclusion reached from these observations was that the dark areas must be elevated regions with low slopes that extend over extremely large distances. Elevation differences of about 10 kilometres were thus implied. In 1967, precise radar-ranging methods were used to scan the surface along a narrow swath centred on latitude 22° N. The timing of the radar echoes led to the first direct evidence that large elevation differences in fact did exist, but it showed, ironically, there was little correlation between the dark areas and elevation. Another investigation using entirely different techniques further confirmed and extended these measurements. The amount of carbon dioxide gas in the atmosphere was measured at hundreds of points of the disk from latitudes 25° S to 40° N and provided the data to make the first crude topographical maps of the planet.

There are now detailed maps of the topography and gravity field of Mars that cover the entire globe. These maps were made by combining information from various experiments, including Earth-based radar, timings of occultations of orbiting spacecraft behind the planet's limb, and ultraviolet and infrared photometry. The main topographic characteristics of Mars are as follows. In the south, except in the Hellas basin, the surface is elevated above the mean by about two kilometres. The reverse is the case in the northern hemisphere. In equatorial latitudes, the circumference of the planet shows a sinusoidal distortion, with high altitude bulges near 110° W longitude (Tharsis) and 210° W (Elysium). The Tharsis bulge rises to an altitude of 10 kilometres, while in Elysium the altitude reaches six kilometres. The frequency of occurrence of a particular surface elevation shows only a single peak near the mean level. This is unlike the Earth, which shows a bimodal distribution as a result of its surface being di-

Main topographic features

vided into ocean floors and continental regions. On Mars, gravity anomalies are strongly correlated with topographic features, indicating that the Martian crust is probably not isostatically compensated. The topography of Mars may still be relaxing from its primitive form, may possibly be supported by internal mantle convection, or is simply supported by uncompensated stresses in the crust.

THE POLAR CAPS

Seasonal changes. The seasonal behaviour of the polar caps is one of the more elaborately documented phenomena on Mars. In early spring the southern polar cap has its greatest dimensions and stretches from the pole to a latitude of about 50° S. As spring proceeds, the cap sublimates and begins to recede at a rate of about 1° of latitude every five days. During this time the edge of the cap takes on a ragged appearance. Eventually, gaps appear that break the cap into well-defined fragments. This process is repeated each year, and the location of the fragments is essentially always the same; the Mariner and Viking cameras, however, have detected small variations in detail from year to year. As the polar snow recedes, a dark blue band, first noted by Wilhelm Beer and Johann von Mädler in 1830, is seen in telescopic observations at the edge of the cap. One-third of the Martian year later, the cap has receded to its smallest extent; it is then not usually visible from Earth, but spacecraft observations show that a small remnant remains.

The polar hood

A brief interlude of atmospheric clarity then follows, which terminates in early fall with the rapid formation of obscuring clouds referred to as the polar hood. Occasionally, the hood is sufficiently transparent in the red region of the spectrum to allow photographs to be taken of the new southern polar cap then forming beneath it. The hood is far more extensive than the cap itself and has been reported to extend to within 35° of the equator. The advance of the polar hood is associated with an atmospheric frontal system, the passage of which is very abrupt. The composition of the particles that make up the polar hood is either water ice, solid carbon dioxide, or, possibly, a mixture of the two.

The behaviour of the northern polar cap is similar, although not exactly the same in detail. The differences are mainly due to a combination of the effects of the lengths of the seasons and the variation in distance from the Sun. The atmospheric frontal system associated with the advance of the polar hood was observed in the northern hemisphere by the Viking 2 lander. Since the front was observed near midday, it was found to be accompanied by a substantial drop in illumination. The northern summer is longer than the southern. The planet is at a greater distance from the Sun during the northern summer, however, and receives less heat during that period, allowing the remnant of the northern cap to be more substantial than its southern counterpart.

Theories of cap composition

Composition. The composition of the remnant Martian polar caps in summer is not precisely known, despite the considerable data on their thermal and radiative properties acquired by the Viking craft. One early hypothesis—that the caps were simply water ice—can be traced to William Herschel, who imagined the polar caps of Mars to be just like those on Earth. In 1898, George Johnstone Stoney questioned this theory and suggested that the caps might consist of frozen carbon dioxide (CO_2); physical evidence to support this idea was not available until 1947, when Gerard P. Kuiper discovered CO_2 to be present, although in unknown proportions, in the planet's atmosphere. Stoney's hypothesis was particularly attractive because no water vapour had then been detected in the atmosphere, but Kuiper, in 1948, was nevertheless persuaded that the caps had reflection spectra that were characteristic of water ice, rather than of CO_2. Similar spectra, published by V.I. Moroz in 1966, indicated the same result, but R.B. Leighton and B.C. Murray published, also in 1966, an important numerical study of the thermal environment on Mars that threw considerable doubt on the water ice hypothesis. Their calculations, although based on simplifications of the actual conditions on Mars, were later supported by measurements taken from lander and orbiting spacecraft. The calculations predicted that atmospheric carbon dioxide gas would freeze out at the poles and showed that polar caps so formed would behave similarly to actual observations.

The question of the composition of the cap remnants remained unsolved, however, until the Viking 2 mission returned information regarding the north polar remnant. The ice of the northern remnant is at temperatures of 205 K, well above the frost-point of CO_2, and is unquestionably mainly water ice. It represents the largest reservoir of available water on the planet. Observations at the south pole are more ambiguous, and it is highly probable that the southern cap remnant is CO_2 ice, rather than water.

Data from the Mariner 6 and 7 spacecraft in 1969 resolved the problem of composition as far as the fully devel-

By courtesy of the Jet Propulsion Laboratory/National Aeronautics and Space Administration

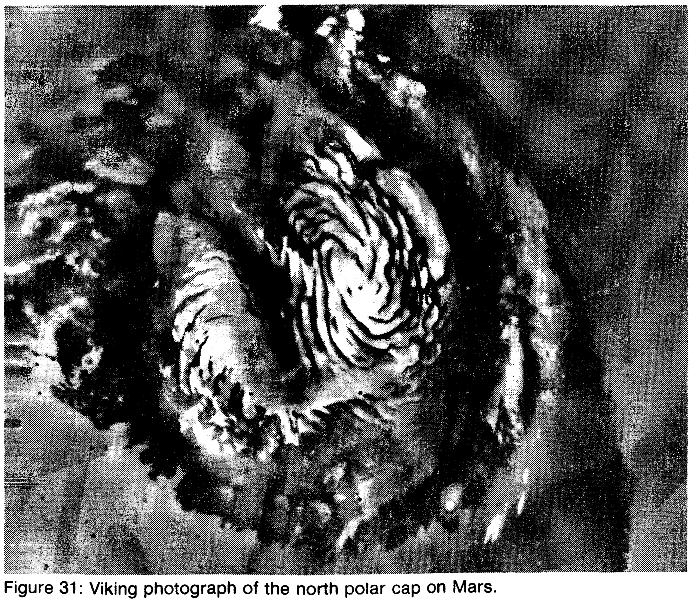

Figure 31: Viking photograph of the north polar cap on Mars. The bright areas are composed of water ice. The dark lines cutting into the cap are valleys, the sides of which are the site of a laminated terrain unique to Mars.

oped caps are concerned. On board the spacecraft were an infrared radiometer that could measure the temperature of the surface and an infrared spectrometer that could look for characteristic features in the spectrum of the reflected light from the polar cap without the interference of absorption in the Earth's atmosphere that plagues Earth-based astronomers. As the field of view of the radiometer swept over the polar cap, the temperature dropped to the value predicted for frozen carbon dioxide, thereby demonstrating that a polar cap composed of CO_2 would be stable. If the measured temperature had been only 10° higher, the CO_2-ice hypothesis would have been untenable. The infrared spectrometer then provided conclusive evidence that the spectrum contained absorption features at 3 and 3.3 micrometres, levels that are characteristic only of solid CO_2.

Relief features. The terrain in the polar regions is among the most distinctive on the planet. Except for winter, when the surface is covered with what are probably several metres of CO_2 snow, wide areas of the surface show characteristic layers, or "laminations," of alternately dark and bright materials. The layers are exposed on the flanks of escarpments and valleys that border or cut into the polar caps. (The valleys have cut into the caps in such a way as to give them a distinctive swirl-like appearance.) The layers may indicate a history of regular climatic variations, as the planet's orbital parameters have varied in response to gravitational interaction with the other planets (primarily Jupiter and Earth), which controls the relative amounts of dust and water ice deposited during successive winter seasons.

Sand dunes

In the north polar region is the largest sea of sand dunes, or "erg," in the solar system. This erg forms a band of windblown sand entirely around the north polar remnant cap. The dunes in this region are spectacular in their regularity over hundreds of kilometres.

THE ATMOSPHERE

Basic atmospheric data. The Martian lower atmosphere consists mainly of carbon dioxide that has been released slowly from the crust and interior over the age of the planet. There is strong evidence that the lower atmosphere was much more extensive in the remote past, and there are signs that rainfall may have occurred in some regions. While only small amounts of water are found in the lower atmosphere today, it supports just about as much water vapour as it is physically able. In this sense, the lower atmosphere is humid, or saturated; it is not in any way to be considered moist, however. Ice clouds have been observed at high altitudes, and in several localities morning ground ice-fogs have been seen. Nitrogen and various rare gases, oxygen, and carbon monoxide are also present in small quantities.

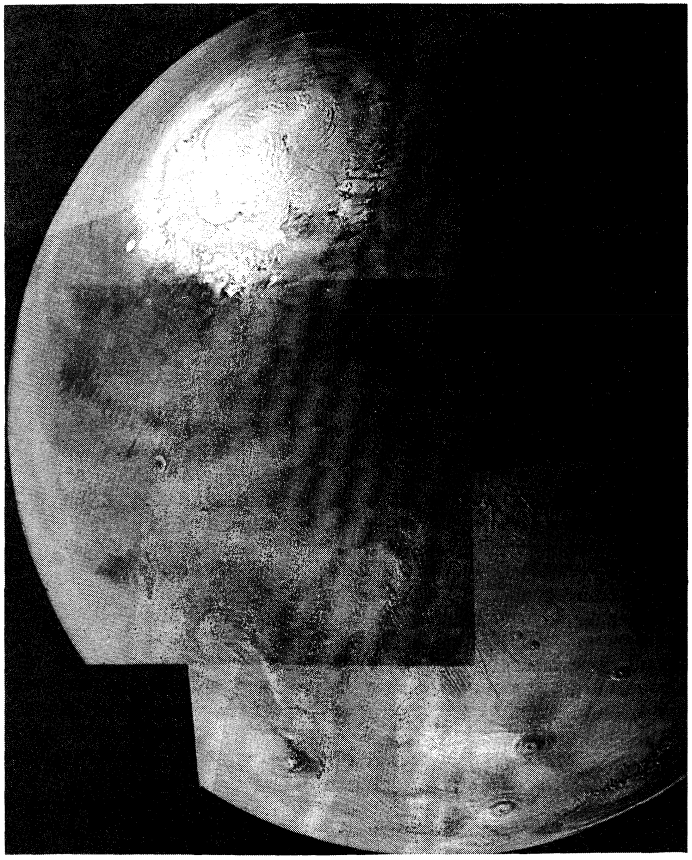

Figure 32: Mariner 9 composite photo of the northern hemisphere of Mars taken during the late Martian spring. The shrinking north polar cap can be seen at top, and Olympus Mons can be seen at lower left.

Table 12: Composition of the Martian Atmosphere
(fraction by weight)

Carbon Dioxide (CO_2)	96.5%
Molecular nitrogen (N_2)	1.8%
Argon (Ar)	1.5%
Molecular oxygen (O_2)	0.1%
Carbon monoxide (CO)*	0.05%
Water vapour (H_2O)*	0.02%
Neon (Ne)	0.0001%
Krypton (Kr)	0.00003%
Xenon (Xe)	0.00002%

*Uncertain, variable, or unevenly distributed in the atmosphere.

The characteristic temperature in the lower atmosphere is about 200 K. This is generally colder than the average surface temperature, which in daytime is about 250 K. The difference is due to the presence of temperature gradients that have an average value of about 1.5 K per vertical kilometre. In the middle and upper atmosphere, large daily waves of temperature and density have been found, indicating a confused and variable structure. There is also an ionosphere that, unlike the Earth's ionosphere, consists primarily of oxygen ions at an altitude near 130 kilometres.

A thin atmosphere

At the planet's surface, the atmosphere is very thin, the average surface pressure being less than one-hundredth that on the Earth. Because of large variations in the altitude of the surface, however, some locations may experience a surface atmospheric pressure up to five times greater than others. The total mass of atmosphere, unlike that of the Earth, undergoes major seasonal variations as the major atmospheric component, CO_2, "snows out" at the winter pole. The annual variation of surface pressure is about 26 percent of the mean value.

Despite its thinness, the Martian atmosphere supports a variety of clouds. One variety, the so-called yellow clouds, are intense dust storms that throw dust into the atmosphere up to heights of 10 kilometres or more. Under special conditions, localized storms have been found to trigger storms of global dimensions that can totally obscure the surface from view; such global storms were experienced by Mariner 9 and the Viking lander craft. Even in their absence, the atmosphere is never clear of dust, the presence of which plays an important role in determining the structure of the atmosphere.

Composition and surface pressure. Precise measurement of the Martian atmosphere was made possible by the Mariner 9 and Viking 1 and 2 missions (see Table 12). Prior telescopic observations had already determined that CO_2 was the atmosphere's primary constituent, that traces of carbon monoxide (CO) and water were definitely present, and that the mean surface pressure was near 5.5 millibars. Kuiper discovered the presence of CO_2 in 1947, at a time when the meager evidence available suggested that, as on Earth, nitrogen was the principal atmospheric component. It was not until 1963 that it was possible to conclude that CO_2 was, in fact, the major atmospheric component.

As a result of more than 500 radio occultation experiments from orbiting spacecraft and direct sampling and chemical analysis of atmospheric gases through mass spectroscopy and gas chromatography, precise knowledge of the atmosphere, both locally and globally, and of its variation in time is now available.

Molecular composition

Below 125 kilometres in altitude, where the atmosphere is well mixed by turbulence, 96.5 percent of the atmosphere by weight is CO_2. This is a comparatively large amount of CO_2, being some nine times the amount now in the Earth's much more massive atmosphere. When consideration is made, however, of the tremendous amount of CO_2 that has been cycled through the Earth's atmosphere and is now chemically locked in terrestrial sedimentary rocks, the Martian CO_2 content actually represents slightly less than 1/1000 of that on the Earth. The balance of the Martian atmospheric content is molecular nitrogen (N_2), argon (Ar), water vapour (H_2O), and rare gases. In addition to these molecules, there are also trace amounts of gases that have been produced from the primary gases by photochemical reactions, generally high up in the atmosphere; this component includes molecular oxygen (O_2), carbon monoxide (CO), nitric oxide (NO), and small amounts of ozone (O_3). The atmosphere supports an ionospheric layer at the top of the atmosphere, where the densities are low enough for the components to separate diffusively according to their mass. The Martian ionosphere is less developed than the F-layer on Earth, but is formed in a similar fashion. Its peak density of 10^5 ions/cm^3 occurs near 130 kilometres altitude and is formed primarily by O_2^+ molecules that have been produced in local chemical reactions. These photochemical reactions are often quite energetic; Michael B. McElroy has shown that the electronic recombination of O_2^+, N_2^+, CO^+, and CO_2^+ ions high in the atmosphere (in the exosphere) can produce energetic neutral nitrogen and carbon atoms that can escape ballistically from the Martian gravitational field. His calculations show that Mars has lost significant amounts of oxygen and nitrogen in this way over geologic time. Finally, an important constituent of the outer limits of the atmosphere is atomic hydrogen (H). This is a relatively easy atom to detect and monitor, for it strongly scatters solar radiation, which is present in abundance at 1,216 angstroms. The rate of decrease in the brightness of the scattered radiation with increasing distance from the planet allows for the determination of the temperature at the top of the atmosphere. This temperature, in turn, is important for understanding the long-term evolution of the atmosphere.

The total mass of gas in the Martian atmosphere is not fixed, and measurements at the Viking lander sites show that there is a regular seasonal variation as CO_2 "snows out" on the winter polar cap and is released from the receding summer polar cap. Seymour Hess and his associates found that this variation has a peak-to-peak amplitude of about 26 percent of the mean atmospheric pressure (7–8 millibars) at the lander sites. Hess has calculated that some 7.9×10^{12} metric tons of CO_2 are involved in this yearly exchange, equivalent to a thickness of at least 23 centimetres of dry ice over the vast area of the polar caps. This translates into several metres of CO_2 snowfall. The Martian atmosphere seems unique in this respect, and several atmospheric phenomena—such as the frequency of dust storms and wind patterns and velocities—are ultimately controlled by it.

Presence of water

Water (H_2O) is a minor constituent of the atmosphere, primarily because of low atmospheric and surface temperatures. At most, H_2O is present at a level of only a few molecules per 10,000, but it seems nevertheless to play an important role in atmospheric chemistry and in meteorology. The atmosphere is effectively saturated at all times with water vapour, yet there is no liquid water. The temperature and pressure of Mars are so low that water molecules can exist only as ice (solid) or as vapour. Although the presence of water vapour on Mars is exceedingly difficult to determine by telescopic observations because of the large amounts of water in the Earth's atmosphere, the discovery of water on Mars was made in this way in 1963 by Lewis D. Kaplan, Guido Munch, and Hyron Spinrad.

Most of the detailed knowledge of the water on Mars comes from the Viking orbiter, which was able to follow the seasonal patterns of water in the atmosphere over a full Martian year. Unexpectedly, atmospheric water vapour—except in a few special localities that show surface ice or local morning fogs—undergoes little daily exchange with the surface, despite the very cold surface temperatures recorded during the Martian night. Water vapour is found to be mixed uniformly up to altitudes of 10 or 15 kilometres and shows strong latitudinal gradients that depend on the season. According to Crofton B. Farmer, the total atmospheric content of water vapour can be most easily understood by imagining a cube of ice some 1.3 kilometres on each side, a size little more than that of a medium-sized terrestrial iceberg. It is inferred that this atmospheric water vapour is in contact with a much larger reservoir in the Martian soil; subsurface layers of ice are thought to be ubiquitous on Mars at latitudes poleward of 40°.

Surface pressure is highly variable because of the meteorological processes mentioned above and the enormous range of topographic elevations on the surface. The pressure at the lowest elevations (for example, at Hellas; −4 kilometres) is as high as 8.4 millibars, while at the crest of Olympus Mons (+27 kilometres) it is only 0.5 millibar. At locations near the mean elevation of the topography, the average pressure is about 5.9 millibars.

Isotopic composition

In addition to knowledge of molecular constituents of the atmosphere, the Viking mass spectroscopy and gas chromatography experiments yielded measurements of the isotopic composition of the major species and rare gases. Values of the ratios of isotopes, carbon-12 to carbon-13 and oxygen-16 to oxygen-18, are similar to those on Earth. The ratio of the isotopes argon-40 to argon-36—a ratio thought to be important in judging the amount of volatile gases that have escaped from the interior of the planet over geologic time—was found to be roughly 10 times the value for the Earth, however. In addition, the ratio of the isotopes nitrogen-14 to nitrogen-15 was found to be 1.62 times larger than the terrestrial value. These latter two measurements, together with many local indications of liquid water on the surface in the remote past as well as similar measurements of the Venutian atmosphere, have had a significant effect upon ideas concerning the evolution of the Martian atmosphere. The enhanced nitrogen ratio is thought to have originated in the selective escape of the lighter nitrogen isotope (nitrogen-14) as a result of photochemical reactions at the top of the atmosphere noted earlier. This idea, if correct, implies that much larger amounts of nitrogen were present in the atmosphere in the past. The similarity of carbon and oxygen isotopic ratios to those of the Earth implies that large volatile reservoirs for these elements exist on Mars. The enhanced argon isotopic ratio—coupled with the fact that the observed relative elemental abundance of the rare gases (argon, xenon, krypton, neon) is similar to terrestrial values—can be interpreted as a sign that Mars was formed with an overall deficiency of volatile elements relative to the Earth. Also, the low total mass of atmosphere may indicate that there has been a much slower release of gases from the interior of Mars than that experienced by the Earth.

The ratio of carbon dioxide and molecular nitrogen content relative to that of the rare gases is 10 times smaller on Mars than on the Earth. This is interpreted by some scientists as a sign that large amounts of CO_2 and N_2 have been lost to Mars during its history. This hypothesis agrees with the ideas derived from the discussion of atmospheric escape, and it is conjectured on the basis of these ideas that Mars may once have had an atmosphere the major constituents of which were carbon dioxide, molecular nitrogen, and water and the dimensions of which were similar to the atmosphere that exists on the Earth today.

Atmospheric structure. The vertical structure of the Martian atmosphere—*i.e.,* the relation of temperature and pressure to altitude—is determined partly by a complicated balance of radiative, convective, and advective energy transport and partly by the way energy (from the Sun) is at first introduced into the atmosphere and then lost by radiation to space. Before 1965, essentially all knowledge of the Martian atmospheric structure was based on extrapolations of indirect data with the help of theoretical models. As a result of a wide range of spacecraft observations, detailed knowledge of the real structure of the atmosphere and how it reacts to changing conditions is now available. Many of the more general concepts, such as the predictions of large diurnal fluctuations in temperature and of large thermal inversions at the surface during the Martian night, were correct. Detailed comparisons have also shown, however, that many of the early ideas were naive.

There are two factors that control the vertical structure of the lower atmosphere—its composition of almost pure carbon dioxide and its content of large quantities of suspended dust. Carbon dioxide, which has a strong infrared spectrum, radiates energy with great efficiency at Martian temperatures and causes the atmosphere to respond rapidly to changes in the amount of solar radiation received. The suspended dust absorbs great quantities of heat directly from the Sun's light and provides a distributed energy source throughout the lower atmosphere.

Temperature variations

Surface temperatures depend on latitude and fluctuate over a wide range from day to night. Under normal weather conditions at the Viking 1 lander site, the temperature regularly varied from a low near 189 K, just before sunrise, to a high of 240 K in the early afternoon. This is a swing equal to 92° of temperature Fahrenheit, much larger than occurs, for example, in desert regions on Earth. This diurnal variation is greatest near the ground and occurs because of the ability of the surface to quickly radiate its heat to space during the night. During dust storms, this ability is impaired and the daily temperature swing is reduced. Above altitudes of a few kilometres, this diurnal swing is damped out, but other oscillations appear throughout the atmosphere as a result of the direct input of energy from the Sun. These oscillations, which are wavelike in nature and are akin to tides, have been measured as pressure and temperature variations and lead to a very complex wavelike, rather than smooth, vertical structure. The mean temperature of the lower atmosphere falls off with altitude at a rate (or lapse) of about 1.4 K per kilometre to a height of about 40 kilometres and is roughly constant at 140 K above that level. This low lapse rate, caused by the large amount of suspended dust, was unexpected; the lower atmosphere, or troposphere, was anticipated to be convectively unstable and to have an adiabatic lapse rate near 5 K per kilometre, and the tropopause, the upper limit of the troposphere, was expected to occur at much lower altitudes (15 kilometres).

Above an altitude of 100 kilometres, the structure of the atmosphere is determined by the onset of diffusive separation of the various atmospheric molecules. The tendency of heavier molecules to lie below the lighter overcomes the tendency of turbulence to mix the atmospheric gases. Absorption of ultraviolet light from the Sun then disassociates and ionizes the atmosphere's constituents and leads to complex sequences of chemical reactions. The net result is the embedding of an ionized layer near 130 kilometres and an increase in temperature, particularly of the ionic component, at higher altitudes. The top of the atmosphere, or exosphere, is characterized by a temperature of about 300 K averaged over a Martian year.

Meteorology and atmospheric dynamics. The global pattern of the atmospheric circulation of Mars shows many superficial similarities to that of the Earth, although the causes of motion arise from different circumstances. The most important of these are the ability of the Martian air to adjust rapidly to local conditions of solar heat input, the lack of oceans that have a large thermal inertia, the great range in altitude on the surface, the strong internal heating of the atmosphere because of suspended dust, and, finally, the seasonal deposition and release of a large fraction of the Martian atmosphere by the polar caps.

Martian winds

There are no direct measurements of wind velocities in the free atmosphere more than one or two metres above the surface, and knowledge of winds is based on inferences from a global series of atmospheric temperature measurements made from the Mariner 9 orbiter. Such observations can be directly related to the zonal wind field if it is assumed that the pressure forces that drive wind motions are balanced by coriolis forces that arise in a moving atmosphere as a result of planetary rotation. Such a geostrophic balance applies on Earth and it is expected that it should apply equally on Mars. The predicted wind fields show a strong dependence on the Martian season, because large horizontal temperature gradients build up across the edge of the newly forming polar cap in autumn and in winter. The result is the formation at high latitudes of strong jet streams with eastward velocities in excess of 100 metres per second. Elsewhere in the atmosphere, the velocities are much lower, on the order of 10 metres per second. Circulation is less dramatic at the equinox, with light winds predominating everywhere. Surface winds in the lowest one or two kilometres of the atmosphere are strongly controlled by frictional forces and turbulence.

Direct measurements of wind velocities at these low altitudes are available at the Viking lander sites, as are indications of the mean direction of local winds from streaks in windblown dust, patterns in dune fields, and patterns in many varieties of clouds. The low-altitude winds are generally regular in their behaviour and light, the mean wind velocity at the Viking lander sites early in the mission being 0.63 metre per second. On Mars, unlike the Earth, there is also a relatively strong meridional circulation that transports the atmosphere to and from the winter and summer poles. The general circulation pattern is occasionally unstable and exhibits large-scale wave motions and instabilities. The effects of a regular series of cyclones and anticyclones can be clearly seen in the pressure and wind records at the Viking lander sites.

Smaller scale wave motions and tides, driven both by the Sun and by surface topography, are ubiquitous in the atmosphere, as attested to by its irregular vertical structure discussed earlier. This is probably why the atmosphere maintains a uniform composition to extremely low pressure levels. The pressure level of the turbopause, or level of mixing, on Mars is some 50 times lower than that of the Earth. This turbulence is presumably also an important factor in maintaining the large quantity of dust supported in the atmosphere. The state of the atmosphere is highly susceptible to the presence of this dust, and one of the most dramatic and interesting of Martian meteorological phenomena is the global dust storm. Mariner 9 and Viking cameras recorded in excess of 20 local dust storms during their primary missions and in two cases experienced their development into global dimensions.

Dust storms

The dust storms tend to begin at preferred locations in the southern hemisphere during the southern spring and summer. The activity is at first local and vigorous (for reasons that are not yet understood), and large amounts of dust are thrown up high into the atmosphere. If the amount of dust reaches a critical quantity, the storm rapidly intensifies and large amounts of dust are carried aloft by the winds to all parts of the planet. This leads in a few days to the total obscuration of the surface. Measurements at the Viking lander sites indicate that atmospheric transmission is reduced by a factor of 20 or more. The intensification process is evidently short-lived for, almost immediately, opacity of the dust begins to fall off, and in a few weeks the atmosphere returns to normal.

THE SATELLITES

The two satellites of Mars, Deimos and Phobos, were discovered in 1877 by Asaph Hall of the U.S. Naval Observatory. Almost 100 years later, a new phase in the exploration of these objects began with photographs of the shadow of Phobos on the surface of Mars by Mariner 7 and with extensive direct photographic observations from the Viking orbiting spacecraft. Viking 1 flew to within 100 kilometres of Phobos, and Viking 2 was navigated closer than 30 kilometres from Deimos.

Orbits of the satellite

The orbit of Phobos is exceptionally close to the planet. At a mean distance of 2.8 planetary radii from the centre

Table 13: The Satellites of Mars

property	Deimos	Phobos
Orbital radius	23,459 km	9,378 km
Orbital period	1.26244 days	0.31891 days
Mean orbital velocity	1.4 km/sec	2.1 km/sec
Dimensions (kilometres)	15 × 12 × 11	27 × 22 × 19
Area	400 km^2	1,000 km^2
Volume	1,000 km^3	5,000 km^3
Mass	2×10^{18} g	9.6×10^{18} g
Mean density	1.9 g/cm^3	2.0 g/cm^3
Mean escape velocity	4.7 m/sec	7.8 m/sec
Albedo	0.07	0.06

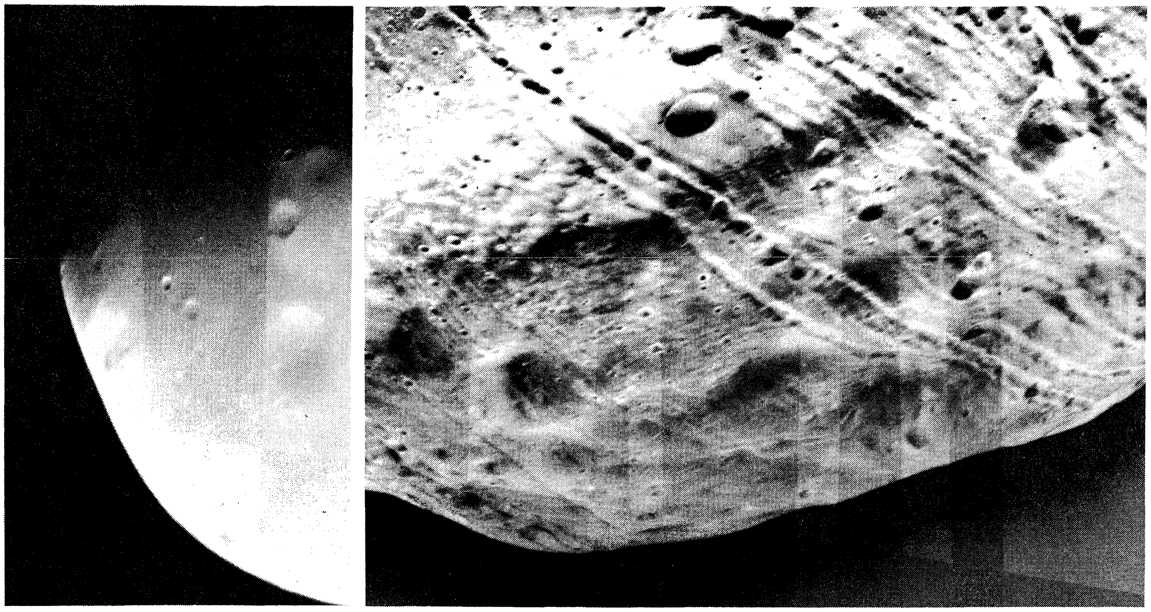

Figure 33: Viking photographs of portions of (left) Deimos and (right) Phobos. The smooth texture of the surface of Deimos stands in contrast to the grooves and pitted craters of the surface of Phobos.

By courtesy of the Jet Propulsion Laboratory/National Aeronautics and Space Administration

of the planet, it is within the Roche limit of 3 planetary radii. (The Roche limit is the minimum distance at which a satellite, if it has no internal strength, can approach its primary body without being torn apart by gravitational forces.) These gravitational, or tidal, forces cause the orbital motion of Phobos to be slowed and may ultimately cause the satellite to fall onto the surface of Mars, possibly in less than 100,000,000 years. The orbit of Deimos suffers an opposite fate, for it moves in a more distant orbit, and tidal forces cause a recession of the satellite from the planet.

The orbital period of Phobos about Mars is seven hours and 39 minutes. This short period means that it travels around Mars twice in a sol. An observer at a suitable point on the planet would see Phobos rise and set twice in a sol.

Not all observers on the surface of Mars could see the moons, however, because of their proximity to the planet and their near equatorial orbits. At latitudes greater than approximately 70° north or south, for example, Phobos could not be seen. The dimensions of the satellites, which cannot be resolved by Earth-based telescopes, have been revealed by photographs taken from the Viking orbiter spacecraft. Each satellite is roughly the shape of a triaxial ellipsoid, with Phobos the larger of the two. In both cases, the long axis of the satellite constantly points towards Mars, and, as with the Earth's moon, both have rotational periods equal to their orbital periods.

Surface features of the satellites

Pictures of the moons' surfaces show striking differences. Phobos' rugged surface is totally covered with craters caused by impacting objects. The largest of these, the Stickney crater, is distinguished by a diameter comparable in size to that of the satellite itself. The surface of Deimos is smooth by comparison, although there are many craters. The chief characteristic of Deimos' surface is that its craters are found to be almost buried in large quantities of fine debris. In addition to a large number of impact craters, Phobos' surface is also characterized by a widespread system of surface fractures, or grooves, many of which are geometrically related to the Stickney crater. It is thought that early in their history these satellites were both subjected to a similar intense bombardment by meteor-like bodies. Their surfaces were fractured and cratered, and large amounts of broken debris were produced. In the case of the more massive Phobos, this debris either remained in place or, if it flew off the satellite, was subsequently lost to Mars. In the case of the more distant and smaller Deimos, any debris that flew off the satellite remained in orbit until it was recaptured by the satellite as a kind of rain that blanketed the surface, inundating the craters and fractures that probably exist there.

The albedo, or reflectivity, of the surfaces of both satellites is very low and has similarities to that of the most primitive types of chondritic meteorites. One theory of the origin of the Martian satellites is that they are asteroids that were captured during the time of Mars's accretion.

The discovery of the satellites was of great importance because the period of their motion and other orbital characteristics provided an estimate of the mass of the parent planet and its internal structure. This information has now been superseded by more accurate and diverse data from orbiting and lander spacecraft. The study of these objects now centres on the contributions they might be able to make toward understanding the general origin of satellites and asteroidal bodies and the kinds of physical and chemical processes that occurred early in the development of the solar system.

THE QUESTION OF LIFE ON MARS

The question of the presence of life on Mars has been an essential element of general discussions of the planet since G.V. Schiaparelli first included an interconnecting system of "canals," or channels, in his maps of the planet in 1877. These canals were perceived in visual telescopic observations as systems of rectilinear markings on the Martian surface. These markings are now known to be an illusion that is probably caused by chance alignments of larger craters and other surface features. Canals, as visualized by Schiaparelli and Lowell, do not exist on Mars.

Observations of seasonal changes in the colour of certain markings on the planet, the ability of major dark areas to recover their appearance after being obliterated by global dust storms, and the springtime "wave of darkening" have also been used to support the speculation that a widespread biota capable of rapid reproduction could be present on the Martian surface. These changes are, in fact, both real and dramatic, but their cause—the movement of vast quantities of fine dust by atmospheric winds—is now known to be physical rather than biological.

The two Viking lander craft searched for the by-products of the metabolism of living organisms, but the results remain a subject for debate because the experiments were limited to samples from only two relatively inhospitable sites and because they addressed only a limited range of many possibilities. What does seem certain is that the surface of Mars does not support a widespread system of living organisms such as that existing on Earth. No trace of the organic detritus that would be associated with a biota such as is ubiquitous on Earth is known to exist on the surface of the planet.

Viking biological experiments

The biological experiments that were conducted by the Viking landers addressed the questions of the nature of organic material, if any, on the surface; the possible presence of objects on the surface whose appearance or motion would suggest living or fossilized organisms; and the possible presence in Martian soil of agents that, under prescribed conditions, could indicate metabolic processes. The answer to the first of these questions was definite and unambiguous; a direct and extremely sensitive chemical analysis on several samples at both lander sites showed no trace of any complex organic materials at all. The cameras on the lander spacecraft addressed the second question in great detail, but no evidence of biological agents or activity of any kind was found. Three separate experiments addressed the last question. One, the pyrolytic release experiment, was designed to look for signs of photosynthesis or chemosynthesis induced by samples of the Martian soil. While this experiment produced some indications of a positive result, the experimenters believe that these can be best explained by nonbiological processes. A second experiment, called the gas exchange experiment, was designed to measure any gaseous products from a soil sample as it was exposed to a humid atmosphere or was treated with a solution of organic nutrients. This experiment also produced a positive result in that the soil samples liberated substantial quantities of oxygen in response to the nutrient. Since this reaction was also found to occur even after the sample had been baked at 145° C for three hours, the experimenters believe that the cause is again nonbiological in origin. Finally, the labelled release experiment was designed to look for the release of radioactive gas when the soil sample was exposed to a radioactive organic nutrient solution. A positive result was again obtained, and in this case the "baked" control sample did become deactivated, as would be expected if the reaction was caused by a biological agent. The consensus of the Viking experimenters is that, while the labelled release experiment did give a positive result, it is still possible to explain it in nonbiological terms, and, taken in the context of the results of the other four experiments, the Viking mission found no persuasive evidence for life on the surface of the planet. (M.J.S.B.)

Jupiter

Jupiter, symbol ♃ in astronomy, is the most massive of the planets and the fifth in distance from the Sun. When ancient astronomers named the planet Jupiter for the ruler of the gods in the Greco-Roman pantheon, they had no idea of the planet's true dimensions, but the name is appropriate, for Jupiter is larger than all of the other planets combined. It has a narrow system of rings and 16 known satellites, one larger than the planet Mercury and three larger than our Moon. Jupiter also has an internal heat source; *i.e.,* it emits more energy than it receives from the Sun. This giant also has the strongest magnetic field of any planet, with a magnetosphere so large that it would exceed the apparent diameter of our Moon if it could be seen from Earth. Jupiter's system is the source of intense bursts of radio noise, at some frequencies occasionally radiating more energy than the Sun.

Knowledge about the Jovian system grew dramatically during the 1970s. The new information came in part from Earth-based observations, but especially from two sets of spacecraft—Pioneers 10 and 11 in 1974–75 and Voyagers 1 and 2 in 1979 (see Figure 34). The Pioneer spacecraft served as scouts for the Voyagers, showing that the radiation environment of Jupiter was tolerable and mapping out the main characteristics of the planet and its environment. The more sophisticated instrumentation on the later spacecraft then filled in the details, providing so much new information that it was still being analyzed in the early 1980s.

BASIC ASTRONOMICAL DATA

Table 14 shows physical and orbital data for Jupiter. Of special interest are the low mean density of 1.33 grams per cubic centimetre (g/cm³)—in contrast with Earth's 5.5 grams per cubic centimetre—coupled with the large dimensions and mass, and the short rotational period. The low density and large mass suggest that Jupiter's composition and structure are quite unlike those of Earth and other inner planets, a supposition supported by detailed investigations of its atmosphere and interior.

Three rotational periods have been established. The two periods labelled Systems I and II (Table 14) are mean values and refer to the speed of rotation at the equator and at higher latitudes, respectively, as exhibited by features observed in the planet's visible cloud layers. Jupiter has no solid surface; the transition from the atmosphere to the core occurs gradually at great depths. This variation in rotation period at different latitudes does not imply, therefore, that the solid body of the planet rotates with either of these mean velocities. In contrast, the apparent constancy of the period deduced from observations at radio wavelengths, System III, during 20 years of observation,

Table 14: Basic Data

Orbital characteristics		
Semimajor axis	5.20 a.u. (483.4 × 10^6 miles)	
Sidereal period	11.86 years	
Eccentricity	0.049	
Inclination	1°19′	
Physical elements		
Mean apparent diameter	47 seconds of arc	
Equatorial radius	71,400 km	= 11.2 (Earth = 1)*
Polar radius	66,770 km	= 10.4 (Earth = 1)
Ellipticity $\left(\frac{R_e - R_p}{R_e}\right)$	0.065	= 18 (Earth = 1)
Mass	18.99 × 10^{29}	= 317.8 × Earth's mass = $\frac{1}{1047.39}$ × Sun's mass
Mean density	1.33 g/cm³	= 0.24 × Earth's density
Surface gravity	2,288 cm/s²	= 2.65 × Earth's gravity
Escape velocity	59.5 km/sec	= 5.45 × Earth's escape velocity
Rotation periods		
System I (±10° from equator)	9h50m30s	
System II (higher latitudes)	9h55m40s	
System III (magnetic field)	9h55m29s	
Inclination of equator to orbit	3°04′	
Miscellaneous data		
Dimensions of Great Red Spot	26,000 km × 14,000 km	
Mean apparent visual magnitude	−2.55	
Magnetic field strength at equator	4.3 gauss	= 13.8 × Earth's surface field

*Radius of Earth = 6,378 km or 3,963 mi

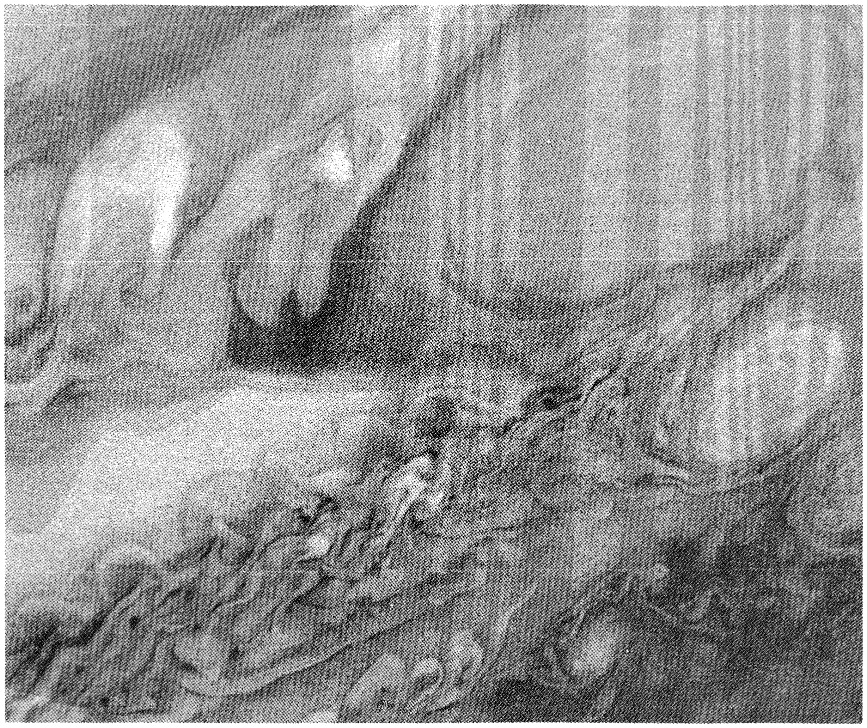

Figure 35: The Great Red Spot (top right) and the surrounding region photographed by Voyager 1 on March 1, 1979. At centre right is one of the white ovals visible from Earth.

suggests that it is associated with the planet's magnetic field, formed deep in Jupiter's liquid or semisolid interior.

THE OUTER LAYERS

The clouds and the Great Red Spot. Even a modest telescope can show much detail on Jupiter. The region of the planet's atmosphere that is seen from Earth contains several different types of clouds that are separated both vertically and horizontally. Changes in these cloud systems can occur in a few hours, but an underlying pattern of latitudinal currents has maintained its stability for decades. (It has become traditional to describe the appearance of the planet in terms of a standard nomenclature for alternating dark belts and bright zones. The currents, however, seem to have greater persistence than this pattern.)

Various cloud forms

The close-up views of Jupiter from the Voyager spacecraft revealed a variety of cloud forms, with a predominance of elliptical features reminiscent of cyclonic and anticyclonic storm systems on Earth. All of these systems are in motion, appearing and disappearing on time scales dependent upon their sizes and locations. Also observed to vary are the pastel shades of various colours present in the cloud layers—from the tawny yellow that seems to characterize the main layer, through browns and grays, to the well-known salmon-coloured Great Red Spot, Jupiter's largest, most prominent, and longest-lived feature (see Figure 35). The vertical and horizontal segregation of the cloud systems is evidently accompanied by chemical differences as well.

Jovian meteorology can be compared with the global circulation of the Earth's atmosphere. On Earth huge spiral cloud systems often stretch over many degrees of latitude and are associated with motion around high- and low-pressure regions. These cloud systems are much less zonally confined than the cloud systems on Jupiter and move in latitude as well as longitude. Local weather on Earth is often closely tied to the local environment, which in turn is determined by the varied nature of the planet's surface.

Absence of a solid surface

Jupiter has no solid surface, hence no relief features, and the planet's large-scale circulation is dominated by latitudinal currents. The lack of physical boundaries on Jupiter's surface makes the persistence of these currents and their associated cloud patterns all the more remarkable. The Great Red Spot, for example, moves in longitude with respect to all three of the rotation systems, yet it does not move in latitude. The three white ovals found at a latitude just south of the Great Red Spot exhibit similar behaviour; white ovals of this size are found nowhere else on the planet. The dark brown clouds, evidently holes in the tawny cloud layer, are found almost exclusively at latitudes near +18°. The blue-gray or purple areas, from which the strongest thermal emission is detected, only occur in the equatorial region of the planet.

The nature of the Great Red Spot. The true nature of Jupiter's unique Great Red Spot was still unknown by the early 1980s, despite extensive observations from the Voyager spacecraft. On a planet whose cloud patterns have lifetimes often counted in days, the Great Red Spot has survived as long as detailed observations of Jupiter have been made—at least 100, and perhaps 300, years. There is some evidence that the spot may be slowly shrinking, but a longer series of observations is needed to confirm this suggestion. Its present dimensions are about 26,000 by 14,000 kilometres, making it large enough to accommodate, side by side, two planets the size of Earth. These huge dimensions are probably responsible for the feature's longevity and possibly for its distinct colour.

The rotation period of the Great Red Spot with respect to the rotation of Jupiter itself shows a variability that has not been successfully correlated with other Jovian phenomena. Earth-based observations in 1966 and 1967 revealed the counterclockwise circulation of the material within the spot itself to have a period of 12 days. This period was confirmed by the Voyager observations, which recorded a large number of interactions between the Great Red Spot and much smaller disturbances moving in the current at the same latitude (Figure 35). The Voyager pictures showed the interior of the spot to be remarkably tranquil, with no clear evidence for the expected upwelling (or divergence) of material from lower depths.

The Great Red Spot, therefore, appears to be a huge anticyclone, a vortex, or eddy, whose lateral dimensions are greater than the Earth's diameter. This lateral size is presumably accompanied by a huge vertical extent that allows the feature to extend well below and well above the main cloud layers. The extension above the main clouds can be observed directly, and it also is manifested by lower temperatures and by less gas absorption above the Great Red Spot than at neighbouring regions on the planet.

The tawny clouds

Cloud composition. The clouds that are recorded in pictures of Jupiter are formed at different altitudes in the planet's atmosphere. Except for the top of the Great Red Spot, the white clouds are the highest, with cloud-top temperatures of about 140 K. The white clouds apparently consist of frozen ammonia crystals and are thus analogous to the water-ice cirrus clouds in the Earth's atmosphere. At lower levels occur the tawny clouds that are widely distributed over the planet. They appear to form at a temperature of about 220 K, which suggests that they probably consist of condensed ammonium hydrosulfide (NH_4SH) and that their colour may be caused by other ammonia-sulfur compounds such as ammonium monosulfide, $(NH_4)_2S$, or ammonium polysulfides, $(NH_4)_2S_x$ (x may equal 2, 3, . . .).

The reasons for invoking sulfur compounds as likely colouring agents (chromophores) lie in the relatively high cosmic abundance of sulfur and the absence of any evidence of hydrogen sulfide (H_2S) in Jupiter's atmosphere. Jupiter is primarily composed of hydrogen and helium. Under equilibrium conditions—allowing all of the elements to react with one another at an average Jovian pressure and temperature—a predominance of methane (CH_4), ammonia (NH_3), water (H_2O), and hydrogen sulfide over other compounds involving these abundant elements would be expected. This outcome is true for carbon, nitrogen, and oxygen, but no form of sulfur has been directly detected on Jupiter. This can be understood if the presence of sulfur compounds—formed in part because of the ease with which hydrogen sulfide can be broken down by solar ultraviolet light—in the lower clouds is postulated. In this hypothesis the sulfur made available by photo-dissociation is free to combine with the more abundant ammonia to form tawny chromophores.

Sulfur compounds have also been proposed to explain the dark brown coloration of the clouds detected at still lower levels, where the measured temperature is 260 K. These clouds are seen through what are apparently holes in the otherwise ubiquitous tawny clouds. They appear bright in pictures of Jupiter that are made from the thermal radiation detected at a wavelength of five micrometres.

Localized cloud chemistry

The colour of the Great Red Spot has been attributed to the presence of complex organic molecules, red phosphorus, or yet another sulfur compound. All of these ideas find support in laboratory experiments, but there are counter arguments in each case. Dark regions occur near the heads of white plume clouds near the planet's equator, where temperatures as high as 300 K have occasionally been measured. Despite their blue-gray appearance, these dark features have a reddish tint. They may be clear gas exhibiting a blue colour (from Rayleigh scattering) overlain with a thin haze of reddish material. That these regions occur only at the equator, the elliptical dark brown clouds only near +18°, and the most prominent red colour on the planet only in the Great Red Spot implies a localization of cloud chemistry that is particularly puzzling in such a dynamically active atmosphere.

At still lower depths in the atmosphere, astronomers expect to find water-ice clouds and water droplet clouds, both consisting of dilute solutions of ammonium hydroxide (NH_4OH). These cloud layers are expected to be reached by a probe to be sent into the Jovian atmosphere by the Galileo Project planned for the late 1980s.

The atmosphere. *The proportions of constituents.* Until a probe has entered Jupiter's atmosphere, studies of the planet's spectrum must be relied upon to provide information about the composition, temperature, and pressure of the atmosphere. In this technique light or thermal radiation from the planet is spread out in wavelengths (colours, in visible light, as in a rainbow) by the dispersing element in a spectrograph. The resulting spectrum indicates that there are discrete intervals at which energy has been absorbed by the constituents of the planet's atmosphere. By measuring the exact wavelengths at which this absorption takes place and comparing the results with spectra of gases obtained in the laboratory, the gases in Jupiter's atmosphere can be identified.

The presence of methane and ammonia in Jupiter's atmosphere was deduced more than 50 years ago, while hydrogen was detected for the first time in 1960. (Although 500 times more abundant than methane, hydrogen has much weaker absorption lines because it is a molecule of two identical atoms that interacts only very weakly with electromagnetic waves.) Subsequent studies led to a growing list of new constituents, including the discovery of hydrogen cyanide (HCN) in 1981. Table 15 includes a list of Jupiter's atmospheric constituents and their abundances as determined by early 1982.

Table 15: Atmospheric Abundances

gas	mixing ratio*	element ratio	Jupiter/Sun
H_2	1		
He	0.12	He/H	1
CH_4	2×10^{-3}	C/H	2
NH_3	2×10^{-4}	N/H	1
C_2H_6	4×10^{-5}		
H_2O	10^{-6}	O/H	10^{-2}
C_2H_2	8×10^{-7}		
PH_3	4×10^{-7}	P/H	1
CH_3D	3.8×10^{-7}	D/H	†
CO	3×10^{-9}		
HCN	2×10^{-9}		
GeH_4	6×10^{-10}	Ge/H	10^{-1}
C_3H_8	(detected)		

*The mixing ratio is the number of molecules of a given atmospheric constituent in a unit volume divided by the number of hydrogen molecules in that same volume.

†Deuterium is not present on the Sun because of nuclear burning. The value of D/H on Jupiter is 3.5×10^{-5} ($\pm 1.5 \times 10^{-5}$), which is approximately 2.3 times the present interstellar value.

If the condition of chemical equilibrium held rigorously in Jupiter's atmosphere, molecules such as carbon monoxide (CO), hydrogen cyanide, acetylene (C_2H_2), and ethane (C_2H_6) would not occur in the abundances shown in Table 15. Sources of energy other than the molecular kinetic energy corresponding to local temperatures are evidently available. Solar ultraviolet radiation is responsible for the breakdown of methane and subsequent reactions of its fragments into acetylene and ethane. In the convective region of the atmosphere, lightning discharges contribute to these processes and may be responsible for the production of hydrogen cyanide. Still deeper, at temperatures around 1200 K, carbon monoxide is made by a reaction between methane and water vapour. Vertical mixing must be sufficiently strong to bring this gas up to a region where it can be detected from outside the atmosphere.

Differences between Jupiter and the Sun

Table 15 includes a comparison of elemental abundances in Jupiter's atmosphere with the composition of the Sun. If the planet had formed by simple condensation from the primordial solar nebula (see below), the abundances of the elements should be the same in both Jupiter and the Sun. Instead, there is a real spread in the values for different elements. On the other hand, except for methane and helium, the abundances of the gases from which the elemental abundances are derived depend on dynamical phenomena in Jupiter's atmosphere—principally condensation and vertical mixing. Thus the apparent enrichment in carbon may be an indication of a real difference in composition between Jupiter and the Sun.

Another difference is indicated by the presence of deuterium (D) on Jupiter. This heavy isotope of hydrogen has disappeared from the Sun as a result of nuclear reactions in the solar interior. Because no such reactions occur on Jupiter, the ratio of deuterium to hydrogen there should be identical to the ratio of those isotopes in the cloud of interstellar gas and dust that collapsed to form the solar system 4,600,000,000 years ago. Since deuterium may have been made primarily in the "big bang" that has been postulated to have begun the expansion of the universe, an accurate measurement of deuterium/hydrogen on Jupiter would allow the calibration of expansion models.

Temperature and pressure. The best profiles for the relation between changes in temperature and pressure in the Jovian atmosphere have resulted from the Pioneer and Voyager measurements. Both passed behind the planet as viewed from Earth, and the attenuation of the signal as

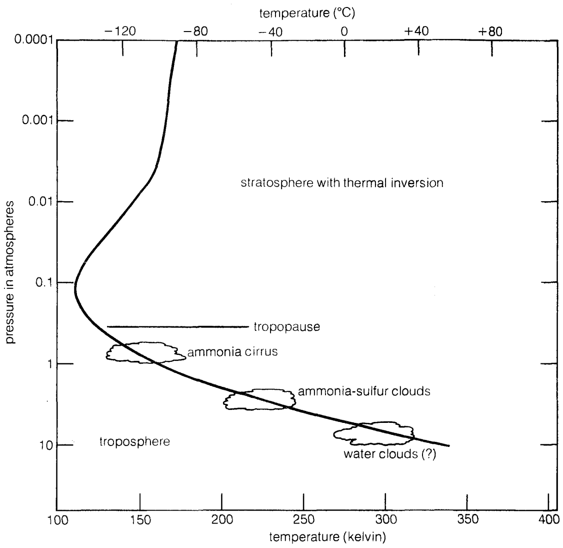

Figure 36: The structure of the atmosphere of Jupiter as deduced from Voyager measurements.

it passed through Jupiter's atmosphere before being completely extinguished provided a measure of the change in atmospheric density, which is a function of temperature and pressure. A self-consistent analysis of the data is in agreement with independent studies based on analyses of the thermal radiation escaping from the planet.

One of the profiles resulting from these studies is shown in Figure 36. From the figure it is possible to locate the positions of the principal cloud decks. It is interesting to notice that temperatures higher than the freezing point of water occur at pressures just a few times greater than the sea-level pressure on Earth. This is mainly a consequence of Jupiter's internal energy source, although some warming would occur just by the trapping of infrared radiation by the atmosphere in the so-called greenhouse effect.

Temperature inversion

The increase in temperature above the tropopause is known as an inversion because temperature normally decreases with height. The inversion is caused by the absorption of solar energy at these altitudes by gases and aerosol particles.

Other likely atmospheric constituents. The list of atmospheric abundances in Table 15 is certainly not complete. For example, although the noble gas neon has about the same cosmic abundance as nitrogen, it, like helium, is very difficult to detect by spectroscopic observations. Neon had not been observed in the Jovian atmosphere by the early 1980s, even though it should be as abundant as ammonia.

Complex organic molecules in Jovian atmosphere

The formation of complex organic molecules in Jupiter's atmosphere is of great interest in the study of the origin of life. The initial chemical processes leading to the formation of living organisms may have occurred on Earth at a time when the composition of the terrestrial atmosphere was very similar to the present Jovian atmosphere, allowing for an appropriate depletion of hydrogen and helium. The active Jovian cloud system is a source of electrical discharges, while solar ultraviolet radiation, precipitation of charged particles, and the internal energy of the planet are also available to drive chemical reactions in the Jovian atmosphere. Thus, Jupiter may well represent an enormous natural laboratory in which the initial steps toward the origin of life are being pursued again and again. A determination of the degree of complexity reached under such conditions constitutes one of the most fascinating problems confronting any program of space exploration.

Radio emission. Jupiter was the first planet found (in 1955) to be a source of radiation at radio wavelengths. The radiation was recorded at a frequency of 22 megahertz (*i.e.,* a wavelength of 13.6 metres, or 1.36 decametres) in the form of noise bursts with peak intensities sometimes great enough to make Jupiter the brightest source at this wavelength, except for the Sun during its most active phase. The bursts of radio noise from three distinct areas constituted the first evidence for a Jovian magnetic field. Subsequent observations at shorter (decimetre) wavelengths revealed that Jupiter is also a source of steady radio emission. It has become customary to refer to these two types of emission in terms of their characteristic wavelengths: decametre radiation (the erratic bursts) and decimetre radiation (the continuous source).

Synchrotron emission

The nonthermal component of the decimetric radiation is interpreted as synchrotron emission; that is, radiation emitted by very high-speed electrons moving in a magnetic field within a toroidal, or doughnut-shaped, region surrounding Jupiter—a phenomenon closely analogous to that of the terrestrial Van Allen belts. The maximum emission occurs at a distance of two planetary radii from the centre of the planet and has been detected at 178–5,000 megahertz. The position of the plane of the polarization (vibrations of the radio emission preferentially being in a plane) and intensity of the radio emission vary with the same period. Both effects are explained if the axis of the planet's magnetic field is inclined by about 10° to the rotational axis. The period of these variations is the period designated as System III (see Table 14).

The radio emission at decametre (10-metre) wavelengths has been studied from Earth in the accessible range of 3.5 to 39.5 megahertz (3.5×10^6 to 39.5×10^6 cycles per second). Freed from the low-frequency cutoff established by the Earth's ionosphere, the radio-wave experiment on the Voyager spacecraft was able to detect emissions from Jupiter down to 60 kilohertz (60×10^3 cycles per second), corresponding to a wavelength of five kilometres. The strength of the radio signal and the frequency of noise storms show a marked time dependence that led to the early detection of three "sources," or emitting regions. The System III coordinate system was initially defined through the periodicity of these sources.

Effect of Io on noise storms

The noise storms are greatly affected by the position of the satellite Io in its orbit. For one source, events are much more likely to occur when Io is 90° from superior geocentric conjunction (*i.e.,* 90° from the position in which Earth, Jupiter, and Io are in a straight line) than otherwise. The noise sources appear to be regions that lie in the line of sight toward the optical disk of the planet (unlike the nonthermal decimetric radiation).

The most promising explanation of the effect of the orbital motion of Io on noise storms relates the emission to a small region of space linked to Io by magnetic field lines (a flux tube) that move with Io. Electrons moving in spirals around the magnetic field lines could produce the observed radiation. Interaction between these electrons and the Jovian ionosphere can be expected and were, in fact, observed by the Voyager spacecraft.

The Jovian magnetosphere. The nonthermal radio emissions described above are the natural result of trapped charged particles interacting with Jupiter's magnetic field and ionosphere. Interpretation of these observations led to a remarkably accurate definition of the basic characteristics of the planet's magnetosphere that was supported by the direct exploration of fields and particles in the vicinity of Jupiter by the Pioneer and Voyager spacecraft. The basic magnetic field of the planet is dipolar in nature, generated by a hydromagnetic dynamo that is driven by convection within the electrically conducting outer layers of Jupiter's interior. The magnetic moment is 19,000 times greater than that of Earth, leading to a field strength at the equator of 4.3 gauss, compared with 0.3 gauss at the Earth's surface. The axis of the magnetic dipole is offset by 0.1 R_J (where R_J is Jupiter's equatorial radius of 71,400 kilometres) from Jupiter's rotational axis, to which it is indeed inclined by 10°. The orientation of the Jovian magnetic field is exactly opposite to the present orientation of the Earth's field, such that a terrestrial compass taken to Jupiter would point south (relative to the planet's vector of angular momentum).

Magnetic links with Io

The magnetic field dominates the region around Jupiter to a distance of about 10 R_J to a point between the orbits of its satellites Europa and Ganymede (see below *The satellites and rings*). Within this region the most striking activity is generated by the satellite Io, whose influence on the decametric radiation has been discussed above. An electrical current of approximately 5×10^6 amperes flows in the magnetic flux tube linking Jupiter and Io. This satellite is also the source of a torus (doughnut-shaped) cloud of ions that surrounds its orbit.

THE INTERIOR

The atmosphere of Jupiter constitutes only a very small fraction of the planet, much as the skin of a fruit compares with its contents. Nothing can be directly observed below this thin outer layer, so that indirect conclusions are drawn from the evidence in order to determine the composition of the interior of Jupiter.

The observed quantities with which the astronomer can work are the atmospheric temperature and pressure, mass, radius, shape, rate of rotation, heat balance, and perturbations of satellite orbits and spacecraft trajectories. From these follow the ellipticity and the departure from an ellipsoid of the planet, quantities that may also be predicted using theoretical descriptions, or models, for the internal distribution of material. Such models can then be tested by their agreement with the observations.

Jupiter's central temperature and pressure

The basic difficulty in constructing a model that will adequately describe the internal conditions for Jupiter is the absence of extensive laboratory data on the properties of hydrogen and helium at pressures and temperatures appropriate to the conditions near the centre of this giant planet. The central temperature is estimated to be close to 25,000 K, to agree with an internal source of heat that allows Jupiter to radiate about twice as much energy as it receives from the Sun. The central pressure is in the range of 50,000,000–100,000,000 atmospheres. The required extrapolation is not quite as dramatic as it may seem, since at such tremendous pressures hydrogen assumes a metallic state, the properties of which can be calculated with some confidence. The difficulty lies, first, in establishing the transition point at which the metallic state occurs and, second, in defining the properties of hydrogen between this transition point and the region where laboratory measurements are available. A third difficulty is posed by the solubility of helium in hydrogen at these pressures and temperatures, resulting in a multicomponent system.

Predominance of hydrogen and helium

Despite these problems, there has been a steady improvement in the precision of the models. Perhaps the most significant early conclusion from these studies was the realization that Jupiter cannot be composed entirely of hydrogen; if it were, it would have to be considerably larger than it is to account for its mass. On the other hand, hydrogen must predominate, constituting at least 78 percent of the planet by mass, no matter in what form—gas, liquid, or solid—it may occur. If it is assumed that the bulk of the rest of the planet is helium, the proportion of hydrogen to helium is on the order of 14:1, in close agreement with the atmospheric value and present ideas for the composition of the Sun (see Table 15). Current models agree on a transition from molecular to metallic hydrogen at approximately 0.75 R_J. It should be stressed that this is not a transition between a liquid and a solid but rather between two liquids with different electrical properties. In the metallic state the electrons are no longer bound, thus giving the hydrogen the conductivity of a metal. No solid surface exists in any of these models, although most contain a rock and ice core with a radius of 0.03–0.10 R_J (0.33–1.1 Earth radii).

The source of internal heat has not been resolved. The favoured explanation in the early 1980s invoked the gradual release of primordial heat left over from the planet's formation. In other words, the conversion of gravitational energy to thermal energy that initially led to a very hot Jupiter is still progressing with a very gradual contraction of the planet (see below *Theories of the origin of the Jovian system*).

THE SATELLITES AND RING

The first objects in the solar system discovered by means of a telescope were the four brightest satellites of Jupiter. Galileo, who first observed them in 1610, proposed that the satellites be named the Medicean stars, in honour of his patron, Cosimo II de' Medici, but they soon came to be known as the Galilean satellites in honour of their discoverer. Galileo regarded their existence as a fundamental argument in favour of the Copernican model of the solar system in which the planets orbit the Sun.

In order of increasing distance from the planet, these satellites are called Io, Europa, Ganymede, and Callisto, for legendary figures closely associated with Jupiter (Zeus) in Greek mythology. The names were assigned by the German astronomer Simon Marius, Galileo's contemporary and rival. There proved to be a certain further aptness in the choice of Io's name: Io—"the wanderer" (Greek *iōn*, "going")—has an indirect influence on the ionosphere of Jupiter. The fifth satellite was also discovered by telescope, while the other 11 known satellites were found photographically (JVI–JXIII) or in pictures obtained by the Voyager spacecraft (JXIV–JXVI). Roman numerals are assigned to the satellites in order of their discovery.

Satellite groups. Jovian satellite data are summarized in Table 16. The orbits of the inner eight satellites have low inclinations and low eccentricities; *i.e.,* they all are nearly circular. The orbits of the outer eight have much higher inclinations and eccentricities. The two innermost satellites (XIV and XVI) seem to be intimately associated with Jupiter's ring and may in fact be two of the sources of the fine particles within the ring itself. There are almost certainly additional members of all of these groups.

The Galilean satellites. Although approximate diameters and spectrophotometric characteristics of the four largest satellites of Jupiter had been determined from ground-based observations, it was the Voyager missions of 1979 that indelibly established these four bodies as worlds in their own right (see Figure 37). Before Voyager, it was known that Callisto and Ganymede were both as large or

Table 16: Satellites of Jupiter

larger than the planet Mercury; that they and Europa had surfaces covered with water ice; that Io was surrounded by a torus of atoms and ions that included sodium, potassium, and sulfur; and that the inner two satellites have mean densities much larger than those of the outer two. This density gradient resembles that found in the solar system itself and seems to result from the same cause (see below *Theories of origin*). The implication is that Io and Europa have a rocky composition similar to that of our Moon, whereas approximately 60 percent of Ganymede and Callisto must be a much less dense substance, with water ice as the most likely candidate.

Callisto. The surface of this satellite is so dominated by impact craters that there are no smooth plains such as the dark maria on the Moon. In other words, there seem to be no areas on Callisto where subsequent internal activity has obliterated any of the record of early bombardment. This record was formed by impacting debris (comet nuclei and asteroidal material) primarily during the first 500,000,000 years after the formation of the solar system in much the same way that the craters on Earth's moon were produced.

Ganymede. Unlike Callisto, Ganymede, an equally icy satellite, reveals distinct patches of dark and light terrain. This contrast is reminiscent of what can be seen on the Moon, but the association of chronology with albedo (reflected brightness) is exactly reversed. The dark regions on Ganymede are the oldest areas, showing the heaviest concentration of craters. The light regions are younger, revealing a complex pattern of parallel and intersecting ridges and grooves in addition to unusually bright impact craters typically surrounded by systems of rays. Like Callisto, Ganymede also exhibits relatively low topographic relief, indicating the action of viscous flow of the icy surface.

Smoothness of Europa

Europa. The surface of Europa is totally different from that of Ganymede and Callisto, despite the fact that the infrared spectrum of this object indicates that it, too, is covered with ice. There are few impact craters on Europa—the number per unit area is about comparable to that on the continental regions of Earth. This indicates that the surface that can be seen is relatively recent. Some scientists think the surface is young enough to suggest that significant resurfacing is still taking place on the satellite. This resurfacing evidently consists of the outflow of water from the interior to form an instant frozen ocean. Its frozen surface is crisscrossed by a pattern of dark stripes and curved ridges. The relief is extremely low, with ridge heights perhaps a few hundred metres at most. Europa thus has the smoothest surface of any of the solid bodies examined in the solar system thus far.

Io. Seen through a telescope, Io looks reddish-orange, while the other satellites are neutral in tint. Io's infrared spectrum shows no evidence of the absorptions of water ice. Scientists expected Io's surface to look different from those of Jupiter's other moons, but the Voyager pictures revealed a landscape even more unusual than anticipated.

Io's volcanoes

Volcanic calderas, instead of impact craters, dot the surface of Io, and 10 volcanoes were observed in eruption when the two Voyager spacecraft flew by in 1979. This unprecedented level of activity makes Io the most tectonically active object in the solar system. The surface of the satellite is continually and completely replaced in spans of time considered short when compared with the age of the solar system. Various forms (allotropes) of sulfur appear to be responsible for the black, orange, and red areas on the satellite's surface, while solid sulfur dioxide is probably the main constituent of the white areas. Sulfur dioxide was detected as a gas near one of the active volcanic plumes by Voyager's infrared spectrometer and was identified as a solid in ultraviolet and infrared spectra obtained from Earth-orbital and ground-based observations. These identifications provide sources for the sulfur and oxygen ions observed in the Jovian magnetosphere.

The energy for this volcanic activity requires a special explanation, since radioactive heating is inadequate for a body as small as Io. The favoured explanation is based on the observation that orbital resonances with the other Galilean satellites perturb Io into a more eccentric orbit than it would assume if only Jupiter controlled its motion. The resulting tides developed by the contest between the other satellites and Jupiter may release enough energy to account for the observed volcanism.

Surface of Amalthea

Other satellites. The only other Jovian satellite that was close enough to the trajectories of the Voyager spacecraft in 1979 to allow surface features to be seen was Amalthea. So small that its gravitational field is not strong enough to deform it into a sphere, it has an irregular, oblong shape (see Table 16). Like Io, its surface exhibits a reddish colour that may result from a coating of sulfur compounds released by Io's volcanoes.

The ring. One of the tasks of the Pioneer 11 mission of 1974 was to monitor the charged particles around Jupiter. As the spacecraft sped toward its closest approach of 1.6 R_J, a sudden decrease in the density of charged particles was detected at a distance of 1.7–1.8 R_J. This led to the suggestion that a moon or a ring of material might be orbiting the planet at this distance. The existence of a ring was verified by the first Voyager spacecraft when it crossed the planet's equatorial plane, and the second spacecraft recorded additional pictures, including a series taken in the shadow of the planet looking back at the ring material. The ring is comprised of large numbers of micrometre-sized particles that produce strong forward scattering of incident sunlight. Submicrometric dust is also present, as indicated by a faint halo of material surrounding the ring plane. The halo particles are charged and move out of the equatorial plane in response to the rocking motion of the magnetic equatorial plane as the planet rotates.

Source of Jupiter's ring

The presence of such small particles requires a source. Indeed, the finest material extends all the way in to the planet itself. It seems likely that the source of this material is large boulders, or small moonlets, within the ring. Visible examples of what are presumably among the largest of such objects are satellites JXIV and JXVI. The ring particles are generated by impacts of micrometeoroids, cometary debris, and possibly volcanically produced material from Io. It seems plausible that the inner edge of Jupiter's ring is defined by the orbit of one of these moonlets, even as the outer edge appears to be defined by satellite JXIV.

THE GRAVITATIONAL INFLUENCE OF JUPITER

Resonances between the paths of Jupiter and the minor planets. Jupiter exerts a gravitational influence extending well beyond its own satellite system to affect minor planets of the solar system and comets as well. Among the minor planets with well-determined solar orbits, the distribution of their periods of revolution about the Sun shows striking gaps; there are no 5.9–, 4.8–, and 4-year periods, which correspond to $^1/_2$, $^2/_5$, and $^1/_3$, respectively, of the orbital period of Jupiter (see Table 14). These commensurabilities evidently lead to resonance-enhanced perturbations that prevent a body from remaining in an orbit of these durations. On the other hand, 19 minor planets are known with periods close to $^2/_3$ that of Jupiter, and none with periods slightly smaller or larger than this. This indicates another type of resonance perturbation, one acting to concentrate rather than disperse.

Trojan planets. Jupiter appears to "collect" minor planets, among which the Trojans form an important group. These bodies all have very nearly the same orbital period as Jupiter and are found at two points that are regions of gravitational stability, where the attraction of Jupiter and the Sun have equal effect (L_4 and L_5 equilibrium points of Lagrange's solution to the three-body problem; see MECHANICS). Perturbations by Saturn appear likely to cause membership of this group to change, a possibility that has led to the suggestion that the Trojans may be former satellites of Jupiter and not true minor planets.

The Jupiter family of comets. Jupiter also has a strong influence on the orbits of comets. A comet that originally has a very long period and an orbit that carries it beyond the planet Pluto may be converted to a short-period comet, with an aphelion of five astronomical units or less, as a result of a near encounter with Jupiter; in other words, the comet's farthest distance from the Sun is reduced to five or less times the mean distance of Earth from the Sun. A pronounced concentration of short-period comets, the paths of which cross the principal plane of the solar system at Jupiter's distance from the Sun (about five as-

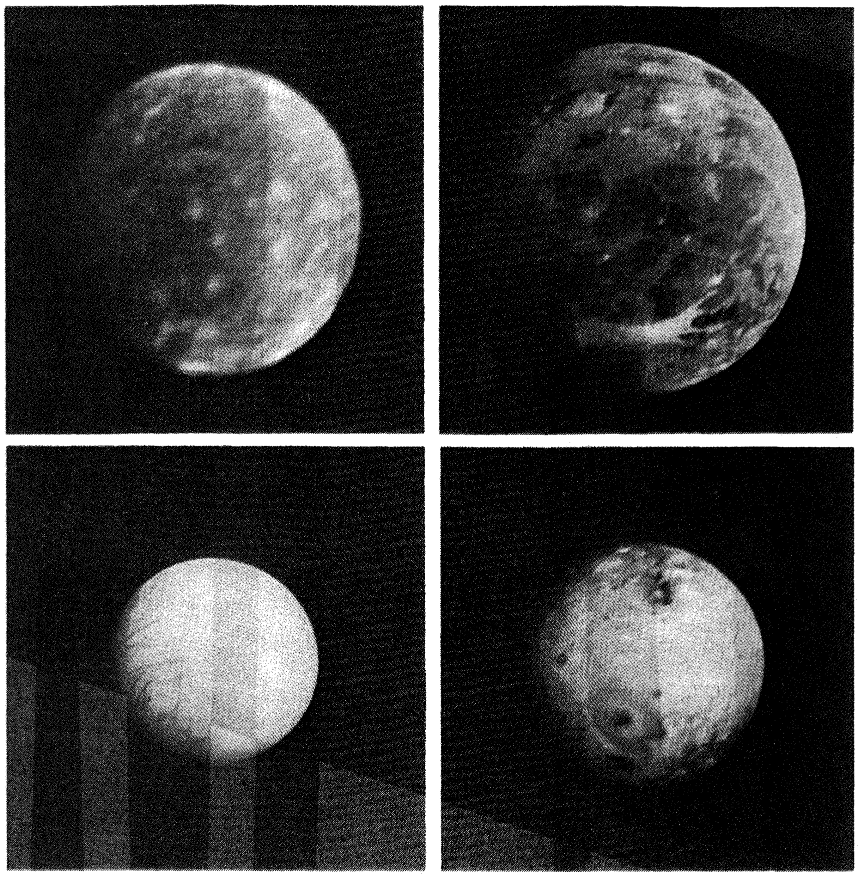

Figure 37: *The four Galilean satellites of Jupiter.*

By courtesy of the Jet Propulsion Laboratory/National Aeronautics and Space Administration

tronomical units), suggests that these comets have been strongly influenced by Jupiter's gravitational field. One may thus speak of a "Jupiter family" of comets, the best known member of which is Encke's Comet.

THEORIES OF THE ORIGIN OF THE JOVIAN SYSTEM

The origin of Jupiter and its satellites is part of the problem of the origin of the entire solar system. Current thinking favours the gradual development of the Sun and planets from a huge cloud of gas and dust containing gravitational instabilities. Details of the later evolutionary picture vary, however, especially on the role of magnetic fields and on the relative importance of condensation and accretion.

Early history of Jupiter. Given the planet's large proportion of hydrogen and its huge mass, it has been traditional to assume that Jupiter formed by condensation from the primordial solar nebula. This hypothesis implies that the elements should all be present on Jupiter in the same proportions that they occur in the Sun. The most recent evidence (Table 15) suggests that this may not be true.

Accretion of dust and ices

Current models for Jupiter's origin suggest that a core formed first as a result of the accretion of grains of dust and ices into accumulating planetesimals. The heavier elements in the core would have been present in solar proportions, but as the core grew and began to attract more volatile material, a nonsolar composition could have resulted. In particular, models have been proposed with a core containing high proportions of water ice and an envelope of hydrogen and helium. Although these light gases, relative to the heavier elements in the core, do not reach their solar abundance, the ratio of hydrogen to helium is solar in all of these models, as appears to be the case on Jupiter itself.

Early history of the satellites. The inner eight satellites of Jupiter are commonly thought to have originated in much the same way as the planet itself. Just as the primordial solar nebula is believed to have broken up into accreting planetesimals with a central condensation that became the Sun, the accumulation of material into a proto-planetary cloud at Jupiter's orbit ultimately led to the formation of the planet and its inner satellites. The analogy goes further. The high temperature of the forming planet apparently prevented volatile substances from condensing at the distances of the innermost satellites. Hence Ganymede and Callisto represent the volatile-rich outer bodies in this system.

The origin of the outer eight satellites, with their orbits of high eccentricities and inclinations, is thought to be quite different. They are members of the population of irregular satellites in the solar system and have most likely been captured by Jupiter.

(T.C.O.)

Saturn

Saturn, symbol ♄ in astronomy, is the sixth planet in order of distance from the Sun. It cannot approach the Earth closer than about 1,190,000,000 kilometres. Its brightness is due to its large size, inferior only to that of Jupiter. Saturn's equatorial diameter is 120,660 kilometres, but its globe is appreciably flattened, and the polar diameter is only 108,000 kilometres.

Saturn's ring system is in a class of its own. While Jupiter and Uranus also have rings, those of Saturn are striking, and a telescope of moderate power will show them excellently. There can be no doubt that Saturn is one of the most beautiful objects in the entire sky.

Saturn was the outermost of the planets known in ancient times. The earliest known observations of it, by the Babylonians, can be reliably dated to the mid-7th century BC, but it was probably noticed much earlier, as it is brighter than most stars. To the naked eye it appears yellowish; it moves slowly against the background of stars. The Greeks named it after Cronus, the original ruler of Olympus, whose Roman equivalent is the god Saturn.

Table 17: Planetary Data for Saturn

Distance from the Sun	mean 9.54 a.u. (1,472,000,000 km) maximum 10.07 a.u. (1,507,000,000 km) minimum 9.01 a.u. (1,347,000,000 km)
Sidereal period of revolution	10,759.20 days, or 29.46 years
Mean synodic period	378.1 days
Rotation period (mean)	10 hours 39 minutes 24 seconds
Mean orbital velocity	9.6 km/sec
Axial inclination	26°7′
Orbital inclination to the ecliptic	2°29′22″
Orbital eccentricity	0.056
Diameter (equatorial)	120,660 km
(polar)	108,000 km
Apparent diameter seen from Earth	maximum 21″ minimum 15″
Mass (Earth=1)	95.26
Volume (Earth=1)	744
Density (water=1)	0.7
Albedo	0.61
Satellites	at least 20

BASIC ASTRONOMICAL DATA

Mass, density, and surface gravity. The mass of Saturn is 95.26 times that of the Earth, or $^1/_{3,500}$ of that of the Sun, and the escape velocity—the velocity which, once attained, will enable an object to "coast" away from the planet—is 32.26 kilometres per second, more than three times that of Earth. The density of Saturn is surprisingly low—only 0.7 that of water—and its surface gravity is 1.16 times that of the Earth. Saturn's outer layers are made up of gas, and it is a world quite unlike our own.

Orbit. Among planetary orbits, that of Saturn is of fairly low eccentricity (0.056), though the difference in distance between perihelion (closest approach to the Sun) and aphelion (farthest retreat from the Sun) amounts to 160,000,000 kilometres. Because Saturn is so far from the Sun and the Earth, phase effects for its disk are negligible; that is, Saturn always appears to be full, or nearly so, in the sense of the Full Moon.

Synodic period

The mean synodic period, the interval between successive oppositions, when the Earth passes approximately between Saturn and the Sun, is 378.1 days, so that Saturn is well placed for observation during several months in each year. Opposition dates from 1982 to 1990 are April 8, 1982; April 21, 1983; May 3, 1984; May 15, 1985; May 27, 1986; June 9, 1987; June 20, 1988; July 2, 1989; and July 14, 1990.

Like all the outer planets, Saturn moves for the greater part of each year eastward against the starry background; its average rate is about 1° in eight days. As it approaches opposition, however, its motion seems to slow down and to stop altogether about 70 days before the opposition date. For a period that may be as little as 133 days or as great as 141 days, it then seems to move in a retrograde, or westward, direction before reaching another stationary point and resuming its eastward movement. This behaviour does not, of course, indicate any real alteration in motion. The apparent regression is due to the fact that the Earth, moving in a much smaller orbit at a greater velocity (average 29.8 kilometres per second as against only 9.6 kilometres per second for Saturn), is catching up with Saturn and passing it.

When at conjunction, on the far side of the Sun, Saturn cannot be observed, as it passes too close to the Sun in the sky. The inclination of the orbit to the ecliptic is 2°29′22″. During its synodic period of 378 days, Saturn advances for nearly eight months and retrogrades slowly for about 4½ months, so that on balance it progresses along its path by about 12° per year. Data for Saturn are given in Table 17.

HISTORY OF OBSERVATION

Early telescopic observations. The first telescopic observations of Saturn are thought to have been made by Galileo in July 1610. He saw the disk of the planet clearly, but his telescope gave a magnification of only 32 diameters and was not good enough to show the ring system in recognizable form; moreover, conditions were unfavourable because the rings were placed almost edgewise. Galileo thought that Saturn must be a triple planet and wrote that "Saturn is not one alone, but is composed of three, which almost touch one another." Two years later, he found to his surprise that the "companions" had vanished, so that Saturn appeared as a single object. The ring system was then edge-on to the Earth, so that it could not be seen at all in Galileo's telescope. The original aspect was again seen in the years following 1613, but Galileo was never able to interpret it correctly. Subsequently, various strange theories were proposed to explain the planet's unusual form; Hevelius of Danzig, for instance, believed Saturn to be elliptical in shape, with two appendages attached to the surface.

The problem was solved by the Dutch astronomer Christiaan Huygens, who began his observations in 1655. The telescopes that he used were much more powerful than Galileo's, and gave sharper definition, so that in a short time he was satisfied that "Saturn is surrounded by a thin, flat ring which nowhere touches the body" of the planet. His theory met with a surprising amount of opposition, but by 1665 it had been universally accepted, even though the nature of the ring system was not established until much later.

Modern Earth-based studies. Saturn's colour is yellowish; darker belts, parallel with its equator, are always seen. These belts are not nearly so conspicuous as those on Jupiter, nor do they show so much detail. Saturn's greater distance and smaller size make it less easy to study than Jupiter; moreover, the beauty of Saturn's ring system tends to divert attention from its disk, particularly when the rings are wide open, thereby hiding a considerable part of the globe.

Saturn's albedo (the proportion of incident sunlight it reflects) is 0.61. The planet's apparent magnitude, however, depends largely upon the angle at which the ring system is displayed, largely because the rings are more reflective than the disk. When the rings are wide open, the magnitude attains −0.3, so that, of the stars, only Sirius and Cano-

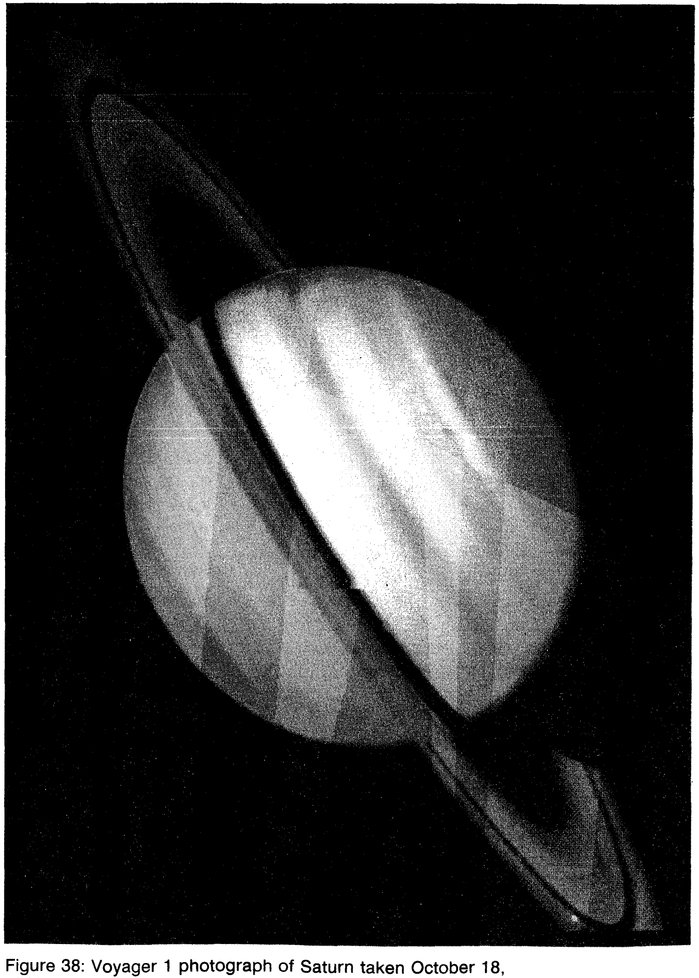

Figure 38: Voyager 1 photograph of Saturn taken October 18, 1980, and colour-enhanced to increase the visibility of features in Saturn's North Temperate Belt.

pus appear brighter than Saturn. At oppositions when the rings are edge on, as in 1980, the magnitude is as low as +0.8, though even at these times Saturn is still prominent.

Polar and equatorial zones

The equatorial zone appears creamy, sometimes almost white, in colour. The polar regions are always less brilliant; the belts, unlike those of Jupiter, do not show obvious colours. As with Jupiter, the two most prominent belts flank the equatorial zone; the other belts are much less conspicuous. Unless the rings are at a narrow angle, one or other of the equatorial belts will be covered.

Well-defined spots on Saturn are rare. The most prominent example sighted during the present century was that discovered on August 3, 1933, by the English amateur W.T. Hay, using a 15-centimetre refractor. The spot took the form of a large white oval patch in the equatorial zone, about one-fifth of the planet's diameter in length and with both ends well defined. During the next few weeks it lengthened rapidly, until by mid-September it had spread out so much that it could no longer be called a spot.

Space probes to Saturn. In September 1979 Pioneer 11 became the first unmanned space probe to rendezvous with Saturn. It had already passed by Jupiter, which had been its main objective, but valuable information about Saturn was obtained. The second probe was Voyager 1, which made its closest approach on November 12, 1980, when it passed only 124,200 kilometres above Saturn's clouds; its twin, Voyager 2, passed within 101,400 kilometres of Saturn's clouds on August 25, 1981.

Detailed views and a great amount of new information were obtained by the Voyager probes. Though Saturn's disk is blander than that of Jupiter because of a greater amount of overlying "haze," much detail was shown. A red spot was detected in the southern hemisphere, with brownish ovals in the northern hemisphere. Measurements of the locations of individual features at different times yielded data concerning the speed of the winds, and it seems that Saturn's circulation is different from that of Jupiter. The maximum westward velocities of Saturn occur near the centres of the darker regions, while on Jupiter they occur at the poleward interfaces between the belts and bright zones. In the polar latitudes, the large-scale light and dark bands break down into small-scale features, giving the impression of waves and eddies. The wind velocity at the cloud tops seems to be about 1,400 kilometres per hour, or twice that of Jupiter.

COMPOSITION

Possible iron and rock core

According to a recent theory, Saturn has an iron and rock core that extends out 13,000 to 14,000 kilometres from its centre and is so compressed that it contains 15 to 20 times the mass of the Earth. Surrounding the core is a layer of electrically conductive metallic hydrogen in liquid form, outside of which is an envelope of hydrogen and helium. There is a magnetic field 1,000 times stronger than that of the Earth, though far weaker than that of Jupiter; the magnetic axis is almost coincident with the axis of rotation, and the magnetosphere extends out beyond the orbit of the largest satellite, Titan. There are fairly strong radiation belts, but these, again, are much weaker than those of Jupiter.

The temperature at the cloud tops of Saturn is approximately −180° C. A theory that the planet might be self-luminous has been disproved. Saturn, like Jupiter, however, releases about twice the amount of energy it receives from the Sun, indicating the existence of an internal source of heat. While Jupiter emits energy from the gravitational contraction that occurred when the planet was formed about 4,600,000,000 years ago, it is unlikely that the heat source of Saturn is similar. Saturn is smaller and less massive and has a lower overall density (less than that of water); therefore, any heat remaining from the gravitational contraction of Saturn would have been dissipated long ago. Instead, the heat source of Saturn may result from the separation of hydrogen and helium in the planet's outer layers, with the heavier helium sinking through the liquid hydrogen middle layer.

THE SATELLITES

Saturn has at least 20 known satellites, details of which are given in Table 18. An additional satellite, named Themis, was reported by W.H. Pickering in the early 20th century, but it has not been recovered and probably does not exist. Several small satellites have been detected since 1977; they are extremely faint.

The satellites Calypso and Telesto move in orbits close to the inner and outer edges of Ring F and presumably keep this ring stable. Janus and Epimetheus move in the same orbit and must periodically approach each other closely, though clearly they do not collide. The satellite designated 1980S6 moves in the same orbit as Dione.

Phoebe, the outermost satellite, was not within range of the Voyager 1 probe, and little is known about it; it may be a captured asteroid. Iapetus is unique in having one hemisphere of high albedo and the other of low albedo; this explains why, as seen from the Earth, it appears much brighter when west of Saturn than when east of the planet. As with all the other satellites, except Phoebe, Iapetus has a captured, or synchronous, rotation; *i.e.*, its axial rotation period is equal to the time taken to complete one orbit, as is true of our Moon with respect to the Earth. Rhea, Dione, Tethys, and Mimas have icy, cratered surfaces; one huge crater on Mimas has more than one-third the diameter of the satellite itself. There is also a very large crater on Tethys. Enceladus has a surface that is smooth over wide areas; other regions have young, well-formed, and relatively small craters.

Dense atmosphere of Titan

Titan, by far the largest of Saturn's satellites, is in a class of its own because of its dense atmosphere. Data obtained from Voyager 1 indicate that the atmospheric pressure at Titan's surface is 1.5 to two times that of the Earth at sea level. The actual surface of the satellite is obscured by the top of an orange-coloured layer of what may be called "photochemical smog." Titan's atmosphere is made up mainly of nitrogen with smaller amounts of methane and cyanide; it is possible that the intensely cold surface is covered, at least in part, by oceans of liquid methane.

Table 18: Selected Satellites of Saturn

satellite	distance from centre of Saturn (kilometres)	period (days)	orbital eccentricity	orbital inclination (degrees)	diameter (kilometres)*
Atlas	137,670	0.602	0.000	0.3	40 × 20
Calypso	294,660	1.888	—	—	34 × 22 × 22
Telesto	294,660	1.888	—	—	34 × 28 × 26
Epimethius	151,422	0.694	0.009	0.33	140 × 120 × 100
Janus	151,472	0.694	0.007	0.14	220 × 200 × 160
Mimas	185,520	0.942	0.020	1.53	392

Hyperion	1,481,100	21.277	0.104	0.43	410 × 260 × 220
Iapetus	3,561,300	79.330	0.028	14.72	1,460
Phoebe†	12,952,000	550.48	0.163	177	220

*The diameters of some of the smaller satellites remain somewhat uncertain. †Phoebe moves around Saturn in a retrograde direction.

THE RINGS

The rings of Saturn are much more prominent than those of Jupiter or Uranus, and they are different in nature. Saturn's rings are made up of icy or ice-covered particles, each ring moving around Saturn in its own independent orbit. The ring plane remains in an almost fixed position with reference to the stars, but as seen from the Earth and the Sun the tilt of the rings is continually changing. Twice in each Saturnian revolution—at alternate intervals of 13 years nine months and 15 years nine months—the plane of the rings passes through the Sun. A few months before and after each such occasion, the ring plane passes through the Earth, which is near the Sun as viewed from Saturn. During the shorter interval, when Saturn passes through perihelion, the south pole of Saturn is tilted toward the Sun, so that the southern aspect of the rings is illuminated and the northern hemisphere of the planet is partly obscured. When the northern face is displayed, and the southern hemisphere of the globe is partly obscured, Saturn passes through aphelion; it is then moving slowly in its orbit, resulting in the inequality of the two intervals between successive edge-on presentations. The ring system is thin, so that at times of edge-on presentation the rings almost disappear as seen from the Earth.

Two of the three main rings—called A (outer) and B—are bright. In 1675 G.D. Cassini, at the Paris Observatory, discovered the gap between them, known as Cassini's Division. The "ring" seen by Huygens was a combination of the two, and his telescope was not good enough to show the division. Ring B is much the brighter of the two. In 1837 J.F. Encke, at Berlin, discovered a less prominent division in Ring A, known as Encke's Division. In 1850 a dusky inner ring, Ring C, was discovered by W.C. Bond and G.P. Bond at Harvard and independently by W.R. Dawes in England; this is generally known as the Crepe (Crêpe) Ring. The outer diameter of Ring A is 272,300 kilometres, the inner diameter 239,600 kilometres; for Ring B the outer and inner diameters are 234,200 kilometres and 181,100 kilometres, respectively. The inner diameter of Ring C is 149,300 kilometres, so that it extends to 17,000 kilometres above the cloud tops.

Dimensions of the main rings

Additional rings have since been discovered. A dusky ring, closer in than Ring C, was reported by telescopic observers; Voyager 1 results indicate that a ring, designated Ring D, does exist there, but whether it is genuinely observable from Earth is dubious. Outside Ring A is the clumpy and braided Ring F; Rings E and G were also shown on the Voyager 1 images.

The Voyager probes showed that the rings are much more complex than had been thought. Each contains hundreds of components, and there are several distinct narrow rings inside the Cassini Division. After examining photographs transmitted by Voyager 2, scientists estimated that the ring system is composed of thousands of rings and smaller "ringlets." It was once thought that the main divisions in the ring system were due to the cumulative perturbation effects of Saturn's satellites, but this explanation is clearly inadequate, and other forces must be involved. (P.Mo.)

Uranus

Uranus, symbol ⛢ in astronomy, is the seventh planet from the Sun in distance. Although less than half the size of Jupiter, it is still the third largest planet of the solar system. Its diameter is four times that of the Earth. Uranus is faintly visible to the naked eye, but it has been recognized as a planet for only 200 years. Physically, Uranus is almost a twin of Neptune, being only 3 percent larger and actually 13 percent less massive than Neptune. These two, with Jupiter and Saturn, constitute the Jovian planets characterized by large size, low density, and compositions consisting primarily of the very light elements.

EARLY OBSERVATIONS

The planets out through Saturn have been known since antiquity; Uranus was the first major body of the solar system to be discovered after the invention of the telescope. The English astronomer William Herschel undertook a survey of all stars down to the eighth magnitude—*i.e.,* those about 10 times fainter than stars visible to the naked eye—using a 15-centimetre telescope of his own manufacture at his observatory in Bath. On March 13, 1781, he found "a curious either nebulous star or perhaps a comet," distinguished from the stars by its clearly visible disk. Its lack of any trace of tail and its slow motion led to the suggestion that the observations were consistent with a planet moving in a nearly circular orbit. Within a year, independent studies established that the orbit was planetary, with a radius exceeding 18 astronomical units. The object was thus twice as far from the Sun as Saturn, and its discovery at once doubled the size of the known solar system.

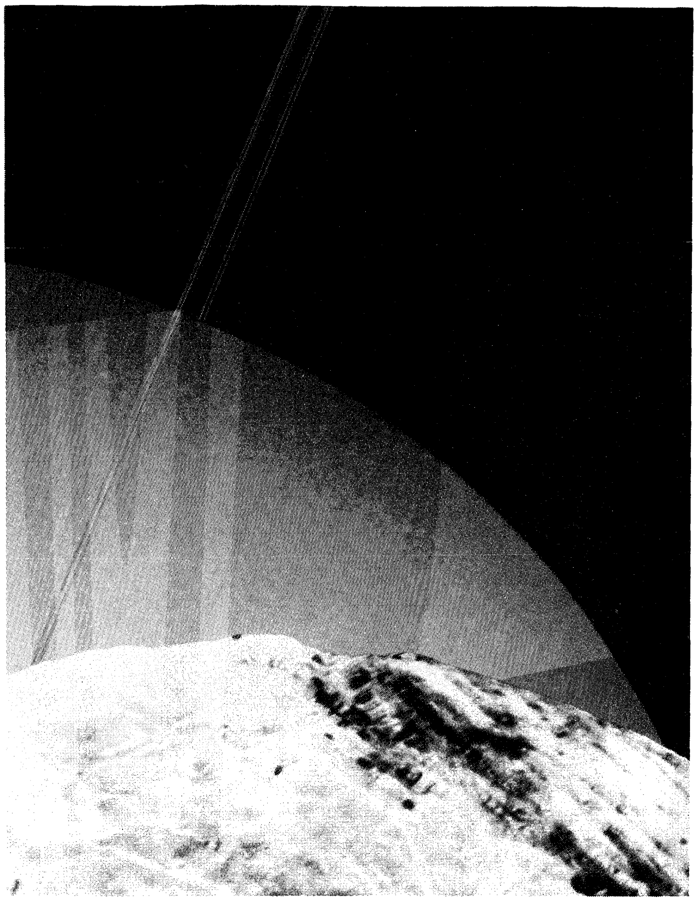

Figure 39: Montage of Voyager 2 photographs taken in January 1986 that simulates a view of Uranus and rings as if seen over the horizon of Miranda, one of the satellites of Uranus.

Three names were seriously considered for the new planet. Herschel proposed first to call it Georgium Sidus (in English, Georgian Planet) after his sovereign patron, King George III of England. The name Georgian appeared intermittently in England for over 50 years, especially in the *Nautical Almanac.* In France the name Herschel was also used occasionally until the mid-19th century. But already in the year of discovery Johann Elert Bode of Germany had suggested Uranus, as the father of Saturn in Roman mythology, who was, in turn, the father of Jupiter. This name was eventually universally accepted.

Progressive improvements in knowledge of the planet's motion made possible the projection of its orbit farther into the past, in a search for prediscovery observations for which accurate coordinates had been noted by observers who assumed the planet to be a star. The earliest of 22 such prediscovery observations proved to have been made in 1690, nearly a century before Herschel's discovery.

BASIC ASTRONOMICAL DATA

Uranus' orbit. The orbit of Uranus departs only slightly from a circle, the deviation corresponding to an elliptical orbit with eccentricity of 0.047. The mean distance from the Sun is 19.18 a.u.; the eccentricity brings Uranus to a perihelion (or point nearest the Sun) of 18.3 a.u. and an aphelion (point farthest from the Sun) of 20.1 a.u. The orbit is very slightly inclined, by 0.77°, to the ecliptic plane (the Earth's orbit).

Uranus completes one revolution around the Sun in 84.01 years. In the nearly 300-year span over which at least some observations exist, the planet has thus completed about three and a half revolutions. This is sufficient to test rigorously any proposed orbit of Uranus, including a careful accounting for the perturbations (gravitational influences) exerted by the other known planets of the solar system. But determinations of precise orbits for Uranus proved vexing from the beginning. By 1830 the observed motion departed from a best fitting ellipse by an intolerable 15″ of arc. Several astronomers suggested that perturbations by a hitherto unknown planet, lying outside the orbit of Uranus, might explain the anomalies. Computations, first in 1843–45 by an English mathematician and astronomer, John Couch Adams, and in 1845–46 by a French astronomer, Urbain-Jean-Joseph Le Verrier, led to precise predictions of the position of the hypothetical planet. The resulting discovery of Neptune in 1846 provided a stunning vindication of gravitational theory.

Appearance and spectrum. Under good conditions, Uranus shows a perceptible blue-green disk, through even a 10-centimetre telescope. This astronomically unusual colour is caused by absorption of red light in its atmosphere. Experienced visual observers report faint markings on the disk, in particular, grayish belts. Photographs taken by the U.S. Voyager 2 spacecraft during its flyby of Uranus (the probe passed within 81,000 kilometres of the planet's cloud tops) in 1986 revealed that such features are similar to the latitudinal cloud belts on Saturn though far less conspicuous. Several individual cloud formations resembling thunderheads on Earth also were detected by the probe but only between 25° and 50° latitude.

Faint markings

On the stellar-magnitude scale, in which larger numbers correspond to fainter brightness, Uranus over the past century had an average visual brightness at mean opposition (that is, when closest to the Earth) of about 5.8 magnitudes (the faintest stars visible to the naked eye on a very clear, totally dark night are about 6.5). The observed brightness can change by half a magnitude from the mean, depending on the Earth–Uranus and Uranus–Sun distances and also possibly on real change of reflectivity. Recent accurate photoelectric measures give a mean-opposition (photoelectric-visual) magnitude of about 5.5.

Uranus' rotation. In the decades 1910–30, several sets of visual observations of Uranus indicated rapid brightness variations. These were interpreted as arising from the rotation of a spotted planet, and a period of rotation of 10.82 hours was inferred. At the same time, spectrographic observations of the tilt of spectral lines in sunlight reflected from Uranus were claimed to be consistent with a rotation period of about 10.75 hours; for the next half century all reference works accepted this rotation period for Uranus. Modern analyses of these older data, however, have shown that they cannot be used to determine the correct value for rotation. Half a dozen attempts with very large telescopes were made in the 1970s to derive the Uranus rotation period using modern spectroscopic equipment; these gave widely divergent values ranging from 13 to 24 hours.

Recent rotation calculations

Voyager 2's discovery in 1986 of a comparatively strong magnetic field around Uranus enabled astronomers to make more accurate estimates of its rotation period. An analysis of field data (*e.g.,* radio emission from the field) indicated that Uranus rotates once every 17.3 hours or so.

The rotation of Uranus leads to an appreciable reduction in the effective force of gravity at the equator, hence to a substantial equatorial bulging. The equatorial diameter is about 3 percent greater than the polar diameter.

Mass, diameter, density, and composition. The orbital period and orbital radius of a satellite suffice to establish the mass of its primary, a result first derived by Newton. Recent determinations give Uranus a mass of 8.6978×10^{25} kilograms. This is about 14.5 times greater than that of the Earth and about 22,900 times less than that of the Sun.

The most accurate value for the size of Uranus comes from stellar occultation data. Timing the interval required for the planet, in its orbital motion, to pass in front of a star yields an equatorial radius of 25,700 kilometres, corresponding to four times the radius of Earth.

With the mass and radius of Uranus given above, its average density is 1.23 times the density of water; for comparison, that of Saturn is 0.70 and that of Earth is 5.52. So low a mean density requires Uranus to be composed of materials far lighter than those that make up the Earth; otherwise, its greater mass would lead to compression producing greater central pressures and densities than the Earth's. By the same reasoning, its average composition must be somewhat heavier than that of Saturn. Theoretical models of Jupiter and Saturn are consistent with a total composition similar to the basic solar chemical abundance (roughly 70 percent hydrogen by mass, most of the remainder helium). But in Uranus these two lightest elements must be accompanied by appreciable amounts of the next heavier common elements, especially carbon, oxygen, and nitrogen. Data transmitted by Voyager 2 has provided strong evidence that beneath Uranus' thick atmosphere lies an immense "ocean" of water and smaller amounts of methane and ammonia. This ocean, possibly more than 8,000 kilometres deep, appears to be heated to several thousand kelvins. The liquid, however, does not boil away because of the tremendous pressure from the weight of the overlying atmosphere. In all likelihood, this vast superheated ocean surrounds a core of heavy, rocky material (*e.g.,* silicate compounds) in a molten state. Investigators theorize that slow churning within the ocean and perhaps the central core generates Uranus' magnetic field.

THE ATMOSPHERE

Since the 1860s the spectrum of Uranus has been known to contain deep absorption bands toward the red. In 1932 these were shown theoretically by Rupert Wildt to be almost certainly due to methane (CH_4). Laboratory and high-resolution spectroscopic studies confirmed this. The photographic spectrum of Uranus is dominated by methane, corresponding to about 3.5 kilometre atmospheres of the gas (a kilometre atmosphere is the amount of a pure gas that would be encountered in a one-kilometre path length if the gas were at 0° C and one earth-atmosphere pressure). Like those of Jupiter and Saturn, Uranus' atmosphere must, nevertheless, consist primarily of hydrogen and helium; but, because both these gases are nearly invisible spectroscopically at low temperatures, the methane dominates. Weak hydrogen quadrupole lines are found in the spectrum of Uranus, in amounts consistent with several hundred kilometre atmospheres of this gas in the visible part of the atmosphere. Other common gases, primarily water and ammonia, would be frozen out of the upper atmosphere and be present in quantity only at depths to which the line of sight from Earth cannot penetrate.

The temperature of a planet can be determined by direct measurement of the infrared radiation that it emits. This technique indicates that the effective temperature of the visible outer atmosphere of Uranus is about 60 K. Data derived from Voyager 2 indicates that temperature increases with depth. Uranus radiates nearly 1.3 times as much heat as it receives from the Sun. Like the other three Jovian planets, it in effect generates its own heat albeit in modest amounts.

Temperature of Uranus

THE SATELLITES

Uranus has 15 known satellites, the most of any planet except for Jupiter and Saturn. In 1787 William Herschel found two of the satellites, later called Oberon and Titania. Two more satellites, Ariel and Umbriel, were discovered in 1851 at Liverpool. The names for these four satellites were apparently proposed by the astronomer Sir John Herschel, the son of William Herschel. The last of the five major Uranian satellites to be found, Miranda, less than 10″ of arc from the planet, was first photographed in 1948 at the McDonald Observatory. Ten substantially smaller satellites were discovered by Voyager 2 inside the orbit of Miranda, the innermost of the major Uranian moons.

Uranus' satellite system is compact and closely coplanar with the planet's equator. But, whereas the equators and satellite orbits of all the other planets have only modest inclinations to the plane of the ecliptic, in the case of Uranus these are all curiously tilted, by an extreme 98°. Thus, the rotation of the planet and revolution of its satellites are essentially perpendicular and even slightly retrograde to the orbital revolution of Uranus about the Sun.

Table 19: Major Satellites of Uranus

name	date found	discoverer	telescope size (in.)	satellite diameter (km)	orbit period (days)	magnitude (V_0)
I Ariel	1851	W. Lassell	24	1,330	2.52	14.4
II Umbriel	1851	W. Lassell	24	1,110	4.14	15.3
III Titania	1787	W. Herschel	19	1,600	8.71	13.9
IV Oberon	1787	W. Herschel	19	1,630	13.46	14.2
V Miranda	1948	G.P. Kuiper	82	484	1.41	16.5

THE RINGS

Uranus occulted a relatively bright star on March 10, 1977. Several observers of this rare event independently noted additional occultations corresponding to a hitherto unknown system of rings. Two additional rings were later discovered by Voyager 2, bringing the total to 11 rings. The entire ring system is thought to extend from about 41,600 to 50,700 kilometres from Uranus' centre. The rings are only about one to 10 kilometres wide, except for the one designated epsilon, which is between 30 and 100 kilometres wide. They consist chiefly of boulder-sized chunks roughly one metre in diameter. The rings have among the lowest reflectivities of any known material in the solar system, similar to the reflectivity of very dark carbonaceous chondritic meteoric material. They lie essentially in the plane of the planet's equator and of the satellite orbits but have very slight tilts and ellipticities, which suggest that they may have been formed fairly recently in the history of the solar system. (H.Sm./Ed.)

Low reflectivities

Neptune

Neptune, symbol ♆ in astronomy, is the eighth planet from the Sun and, until Pluto was discovered in 1930, was the outermost known planet in the solar system. Its mean distance from the Sun is almost exactly 30 astronomical units. Because part of Pluto's orbit is closer to the Sun than its orbit, Neptune periodically becomes, in fact, the most distant planet from the Sun. Such is the case as Pluto moved inside Neptune's orbit in 1979 and will remain there until early 1999. Neptune, being only as bright as a star of the eighth magnitude, is invisible without optical aid.

EARLY OBSERVATIONS AND DISCOVERY

The detection of Neptune through its action upon Uranus is one of the fascinating stories in the history of astronomy and a striking example of the precision of the theory of planetary motions. Before its actual discovery by the English astronomer Sir William Herschel in 1781, Uranus had been observed as a fixed star on at least 17 other occasions, first by the English astronomer John Flamsteed in 1690. The French astronomer Alexis Bouvard, in 1820, constructed tables of the motions of Jupiter, Saturn, and Uranus; the observed positions of Jupiter and Saturn were represented satisfactorily, but he found it impossible to do this for Uranus. During the next two decades there was continued divergence between the theory of perturbations, describing how the known planets should alter slightly one another's motions, and the observations. The idea of an ultra-Uranian planet occurred to Bouvard, the German astronomer Friedrich Wilhelm Bessel, the American astronomer William J. Hussey, and others.

Bessel, in 1842, announced his intention of investigating the problem of the motion of Uranus. Unfortunately, he died before much had been done. Meanwhile an English astronomer, John Couch Adams, and a French astronomer, Urbain-Jean-Joseph Le Verrier, were also tackling the problem energetically.

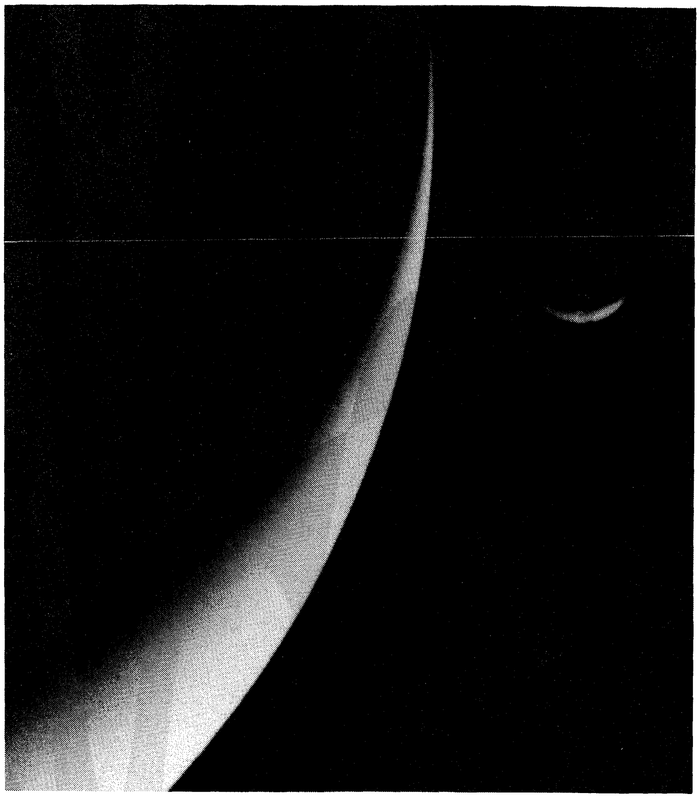

Figure 40: The crescents of Neptune and its largest satellite, Triton (background), photographed from the Voyager 2 space probe in August 1989. The image was taken at a distance of some 4.86 million kilometres from the planet.

By courtesy of the National Aeronautics and Space Administration

Adams, at St. John's College, Cambridge, began serious work in 1843 and by September 1845 had communicated his results to James Challis, one of his colleagues, and the following month to the Astronomer Royal, Sir George Biddell Airy. Adams said that his calculations would account for the irregularities in the motion of Uranus by the action of an exterior planet whose orbital elements were tabulated. The position of the exterior planet, as derived from Adams' work, was later found to be so close to the true value that two evenings of assiduous searching should have been sufficient to locate it. Adams also demonstrated that the observations of Uranus from 1780 onward were in good agreement with his theory. Instead of looking for the unknown planet, however, Airy did no more than to ask, in a reply, whether the assumed perturbations would also explain the known error in the calculated distance of Uranus from the Sun.

Meanwhile Le Verrier in France, working on similar lines, had published the results of his thorough mathematical investigations in a communication to the French Academy of Sciences on November 10, 1845. A second memoir was presented by Le Verrier on June 1, 1846.

The close agreement between the elements found by the two investigators is clear from the tabulated values (see

Table 20: Physical Data for Neptune

Mean distance from Sun	4,500,000,000 km (30.1 a.u.)
Eccentricity of orbit	0.009
Inclination of orbit to ecliptic	1°46′34″
Sidereal period of revolution	60,190 days, or 164.8 years
Rotation period	16 hours 3 minutes
Albedo	0.84
Mean synodic period	367.49 days
Mean orbital velocity	5.44 km/sec
Mean daily motion	0° .005981
Inclination of equator to ecliptic	28°8′
Mass (Earth = 1)	17.2
Diameter	49,530 km
Density	1.64 gm/cc
Apparent magnitude	+7.8
Satellites	8

Table 21) and led Airy to suggest to Challis, on July 9, 1846, that a search for the unknown planet be made with the Northumberland telescope, then at Cambridge Observatory. Challis commenced on July 29, sweeping each region twice, so that a comparison of the two sets of observations would then reveal the unknown planet by its motion. It subsequently transpired that Challis observed the planet on August 4 but failed to compare his observations with those of the previous night.

On August 31, Le Verrier's final paper was presented to the French Academy, and on September 18 he wrote to the German astronomer Johann Gottfried Galle at Berlin suggesting that he search for the planet, with the hope of distinguishing it from a star by its disklike appearance. On September 23, the planet was located on the first attempt by Galle and another German astronomer, Heinrich Louis d'Arrest, not by its disklike appearance but rather by the absence of an observed starlike body from one of the new star charts prepared at the observatory.

Table 21: Orbital Data According to Le Verrier and Adams

element	Le Verrier	Adams	
		hypothesis I	hypothesis II
Semimajor axis (a.u.)	36.154	38.38	37.27
Eccentricity	0.1076	0.16103	0.12062

True longitude	326°32′	328°	329°

Controversy over the credit for Neptune's discovery

The question whether Le Verrier should receive sole credit was warmly discussed by French and British astronomers; Adams and Le Verrier took no part in the controversy. The French physicist D.-F.-J. Arago went so far as to suggest that the new planet be named Le Verrier, but this was received with such little favour outside France that he withdrew it, proposing Neptune instead.

The mathematical methods employed in the solution of the problem and, in particular, the choice of the value of the semimajor axis of the orbit have been questioned. At the date of its discovery, Neptune was only 1° from the place predicted by Le Verrier and approximately 2½° from the position predicted by Adams. However, it has since been shown that it was fortunate that the search was made around the middle of the 19th century, because, if the orbit worked out by Adams had been used for a search in 1770, then Neptune would have been nearly 30° from its predicted position and not much less if Le Verrier's orbit had been used. Figure 41 shows just how sharply the actual and predicted positions would have diverged after 1850–60.

BASIC ASTRONOMICAL DATA

Appearance. The great distance and relative faintness of Neptune make it exceedingly difficult for any details to be observed from the Earth, even with large telescopes. It was not until the U.S. Voyager 2 probe passed within 5,000 kilometres of Neptune's cloud tops on August 25, 1989, that scientists were able to study the physical features of the planet.

Neptune is seen by light reflected from the Sun, and its greenish blue hue is due to absorption of the red, orange, and yellow solar rays by its extensive atmosphere. Strong absorption bands in the infrared region of the spectrum had been identified in 1932 as being due to methane (CH_4); some unidentified bands at a wavelength of about 7500 angstroms, near the deep red end of the visible spectrum, were found by the U.S. astronomer G.P. Kuiper in 1949.

Atmosphere. Neptune's atmosphere consists of hydrogen and helium mixed with methane. Images and data transmitted by Voyager 2 revealed that winds of about 300 metres per second (700 miles per hour) blow westward around the planet. Several enormous storm systems were also detected by the spacecraft. The largest of these systems, the so-called Great Dark Spot (or GDS), is as wide as the Earth and resembles Jupiter's Great Red Spot. Located about 20° latitude, this whirlwind turns in a counterclockwise direction. Wispy clouds of methane hover over the southern rim of the Great Dark Spot some 50 kilometres above a layer of hazy methane stratus clouds that envelops much of Neptune. A second giant storm system shaped somewhat like an eye appears to the south of the Great Dark Spot.

Great Dark Spot

From R.A. Lyttleton, *Mysteries of the Solar System* (1968); Clarendon Press, Oxford

Magnetic field. Voyager 2 discovered that Neptune has a complex magnetic field. While the field is not as strong as those surrounding the other giant outer planets and Earth, it is still capable of trapping galactic cosmic-ray and solar wind particles—*e.g.*, energetic protons and electrons—in a roughly doughnut-shaped region termed a magnetosphere. The magnetic field rotates with the planet, and, as it does so, accelerates the electrons to high speeds approaching that of light. This causes them to emit radio energy, which is released in beams whose intensity varies regularly with the field's (and hence the planet's) period of rotation.

Voyager 2 detected auroras in Neptune's atmosphere. These luminous phenomena are associated with the charged solar wind particles captured by a planet's magnetic field. The auroral displays on Neptune are spread over a fairly wide region rather than being confined around the magnetic poles, as on the Earth.

The dipole axis of Neptune's magnetic field is tilted 47° from the rotation axis and is displaced from the planetary centre by some 10,000 kilometres. With the exception of Uranus' magnetic field, which is similarly tilted, those of the other planets generally coincide with their rotation axis. (Neptune's axis of rotation is tilted roughly 29° to the plane of the planet's orbit around the Sun.) The tilted magnetic fields of Neptune and Uranus have led some investigators to speculate that the fields of both planets result from the convection of electrically conducting fluids near their surface rather than within a molten metallic core, as in the case of the Earth. In effect, the electric dynamo of Neptune and Uranus operates around their core instead of in it.

Rotation. Spectroscopic observation of Neptune in 1928 led astronomers to believe that the planet's rotation period was about 15 hours. Although this value was subsequently refined, investigators remained uncertain as to its preciseness. Voyager 2's measurements of radio emissions from Neptune's magnetic field enabled them to determine that the planet actually completes one orbit in 16 hours and 3 minutes.

Composition, diameter, and density. Like the other giant outer planets, Neptune has no solid surface. It consists

Table 22: Elements of Neptune's Orbit

Mean anomaly	133° 44′ 09″.783
Perihelion	270° 03′ 30″.833

Inclination	1° 46′ 33″.651
Eccentricity	0.009
Semimajor axis	29.9871290465

chiefly of water and molten rock, resembling its neighbour Uranus.

Neptune has an equatorial diameter of about 49,530 kilometres. Analysis of Voyager 2 data suggests that Neptune is the densest of all the giant planets, having an estimated density of 1.64 grams per cubic centimetre.

SATELLITES AND RINGS

Satellites. It had long been known that Neptune had two satellites, Triton and Nereid. Triton, the larger and brighter of the two, was discovered visually by W. Lassell, using a 60-centimetre telescope at Liverpool, England, in 1846, within a month of the discovery of the planet itself. It was originally assumed that Triton revolved around Neptune in the same direction as the planet's rotation, implying that Neptune's north pole pointed south of the ecliptic, like that of Uranus (in those days no retrograde satellites were known). In 1928, however, careful spectroscopic work at Lick Observatory, California, showed that Neptune rotated in the direct sense unlike Uranus; thus Triton moved around Neptune in the retrograde direction, opposite to that of the planet's spin. The orbit of Triton is circular and was seen edge on from the Earth in 1953. Nereid was discovered photographically in 1949 by G.P. Kuiper, with the aid of the 208-centimetre McDonald telescope in Texas.

Triton's retrograde orbit

Voyager 2 provided a wealth of information about Triton and sighted six additional satellites. Triton proved to be smaller than initially thought: its diameter is only 2,705 kilometres, about 1,000 kilometres less than originally estimated using ground-based observations. Triton is composed of ice and rock and appears to have a very thin atmosphere of nitrogen and methane. It may be the coldest object in the entire solar system, having a surface temperature of −240° C or less.

Triton has an unusual landscape, one that has been likened to the rind of a cantaloupe. High-resolution images transmitted by Voyager 2 cameras showed that its equatorial zone has enormous canyons and narrow ridges that cut across one another along various segments. There are vast expanses of ice flows, presumably frozen water mixed with methane and ammonia. Some of these are pitted by meteorite craters reminiscent of those on the Moon. Triton's southern polar cap is covered by nitrogen frost, over which numerous feathery, dark streaks can be seen drifting northward. It has been proposed that these streaks, along with various features of Triton's terrain, are manifestations of a phenomenon referred to as "icy volcanism." According to this theory, seasonal heating of the surface causes some of the thick frost cover to evaporate and break up. The decrease in the volume of icy matter results in a reduction in the pressure exerted on subsurface reservoirs of nitrogen and smaller amounts of methane. When the confining pressure drops to a certain point, the liquid, heated by some internal heat source, vaporizes and discharges through fissures in the overlying ice layer. Exposure to the below-freezing air causes the gases to condense to ice crystals. Some of these crystals, primarily of methane, are carried by winds blowing across the polar caps, thereby producing the dark streaks. The long thin ridges mentioned above probably formed where the liquid nitrogen and methane oozed onto the surface from cracks in the surface and quickly froze. The flows of ice on the broad plains, which resemble volcanic lava flows, are thought to have formed in a similar way. In this case, however, ices composed of a mixture of ordinary water, methane, and most likely ammonia may have poured out from the interior of Triton early in its history and spread across wide areas. It is explained that mixed ices can flow at substantially lower temperatures than can ice consisting of pure water.

The other satellites of Neptune are much smaller than Triton. One of the newly discovered moons, simply designated 1989 N1, is the second largest, measuring about 400 kilometres in diameter, while Nereid, at 340 kilometres, is third. The remaining moons range from about 50 to 200 kilometres in diameter (see Table 23). Voyager 2 images of 1989 N1 indicate that it is irregularly shaped and that its surface is heavily pocked with impact craters. The shapes and surfaces of the other Neptunian moons are similar.

Table 23: Satellite Data

satellite name or designation	distance from centre of Neptune (in kilometres)	diameter (in kilometres)
Nereid	5,513,400	340
Triton	354,800	2,705
1989 N1	117,600	400
1989 N2	73,600	190
1989 N4	62,000	150
1989 N3	52,500	180
1989 N5	50,000	80
1989 N6	48,000	54

Rings. Neptune has a system of four rings encircling it. The rings are composed of dust particles, most likely the debris ejected from the satellites during meteorite impacts. The outermost ring has a dense core with three segments consisting of numerous small "moonlets" (no more than 10 kilometres in diameter). It is surrounded by a diffuse dust halo that extends about 50 kilometres wide. The ring is orbited by one of the smaller satellites, 1989 N4, which is thought to confine the ring's constituent particles. The third ring inward toward Neptune also has a so-called shepherd satellite, the moon designated as 1989 N3. The other two rings of Neptune are very diffuse and broad.

Rings of dust particles

(G.E.T./Ed.)

Pluto

Pluto, symbol ♇ in astronomy, is the ninth and most distant of the known planets in the solar system. The principal orbital and physical data of Pluto and its satellite, Charon, are shown in Table 24.

DISCOVERY OF PLUTO AND CHARON

Before Pluto's discovery in 1930, several astronomers had interpreted the motions of Uranus and Neptune as revealing gravitational perturbations beyond those accountable for by all of the planets known at that time. Their calculations were similar to those that led John Couch Adams and Urbain-Jean-Joseph Le Verrier in the 1840s to predict correctly the position of Neptune. Also among those who thus predicted a planet beyond Neptune was Percival Lowell, to whom credit for a prediction was generally given. Not only were his predicted orbital elements close to those of Pluto but he also initiated the effort that led ultimately to its discovery by his successors at the Lowell Observatory in Flagstaff, Arizona. Although Lowell's *Memoir on a Trans-Neptunian Planet* (*Memoirs of the Lowell Observatory*, vol. 1) was not published until 1915, the year before his death, he and his colleagues carried out intermittent searches between 1905 and 1916 with a variety of telescopes of limited capability. On the basis of experience gained while conducting these early efforts, a fast wide-field telescope was designed specifically for the trans-Neptunian planet search.

Percival Lowell's contributions

After the telescope was completed in 1929, the project was placed in the hands of Clyde William Tombaugh. He painstakingly compared pairs of photographic plates of selected sky regions, taken several days apart, looking for images of moving objects. The project was carefully planned so that, among the millions of stellar and starlike images, other moving bodies such as the numerous asteroids could be easily recognized and not be incorrectly identified as the sought-for planet. On February 18, 1930, Tombaugh discovered the trans-Neptunian planet on plates that he had taken on January 21, 23, and 29, 1930. Announcement of the discovery was not made until March 13, 1930, the anniversary of Lowell's birth, but in the interval the Lowell Observatory astronomers were able to assemble further supporting evidence to confirm the discovery. After long deliberation over many suggested names for the new planet, the name Pluto was chosen because it could be represented by the symbol ♇, made up of Percival Lowell's initials.

Even while the announcement of this significant discovery was drawing the attention of the entire astronomical world to the new planet, certain grave doubts were being expressed as to whether it indeed was Lowell's trans-Neptunian planet. The difficulty was that Pluto was much fainter—about one-tenth as bright—than had been expected, and its telescopic image had no measurable diameter. It was therefore difficult to resist the conclusion that Pluto was altogether too small and, hence, of insufficient mass to have caused the large perturbations in Uranus' and Neptune's motions that had led Lowell and others to predict its existence and orbital motion. Soon after Pluto's discovery, Ernest William Brown demonstrated mathematically that Lowell's prediction was, in fact, dynamically invalid. Then, while he was associated with the Lick Observatory, Mt. Hamilton, California (1932–36), E.C. Bower, among others, convincingly demonstrated that Pluto's mass was probably less than one-half that of the Earth and that the resulting perturbations to the motions of Uranus and Neptune must have been significantly smaller than the probable errors of the earliest observations of these bodies. Modern data have since confirmed this conclusion. Thus, Pluto, at first considered as the second planet, after Neptune, to have been discovered through prediction, is actually the second planet, after Uranus, to have been discovered by accident. Or perhaps more properly, it is the first planet to have been discovered through a systematic, comprehensive search.

In 1978 the existence of a satellite of Pluto was established by James W. Christy and Robert S. Harrington of the U.S. Naval Observatory, who discovered that photographic images of Pluto periodically appeared slightly elongated. The satellite, named Charon, orbits the planet with a period of 6.39 days, in synchronism with the known period of variation in Pluto's brightness. Charon's orbit is probably circular, with a radius of about 20,000 kilometres.

BASIC ASTRONOMICAL DATA

Pluto's orbit. Pluto moves in a markedly eccentric orbit about the Sun with a period of about 248 years. The orbit is more eccentric than that of any other planet and has a very high inclination, about 17°, to the mean plane of the solar system. Because of the high eccentricity of the orbit, Pluto is closer to the Sun than is Neptune at times around perihelion as, for example, in the interval 1979–99.

Conjunctions with Neptune and Uranus

The near commensurability of the periods of revolution of the three outermost planets brings the planets into successive conjunctions at about the same places in space. At intervals of approximately 500 years, during which Pluto makes two revolutions and Neptune three, these two planets come closest to each other and are then separated by only 18 astronomical units; this phenomenon last occurred in 1891 and will occur again in 2391. Similarly, Pluto and Uranus have close conjunctions, although in two series. For example, in the years 1854, 2107, and 2360, Pluto and Uranus are approximately 29 a.u. apart, and in the years 1713, 1966, and 2220 they are only 14 a.u. apart.

Mass, diameter, and density. The difficult problem of determining the mass of Pluto was resolved with the discovery of Pluto's satellite and the determination of its orbital period around, and its mean distance from, the planet. Before the discovery of Charon, estimates of Pluto's mass ranged from about $^1/_5$ that of Earth to seven times that of Earth, with indeterminate uncertainties. Pluto's mass is now believed to be only about $^1/_{500}$ that of the Earth, with an uncertainty of 20 percent. While these later figures are subject to improvement as refined studies progress, there is no doubt that they are more reliable than those made before the discovery of Charon.

Following upon the determination of the combined mass of Pluto and Charon, the chief problem is the measurement of their diameters. This is not to say that other unknowns—such as their chemical compositions, the physical nature of their surfaces, or their origins—are less interesting or important. It is simply an acknowledgment that, without reliable determinations of Pluto's and Charon's diameters and mean densities, many of these other problems will remain obscured and their answers speculative.

Pluto's diameter

The diameter of Pluto has been the subject of several investigations, but it was not determined with confidence until the late 1980s. At that time, several groups of astronomers, using the most advanced telescopes and detectors, determined that the planet measures from about 2,200 to 2,300 kilometres across. In effect, Pluto is much smaller than the Moon.

Table 24: Orbital and Physical Data for Pluto

Mean distance from Sun	39.53 a.u.
Least distance from Sun	29.81 a.u.
Greatest distance from Sun	49.26 a.u.
Eccentricity	0.246
Inclination tò ecliptic	17.123°
Period of revolution	248.5 years
Time of perihelion	1989.8
Visual magnitude at mean opposition	15.0
Period of axial rotation	6.3867 days
Satellites	one known; 1978 P1 (Charon)
Diameter (estimated)	Pluto: 2,200–2,300 kilometres Charon: about 1,200 kilometres
Mass	Pluto and Charon together: 0.0025 terrestrial mass Pluto probably about 10 times as massive as Charon
Density	probably between 0.4 and 0.9 gram per cubic centimetre
Composition	uncertain, may consist of a large proportion of frozen methane
Inclination of Charon's Orbital plane with respect to Pluto's orbital plane around the Sun	111°

A secure measurement of the diameters of celestial bodies can be made if the bodies occult a star in the course of their apparent motion across the sky and if the occultation is observed from two observatories located at different latitudes on the Earth. In 1980, such an occultation occurred in the Pluto–Charon system, but it was evidently observed only at the South African Astronomical Observatory. The occulting body apparently was Charon, and the results show that Charon is at least 1,200 kilometres in diameter. In 1965, numerous North American observatories had been alerted to a possible occultation by Pluto–Charon, but no such occultation was observed.

On the basis of the data given above for current estimates of the masses and diameters of Pluto and Charon, it appears that the mean density of Pluto and Charon lies between 0.4 and 0.9 grams per cubic centimetre. This low value of density has led some investigators to propose that these bodies may be made up of a large proportion of solid methane, instead of the denser, rocky materials found in the terrestrial planets.

THE SURFACES OF THE PLANET AND ITS SATELLITE

Because the telescopic image of Pluto is generally indistinguishable from that of a faint star, all efforts made by the early 1980s to detect surface features by conventional methods were unsuccessful. That the surface is not uniform has been known since 1955, when M.F. Walker and R.H. Hardie at the Lowell Observatory found that the brightness of the planet varied regularly by about 12 percent within a period of 6.39 days. The variation in apparent brightness is now interpreted as due to the combined effects of irregular surface reflection properties and an axial rotation of the planet with a period of 6.39 days. Studies since 1955 have shown that the range of brightness variation has gradually increased; analysis of this increase has in turn allowed for an estimation of the orientation of Pluto's spin axis in space.

Variations in apparent brightness

Information about the surfaces of both Pluto and Charon remains limited. Observations of the Infrared Astronomical Satellite (IRAS) reveal that Pluto has a dark band along its equator and polar caps of frozen methane, which vary over time. The infrared spectrum of Charon, on the other hand, indicates that water ice rather than methane frost covers its surface.

POSSIBLE ATMOSPHERE

Whether Pluto has an atmosphere is not known with any degree of assurance, but certain conditions relating to a possible atmosphere can be stated in general terms. It can be estimated that the average surface temperature on the sunlit portion of Pluto's surface is about 60 K when the planet is at perihelion and 47 K at aphelion. The dark side of the planet probably has a temperature of about 20 K. At such temperatures, virtually all materials are frozen, or at least liquefied, except for a few gases such as hydrogen and helium. These gases are so light in molecular weight, and Pluto's gravity is so low, that it is unlikely that they could be retained in free form. There is some possibility, however, that frozen methane might sublimate slightly on the sunlit side of Pluto to produce an atmosphere of low density. A clearer picture of the atmospheric and surface conditions of Pluto awaits improvements in the resolution of spectrophotometric techniques and further exploration by spacecraft.

COMPARISON WITH OTHER PLANETS

Pluto differs greatly from the major planets in its general physical properties—the other outer planets have great mass, large size, extensive atmosphere, and very rapid axial rotation—and has much higher orbital eccentricity and inclination. Thus, Pluto probably had an origin and evolution different from that of the major planets. Because Pluto's physical properties appear more akin to those of the satellites, especially Triton, and because Pluto's orbit nearly intersects Neptune's, it has been proposed by R.A. Lyttleton and others that Pluto may in fact be a runaway satellite originally bound to Neptune.

Similarity to satellites

Whether there is any validity to the apparent perturbations shown in the motions of Uranus and Neptune that led to the prediction and ultimate discovery of Pluto remains open to question. There is little doubt that many of the earliest observed positions of these planets were adversely affected by errors due to primitive techniques. In recent years, however, the entire subject was again under review with renewed vigour and the advantage of an enormously wider range of computational techniques than was available to the investigators of the early 1900s. It is not inconceivable that current studies may point to the existence of another planet that is as yet undiscovered.

(R.H.H./Ed.)

OTHER CONSTITUENTS OF THE SOLAR SYSTEM

Asteroids

Asteroids are rocky bodies about 1,000 kilometres or less in diameter that orbit the Sun primarily between the orbits of Mars and Jupiter. Because of their small size and large numbers relative to the nine major planets, asteroids are also called minor planets. The two designations are frequently used interchangeably, though dynamicists, astronomers who study individual objects with dynamically interesting orbits or groups of objects with similar orbital characteristics, generally use the term minor planet, whereas those who study the physical properties of such objects usually refer to them as asteroids. The term planetoid is sometimes used as well.

Nomenclature

HISTORICAL SURVEY OF MAJOR ASTEROID DISCOVERIES

Early observations. The first asteroid was discovered on Jan. 1, 1801, by Giuseppe Piazzi at Palermo. At first Piazzi thought that he had discovered a comet; however, after the orbital elements of the object had been computed it became clear that the object moved in a planetlike orbit between the orbits of Mars and Jupiter. Due to illness, Piazzi was only able to observe the object until February 11, and, as no one else was aware of its existence, it was not reobserved before it moved into the daytime sky. The short arc of observations did not allow computation of an orbit of sufficient accuracy to predict where the object would reappear when it moved back into the night sky, and so it was "lost." There matters might have stood were it not for the fact that this object was located at the heliocentric distance predicted by the Titius-Bode law (also known as Bode's law) of planetary distances proposed in 1766 by the German astronomer Johann D. Titius and popularized by his compatriot Johann E. Bode, who used the scheme to advance the notion of a "missing" planet between Mars and Jupiter. The discovery of Uranus in 1781 by the German-born British astronomer William Herschel at a distance that closely fit the distance predicted by the Titius-Bode law was taken as strong evidence of its correctness. Some astronomers were so convinced that during an astronomical conference in 1796 they agreed to undertake a systematic search. Ironically, Piazzi was not a party to this attempt to locate the missing planet. Nonetheless, Bode and others, on the basis of the preliminary orbit, believed that Piazzi had found and then lost it. This led the German mathematician Carl Friedrich Gauss to develop in 1801 a method for computing the orbit of an asteroid from only a few observations, a technique that has not been significantly improved since. Using Gauss's predictions, the German astronomer Franz von Zach recovered Ceres on Jan. 1, 1802. Piazzi named this object Ceres after the ancient Roman grain goddess and patron goddess of Sicily, thereby initiating a tradition that continues to the present day: asteroids are named by their discoverers (in contrast to comets, which are named for their discoverers).

Identification of Ceres

The discovery of three more faint (compared with Mars and Jupiter) objects in similar orbits over the next six years (Pallas, Juno, and Vesta, respectively) complicated this elegant solution to the missing-planet problem and gave rise to the surprisingly long-lived, though no longer generally accepted, idea that the asteroids were remnants of a planet that had exploded.

Following this flurry of activity, the search for the planet appears to have been abandoned until 1830 when Karl L. Hencke renewed it. In 1845 he discovered the fifth asteroid, which he named Astraea.

Modern research. There were 88 known asteroids by 1866, when the next major discovery was made: Daniel Kirkwood, a U.S. astronomer, noted that there were gaps in the distribution of asteroid distances from the Sun (see below *Distribution and Kirkwood gaps*). The introduction of photography to the search for new asteroids by the German astronomer Max Wolf in 1891, by which time 322 asteroids had been identified, accelerated the discovery rate. By the end of the 19th century, 464 had been found. The asteroid designated 323 Brucia, detected by Wolf in 1891, was the first to be discovered by means of photography.

Application of photography

The first measurements of the sizes of asteroids were made in 1894 and 1895 by the U.S. astronomer Edward E. Barnard, who used a filar micrometer (an instrument normally employed for visual measurement of the separations of double stars) to estimate the diameters of the first four asteroids. Barnard's results established that Ceres was the largest asteroid, with an estimated diameter of nearly 800 kilometres. These values remained the best available until new techniques were introduced during the early 1970s (see below *Size and albedo*). The first four asteroids came to be known as "the big four," and, because all other asteroids were much fainter, they were believed to be considerably smaller as well.

In 1918 the Japanese astronomer Kiyotsugu Hirayama recognized clustering in three of the orbital elements of various asteroids (semimajor axis, eccentricity, and inclination). He speculated that objects sharing these elements had been formed by explosions of larger parent asteroids and called such groups of asteroids "families."

The idea that Jupiter was responsible for interrupting the formation of a planet from the swarm of planetesimals accreting near a heliocentric distance of 2.8 a.u. was introduced in 1944 by O.J. Schmidt. In 1951 the Estonian astronomer Ernest J. Öpik calculated the lifetimes of asteroids with orbits that passed close to those of the major planets and showed that most such asteroids were destined to collide with a planet or be ejected from the solar system on time scales of a few hundred thousand to a few million years. Since the age of the solar system is approximately 4,500,000,000 years, this meant that the asteroids seen today in such orbits must have entered them recently and implied a source for the asteroids. Öpik believed this source to be comets that had been captured by the planets and that had lost their volatile material through repeated passages inside the orbit of Mars.

The mass of Vesta was deduced by the German-born U.S. astronomer Hans G. Hertz in 1966 from measurements of its perturbations on the orbit of 197 Arete. The first mineralogical determination of the surface composition of an asteroid was made in 1969 by Thomas McCord, John B. Adams, and Torrence V. Johnson of the United States, who used a technique known as spectrophotometry to identify the mineral pyroxene in the surface material of 4 Vesta. In 1970 the first reliable albedos (reflectivities) and diameters of asteroids were determined by two groups of U.S. astronomers—Joseph F. Veverka, Benjamin H. Zellner, and their colleagues, who used a technique based on polarization measurements, and David A. Allen and Dennis L. Matson, who employed infrared radiometry.

Development of classification systems. In 1975 Zellner, together with Clark R. Chapman and David D. Morrison, grouped the asteroids into three broad taxonomic classes, which they designated C, S, and M (see below *Composition*). They estimated that about 75 percent belonged to class C, 15 percent to class S, and 5 percent to class M. The remaining 5 percent were unclassifiable in their system due to either poor data or genuinely unusual properties. Furthermore, they noted that the S class dominated the population at the inner edge of the asteroid belt, whereas the C class was dominant in the middle and outer regions of the belt. In 1982 other U.S. astronomers, Jonathan C. Gradie and Edward F. Tedesco, expanded this taxonomic system and recognized that the asteroid belt consisted of rings of differing taxonomic classes with the S, C, P, and D classes dominating the populations at heliocentric distances of approximately 2, 3, 4, and 5 a.u., respectively (see below *Composition;* see also Figure 42).

ORBITS OF ASTEROIDS

Asteroid designations

Because of their large numbers (about 3,500 identified as of 1987), asteroids are assigned numbers as well as names. The numbers are assigned consecutively after accurate orbital elements have been determined. (For example, Ceres is officially known as 1 Ceres, Pallas as 2 Pallas, and so forth.) The discoverers have the right to choose a name for their discoveries as soon as they are numbered. Nowadays the names selected are submitted to the International Astronomical Union for approval.

Prior to the mid-20th century, asteroids were sometimes assigned numbers before accurate orbital elements had been determined, and so some numbered asteroids cannot be located now. These objects are referred to as "lost" asteroids. As of 1987, asteroids 719 Albert, 724 Hapag, and 878 Mildred were still lost.

The Minor Planet Center at the Harvard-Smithsonian Center for Astrophysics in Cambridge, Mass., maintains computer files for all measurements of asteroid positions. The Institute for Theoretical Astronomy in Leningrad publishes each year the *Ephemerides of Minor Planets,* which contains the orbital elements of all numbered asteroids, together with their opposition dates and ephemerides.

Deviations from circular orbits

Although most asteroids travel in fairly circular orbits, there are some notable exceptions. One of the most extreme of these is 3200 Phaethon, discovered by the Infrared Astronomical Satellite (IRAS) in 1983. (It was the first asteroid to be discovered by a spacecraft.) Phaethon approaches to within 0.14 a.u. of the Sun, well within Mercury's perihelion distance of 0.31 a.u. Phaethon's aphelion (2.4 a.u.) is in the main asteroid belt. This object is the parent body of the Geminid meteor stream and, since the parent bodies of all other meteor streams identified to date are comets, it is considered by some to be a defunct comet. Another asteroid, 944 Hidalgo, is also thought by some to be a defunct comet because of its unusual orbit. This object, discovered in 1920 by Walter Baade at the Bergedorf Observatory near Hamburg, has a perihelion distance of 2.02 a.u. at the inner edge of the main asteroid belt and an aphelion distance of 9.68 a.u. just beyond the orbit of Saturn at 9.54 a.u. Finally, there is the case of 2060 Chiron, discovered in 1977 by Charles Kowal at the Palomar Observatory near San Diego, Calif. This object is classified as an asteroid but is considered by some to be an inactive cometary nucleus. It travels in an orbit that lies wholly outside of the asteroid belt, having a perihelion distance of 8.43 a.u. (between the orbits of Jupiter and Saturn) and an aphelion distance of 18.8 a.u., which nearly reaches the orbit of Uranus at 19.2 a.u. Chiron is the most distant body in the solar system besides some comets that moves in what is known as a chaotic orbit. Astronomers believe that it will eventually collide with a planet or be permanently ejected from the solar system (see also below *Groups of comets and other unusual cometary objects*).

Cause of the Kirkwood gaps

Distribution and Kirkwood gaps. About 95 percent of the known asteroids move in orbits between those of Mars and Jupiter. These orbits, however, are not uniformly distributed but, as shown in Figure 42, exhibit "gaps" in the distribution of their semimajor axes. These so-called Kirkwood gaps are due to resonances with Jupiter's orbital period. An asteroid with a semimajor axis of 3.3 a.u., for example, makes two circuits around the Sun in the time it takes Jupiter to make one and is thus said to be in a one-to-two (written 1/2) resonance orbit with Jupiter. Consequently, once every two orbits Jupiter and an asteroid in such an orbit would be in the same relative positions, and such an asteroid would experience a force in a fixed direction. Repeated applications of this force would eventually change the semimajor axes of asteroids in such orbits, thus creating a gap at that distance. Gaps occur at 1/4, 2/7, 1/3, 2/5, 3/7, and 1/2 resonances, while concentrations occur at the 2/3 (Hilda group), 3/4 (Thule), and 1/1 (Trojan group) resonances. An adequate explanation of why some resonances produce gaps and others produce concentrations has yet to be found.

Families. Within the main asteroid belt are groups of asteroids that cluster in certain orbital elements (semimajor axis, eccentricity, and inclination). Such groups are called

Figure 42: (Top) Number distribution (*N*) in semimajor axis (*a*) for asteroids with diameters greater than about 50 kilometres. The fractions below the centre indicate the locations of the major orbital period resonances with Jupiter. The deep Kirkwood gaps occur within the main belt near the 1/3, 2/5, and 3/7 resonances, whereas the concentrations are found at the 2/3, 3/4, and 1/1 resonances. The main belt is confined to the region between the 1/4 and 1/2 resonances. The Kirkwood gap at the 2/7 resonance is too narrow to be displayed at the scale plotted. (Bottom) Fractional number distribution (*f*) of the major asteroid classes from Table 25. The sum of the various classes found at any given semimajor axis must equal 1. The F and R classes do not appear because they do not constitute more than 2 percent of the total number of asteroids found at any given semimajor axis.

families and assigned the name of the lowest numbered asteroid in the family. Asteroid families are thought to be formed when an asteroid is disrupted in a catastrophic collision. Theoretical studies indicate that such catastrophic collisions between asteroids are common enough to account for the number of families observed. About 40 percent of all known asteroids belong to such families.

The three largest families (Eos, Koronis, and Themis) have been determined to be compositionally homogeneous. If the asteroids belonging to them are considered to be fragments of a single parent body, then their parent bodies must have had diameters of 200, 90, and 300 kilometres, respectively. The smaller families have not been as well studied because their numbered members are fewer and smaller (and hence fainter). Nevertheless, it is known that some of the smaller families are compositionally inhomogeneous and that, at least in some cases, what are observed are pieces of a geochemically differentiated parent body. It is theorized that some of the Earth-crossing asteroids and meteorites reaching the terrestrial surface are fragments produced in collisions similar to those that produced the asteroid families.

Outer-belt asteroids. The vast majority of asteroids have orbital periods between three years and six years—*i.e.,* between one-fourth and one-half of Jupiter's orbital period (see Figure 42). These asteroids are said to be main-belt asteroids. Besides the few asteroids with unique orbits, some of which were noted above, there are a number of groups that fall outside the main belt. Those that have orbital periods greater than one-half that of Jupiter are called outer-belt asteroids. There are four such groups: the Cybeles, Hildas, and Thule, named after the lowest numbered asteroid in each group, as well as the Trojan group, so called because all of its members are named after characters from Homer's epic work on the Trojan War, the *Iliad.* There are about 65 known Cybeles asteroids, 40 known Hildas, one known Thule, and 45 known Trojans.

Asteroid groups that fall outside the main belt

Trojan asteroids. In 1772 the French mathematician and astronomer Joseph-Louis Lagrange predicted the existence and location of two groups of asteroids located near the (L_4 and L_5) equilateral triangular stability points of a three-body system formed by the Sun, Jupiter, and asteroid. These are two of the five stable points in the circular, restricted three-body problem. (The other three stable points are located along a line passing through the Sun and Jupiter. Because of the presence of other planets, principally Saturn, the Sun–Jupiter–Trojan asteroid system is not a true three-body system, and so these other three points are not stable and no asteroids have been found near them. In fact, most of Jupiter's Trojan asteroids do not move in the plane of its orbit but rather in orbits inclined by up to 25° and at longitudes that differ by as much as 40° from the longitudes of the true Lagrangian points.)

In 1906 Max Wolf discovered 588 Achilles near the Lagrangian point following Jupiter in its orbit. Within a year August Kopff had discovered two more: 617 Patroclus, located near the following Lagrangian point, and 624 Hector near the preceding Lagrangian point. It was decided to name these asteroids after the participants in the Trojan War as given in the *Iliad* and, furthermore, to name those near the preceding point after Greek warriors and those near the following point after Trojan warriors. With the exception of two "spies" (Hector, the lone Trojan in the Greek camp, and Patroclus, the lone Greek in the Trojan camp), this tradition has been maintained.

The term Trojan has since been applied to any object occupying the equilateral Lagrangian points of other pairs of bodies. Searches have been made for Trojans of the Earth, Saturn, and Neptune, as well as of the Earth–Moon system, but so far none have been found. It is doubtful whether truly stable orbits could exist near these Lagrangian points because of perturbations by the major planets.

Although only about 45 Trojans have been numbered, photographic surveys have shown that there are about 900 such asteroids with diameters greater than 15 kilometres. Curiously, about 700 of these are located near the preceding Lagrangian point and only 200 near the following Lagrangian point. The reason for this disparity is unknown.

Inner-belt asteroids. There is only one known group of inner-belt asteroids—namely, the Hungarias. The Hungaria asteroids have a mean semimajor axis of 1.91 a.u.; thus, their orbital periods are less than one-fourth that of Jupiter (see Figure 42). Hungarias have nearly circular orbits (the mean eccentricity is 0.08) but large inclinations, the mean inclination being 22.9°. Two dynamic families (the Hungaria family and the Strackea family) exist within the Hungaria group. Because of the low eccentricities of their orbits, the mean perihelion distance of a Hungaria asteroid is 1.76 a.u. Accordingly, a typical Hungaria cannot pass close to Mars, whose aphelion distance is 1.67 a.u. A few Hungarias, however, have perihelion distances a few hundredths of 1 a.u. less than Mars's aphelion distance and so are shallow "Mars crossers" (see below) as well.

The Hungaria group

Near-Earth asteroids. Asteroids that can pass inside the orbit of Mars are said to be near-Earth asteroids. The near-Earth asteroids are subdivided into several classes. The most distant—those that can cross the orbit of Mars but that have perihelion distances (q) greater than 1.3 a.u.—are dubbed Mars crossers. This group is further subdivided into two groups: shallow Mars crossers ($1.58 \leq q < 1.67$ a.u.) and deep Mars crossers ($1.3 < q < 1.58$ a.u.).

Classes of near-Earth asteroids

The next most distant group of near-Earth asteroids are the Amors ($1.017 < q \leq 1.3$ a.u.). Amor asteroids have perihelion distances greater than the Earth's present aphelion distance (Q) of 1.017 a.u. and therefore do not at present cross the planet's orbit. Because of strong gravitational perturbations produced by their close approaches to the Earth, however, the orbital elements of all the Earth-approaching asteroids, except the shallow Mars crossers, change appreciably on a time scale of a few years or tens of years. For this reason about half the known Amors, including 1221 Amor, are part-time Earth crossers. Only asteroids that cross the orbits of planets, such as the Earth-approaching asteroids and objects like 944 Hidalgo and 2060 Chiron, suffer significant changes in their orbital elements on time scales shorter than many millions of years. Hence, the outer-belt asteroid groups (Cybeles, Hildas, Thule, and the Trojans) do not interchange members.

There are two groups of near-Earth asteroids that deeply cross the Earth's orbit on an almost continuous basis. The first of these to be discovered were the Apollo asteroids, 1862 Apollo being detected by the German astronomer Karl Wilhelm Reinmuth in 1932 but lost shortly thereafter and not rediscovered until 1978. Apollo asteroids have semimajor axes (a) that are greater than or equal to 1.0 a.u. and perihelion distances that are less than or equal to 1.017 a.u.; thus, they cross the Earth's orbit when near the perihelia of their orbits. For the other group of Earth-crossing asteroids, named Atens after 2062 Aten discovered in 1976 by Eleanor F. Helin of the United States, $a < 1.0$ a.u. and $Q \geq 0.983$ a.u., the present perihelion distance of the Earth. These asteroids cross the Earth's orbit when near the aphelia of their orbits.

As of 1986, the number of known Aten, Apollo, and Amor asteroids were six, 40, and 42, respectively. Of these 88 objects, 26 were discovered before 1961 (eight of which have since been lost), whereas 51 were discovered between 1975 and early 1986 (none of which have been lost). It is estimated that there are roughly 100 Atens, 700 Apollos, and 1,000 Amors that have diameters larger than about one kilometre.

THE NATURE OF ASTEROIDS

Rotation and shape. Asteroid rotation periods and shapes are determined primarily by monitoring their changing brightness on time scales of hours to days. Short-period fluctuations in brightness caused by the rotation of an irregularly shaped and/or spotted body (a spotted body being a spherical object with albedo differences) give rise to a light curve (a graph of brightness versus time) that repeats at regular intervals corresponding to an asteroid's rotation period. The range of brightness variation is more difficult to interpret but is closely related to an asteroid's shape and/or spottedness.

Rotation periods have been determined for more than 400 asteroids. They range from 2.3 hours to 48 days, but the majority (more than 80 percent) lie between four hours and 20 hours. Periods longer than a few days may actually be due to precession caused by an unseen satellite. The mean rotation period is roughly 10 hours for the entire sample. The largest asteroids (those with diameters greater than about 175 kilometres), however, have a mean rotation period close to seven hours, whereas this value is about 10 hours for smaller asteroids. The largest asteroids may have preserved their primordial rotation rates, but the smaller ones have almost certainly had theirs modified by subsequent collisions. The difference in rotation rates between the larger and the smaller asteroids is believed to stem from the fact that large asteroids retain all of their collisional debris from minor collisions, whereas smaller asteroids retain more of the debris ejected in the direction opposite to that of their spins, causing a loss of angular momentum and thus a reduction in speed of rotation.

Major collisions can completely disrupt smaller asteroids. The debris from such collisions comprise still smaller asteroids, which can have virtually any shape or spin rate. Thus, the fact that no rotation periods shorter than about 2.5 hours have been observed implies that the material of which asteroids are made is not strong enough to withstand the centripetal forces that such rapid spins would produce.

For mathematical reasons it is impossible to distinguish between the rotation of a spotted sphere and an irregular shape of uniform reflectivity on the basis of observed brightness changes alone. Nevertheless, the fact that opposite hemispheres of most asteroids appear to have albedos differing by no more than a few percent suggests that their brightness variations are due mainly to changes in their projected, illuminated, visible, cross-sectional areas. Hence, in the absence of evidence to the contrary, it is generally accepted that variations in reflectivity contribute little to the observed rotational light-curve amplitude. Asteroid 4 Vesta is a notable exception to this generalization because it is known that the difference in reflectivity between its opposite hemispheres is alone sufficient to account for its entire light-curve amplitude.

Asteroid light-curve amplitudes range from zero to a factor of 6.5 in the case of the Apollo asteroid 1620 Geographos. A light-curve amplitude of zero is caused by viewing an asteroid along one of its rotational poles, while the 6.5 to one variation in brightness is believed to result from either of two possibilities: Geographos is a cigar-shaped object that is viewed along a line perpendicular to its rotational axis, or it is a pair of objects nearly in contact that orbit each other around their centre of mass. The mean rotational amplitude for asteroids is about a factor of 1.3. These data, together with the assumptions mentioned above, allow astronomers to estimate asteroid shapes.

Asteroids exhibit a wide range of shapes (see Figure 43). Some of them, such as 1 Ceres, 2 Pallas, and 4 Vesta, are nearly spherical, whereas others, like 15 Eunomia, 107 Camilla, and 511 Davida, are quite elongated. Still others, as, for example, 624 Hektor and 1580 Betulia (not shown in Figure 43, but whose proposed shape is that of a kidney bean), may have bizarre shapes.

Application of thermal radiometry

Size and albedo. The most widely used technique for determining the sizes of asteroids is that of thermal radiometry. This technique makes use of the fact that the infrared radiation (heat) emitted by an asteroid must balance the solar radiation it absorbs. By using a so-called thermal model to balance the intensity of infrared radiation with the intensity at visual wavelengths, investigators are able to arrive at the diameter of the asteroid. Several other techniques—polarimetry, speckle interferometry, and radar—also are used, but they are limited to brighter, larger, and/or closer asteroids.

The only technique that measures the diameter directly (*i.e.,* without having to "model" the actual observations) is that of stellar occultation. In this method, investigators measure the length of time that a star disappears due to the passage of an asteroid between the Earth and the star. Then, using the known distance and the rate of motion of the asteroid, they are able to determine the latter's diameter uniquely. The results of this method have made it possible to reliably calibrate the indirect techniques, thermal radiometry in particular. As a consequence, asteroid diameters obtained by means of such techniques are now thought to have uncertainties of less than 10 percent. Because passages of asteroids in front of stars are rare and best applied to fairly spherical asteroids and because only one cross section is measured, the majority of asteroid sizes have been obtained using indirect techniques.

By the mid-1980s about 20 asteroids, including 1 Ceres, 2 Pallas, and 3 Juno, had had their diameters determined by means of the stellar-occultation method, whereas about 600 had had theirs measured with the indirect techniques, principally thermal radiometry.

Asteroid 1 Ceres, with a diameter of 940 kilometres, is the largest, followed by 2 Pallas at 535 km and 4 Vesta at 500 km. The fourth largest asteroid, 10 Hygiea, has a diameter of 430 km. There are two asteroids with diameters between 300 and 400 km and about 24 with diameters between 200 and 300 km. In sum, there are about 30 asteroids with diameters greater than 200 km. The smallest known asteroids are members of the Earth-crossing groups, since these asteroids can approach the Earth to within a few hundredths of 1 a.u. The smallest observed Earth-approaching asteroids measure less than 0.5 km across. It has been estimated that there are 250 asteroids larger than 100 km in diameter and perhaps 1,000,000 with diameters greater than 1 km.

Albedo

A parameter closely related to size is albedo, or reflectivity. This property also provides compositional information. Albedo is the ratio between the amount of light actually reflected and that which would be reflected by a uniformly scattering disk of the same size. Snow has an albedo of approximately 1.0 and coal an albedo of about 0.05.

An asteroid's albedo and diameter are closely related. For example, if 1 Ceres and 4 Vesta could both be observed at the same distance, Vesta would be the brighter of the two by about 10 percent. Vesta's diameter, however, is less than 55 percent that of Ceres. It appears brighter because its albedo is around 0.35, compared with 0.09 for Ceres.

The asteroids fall into three albedo groups: low (0.02–0.065), moderate (0.066–0.23), and high (greater than 0.23). About 80 percent of the known asteroids are low-albedo objects, and most of them are located in the outer half of the main asteroid belt and among the outer-belt populations. Roughly 19 percent of all known asteroids belong to the moderate-albedo group, the vast majority of which are found in the inner half of the main belt. The high-albedo asteroids make up the remaining 1 percent of the asteroid population. For the most part, they occupy

From K. Beatty, B. O'Leary, and A. Chaikin (eds.), *The New Solar System*, 2nd ed.

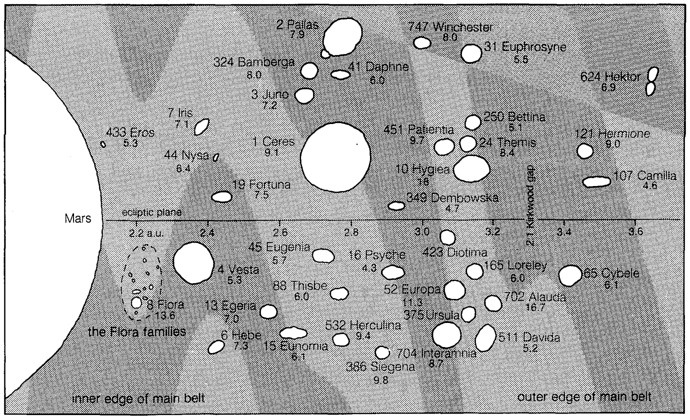

Figure 43: This representation of notable asteroids includes all those exceeding 200 kilometres in diameter. The asteroids are depicted in their correct relative sizes and shapes (the limb of Mars is included for comparison), and their rotational pole orientations (if known) are indicated. They are positioned at their correct relative distances from the Sun. Asteroids located near the top or bottom of the diagram travel in relatively eccentric and/or inclined orbits, whereas those near the ecliptic move in fairly circular, noninclined orbits. Rotational periods (in hours) are indicated beneath the names of the asteroids. Among the special smaller asteroids shown are the members of the Flora families larger than 15 kilometres across.

the same regions of the main asteroid belt as the moderate-albedo objects and make up the majority of the Hungaria group as well.

Mass and density. Because asteroid masses are low, they have a negligible effect on the orbits of the major planets. The masses of the three largest asteroids, however, have been measured by noting their effect on the orbits of other asteroids that they happen to approach closely at regular intervals. Since the diameters of these three largest asteroids also have been determined and since their shapes are either spherical or ellipsoidal, their volumes are known as well. Knowledge of the mass and volume of an asteroid allows its density to be computed.

The mass of the largest asteroid, Ceres, is 1.2×10^{24} grams (0.0002 the mass of the Earth). The masses of the second and third largest asteroids, Pallas and Vesta, are only 0.18 and 0.23 times the mass of Ceres. The mass of the entire asteroid belt is roughly three times that of Ceres. Most of the mass in the asteroid belt is concentrated in the larger asteroids. The 10th largest asteroid has only $^1/_{60}$ the mass of the largest, and about 90 percent of the total mass is contained in asteroids with diameters exceeding 100 kilometres. Ninety-one percent of the total mass of the asteroids is located in the main belt, 8 percent is in the outer belt, and the remainder is distributed among the inner belt and planet-crossing asteroid populations.

The densities of the largest asteroids as compared with those of the inner planets

The densities of Ceres, Pallas, and Vesta are 2.7, 2.7 and 4.2 grams per cubic centimetre, respectively. These compare with 5.4, 5.2, and 5.5 g/cm^3 for Mercury, Venus, and the Earth, respectively; 3.95 g/cm^3 for Mars; and 3.34 g/cm^3 for the Moon. The densities of Ceres and Pallas are similar to those of a class of meteorites known as carbonaceous chondrites, which contain a larger fraction of volatile material than do ordinary terrestrial rocks and hence have a somewhat lower density (see below *Specific asteroidal source regions for recovered meteorites*). The density of Vesta is similar to those of the rocky planets. Insofar as Ceres, Pallas, and Vesta are typical of asteroids in general and the first two are members of the most common asteroid compositional class, it can be concluded that asteroids are rocky bodies.

Composition. The combination of spectral reflectance measurements (measures of the amount of reflected sunlight at various wavelengths between about 0.3 and 1.1 micrometres) and albedos is used to classify asteroids into various taxonomic groups. If sufficient spectral resolution is available (*i.e.,* if about 25 approximately equally spaced wavelengths were sampled), these measurements also can be used to infer the composition of the surface reflecting the light. This can be done by comparing the asteroid data with that obtained in the laboratory using meteorites or terrestrial rocks or minerals.

Basic taxonomic classes

By the mid-1980s, high-resolution (24-wavelength) spectral reflectances had been obtained for about 300 asteroids, and low- (three-wavelength) or moderate- (eight-wavelength) resolution data had been secured for roughly 1,000, with albedos available for about 500 of these. Table 25 summarizes the nine taxonomic classes into which the asteroids can be divided on the basis of such data.

Asteroids of the C and F classes have low albedos and spectral reflectances similar to those of carbonaceous chondritic meteorites and carbon-rich terrestrial materials (*e.g.,* lampblack, or amorphous carbon), magnetite, and montmorillonite. Some C-class asteroids are known to have hydrated minerals on their surfaces, whereas Ceres probably has water present as a layer of permafrost. S-class asteroids have moderate albedos and spectral reflectances similar to the stony-iron meteorites, and they are known to contain significant amounts of silicates, including the minerals olivine, pyroxene, and feldspar on their surfaces. M-class asteroids are moderate-albedo objects, may have significant amounts of nickel-iron metal in their surface material, and exhibit spectral reflectances similar to the nickel-iron meteorites. P- and D-class asteroids have low albedos and no known meteorite or naturally occurring mineralogical counterparts, but they may contain a large fraction of carbon polymers in their surface material. R-class asteroids are very rare; only one (the high-albedo asteroid 349 Dembowska) has been identified for certain. The surface material of Dembowska has been identified as being most consistent with an olivine-rich composition that has no known meteoritic analogue. The E-class asteroids have the highest albedos and spectral reflectances that match those of the enstatite chondrite meteorites. Vesta, though having a high albedo and unique spectral reflectance, is sometimes referred to as a U-class asteroid. Its reflectance properties closely match those of one particular type of basaltic achondritic meteorite, the eucrite. The match is so good that some believe that Vesta is the parent body of the eucrite meteorites; that is to say, the eucrites exhibited in museums are chips from the surface of Vesta that were knocked off during a major cratering event. (For additional information about achondrite meteorites, see below *Types of meteorites.*)

The C-class asteroids are the most common, both numerically and by mass; 66 percent of the larger asteroids (those with diameters greater than 100 kilometres) and nearly 75 percent of the mass of such objects belong to this class. The next most common taxonomic class is S class, in which 15 percent of the asteroids and 7.5 percent of the mass are found. About 8 percent by number and 2.5 percent by mass are in the D class, and approximately 4 percent by number and 2 and 3 percent, respectively, by mass are in the P and M classes. The F class contains 2 percent by number and 1.8 percent by mass, and the remaining classes (E, R, and U) account for less than 1 percent of the population by number or mass. The unique asteroid Vesta contains about 8 percent of the mass of the entire asteroid belt.

The distribution of the taxonomic classes throughout the asteroid belt is highly structured, as can be seen from Figure 42. Some believe this variation with distance from the Sun means that the asteroids formed at or near their present locations and that a detailed comparison of the chemical composition of the asteroids in each region will provide constraints on models for the conditions that may have existed within the contracting solar nebula at the time the asteroids were formed.

Table 25: Summary of Asteroid Taxonomic Classes

class	albedo*	spectral reflectivity (0.3–1.1 micrometres)
C	low	neutral, slight absorption at wavelengths of 0.4 micrometre or shorter
D	low	very red at wavelengths of 0.7 micrometre or longer
F	low	flat
P	low	featureless, sloping up into red†
S	moderate	reddened, typically with an absorption band between 0.9 and 1.0 micrometre
M	moderate	featureless, sloping up into red†
E	high	featureless, sloping up into red†
R	high	very red with a deep absorption band between 0.9 and 1.0 micrometre
U	varies	unclassifiable in this system‡

*Low = visual geometric albedo between 0.02 and 0.065; moderate = visual geometric albedo between 0.066 and 0.23; and high = visual geometric albedo greater than 0.23.

†Classes E, M, and P are spectrally indistinguishable at these wavelengths and require an independent albedo measurement for unambiguous classification. ‡Includes Pallas and other unique or rare objects.

THE ORIGIN AND EVOLUTION OF THE ASTEROIDS

Available evidence indicates that the asteroids are the remnants of a "stillborn" planet. It is thought that at the time the planets were forming from the low-velocity collisions among asteroid-sized planetesimals, one of them grew at a high rate and to a size larger than the others. In the final stages of its formation this planet, Jupiter, gravitationally scattered large planetesimals, some of which may have been as massive as the Earth is today. These planetesimals were eventually either captured by Jupiter or another of the trans-Jovian planets or ejected from the solar system. While they were passing through the inner solar system, however, such large planetesimals strongly perturbed the orbits of the planetesimals in the region of the asteroid belt, raising their mutual velocities to the average five kilometres per second they exhibit today. These high-velocity collisions ended the accretionary collisions by transforming them into catastrophic disruptions. Only objects larger than about 500 kilometres in diameter could have survived collisions with objects of comparable size at collisional velocities of five kilometres per second. Since that time, the asteroids have been collisionally evolving so that, with the exception of the very largest, most present-day asteroids are either remnants or fragments of past collisions.

Evidence of differentiation

While breaking larger asteroids down into smaller ones, collisions expose deeper layers of asteroidal material. If asteroids were compositionally homogeneous, this would have no noticeable result. Some of them, however, have become differentiated since their formation. This means that some asteroids, originally formed from so-called primitive material (*i.e.,* material of nonvolatile solar composition), were heated, perhaps by short-lived radionuclides or solar magnetic induction, to the point where their interiors melted and geochemical processes occurred. In certain cases, temperatures became high enough for iron to form. Being denser than other materials, the iron then sank to the centre, forming an iron core and forcing basaltic lavas onto the surface. At least one asteroid with a basaltic surface, Vesta, survives to this day. Other differentiated asteroids were disrupted by collisions that stripped away their crusts and mantles and exposed their iron cores. Still others may have had only their crusts partially stripped away, which exposed surfaces such as those visible today on the E- and R-class asteroids.

Collisions were responsible for the formation of the Hirayama families and at least some of the planet-crossing asteroids. A number of the latter enter the Earth's atmosphere, giving rise to sporadic meteors. Larger pieces survive passage through the atmosphere, and some of these end up in museums and laboratories as meteorites (see below *Relationship of meteoroids to asteroids and comets* and *Meteorites, asteroids, and the early solar system*). The very largest produce craters such as Meteor Crater in Arizona in the southwestern United States, and one may even have been responsible for the extinction of the dinosaurs some 65,000,000 years ago. This extinction may have been triggered by an explosion resulting from the impact of an asteroid measuring about 10 kilometres in diameter. (Some investigators believe that a cometary body rather than an asteroid may have caused such an explosion.) Fortunately, collisions of this sort are rare. According to current estimates, three asteroids of one-kilometre diameter collide with the Earth every 1,000,000 years.

(E.F.T.)

Comets

GENERAL CONSIDERATIONS

Differences between cometary nuclei and asteroids

Basic features. The traditional definition of a comet is a nebulous body with a "hairy" tail that makes a transient appearance in the sky. The word comet comes from the Greek *komētēs* meaning "hairy one," a description that fits the bright comets noticed by the ancients. Many comets, however, do not develop tails. Moreover, comets are not surrounded by any nebulosity during most of their lifetime. The only permanent feature of a comet is its nucleus, which is a small body that may be seen as a stellar image in large telescopes when tail and nebulosity do not exist, particularly when the comet is still far away from the Sun. Two characteristics differentiate the cometary nucleus from a very small asteroid—namely, its orbit and its chemical nature. A comet's orbit is more eccentric; therefore, its distance to the Sun varies considerably. Its material is more volatile. When far from the Sun, however, a comet remains in its pristine state for eons without losing any volatile components due to the deep cold of space. For this reason, astronomers believe that pristine cometary nuclei may represent the oldest and best-preserved material in the solar system.

During a close passage near the Sun, the nucleus of a comet looses water vapour and other more volatile compounds, as well as dust dragged away by the sublimating gases. It is then surrounded by a transient dusty "atmosphere" that is steadily lost to space. This feature is the coma, which gives a comet its nebulous appearance. The nucleus surrounded by the coma makes up the head of the comet. When even closer to the Sun, solar radiation usually blows the dust of the coma away from the head and produces a dust tail, which is often rather wide, featureless, and yellowish. The solar wind, on the other hand, drags ionized gas away in a slightly different direction and produces a plasma tail, which is usually narrow with nods and twists and has a bluish appearance.

Designations. In order to classify the chronological appearance of comets, the *Astronomische Nachrichten* ("Astronomical Reports") introduced in 1870 a system of preliminary and final designations that is still used today with only minor modifications. The preliminary designation classifies comets according to their order of discovery, using the year of discovery followed by a lowercase letter in alphabetical order, as in 1987a, 1987b, 1987c, and so forth. Comets are reclassified as soon as possible—usually a few years later—according to their chronological order of passage at perihelion (closest distance to the Sun); a Roman numeral is used in this case, as in 1987 I, 1987 II, 1987 III, and so on. Since the discovery may have taken place at any time either before or after perihelion passage, the two chronologies are not necessarily in the same order, and even the year may change in the final designation. The official designation generally includes the name(s) of its discoverer(s)—with a maximum of three names—preceded by a P/ if the comet is on a periodic orbit. If a person discovers several comets, an Arabic numeral is used after his name, as in 1867 II Tempel 1 and 1873 II Tempel 2. The discoverer's rule has not always been strictly applied: comets P/Halley, P/Lexell, P/Encke, and P/Crommelin have been named after the astronomers who proved their periodic character. Some comets become bright so fast that they are discovered by a large number of persons at almost the same time. They are given an arbitrary impersonal designation such as Brilliant Comet (1882 II), Southern Comet (1947 XII), or Eclipse Comet (1948 XI). Finally, comets may be discovered by an unusual instrument without direct intervention of a specific observer, as in the case of the Earth-orbiting Infrared Astronomical Satellite (IRAS). Its initials are used as if it were a human observer, as in 1983 VII IRAS-Araki-Alcock.

HISTORICAL SURVEY OF COMET OBSERVATIONS AND STUDIES

Early observations. In ancient times, without interference from streetlights or urban pollution, comets could be seen by everyone. Their sudden appearance—their erratic behaviour against the harmonious order of the heavenly motions—was interpreted as an omen of nature that awed people and was used by astrologers to predict flood, famine, pestilence, or the death of kings. The Greek philosopher Aristotle (4th century BC) thought that the heavens were perfect and incorruptible. The very transient nature of comets seemed to imply that they were not part of the heavens but were merely earthly exhalations ignited and transported by heat to the upper atmosphere. Although the Roman philosopher Seneca (1st century AD) had proposed that comets could be heavenly bodies like the planets, Aristotle's ideas prevailed until the 14th century AD. Finally, during the 16th century the Danish nobleman Tycho Brahe established critical proof that comets are heavenly bodies. He compared the lack of diurnal par-

The studies of Tycho Brahe

allax of the comet of 1577 with the well-known parallax of the Moon (the diurnal parallax is the apparent change of position in the sky relative to the distant stars due to the rotation of the Earth). Tycho deduced that the comet was at least four times farther away than the Moon, establishing for the first time that comets were heavenly bodies.

The impact of Newton's work. The German astronomer Johannes Kepler still believed in 1619 that comets travel across the sky in a straight line. It was the English physicist and mathematician Isaac Newton who demonstrated in his *Principia* (1687) that, if heavenly bodies are attracted by a central body (the Sun) in proportion to the inverse-square of its distance, they must move along a conic section (circle, ellipse, parabola, or hyperbola). Using the observed positions of the Great Comet of 1680, he identified its orbit as being nearly parabolic.

Newton's friend, the astronomer Edmond Halley, endeavoured to compute the orbits of 24 comets for which he had found accurate enough historical documents. Applying Newton's method, he presupposed a parabola as an approximation for each orbit. Among the 24 parabolas, three were identical in size and superimposed in space. The three relevant cometary passages (1531, 1607, and 1682) were separated by two time intervals of 76 and 75 years. Halley concluded that the parabolas were actually the end of an extremely elongated ellipse. Instead of three curves open to infinity, the orbit is closed and brings the same comet periodically back to the Earth. As a consequence, it would return in 1758, he predicted. Observed on Christmas night, 1758, by Johann Georg Palitzsch, a German amateur astronomer, the comet passed at perihelion in March 1759 and at perigee (closest to the Earth) in April 1759. The perihelion date of 1759 had been predicted by Alexis-Claude Clairaut, a French astronomer and physicist, with an accuracy of one month. Clairaut's work contributed much to the acceptance of Newton's theory on the Continent. With this, the until-then anonymous comet came to be called Halley's comet (or, in modern nomenclature, Comet P/Halley).

Passages of Comet P/Halley. Since 1759, Comet Halley has reappeared three more times—in 1835, 1910, and 1986. Its trajectory has been computed backward, and all of its 30 previous passages described in historical documents over 22 centuries have been authenticated. Comet Halley's period has irregularly varied between 74.4 years (from 1835 to 1910) and 79.6 years (from AD 451 to 530). These variations, which have been accurately predicted, result from the changing positions of the giant planets, mainly Jupiter and Saturn, whose variable attractions perturb the trajectory of the comet. The space orientation of the orbit has been practically constant, at least for several centuries. Since its returns are not separated by an integer number of years, however, the comet encounters the Earth each time on a different point of its orbit around the Sun; thus, the geometry of each passage is different and its shortest distance to the planet varies considerably. The closest known passage to the Earth, 0.033 a.u., occurred on April 9, AD 837.

The 1986 passage of Comet Halley

The perigee distance of most of Comet Halley's historical passages has been between 0.20 and 0.50 a.u. The last perigee, on April 11, 1986, took place at 0.42 a.u. from the Earth (Figure 44). By contrast, the comet passed at only 0.14 a.u. from the Earth in 1910. Seen from closer range, it was brighter and had a longer tail than on its return in 1986. This is one reason why the 1986 passage proved so disappointing to most lay observers. Yet, a far more important factor had to do with geometry: in the latitudes of the major Western countries, the comet was hidden by the southern horizon during the few weeks in April 1986 when it was at its brightest. Moreover, the night sky of most Western countries is brightly and constantly illuminated by public and private lights. Even in the absence of moonlight, the nighttime sky is pervaded by a milky glare that easily hides the tail of a comet.

Each century, a score of comets brighter than Comet Halley have been discovered. Yet, they appear without warning and will not be seen again. Many are periodic comets like Comet Halley, but their periods are extremely long (millennia or even scores or hundreds of millennia), and they have not left any identifiable trace in prehistory. Bright Comet Bennett 1970 II will return in 17 centuries, whereas the spectacular Comet West 1976 VI will reappear in about 500,000 years. Among the comets that can easily be seen with the unaided eye, Comet Halley is the only one that returns in a single lifetime. Approximately 100 comets whose periods are between three and 200 years are known, however. Unfortunately they are or have become too faint to be readily seen without the aid of telescopes (see below *Periodic comets*).

Modern cometary research. During the 19th century it was shown that the radiant (*i.e.,* spatial direction) of the spectacular meteor showers of 1866, 1872, and 1885 coincided well with three known cometary orbits that happened by chance to cross the Earth's orbit at the dates of the observed showers. The apparent relationship between comets and meteor showers was interpreted by assuming that the cometary nucleus was an aggregate of dust or

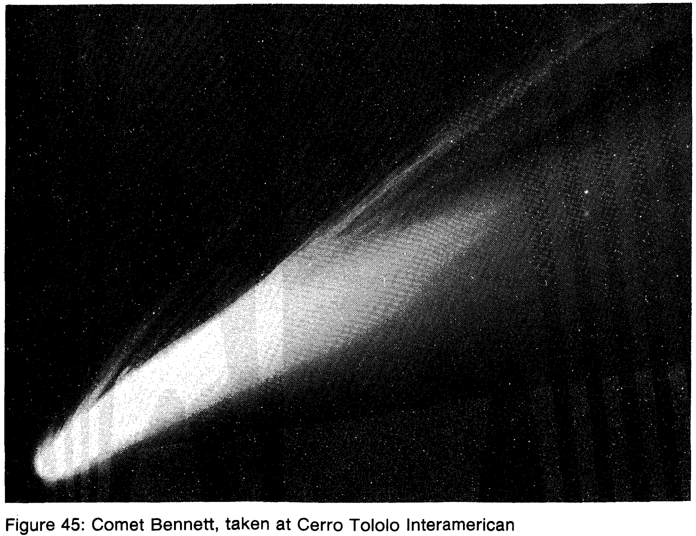

Figure 45: Comet Bennett, taken at Cerro Tololo Interamerican Observatory, Chile, March 16, 1970.

sand grains without any cohesion. (This conception of the cometary nucleus became known as the "sandbank" model [see below *Cometary models*].) Meteor showers were explained by the spontaneous scattering of the dust grains along a comet's orbit, and the cometary nucleus began to be regarded only as the densest part of a meteor stream. At the end of the 19th and the beginning of the 20th century, spectroscopy revealed that the reflection of sunshine by the dust was not the only source of light in the tail; it showed the discontinuous emission that constitutes the signature of gaseous compounds. More specifically, it revealed the existence in the coma of several radicals—molecular fragments such as cyanogen (CN) and the carbon forms C_2 and C_3, which are chemically unstable in the laboratory because they are very reactive in molecular collisions. Spectroscopy also enabled investigators to detect the existence of a plasma component in the cometary tail by the presence of molecular ions, as, for example, those of carbon monoxide (CO^+), nitrogen (N_2^+), and carbon dioxide (CO_2^+). The radicals and ions are built up by the three light elements carbon (C), nitrogen (N), and oxygen (O). Hydrogen (H) was added when the radical CH was discovered belatedly on spectrograms of Comet Halley taken in 1910. The identification of CH was proposed by the American astronomer Nicholas Bobrovnikoff in 1931. In 1941, the Belgian astronomer Pol Swings and his coworkers identified three new ions: CH^+, OH^+, and CO_2^+. The emissions of the light elements hydrogen, carbon, oxygen, and sulfur and of carbon monoxide were finally detected when the far ultraviolet spectrum (which is absorbed by the Earth's atmosphere) was explored during the 1970s with the help of rockets and satellites. This included the very large halo (10^7 kilometres) of atomic hydrogen (the Lyman-alpha emission line) first observed in comets Tago-Sato-Kosaka 1969 IX and Bennett 1970 II.

Spectroscopic discoveries

Although the sandbank model was still seriously considered until the 1960s and 1970s by a small minority (most notably the British astronomer Raymond A. Lyttleton), the presence of large amounts of gaseous fragments of volatile molecules in the coma suggested to Bobrovnikoff the release by the nucleus of a bulk of unobserved "parent" molecules such as H_2O, CO_2, and NH_3 (ammonia). In 1948, Swings proposed that these molecules should be present in the nucleus in the solid state as ices.

In a fundamental paper, the American astronomer Fred L. Whipple set forth in 1950 the so-called dirty snowball model, according to which the nucleus is a lumpy piece of icy conglomerate wherein dust is cemented by a large amount of ices—not only water ice but also ices of more volatile molecules. This amount has to be substantial enough to sustain the vaporizations for a large number of revolutions. Whipple noted that the nuclei of some comets at least are solid enough to graze the Sun without experiencing total destruction, since they apparently survive unharmed. (Some but not all Sun-grazing nuclei split under solar tidal forces.) Finally, argued Whipple, the asymmetric vaporization of the nuclear ices sunward produces a jet action opposite to the Sun on the solid cometary nucleus. When the nucleus is rotating, the jet action is not exactly radial. This explained the heretofore mysterious nongravitational force identified as acting on cometary orbits. In particular, the orbital period of P/Encke mysteriously decreased by one to three hours per revolution (of 3.3 years), whereas that of P/Halley increased by some three days per revolution (of 76 years). For Whipple, a prograde rotation of the nucleus of P/Encke and a retrograde rotation of that of P/Halley could explain these observations. In each case, a similar amount of some 0.5 to 0.25 percent of the ices had to be lost per revolution to explain the amount of the nongravitational force. Thus, all comets decay in a matter of a few hundred revolutions. This duration is only at most a few centuries for Encke and a few millennia for Halley. At any rate, it is millions of times shorter than the age of the solar system.

Dirty snowball model

The observed comets, however, have obviously survived until now. If they have existed for a very long time, they must have been stored in an extremely cold place far away from the Sun before recently coming into the inner solar system where they could be seen from Earth. A reply to such a suggestion had already been anticipated in 1932 by the Estonian-born astronomer Ernest J. Öpik, who proposed the possible existence of a large cloud of unobservable comets surrounding the solar system. Nearly 20 years later, the Dutch astronomer Jan Hendrick Oort established the existence of such a cloud of comets by indirect reasoning based on observations. Since the appearance of his theory in 1950, this enormous cloud of comets has come to be called the Oort cloud.

The Oort cloud

Oort showed by statistical arguments that a steady flux of a few "new" comets are observed per year (new meaning that they had never been through the solar system before; see below *Periodic comets*). This flux comes from the fringe of the Oort cloud. He identified it by looking at the distribution of the original values of the total energies of cometary orbits. These energies are in proportion to a^{-1}, with a being the semimajor axis of the cometary orbit. The original value of a refers to the orbit when the comet was still outside of the solar system, as opposed to the osculating orbit, which refers to the arc observed from the Earth after it has already been modified by the perturbations of the giant planets. Passages through the solar system produce a rather wide diffusion in orbital energies (in a^{-1}). In 1950 Oort accounted for only 19 accurate original orbits of long-period comets. The very fact that 10 of the 19 orbits were concentrated in a very narrow range of a^{-1} established that most of them had never been through this diffusion process due to the planets. The mean value of a for these new comets suggested the distance they were coming from: about 10^5 a.u. This distance is also the place where perturbations resulting from the passage of nearby stars begin to be felt. The distance coincidence suggested to Oort that stellar perturbations were indeed the mechanism by which comets were sent into the planetary system.

Subsequent work by the American astronomer Brian G. Marsden and his coworkers confirmed the existence of the Oort cloud. Their list of approximately 90 original orbits crammed within an extremely narrow range of a^{-1} corroborated Oort's initial effort. The mean aphelion distance of this list of new comets implies, however, that the Oort cloud margin is only at some 40,000 to 50,000 a.u., which makes the standard mechanism of stellar perturbations much less effective than Oort had believed. Comets must therefore come down from the Oort cloud in several steps, penetrating first into the outer solar system where the perturbations of Uranus and Neptune are weak enough not to remove them from the action of passing stars except after several revolutions.

During the late 1980s astronomers explored new ideas with which to determine how the outer perturbations on the Oort cloud could increase. Dark molecular clouds, for example, may be substituted for stars as major perturbing agents. The hypothesis that there exists some extra undetected matter (like black dwarfs) in the disk of the Galaxy has also been used. Then, the total mass distribution in the galactic disk may be large enough to induce tidal forces in the Oort cloud that would change cometary orbits.

MOTION AND DISCOVERY OF COMETS

Types of orbits. In the absence of planetary perturbations and nongravitational forces, a comet will orbit the Sun on a trajectory that is a conic section with the Sun at one focus. The total energy E of the comet, which is a constant of motion, will determine whether the orbit is an ellipse, a parabola, or a hyperbola. The total energy E is the sum of the kinetic energy of the comet and of its gravitational potential energy in the gravitational field of the Sun. Per unit mass, it is given by $E = \frac{1}{2}v^2 - GMr^{-1}$, where v is the comet's velocity and r its distance to the Sun, with M denoting the mass of the Sun and G the gravitational constant. If E is negative, the comet is bound to the Sun and moves in an ellipse. If E is positive, the comet is unbound and moves in a hyperbola. If E = 0, the comet is unbound and moves in a parabola.

Total energy of a comet

In polar coordinates written in the plane of the orbit, the general equation for a conic section is

$$r = q(1 + e)\,(1 + e\cos\theta)^{-1},$$

where r is the distance from the comet to the Sun, q the perihelion distance, e the eccentricity of the orbit, and θ an angle measured from perihelion. When $0 \leq e < 1$, $E < 0$ and the orbit is an ellipse (the case $e = 0$ is a circle, which constitutes a particular ellipse); when $e = 1$, $E = 0$ and the orbit is a parabola; and when $e > 1$, $E > 0$ and the orbit is a hyperbola.

Orbital elements

In space, a comet's orbit is completely specified by six quantities called its orbital elements. Among these are three angles that define the spatial orientation of the orbit: *i,* the inclination of the orbital plane to the plane of the ecliptic; Ω, the longitude of the ascending node measured eastward from the vernal equinox; and *ω*, the angular distance of perihelion from the ascending node (also called the argument of perihelion). The three most frequently used orbital elements within the plane of the orbit are *q,* the perihelion distance in astronomical units; *e,* the eccentricity; and *T,* the epoch of perihelion passage.

Identifying comets and determining their orbits. Up to the beginning of the 19th century, comets were discovered exclusively by visual means. Many discoveries are still made visually with moderate-sized telescopes by amateur astronomers. Although comets can be present in any region of the sky, they are often discovered near the western horizon after sunset or near the eastern horizon before sunrise, since they are brightest when closest to the Sun. Because of the Earth's rotation and direction of motion in its orbit, discoveries before sunrise are more likely, as confirmed by discovery statistics. At discovery, a comet may still be faint enough not to have developed a tail; therefore, it may look like any nebulous object—*e.g.,* an emission nebula, a globular star cluster, or a galaxy. The famous 18th-century French comet hunter Charles Messier (nicknamed "the ferret of comets" by Louis XV for his discovery of 21 comets) compiled his well-known catalog of "nebulous objects" so that such objects would not be mistaken for comets. The final criterion remains the apparent displacement of the comet after a few hours or a few days with respect to the distant stars; by contrast, the nebulous objects of Messier's catalog do not move. After such a displacement has been undisputably observed, any amateur wishing to have the comet named for himself must report his claim to the nearest observatory as soon as possible.

Photographic discovery of comets

Most comets are and remain extremely faint. Today, a larger and larger proportion of comet discoveries are thus made fortuitously from high-resolution photographs, as, for instance, those taken during sky surveys by professional astronomers engaged in other projects.

The faintest recorded comets are approaching the limit of detection of large telescopes (those that are two metres or more in diameter). That is to say, they are of the 22nd–23rd magnitude, or 10^6 to 10^7 times fainter than the limit of the naked eye. Several successive photographic observations of these faint moving objects are necessary to ensure identification and simultaneous calculation of a preliminary orbit. In order to determine a preliminary orbit as quickly as possible, the eccentricity $e = 1$ is assumed since some 90 percent of the observed eccentricities are close to one, and a parabolic motion is computed. This is generally sufficient to ensure against "losing" the comet in the sky.

The best conic section representing the path of the comet at a given instant is known as the osculating orbit. It is tangent to the true path of the chosen instant, and the velocity at that point is the same as the true instantaneous velocity of the comet. Nowadays, high-speed computers make it possible to produce a final ephemeris (table of positions) that is not only based on the definitive orbit but also includes the gravitational forces of the Sun and of all significant planets that constantly change the osculating orbit. In spite of this fact, the deviation between the observed and the predicted positions usually grows (imperceptibly) with the square of time. This is the signature of a "neglected" acceleration, which comes from a nongravitational force (see above). Formulas representing the smooth variation of the nongravitational force with heliocentric distance are now included for many orbits. The best formula assumes that water ice prevails and controls the vaporization of the nucleus.

Nongravitational forces

COMETARY STATISTICS

The *Catalog of Cometary Orbits,* compiled by Marsden, remains the standard reference for orbital statistics. Its 1986 edition lists 1,187 computed orbits from 239 BC to AD 1985; only 91 of them were computed using the rare accurate historical data from before the 17th century. More than 1,000 are therefore derived from cometary passages during the last three centuries. The 1,187 cometary apparitions of Marsden's catalog involve only 748 individual comets; the remainder represents the repeated returns of periodic comets.

Short- and intermediate-period comets

Periodic comets. The periodic comets are usually divided into short-period comets (those with periods of less than 200 years) and long-period comets (those with periods of more than 200 years). Of the 135 short-period comets, 85 have been observed at two or more perihelion passages. In 1986, four of these comets had been definitely lost, and three more were probably lost, presumably because of their decay in the solar heat. Some authors have found it advantageous to change the definition of short-period comets by diminishing their longest-period cutoff to 20 years. This leaves 116 short-period comets (new style) in the *Catalog;* the 19 others having periods between 20 and 200 years are called intermediate-period comets. These two new classes are separated by a period gap of close to 20 years. The average short-period comet has a seven-year period, a perihelion distance of 1.5 a.u., and a small inclination (13°) on the ecliptic. All short-period comets (new style) revolve in the direct sense around the Sun, just as the planets do. The intermediate-period comets have on average a larger inclination of the ecliptic, and four of them turn around the Sun in the retrograde. The most famous of the latter is P/Halley (30 appearances); the others are P/Tempel-Tuttle (four appearances), P/Pons-Gambart, and P/Swift-Tuttle (the last two with only one appearance each). Ten of the 19 intermediate-period comets have been observed during a single appearance.

Long-period comets

The comets with long-period orbits are distributed at random in all directions of the sky, and roughly half of them turn in the retrograde direction. Of the 613 comets of long period contained in the *Catalog,* 179 have osculating elliptic orbits, and 112 have osculating orbits that are very slightly hyperbolic. Finally, 322 are listed as having parabolic orbits, but this is rather fallacious because either it has not been possible to detect unequivocal deviations from a parabola on the (sometimes very short) arc along which the comets have been observed or, more simply, the final calculations have never been made. The parabola is always assumed first in the preliminary computation as it is easier to deal with. If the osculating orbit is computed backward to when the comet was still far beyond the orbit of Neptune and if the orbit is then referred to the centre of mass of the solar system, the original orbits almost always prove to be elliptic. (The centre of mass of the solar system is different from the centre of the Sun primarily because of the position of massive Jupiter.) Twenty-two original orbits remain (nominally) slightly hyperbolic beyond the orbit of Neptune, but 19 remain not significantly different from a parabola. Even the three that are significantly different near 50 a.u. are likely to become elliptic when they are 50,000 or 100,000 a.u. from the Sun. The reason is that, though the mass of the Oort cloud remains uncertain, it should be added to the mass of the inner solar system to compute the orbits. The smallest possible mass of the Oort cloud is likely to transform the orbits into ellipses. It is thus reasonable to believe that all observed comets were initially on elliptic orbits bound to the solar system. Accordingly, all parabolic and nearly parabolic comets are thought to be comets of very long period.

The future orbit of a long-period comet is obtained when the osculating orbit is computed forward to when the comet will be leaving the planetary system (beyond the orbit of Neptune) and is referred to the centre of mass of the solar system. Because of the planetary perturbations, slightly more than half of the future orbits become strongly elliptic, whereas slightly less than half become strongly hyperbolic. Roughly half of the long-period comets are thus "captured" by the solar system on more strongly bound orbits; the other half are ejected forever out of the system.

"New" comets

Among the very-long-period comets, there is a particular class that Oort showed as having never passed through the planetary system before (see above), notwithstanding the fact that their original orbits were elliptic, which implies repeated passages. This paradox vanishes when it is understood that their perihelia were outside of the planetary system before their first appearance but that their orbits have been perturbed near aphelia (either by stellar or dark interstellar-cloud passages or by galactic tides) in such a way that their perihelia were lowered into the planetary system. The first passage of a "new" comet is usually brighter than an average passage (a large fraction of the famous bright historical comets were such new comets). This is possibly explained by the presence of more volatile gases and of a larger component of very fine dust. The most volatile gases may have disappeared during subsequent passages, and the finest dust may have agglomerated into larger dust grains that reflect less light for the same production rate. About 90 comets have been identified as new in long-period orbits. If the same proportion exists in the poorly computed parabolic orbits, the total must be close to 170 new comets in Marsden's catalog, but 80 of them have not been identified.

Groups of comets and other unusual cometary objects. Some comets travel in strikingly similar orbits, only the time of perihelion passages being appreciably different. Members of such a group of comets are thought to be fragments from a larger comet that was tidally disrupted earlier by the Sun or in some cases by the differential jet action of nongravitational forces on a fragile nucleus. Many such breakups have been observed historically. Slight differences in the resultant velocities—though they occur very gently—are sufficient to cause cometary fragments to separate along orbits close to but distinct from each other, particularly as far as their total energy is concerned. A very slight variation in a^{-1} introduces an orbital period that may vary by several years, and when the cometary fragments return they will go through perihelion at widely separated epochs. The best-known example is the famous group of "Sun-grazing" comets (also called the Kreutz group), which has 12 definite members (plus one probable) with perihelion distances between 0.002 and 0.009 a.u. (less than half a solar radius). Their periods are scattered from 400 to 2,000 years, and their last passages occurred between 1880 and 1970. The most famous fragment of the group is Comet Ikeya-Seki 1965 VIII.

The "Sun-grazing" comet group

Comet P/Schwassmann-Wachmann 1, which has a period of 15 years, is in a quasi-circular and somewhat unstable orbit between Jupiter and Saturn, with a perihelion q that equals 5.45 a.u. and an aphelion of 6.73 a.u. It can be observed every year for several months when opposite to the Sun in the sky. Without any visible tail, it has irregular outbursts that make its coma grow in size for a few weeks and become up to 1,000 times as bright as normal. Another unusual object is the so-called asteroid 2060 Chiron, which has a similar orbit between Saturn and Uranus. Though classified as an asteroid, its icy nucleus of 350 kilometres would seem to suggest that it is a giant comet provisionally parked in a quasi-circular but unstable orbit. Within a few thousand years, Chiron might be perturbed enough by Saturn to become a spectacular comet. Two bright comets, Morehouse 1908 III and Humason 1962 VIII, exhibited a peculiar tail spectrum in which the ion CO^+ prevailed in a spectacular way, possibly because of an anomalous abundance of a parent molecule (carbon monoxide, carbon dioxide, or possibly formaldehyde [CH_2O]) vaporizing from the nucleus. Finally, Comet Halley is the brightest and therefore the most famous of all short- and intermediate-period comets as the only one that returns in a single lifetime and can be seen with the naked eye.

THE NATURE OF COMETS

The nucleus. As previously noted, the traditional picture of a comet with a hazy head and a spectacular tail applies only to a transient phenomenon produced by the decay in the solar heat of a tiny object known as the cometary nucleus. In the largest telescopes, the nucleus is never more than a bright point of light at the centre of the cometary head. At substantial distances from the Sun, the comet seems to be reduced to its starlike nucleus. The nucleus is the essential part of a comet because it is the only permanent feature that survives during the entire lifetime of the comet. In particular, it is the source of the gases and dust that are released to build up the coma and tail when a comet approaches the Sun. The coma and tail are enormous: typically the coma measures 100,000 kilometres or more in diameter, and the tail extends about 100,000,000 kilometres in length. They scatter and continuously dissipate into space but are steadily rebuilt by the decay of the nucleus, whose size is usually in the range of 10 kilometres.

The evidence on the nature of the cometary nucleus remained completely circumstantial until March 1986, when the first close-up photographs of the nucleus of Comet Halley were taken during a flyby by the *Giotto* spacecraft of the European Space Agency (Figure 46). Whipple's basic idea that the cometary nucleus was a monolithic piece of icy conglomerate (see above) had been already well supported by indirect deductions in the 1960s and '70s and had become the dominant though not universal view. The final proof of the existence of such a "dirty snowball," however, was provided by the photographs of Comet Halley's nucleus.

If there was any surprise, it was not over its irregular shape (variously described as a potato or a peanut), which had been expected for a body with such small gravity (10^{-4}). Rather, it was over the very black colour of the nucleus, which suggests that the snows or ices are indeed mixed together with a large amount of sootlike stuff (*i.e.*, carbon and tar in fine dust form). The very low geometric albedo (2 to 4 percent) of the cometary nucleus puts it among the darkest objects of the solar system. Its size is thus somewhat larger than anticipated: the roughly elongated body measures 15 by eight kilometres and has a total volume of some 500 cubic kilometres. Its mass is rather uncertain, estimated in the vicinity of 10^{17} grams, and its bulk density is very small, ranging anywhere from 0.1 to 0.8 gram per cubic centimetre. The infrared spectrometer on board the Soviet Vega 2 spacecraft estimated a surface temperature of 300 to 400 K for the inactive "crust" that seems to cover 90 percent of the nucleus. Whether this crust is only a warmer layer of outgassed dust or whether

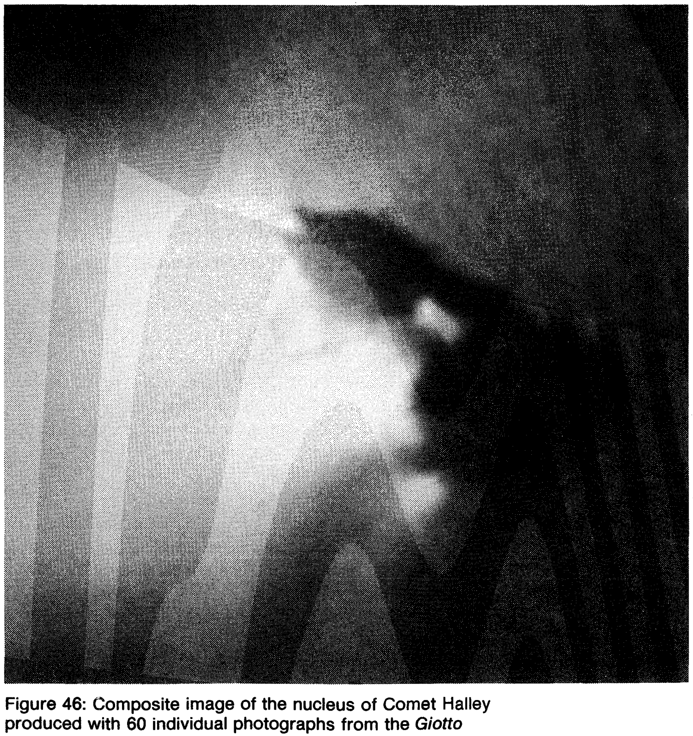

Figure 46: Composite image of the nucleus of Comet Halley produced with 60 individual photographs from the *Giotto* spacecraft. The photographs were taken on March 13 and 14, 1986, at various distances with the Halley Multicolour Camera carried on board the probe.

the dust particles are really fused together by vacuum welding under contact is still open to speculation.

Chemical composition of Comet Halley's nucleus

The 10 percent of the surface of Halley's nucleus that shows signs of activity seems to correspond to two large and a few smaller circular features resembling volcanic vents. Large sunward jets of dust originate from the vents; they are clearly dragged away by the gases vaporizing from the nucleus. This vaporization has to be a sublimation of the ices that cools them down to no more than 200 K in the open vents. The chemical composition of the vaporizing gases, as expected, is dominated by water vapour (more than 80 percent of the total production rate). The next most abundant volatile (close to 10 percent) appears to be carbon monoxide (CO), though it could come from the dissociation of another parent molecule (*e.g.*, CO_2 or CH_2O). Following CO in abundance is carbon dioxide (nearly 5 percent). Methane (CH_4) and ammonia (NH_3), on the other hand, seem to be close to the 1 percent level, and the percentage of carbon disulfide (CS_2) is even lower; at that level, there also must be unsaturated hydrocarbons and amino compounds responsible for the molecular fragments observed in the coma. This is not identical to—though definitely reminiscent of—the composition of the volcanic gases on the Earth, which also are dominated by water vapour but contain much more CO_2 than CO and occasionally some methane and sulfur in the molecular species, S_2, as well. The major difference may stem from the different temperature involved—often near 1,300 K in terrestrial volcanoes, as opposed to 200 K for cometary vaporizations. This may make the terrestrial gases closer to thermodynamic equilibrium. The dust-to-gas mass ratio is uncertain but is possibly in the vicinity of 0.4 to 1.1.

The dust grains are predominantly silicates. Mass spectrometric analysis by the *Giotto* spacecraft revealed that they contain as much as 20–30 percent carbon, which explains why they are so black. There also are grains composed almost entirely of organic material (molecules made of atoms of hydrogen, carbon, nitrogen, and oxygen).

There is some uncertainty concerning the rotation of Halley's nucleus. Two different rotation rates of 2.2 days and 7.3 days have been deduced by different methods. Both may exist, one of them involving a tumbling motion, or nutation, that results from the irregular shape of the nucleus, which has two quite different moments of inertia along perpendicular axes.

Scientific knowledge of the internal structure of the cometary nucleus was not enhanced by the flyby of Comet Halley, and so it rests on weak circumstantial evidence from the study of other comets. Earlier investigations had established that the outer layers of old comets were processed by solar heat. These layers must have lost most of their volatiles and developed a kind of outgassed crust, which probably measures a few metres in thickness. Inside the crust there is thought to exist an internal structure that is radially the same at any depth. Arguments supporting this view are based on the fact that cometary comas and tails do not become essentially different when comets decay. Since they lose more and more of their outer layers, however, the observed phenomena come from material from increasingly greater depths. These arguments are specifically concerned with the dust-to-gas mass ratio, the atomic and molecular spectra, the splitting rate, and the vaporization pattern during fragmentation.

Variation in size of nuclei

Before the *Giotto* flyby of Comet Halley, other cometary nuclei had never been resolved optically. For this reason, their albedo (fraction of incident light reflected) had to be assumed first in order to compute their sizes. Techniques proposed to deduce the albedo yielded only that of the dusty nuclear region made artificially brighter by light scattering in the dust. In 1986 the albedo of Comet Halley's nucleus was found to be very low (A = 2 to 4 percent). If this value is typical for other comets, then 11 of 18 short-period comets studied would be between six and 10 kilometres in diameter; only seven of them would be somewhat outside these limits. Comet Schwassmann-Wachmann 1 (see above) would be a giant with a diameter of 96 kilometres; 10 long-period comets would all have diameters close to 16 kilometres (within 10 percent). Since short-period comets have remained much longer in the solar system than comets having very long periods, the smaller size of the short-period comets might result from the steady fragmentation of the nucleus by splitting. Yet, the albedo may also diminish with aging. At the beginning, if the albedo were close to that of a slightly less dirty snow (A = 10 percent), the nuclear diameter of long-period comets would come very close to that of the largest of the short-period comets. The diameters of new comets also have been shown to be rather constant and most likely measure close to 10 kilometres. Of course, these are mean "effective" diameters of unseen bodies that are all likely to be very irregular.

The region around the nucleus, up to 10 or 20 times its diameter, contains an amount of dust large enough to be partially and irregularly opaque or at least optically thick. It scatters substantially more solar light than is reflected by the black nucleus. Dust jets develop mainly sunward, activated by the solar heat on the sunlit side of the nucleus. They act as a fountain that displaces somewhat the centre of light from the centre of mass of the nucleus. This region also is likely to contain large clusters of grains that have not yet completely decayed into finer dust; the grains are cemented together by ice.

Molecular collision zone

The gaseous coma. The coma, which produces the nebulous appearance of the cometary head, is a short-lived, rarefied, and dusty atmosphere escaping from the nucleus. It is seen as a spherical volume having a diameter of 10^5 to 10^6 kilometres, centred on the nucleus. The coma gases expand at a velocity of about 0.6 kilometres per second. This velocity can be measured from the motion of expanding "halos" triggered by outbursts in the nucleus, from the speed required to produce the Greenstein effect (see below), and from the fluid dynamics required to drag dust particles away at those places where they are observed in the dust tails. This expansion velocity varies somewhat with heliocentric distance r: $v = 0.58r^{-0.5}$ (in kilometres per second, when r is in astronomical units). The light of the spherical coma comes mainly from molecular fragments that have been produced by the dissociation of unobserved "parent molecules" in a zone on the order of 10^4 kilometres around the nucleus. This also is the approximate size of the zone where molecular collisions continue to occur; beyond that zone, the gas becomes too rarefied for such interaction to occur. The zone simply expands radially without molecular collisions into the vacuum of space. The parent molecules (*e.g.*, those of water vapour, carbon dioxide, and hydrogen cyanide [HCN]) are generally not observed because they do not fluoresce in visible light. So far, only a few have been observed at millimetre or centimetre wavelengths by radio telescopes; many more are needed if they are to be regarded as the source of the various radicals and ions that have been detected (Table 26).

If the mixture of original parent molecules has been frozen out of thermodynamic equilibrium in the nuclear ices, many chemical reactions can still take place in the molecular collision zone. At the usually cold temperature of vaporization, the kinetics of fast ion-molecular reactions would prevail. The reactions might reshuffle the original molecules present in the nucleus into new parent species, which would be the ones subsequently photodissociated into observed fragments by solar light. (This complex situation is still far from being completely understood.) In turn, the observed fragments, after having absorbed and reemitted photons from the solar light several times, would photodissociate or photoionize, which make them disappear from sight at the fuzzy limit of the light-emitting coma (typically 2–5 × 10^5 kilometres). A composite list of all observed species in cometary comas and tails is given in Table 26. It is based mainly on observations of the bright comets of the 1960s, '70s, and '80s, including spacecraft results from Comet Halley.

Table 26: Observed Chemical Species in Comets

Organic	C, C_2, C_3, CH, CN, CO, CO_2, CS, HCN, CH_3CN, HCO, H_2CO
Inorganic	H, NH, NH_2, O, OH, H_2O, S, S_2, NH_3, NH_4
Metals	Na, K, Ca, V, Mn, Fe, Co, Ni, Cu
Ions	C^+, CH^+, CO^+, CO_2^+, N_2^+, O^+, OH^+, H_2O^+, H_3O^+, S^+, S_2^+, H_2S^+, CS_2^+,
Dust	silicates, organic compounds

The organic radicals given in the Table were seen in cometary heads as visual or ultraviolet emission lines or bands. The exceptions were water vapour, along with hydrogen cyanide and methyl cyanide (CH_3CN); these species, which could be called parent molecules, were observed as pure rotation lines at radio frequencies. The metals—except for sodium (Na), which is observed in many comets—were seen as visual lines in Sun-grazing comets alone. They are assumed to result from the vaporization of dust grains by solar heat. Sodium is a volatile metal that is not unlikely to vaporize easily from dust grains at large distances from the Sun (more than 1 a.u.). The ions were seen in the visual or ultraviolet emission lines or bands at the onset of the plasma tail or detected by spacecraft. The silicate signature was found in infrared emission bands at the onset of dust tails. The occurrence of the silicate elements, as well as the presence of a rather large amount of organic compounds, was confirmed by the mass spectrometric analysis of dust grains during the *Giotto* flyby of Comet Halley.

Swings effect

An extremely weak coma appeared in 1984 when Comet Halley still was 6 a.u. from the Sun; this is the best case study to date. Rarely have comas been detected beyond 3 or 4 a.u., where they are still quite small; they grow to a maximum near 1.5 a.u. and seem to contract as they approach closer to the Sun. This effect comes from the more rapid decay in solar light (by photoionization or photodissociation) of the visible radicals that emit the coma light. The discrete emission of light by cometary atoms, radicals, or ions is due to the selective absorption of sunlight followed by its reemission either at the same wavelength (resonance) or at a different wavelength (fluorescence). In 1941, Pol Swings explained the peculiar appearance of some of the molecular bands in comets by the irregular spectral distribution of the exciting solar radiation owing to the presence of Fraunhofer lines (dark, or absorption, lines) in this radiation. The temporal variations that occur in the molecular bands as a comet approaches the Sun were explained quantitatively by the variable shift in the apparent wavelengths of the solar Fraunhofer lines due to the variable radial velocity of the comet. This is the so-called Swings effect. Later, the American astronomer Jesse Greenstein explained, by a differential Swings effect, the observed differences in the molecular bands in front of and behind the nucleus: the radial expansion velocity of the coma introduces a different shift forward and backward. This differential Swings effect is often referred to as the Greenstein effect (Figure 47).

Exceptions to the resonance-fluorescence mechanism are known and are exemplified by the case of the emission of the "forbidden" red doublet of atomic oxygen at wavelengths of 6300 and 6364 angstroms. Such an emission cannot be excited by direct absorption of sunlight but is produced directly by the photodissociation of H_2O into $H_2 + O$ (in the ^1D state) and, in an accessorial manner, of CO_2 into $CO + O$ (in the ^1D state). The ^1D state is an excited state of the oxygen atom that decays spontaneously into the ground state by emitting the forbidden red doublet, provided that it had not been quenched earlier by molecular collisions.

Halo of atomic hydrogen

The large atomic hydrogen halo detected up to 10^7 kilometres from the nucleus is nothing more than a large coma visible in ultraviolet (Lyman-alpha line). It is two orders of magnitude larger than the comas that can be seen in visible light only because the hydrogen atoms, being lighter, move radially away 10 times faster and are ionized 10 times more slowly than the other radicals.

Cometary tails. The tails of comets are generally directed away from the Sun. They rarely appear beyond 1.5 or 2 a.u. but develop rapidly with shorter heliocentric distance. The onset of the tail near the nucleus is first directed toward the Sun and shows jets curving backward like a fountain, as if pushed by a force emanating from the Sun. The German astronomer Friedrich Wilhelm Bessel began to study this phenomenon in 1836, and Fyodor A. Bredikhin of Russia developed, in 1903, tail kinematics based on precisely such a repulsive force that varies as the inverse square of the distance to the Sun. Bredikhin introduced a scheme for classifying cometary tails into three types, depending on whether the repulsive force was more than 100 times the gravity of the Sun (Type I) or less than one solar gravity (Types II and III). Subsequent research showed that Type-I tails are plasma tails (containing observed molecular ions as well as electrons not visible from ground-based observatories), and Types II and III are dust tails, the differences between them being attributable to a minor difference in the size distribution of the dust grains. As a result of these findings, the traditional classification formulated by Bredikhin is no longer considered viable and is seldom used. Most comets (but not all) simultaneously show both types of tail: a bluish plasma tail, straight and narrow with twists and nods; and a yellowish dust tail, wide and curved, which is often featureless (see Figure 48).

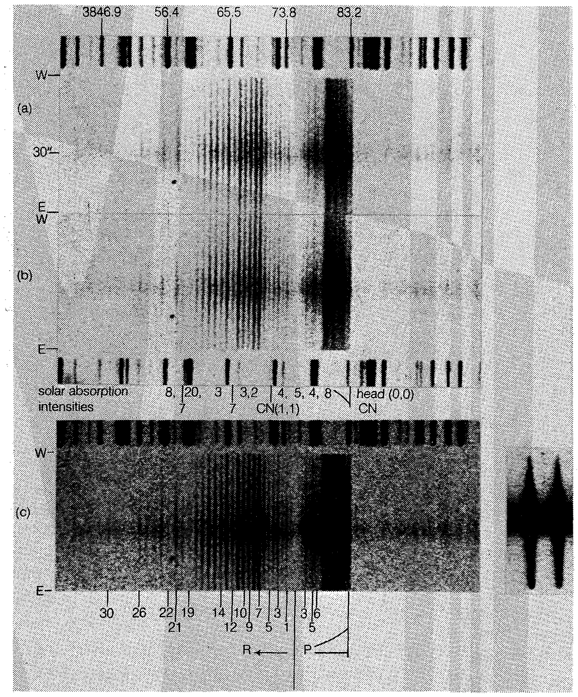

Figure 47: High-dispersion spectrum of the cyanogen (CN) bands near 3880 angstroms in Comet Mrkos, showing band irregularities (Swings and Greenstein effects; see text).

Plasma tail

The plasma tail has its onset in a region extremely close to the nucleus. The ion source lies deep in the collision zone (typically 10^3 kilometres). It is likely that charge-exchange reactions compete with the photoionization of parent molecules, but the mechanism that produces ions is not yet quantitatively understood. In 1951 the German astronomer Ludwig Biermann predicted the existence of the solar wind (see above) in order to account for the rapid accelerations observed in plasma tails as well as their aberration (*i.e.,* deviation from the direction directly opposite to the Sun). The cometary plasma is blown away by the magnetic field of the solar wind until it reaches its own velocity—nearly 400 kilometres per second. This action explains the origin of the large forces postulated by the Bessel–Bredikhin theory. Spectacular changes observed in the plasma tail, such as its sudden total disconnection, have been explained by discontinuous changes in the solar wind flow (*e.g.,* the passage of magnetic sector boundaries).

In 1957 the Swedish physicist Hannes Alfven predicted the draping of the magnetic lines of the solar wind around the cometary ionosphere. This phenomenon was detected by the International Cometary Explorer spacecraft, launched by the National Aeronautics and Space Administration (NASA), when it passed through the onset of the plasma tail of Comet P/Giacobini-Zinner on Sept. 11, 1985. Two magnetic lobes separated by a current-carrying neutral sheet were observed as expected. A related feature known as the ionopause was detected by the *Giotto* space probe during its flyby of Comet Halley in 1986. The ionopause is a cavity without a magnetic field that

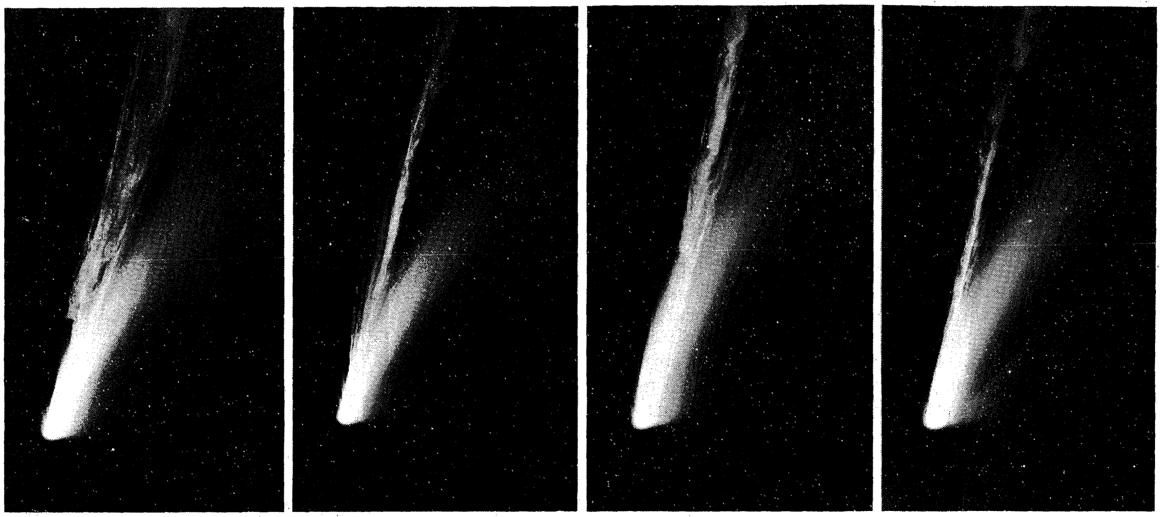

Figure 48: Comet Mrkos, photographed Aug. 22, 24, 26, 27, 1957. The straight tail with prominent streamers and irregularities, best seen at upper left in all photographs, is formed of ionized molecules; the more uniform, curved tail is composed primarily of small solid particles.

By courtesy of Mount Wilson Observatory

contains only cometary ions and is separated from the solar wind by a sharp discontinuity. Halley's ionopause lies about 4,000 to 5,000 kilometres from the nucleus of the comet. An analysis of all the encounter data indicates that a complete understanding of cometary interaction with the solar wind has not yet been achieved. It is well understood, however, that the neutral coma remains practically spherical. The solar wind is so rarefied that there are no direct collisions of its particles with the neutral particles of the coma, and, as these particles are electrically neutral, they do not "feel" the magnetic field.

Dust tail

The source of the dust tail is the dust dragged away by the vaporizing gases that emanate from the active zones of the nucleus, presumably from vents like those observed on Comet Halley's nucleus (Figure 46). The dust jets are first directed sunward but are progressively pushed back by the radiation pressure of sunlight. The repulsive acceleration of a particle varies as $(sd)^{-1}$ (with linear size s and density d). For a given density, it thus varies as s^{-1}, separating widely the particles of different sizes in different parts of the tail. Studying the dust tail isophotes of varying brightnesses therefore yields the dust grain distribution. This distribution may peak for very fine particles near 0.5 micrometre (μm), assuming a density of two, as in the case of Comet Bennett; however, it falls off with s^{-n} (with n ranging from three to five) for larger particles. This mechanism neglects particles much smaller than the mean wavelength of sunlight. Because such particles do not reflect light, they do not feel its radiation pressure. (They are not detected from ground-based observations anyway.)

One of the major results of the *Giotto* flyby of Halley's nucleus was the detection of abundant particles much smaller than the wavelength of light, indicating that the size distribution does not peak near 0.5 μm but seems rather to grow indefinitely with a slope close to a^{-2} for finer and finer particles down to possibly 0.05 μm (10^{-17} gram). The dust composition analyzers on board the *Giotto* and Vega spacecraft revealed the presence of at least three broad classes of grains. Class 1 contains the light elements hydrogen, carbon, nitrogen, and oxygen only (in the form of either ices or polymers of organic compounds). The particles of class 2 are analogous to the meteorites known as CI carbonaceous chondrites but are possibly slightly enriched in carbon and sulfur. Class 3 particles are even more enriched in carbon, nitrogen, and sulfur; they could be regarded as carbonaceous silicate cores (like those of class 2) covered by a mantle of organic material (similar to that of class 1) that has been radiation-processed. Most of the encounter data were excellent for elemental analyses but poor for determining molecular composition, because most molecules were destroyed by impact at high encounter velocity. Hence, there still remains much ambiguity regarding the chemical nature of the organic fraction present in the grains.

Meteors are extraterrestrial particles of sand-grain or small-pebble size that become luminous upon entering the upper atmosphere at very high speeds. Meteor streams have well-defined orbits in space. More than a dozen of these orbits have practically the same orbital elements as the orbits of the identical number of short-period comets (see below *Orbits of meteoroids and meteor showers*). Fine cometary dust consists primarily of micrometre- or submicrometre-sized particles that are much too small to become visible meteors (they are more like cigarette smoke than dust). Moreover, they are scattered in the cometary tail very far from the comet orbit. The size distribution of cometary dust grains, however, covers many orders of magnitude; a small fraction of them may reach 0.1 millimetre to even a few centimetres. Because of their large size, the dust grains are almost not accelerated by the radiation pressure of sunlight. They remain in the plane of the cometary orbit and in the immediate vicinity of the orbit itself, even though they separate steadily from the nucleus. They sometimes become visible as an anti-tail—*i.e.,* as a bright spike extending from the coma sunward in a direction opposite to the tail (Figure 49). This phenomenon occurs as a matter of geometry: it takes place for only a few days when the Earth crosses the plane of the cometary orbit. At such a time, this plane is viewed through the edge and all large grains are seen accumulated along a line. The same grains scatter farther and farther away from the nucleus until some are along the entire cometary orbit. When the Earth's orbit intersects such an orbit (an event that occurs year after year at the same calendar date), these large grains produce meteor showers.

Anti-tail

Extremely fine cometary grains also may penetrate the Earth's atmosphere, but they can be slowed down gently without burning up. Some have been collected by NASA's U-2 aircraft at very high altitudes. Grains of this kind are known as Brownlee particles and are believed to be of cometary origin (Figure 50). Their composition is chondritic, though they show somewhat more carbon and sulfur than the CI carbonaceous chondrites, and their structure is fluffy with many pores. Similar grains were found in space during the space probe exploration of Comet Halley.

COMETARY MODELS

As previously noted, the sandbank model of the cometary nucleus fell into disregard by the late 1950s and early 1960s and was supplanted by the dirty snowball (or icy conglomerate) concept. Much circumstantial evidence supported the latter, but confirmation was lacking until 1986 when the *Giotto* spacecraft returned detailed, close-up photographs of Comet Halley's nucleus. Yet, while

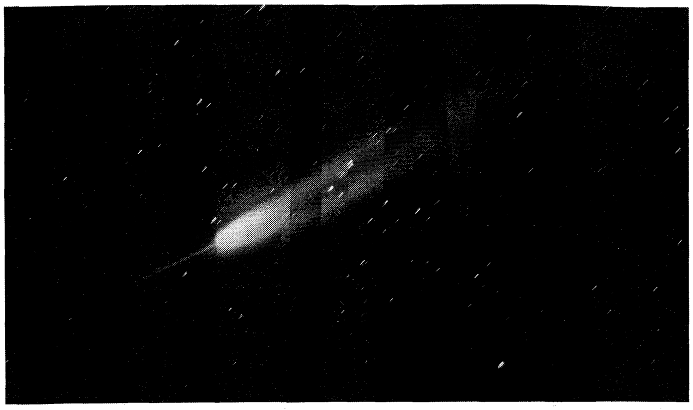

Figure 49: Comet Arend-Roland photographed on April 25, 1957. The prominent anti-tail extending from the coma appears to precede the comet, though it actually trails from behind.

By courtesy of Lick Observatory, University of California

these photographs corroborated the general idea of the model, they revealed that "dirty snowball" was in fact a misnomer because snow (even when dirty) is suggestive of something white or at least gray in colour. In actuality, the cometary nucleus proved to be pitch-black owing to the large amount of very fine, black sootlike particles intermixed with the volatile ices (see above).

Many variations of the icy conglomerate model have been proposed since the early 1980s, as, for example, the fractal model, rubble-pile model, and icy-glue model. These names, however, suggest only slightly different types of accretion of primordial particles; they all share common features—namely, irregular shape, heterogeneous mixture, and very low density because of cavities and pores. The existence of a crust or dust mantle of a different nature had already been proposed before the 1986 spacecraft encounter with Comet Halley for two reasons. First, cosmic-ray processing of the outer layers had been described by L. Shul'man of the Soviet Union (1972) and later advocated by Fred Whipple and Bertram Donn of the United States, while the outgassing of the outer layers by solar heat had also been assumed since the proposal of Whipple's model (1950). Second, detailed models of the formation and disruption of such mantles due to solar-radiation processing of the upper layers had been studied by Devamitta Asoka Mendis of the United States (1979) and M. Horanyi of Hungary (1984).

Elemental abundances of the cometary nucleus

An average heuristic model for the elemental abundances of the cometary nucleus was developed by the American astronomer Armand H. Delsemme in 1982. Delsemme computed the H:C:N:O:S ratios from ultraviolet and visual observations of atomic and molecular species in bright comets detected during the 1970s and deduced the abundances of metals from the chondritic composition of cometary dust. In this model, hydrogen was depleted by a factor of 10^3 with respect to solar or cosmic abundances, and carbon was depleted by a factor of four in the gaseous fraction. The results of the 1986 study of Comet Halley confirmed the average chemical model and showed that the carbon missing in the gas was actually present in the dust. Except for hydrogen (and presumably helium), it appears that all elements are roughly in cosmic proportions in comets in spite of their extremely low gravity (10^{-4} times that of the Earth). This emphasizes the pristine nature of comets. Unlike most bodies of the solar system, comets obviously have never been severely processed by any heating episode since their formation. If the accretion of comets occurred at very low temperatures, near absolute zero (0 K), the water ice in a newly formed comet must be amorphous. Idealized models show that the transition to cubic ice might be the cause of sudden flare-ups between 3 and 6 a.u.

ORIGIN AND EVOLUTION OF COMETS

Evolution of orbits

All observed comets make up an essentially transient system that decays and disappears almost completely in less than 1,000,000 years. Since they all pass through the solar system, planetary perturbations eject a fraction of them into deep space on hyperbolic orbits and capture another fraction on short-period orbits. In turn, those that have been captured decay rapidly in the solar heat. Fortunately, there is a permanent source of new comets that maintains the steady state—namely, the outer margin of the Oort cloud. As explained above, these so-called new comets are those Oort-cloud comets whose perihelia have been brought down into visibility—*i.e.,* into the inner planetary system where they display their spectacular decay through comas and tails. Comets within the bulk of the Oort cloud are unobservable, not only because they do not develop comas and tails but also because they are too far away.

Formation of the Oort cloud. Any modern theory about cometary origins must first explain the origin of the Oort cloud. None of the comets observed today left the Oort cloud more than 3,000,000 or 4,000,000 years ago. The Oort cloud is, however, gravitationally bound to the solar system, which it follows in its orbit around the Milky Way Galaxy. Therefore, it is likely that the Oort cloud has existed for a long time. The most probable hypothesis is that it was formed at the same time as the giant planets by the very process that accreted them. The Soviet astronomer V.S. Safronov developed this accretionary theory of the planetary system mathematically in 1972. According to his model, the planets originated from a disk or a ring of dust around the Sun, and cometary nuclei are nothing more than primordial planetesimals that accreted first and became the building blocks of the planets. From the accreted mass of the giant planets, Safronov predicted the correct order of magnitude of the mass of the Oort cloud, which was built up by those planetesimals that missed colliding with the planetary embryos and were thrust far away by their perturbations. In effect, the Oort cloud in this theory becomes the necessary consequence and the natural by-product of the accretion of the giant planets.

The Oort cloud as a by-product of the accretion of the giant planets

Later in the 1970s the American astronomer A.G.W. Cameron developed a much more massive model of the protostar nebula, in which the comets accreted in a circular ring at some 1,000 a.u. from the Sun, which is far beyond the present limits of the planetary system. The primeval circular orbits were then transformed into the elongated ellipses present in the Oort cloud by mass loss of the primitive solar nebula. Both the Cameron and Safronov models put the origin of comets together with that of the solar system some 4,500,000,000 years ago. Plausibility is given to the general idea of accretion from dust disks by the existence of such disks around many young stars—a fact established by infrared observations in the 1980s and confirmed visually in at least one case (β Pictoris). Further support is found in clues derived from meteorites.

Since the early 1980s, new ideas have been explored to determine whether the Oort cloud could be much younger than the solar system or at least periodically replenished. The role of the massive and dense molecular clouds that exist in interstellar space has been reexamined in different ways. Could comets have accreted in these clouds directly from interstellar grains? Mechanisms for later capturing them into the Oort cloud cannot be very effective, but the efficiency is not capital and some possibilities have been proposed. Since the solar system itself was probably formed from the gravitational collapse of such a molecular cloud, it seems more likely that either comets or the interstellar grains that were going to accrete into comets followed suit during gaseous collapse and were put into the Oort cloud at the same time that the planets were being formed. Elemental isotopic ratios deduced from the Comet Halley flyby have not brought about any conspicuous anomalies that could be attributed to matter coming from outside the solar system. So far, observational clues all favour the idea of cometary matter deriving from the same primeval reservoir as the stuff of the solar system, but it must be recognized that the evidence remains weak.

Possible pre-solar-system origin of comets. Telltales based on the chemical constitution of cometary nuclei as well as on the evolution of their orbits suggest that the origin of comets goes back beyond that of the planets and their satellites. Two scenarios are among the likeliest possibilities. In the first, comets had already accreted in all dense molecular clouds of the Milky Way Galaxy by the agglomeration of interstellar grains covered by a frost of organic molecules that cemented them together. Later, such a cloud collapsed to form the solar system. In the second scenario, dense molecular clouds were not able to accrete their frosty interstellar grains into larger bodies. When one of these molecular clouds collapsed to form the future solar system, however, the interstellar grains did likewise and eventually formed a dusty disk around the central star—the proto-Sun. Accretion into objects of 10-kilometre diameter is more likely in dusty disks of this type. The outer grains of the disk had not lost their frost, and some of them were ejected into the Oort cloud during the accretion of planetesimals into giant planets after some very moderate processing by heat. It is hoped that one day, space probes will secure data that will make it possible to determine whether frosty interstellar grains have lost their identity or can still be recognized as pristine and unaltered objects in cometary dust.

Comets seem to be the most pristine objects of the solar system, containing intact the material from which it was formed. Included are the hydrogen, carbon, oxygen, nitrogen, and sulfur atoms needed to build the volatile molecules present in the terrestrial biosphere (including the oceans and the atmosphere). Comets also seem to be the link between interstellar molecules and the most primitive meteorites known—the carbonaceous chondrites (see below *Types of meteorites*). The molecules required to initiate prebiotic chemistry (*e.g.,* hydrogen cyanide, methyl cyanide, water, and formaldehyde) are present in interstellar space just as they are in comets; larger prebiotic chemistry molecules (*e.g.,* amino acids, purines, and pyrimidines) occur in some chondrites and possibly in comets. An early cometary bombardment of the Earth, predicted in some accretion models of the solar system, may have brought the oceans and the atmosphere, as well as a veneer of the molecules needed for life to develop on the Earth. Comets could well be the link between interstellar chemistry and life. (A.H.De.)

Meteoroids, meteors, and meteorites

METEOROIDS

General considerations. The solar system contains many small bodies that move in orbits sufficiently eccentric to cross over and intersect the orbit of the Earth. When their orbits do intersect that of the Earth, the probability of the objects colliding with the planet becomes quite high. A body of this kind entering the Earth's atmosphere is called a meteoroid. Such bodies range from small particles less than one micrometre in size (about 10^{-12} gram in mass) up through objects several centimetres or metres in diameter and grade into kilometre-sized bodies large enough to be observed as astronomical objects through telescopes. They enter the upper atmosphere with velocities of 11 to 72 kilometres per second. Interaction with the atmosphere heats incoming objects that are larger than about 10^{-2} centimetre to temperatures high enough to cause them to become incandescent, vaporize, and heat the surrounding air. As a result of this sequence, such objects are observable from the ground as meteors or, in more popular language, "shooting stars" or "falling stars." Strictly speaking, the term meteor refers only to the phenomena associated with the collision of a meteoroid with the Earth's atmosphere. Scientific usage is not all that strict, however, and the body itself is often called a meteor. Unusually luminous meteors are termed fireballs or bolides.

'ariations
ı size

Due to its fairly low entry velocity, large mass, and physical strength, a meteoroid sometimes survives its passage through the atmosphere, falls to the ground, and may be recovered as a meteorite. Recovered meteorites, ranging in mass from a few grams to several tons, are often exhibited in museums. Most meteorites either consist of rocky—chiefly silicate—material (stony meteorites) or are composed primarily of nickel-iron alloy (iron meteorites; Figures 51 and 52). In stony-iron meteorites, massive nickel-iron alloy is intermixed with silicate material.

In addition to these relatively large meteorites, it is possible to recover much smaller objects about 10^{-3} centimetre in diameter called micrometeorites on filters attached to aircraft flying in the stratosphere. These micrometeorites (often referred to as interplanetary or cosmic dust) also accumulate on the bottom of the deep ocean. The larger ones can be identified and separated from cores drilled from the muddy deposits on the seafloor.

Micrometeorites

The largest meteoroidal bodies are observable through telescopes as astronomical objects. These include the Apollo objects, bodies of asteroidal appearance with diameters ranging from a few hundred metres to several kilometres that come closer to the Sun than to the Earth's orbit. There are about 700 of these larger than one kilometre in diameter. Because comets can strike the Earth, they, too, can be thought of as large meteoroidal bodies.

When meteoroids are sufficiently large (*i.e.,* 100 metres

to several kilometres in diameter), they can pass through the atmosphere without slowing down appreciably. When they strike the Earth's surface at velocities of many kilometres per second, the kinetic energy released is sufficient to produce an impact crater. In many ways such craters resemble those produced by nuclear explosions. They are often called meteorite craters, in spite of the fact that the impacting meteoroids themselves are almost entirely vaporized during the explosion. High-velocity impact by objects of this kind on the Moon, Mercury, and Mars are in large part responsible for the heavily cratered appearance of the surface of these bodies. The cratering record on the Earth and Moon also shows that there are many meteoroids in the intermediate mass range between the larger recovered meteorites (a few metres in diameter) and the Apollo objects.

G. Kurat

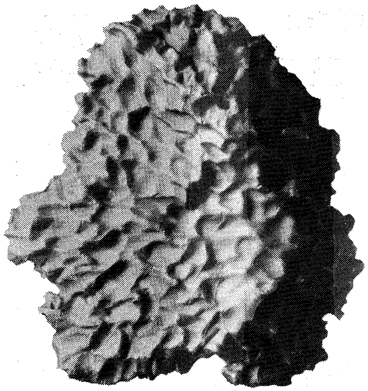

Figure 52: Cabin Creek (Arkansas) iron meteorite (medium octahedrite; reduced 8.1 ×). The dimpled appearance of the face of the meteorite was caused by melting of its surface upon entering the Earth's atmosphere.

Relationship of meteoroids to asteroids and comets. Most of the mass of the solar system resides in its larger bodies, the Sun and the planets. The planets move about the Sun in stable and well-separated orbits. It is almost certain that these orbits and thus the positions of the planets have undergone only minor changes since the formation of the solar system some 4,500,000,000 years ago. In addition, the planets are large enough to retain on their surfaces nearly all the debris produced by impact craters.

On the other hand, a smaller fraction of the mass of the solar system is found in bodies of such small size or in orbits so eccentric that their physical survival or orbital stability has been in jeopardy throughout the history of the solar system. Most of these bodies are found in either of two regions of the solar system: the asteroid belt, between the orbits of Mars and Jupiter (mostly between 2.2 and 3.4 a.u.), and the cometary, or Oort, cloud extending far beyond the orbits of Neptune and Pluto to distances of more than 10^4 a.u.

The members of the asteroid belt have high enough eccentricities and inclinations that they collide with one another at velocities averaging about five kilometres per second. Because of this, it is unlikely that most asteroids larger than about 75 kilometres in diameter have survived collisional destruction over the entire 4,500,000,000-year history of the solar system. The present-day smaller asteroids are debris formed by fragmentation of larger asteroids caused by this natural grinding process in the asteroid belt. The grinding extends down to bodies the size of meteorites exhibited in museums and even to much smaller particles in the form of fine dust.

Fragmentation of asteroids

Some of this collisional debris is orbitally unstable. The same collisions that produced the fragments propel a portion of them into chaotic orbits controlled by dynamical resonances with the motions of the planets. As a result of collisions and orbital instability, asteroidal material is injected into orbits that cross the Earth's orbit. Some of this matter collides with the atmosphere of the Earth and becomes visible meteors. A small number of the particles survive as meteorites.

The much more distant cometary bodies also are vulnerable to destruction. Their orbits extend to the threshold of interstellar space. Passing stars and interstellar molecular clouds gravitationally perturb some of these bodies into orbits with perihelia within several astronomical units of the Sun. A small fraction of the comets that are perturbed into orbits approaching the Sun experience close approaches to planets, particularly Jupiter, and this leads to further orbital perturbations. In some cases, this causes the orbital eccentricity and orbital period of a comet to be drastically reduced to periods from about three to several hundred years.

Comets are small bodies consisting of a mixture of ice and less volatile material, the latter mostly in the form of dust (see above *The nature of comets*). When a comet is perturbed into an orbit that comes within a few astronomical units of the Sun, the ice begins to evaporate, giving rise to the luminous object commonly thought of as a comet. Dust is swept away from the comet along with the evaporating ice. Most of the fine dust escapes the Sun's gravitational field and is lost to interstellar space. Some of the dust, however, is in larger particles typically millimetres to centimetres in size. As compared with the finer particles of dust, these larger bodies have a smaller ratio of surface area to mass, and this renders them less susceptible to the solar radiation forces, proportional to the cross-sectional area, that drive the finest dust out of the solar system. Thus, these larger cometary particles can remain in short-period orbits and can intersect the orbit of the Earth. When they collide with the atmosphere, meteoroids of this kind also appear as meteors.

The best evidence for the cometary origin of certain meteoroids is identification of the orbits of meteoroids with those of known periodic comets (see above *Modern cometary research*). It is possible to determine these orbits by photographing the meteors with special cameras as they pass through the Earth's atmosphere. This identification has been made for several of the meteors that produce meteor showers. In this way inferences can be made about the physical properties of particulate cometary material.

Associatior of meteor showers with meteoroids of cometary origin

The asteroid belt and the outermost part of the solar system should be thought of as long-lived though somewhat leaky reservoirs of meteoroidal bodies. They are long-lived enough to retain a significant quantity of primordial solar system material but leaky enough to permit the escape of the observed quantity of Earth-crossing material. This quantity of Earth-crossing material represents an approximate steady-state balance between the input from the storage regions and the loss by ejection from the solar system, collision with the Earth, the Moon, and other planets, or vaporization by impact.

Evidence for meteoroids of asteroidal origin: radiometric ages of meteorites. The most meaningful way of describing and classifying meteoroids would be in terms of their various sources in the solar system. To do so, it is necessary to find criteria that discriminate among these sources.

Unlike the association of some meteoroids with the actual observed orbits of comets, direct orbital identification is not possible for meteoroids of asteroidal origin. The asteroids in the asteroid belt that are the ultimate parents of these meteoroids are not in Earth-crossing orbits. A meteoroid entering the atmosphere must be in an Earth-crossing orbit. Therefore, the observed meteoroid orbit cannot be the same as that of its source. The evolution of the asteroidal collision debris from the asteroid belt is complex, involving collisional fragmentation and major orbital changes caused by planetary gravitational perturbations. Although this evolution is quantitatively understandable in terms of known physical processes, the complex history destroys the information required to directly link the meteoroid with its source. Unlike cometary meteors, there is, for example, no good evidence that asteroidal meteors occur in streams, nor would such clustering of orbits be expected on theoretical grounds. The link between asteroidal meteoroids and their sources must be established in ways that are less direct.

This link is supplied by laboratory investigations of meteoroids that have survived passage through the atmosphere—namely, meteorites. As a result of these investigations, it is generally believed that nearly all recovered meteorites are fragments of asteroids. A small fraction, about 0.5 percent, may be of lunar or Martian origin. It is possible, but not at all firmly established, that some meteorites may be derived from comets.

The reasoning that leads to identification of most meteorites as asteroidal meteoroids is fairly complex but quite compelling. Perhaps the best starting point would be that based on studies of the daughter isotopes produced by the radioactive decay of radioactive parent isotopes of such elements as uranium, thorium, rubidium, potassium, and samarium. As is commonly done for terrestrial rocks, the ages of meteorites can be determined by isotopic measurements of this kind.

Isotopic measurements

When this is done, all but a very few meteorites show good evidence of having been formed, from the mineralogical point of view, some 4,500,000,000 years ago. Similar techniques have been used to infer, somewhat less directly, the age of the Earth and the Moon, with the same result. Within an uncertainty of less than about 100,000,000 years, this age represents the time in the past when the Sun, the planets, and their natural satellites, along with the asteroids and comets, formed from interstellar dust and gas. Because of geologic processes that produced younger rocks on the Earth and Moon, their evidence for this primordial age of formation has been obscured but not erased. By contrast, the evidence for the age of the solar system is clearly preserved in meteorites.

Although present-day meteorites are the products of a long series of events that caused physical fragmentation, in most cases the mineral grains of which they are composed have undergone little chemical alteration since the early years of the solar system. As a consequence, the isotopic ratios from which the ages are calculated preserve the evidence for this very ancient time of formation.

If meteorites are asteroidal fragments, this is what would be expected. Theoretical calculations of the thermal evolution of bodies as small as asteroids predict that they would not exhibit the long-continuing history of igneous and metamorphic rock formation characteristic of large bodies such as the Earth and Moon. As in the case of the latter, however, the decay of radioactive isotopes produces heat in the interiors of asteroids. Yet, because of their small size, this heat is readily conducted to the surface and radiated to space. The internal temperature thus would never rise high enough to produce the metamorphism or melting that would chemically alter the ancient mineralogy. In the much larger Earth, on the other hand, the heat is not efficiently transported to the surface by convection until the temperature increases to near its melting point.

By itself, this preservation of ancient mineralogy does not, however, clearly indicate that the meteorites are of asteroidal rather than of cometary origin. Comets are even smaller bodies than asteroids and would be heated even less. If, in addition to the volatile material and fine dust emitted by comets as they approach the Sun, there exists ancient rocky material in their nuclei, one would expect the primordial isotopic age record to be preserved in cometary meteoroids as well.

Distinuishing etween steroidal nd ometary ources

The clue to the distinction between asteroidal and cometary sources for at least the most common meteorites is provided by minor mineralogical disturbances that slightly alter the otherwise clear preservation of the primordial isotopic age record in meteorites. Such disturbances are attributable to metamorphism associated with evidence for collisional shocks preserved in the detailed mineralogy of meteorites. For example, many representatives of one very common type of chondritic meteorite, the hypersthene chondrite, display glass veins and other evidence of shock-induced metamorphism of the sort that would be expected to result from collisions between asteroids. (Chondrites, the most common type of stony meteorite, are so called because they contain small primordial silicate spherules known as chondrules.) Ages measured by the decay of potassium to argon show that this shock metamorphism took place quite late in the history of the solar system—about 500,000,000 years ago. Ages measured by other isotopic decay systems on these same meteorites still display the more common value of 4,500,000,000 years (Figure 53). Furthermore, these shocked meteorites exhibit a very strong chemical and textural kinship to unshocked meteorites that record completely the isotopic age of the solar system. It is not plausible that such similar rocks should be provided by sources from regions as far removed from one another as the asteroid belt and the cometary cloud. Other evidence for impact events late in solar system history is provided by dating shocked fragments of meteoritic material embedded in meteorites of different types which are presumably a result of collisions in space. Quantitative comparison of the collisional history expected for the sparsely populated, low relative velocity source regions of comets with that expected for the more densely populated, higher velocity asteroid belt argues strongly for the asteroid belt being the actual site of these collisions and thus the source region for the meteorites.

Wetherill in *Journal of Geophysical Research* (1968–71), copyright by the American Geophysical Union. (Right) Data compiled by J.T. Wasson (1985) based on data from D. Bogard, *Journal of Geophysical Research*, vol. 81, p. 5664, (1976), copyright by the American Geophysical Union; G. Turner, *Meteorite Research* (1969); and G. Turner *et al.*, *Proceedings of the Ninth Lunar Planetary Scientific Conference* (1979)

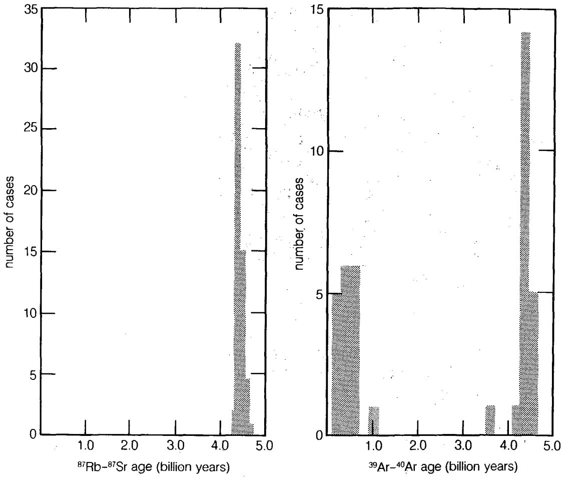

Figure 53: *Distribution of formation and metamorphism ages of ordinary chondrite meteorites.*
(Left) Ages measured by the decay of ^{87}Rb to ^{87}Sr. The "isotopic clocks" of these meteorites were set by heating events essentially at the beginning of solar system history.
(Right) Ages based on the decay of ^{40}K to ^{40}Ar. Many of these ages also cluster around 4,500,000,000 years, but a significant number have been "reset" by collisionally induced shock metamorphism on the asteroid from which the meteorite was fragmented.

Such conclusions are supplemented by observational and theoretical dynamical studies of meteorite orbits. The results of these studies are in agreement with an asteroidal origin for at least the most abundant types of meteorites but are not in agreement with a cometary origin.

Meteoroids of less certain origin. Identification of many meteoroids with either asteroids or comets can be securely established. It is then possible to extend these identifications by extrapolation to cases where the distinction is less obvious. There are, for example, many shower meteors in meteor streams for which no comet is presently identifiable; however, the orbits and characteristics of their passage through the atmosphere are very similar to those of stream meteors that are associated with known comets. Even when such meteors are not in streams, their orbits with aphelia and physical characteristics similar to those of cometary stream meteors leave little room to question their cometary parentage. It also has been possible to identify a number of very bright meteors (fireballs) with asteroidal meteorites by comparing the details of their atmospheric flight with those of recovered meteorites (see below *Fireball networks*).

There are many meteoroids whose asteroidal or cometary nature remains highly uncertain. These include objects that are presently in orbits very similar to identifiably asteroidal meteoroids but that exhibit in their atmospheric flight the greater fragility associated with meteoroids known to be derived from comets. Are these fragments of comets that have been perturbed into orbits traditionally associated with asteroids, or do they represent a type of asteroidal material that is too weak to survive as a meteorite? Answers to such questions are needed if scientists are to use the information preserved in primitive bodies—comets and asteroids—in the most effective way. There is much more that can be learned from further observational studies of meteors, laboratory investigations of meteorites, Earth-based observations of comets and asteroids, and spacecraft missions to these small primitive bodies. Continuation of this work holds much promise for clarifying the processes by which both the Earth and the solar system came into existence.

In addition to cometary and asteroidal sources, a very minor but identifiable contribution to the meteoroidal population is derived from the Moon. Such particles are ejected from primary cratering of the lunar surface by large meteorites. By comparison with lunar rocks returned by the U.S. Apollo missions, several small meteorites collected on the Antarctic ice sheet have been positively identified as lunar meteorites. It also appears probable that certain relatively rare types of meteorites (shergottites, nakhlites, and chassignites) are fragments of igneous rocks from Mars. Some day evidence for meteoroids from Mercury, Venus, Earth, and the interstellar medium may be identified.

METEORS

Characteristic observational effects. On any clear night in the countryside beyond the bright lights of cities, one can observe with the naked eye several meteors (or shooting stars) per hour as they streak through the sky, with durations ranging from a small fraction of a second up to several seconds. Quite often they vary in brightness along the path of their flight, appear to emit "sparks" or flares, and sometimes leave a luminous train that lingers after their flight has ended. These meteors are the result of the high-velocity collision of meteoroids with the Earth's atmosphere. Nearly all such interplanetary bodies are small fragments derived from comets or asteroids.

The observed apparent brightness of these easily observable meteors covers the same range of brightness as the stars visible to the unaided eye (*i.e.,* from about zero to fifth astronomical magnitude). They constitute a portion of an Earth-impacting interplanetary flux of similar bodies ranging in mass from less than one nanogram up to millions of tons. The smaller bodies are too faint to be seen with the naked eye but are observable with the aid of binoculars and telescopes or by radar reflection. Brighter meteors—of magnitudes ranging in brightness from that of Venus (−4 magnitude) to greater than that of the Full Moon—are less common but are not really unusual. These are produced by meteoroids with masses ranging from several grams up to about one ton.

The brightest meteor (possibly of cometary origin) for which historical documentation exists struck on June 30, 1908, in the Tunguska region of central Siberia and rivaled the Sun in brightness. The energy delivered to the atmosphere by this impact was roughly equivalent to that of a 10-megaton thermonuclear explosion and caused the destruction of forest over an area of about 2,000 square kilometres. The geologic record of cratering attests to the impact of much more massive meteoroids, including objects with kinetic energies equivalent to 100,000,000 megatons. Fortunately, impacts of this magnitude occur only once or twice every 100,000,000 years. It is hypothesized that large impacts of this kind may have played a major role in determining the course of biologic evolution by causing simultaneous mass extinctions of many species of organisms, possibly including the dinosaurs some 65,000,000 years ago. If so, the replacement of reptiles by mammals as the dominant land animals, the eventual consequence of which was the rise of the human species, would be the result of a grand example of a phenomenon observable every clear night.

Heights and velocities

The visibility of meteors is a consequence of the high velocity of meteoroids in interplanetary space. Before entering the region of the Earth's gravitational influence, their velocities range from a few kilometres per second up to as high as 72 kilometres per second. As they approach the Earth, within a few Earth radii, they are accelerated to even higher velocities by the planet's gravitational field. As a consequence, the minimum velocity with which a meteoroid can enter the atmosphere is equal to the Earth's escape velocity of 11 kilometres per second. Even at this minimum velocity, the kinetic energy of a meteoroid would be 6×10^4 joules per gram of its mass. This can be compared with the energy of about 4×10^3 joules per gram produced by chemical explosives, such as TNT. As the meteoroid is slowed down by friction with atmospheric gas molecules, this kinetic energy is converted into heat. Even at the low atmospheric density at altitudes of 100 kilometres (6×10^{-10} gram per cubic centimetre compared with 10^{-3} gram per cubic centimetre at sea level), this heat is sufficient to vaporize and dissociate and ionize the surface material of the meteoroid and dissociate and ionize the surrounding atmospheric gas as well. Electronic transitions effected by this excitation of atmospheric and meteoroidal atoms produce a luminous region, which travels with the meteoroid and greatly exceeds its dimensions. At deeper levels in the atmosphere, a shock wave may be produced in the air ahead of the meteoroid. This shock wave interacts with the solid meteoroid and its vapour in a complex way. About 0.1 to 1 percent of the original kinetic energy of the meteoroid is transformed into visible light.

Ablation and fragmentation

This great release of energy destroys meteoroids of small mass—particularly those with relatively high velocities—very quickly. This destruction is the result both of ablation (the loss of mass from the surface of the meteoroid by vaporization or as molten droplets) and of fragmentation caused by aerodynamic pressure that exceeds the crushing strength of the meteoroid. For these reasons, numerous meteors end their observed flight at altitudes above 80 kilometres, and penetration to as low as 50 kilometres is unusual. Nevertheless, some meteoroids survive to much lower altitudes due to a combination of relatively low entry velocity (< 25 kilometres per second), large mass (> 100 grams), and fairly high crushing strength (>10^7 dynes per square centimetre). Those that are recoverable as meteorites lose their kinetic energy before the meteoroid is completely destroyed. They are effectively stopped by the atmosphere at altitudes of five to 25 kilometres. Following this atmospheric braking, they begin to cool, their luminosity fades, and they fall to the Earth at low terminal velocities of 100 to 200 metres per second. This "dark flight" of the meteoroid may be several minutes in duration, in contrast to the few seconds of visible flight.

The passage of meteoroids through the atmosphere produces atmospheric shock waves that penetrate to the ground. The penetration of a meteoroid in the kilogram range to altitudes of about 40 kilometres can thereby produce sounds on the ground similar to sonic booms or thunder. Sometimes these sound waves are intense enough to become coupled to the ground and be recorded by seismometers.

The effect of the final impact with the ground of meteorites in the kilogram mass range could be considered an anticlimax. The fall can go unnoticed by those near the impact site, the impact being signaled only by a whistling sound and a thud. For this reason, many meteorites are recovered only because at least one fragment of the meteoroid strikes a house, drawing the attention of the residents to an unusual event.

Orbits of meteoroids and meteor showers. Prior to entering the gravitational field of the Earth, a meteoroidal body, like all bodies of the solar system, moves around the Sun in an elliptic Keplerian orbit. If this orbit can be determined, valuable information relevant to identifying the source—the parent body—of the meteoroid can be obtained.

When the coordinates in the sky of the trajectory of a meteor are observed from two or more well-separated stations, the direction in which the meteoroid was moving in space before it encountered the Earth can be estimated reasonably well by triangulation. This direction is called the radiant of the meteor. If the motion of the meteoroid is thought of as a velocity vector, such observations determine approximately the direction of this vector. To determine the meteoroid's orbit, however, requires ascertaining not only the direction but also the magnitude of the velocity vector. Although well-trained visual observers are able to estimate the coordinates of the meteor trajectories and thereby determine radiants fairly well, their velocity estimates have proved to be too uncertain to be useful for orbit determination.

This problem was overcome during the 1940s by the introduction of astronomical cameras specially designed for studying meteors. These wide-field cameras were equipped with a rotating shutter that periodically interrupted the light to the photographic plate. The shutter breaks permitted calculation of the speed of a meteor along its path. The position of the meteor's trajectory with respect to the stars photographed on the same plate also was measured accurately. Such observations made at two or more stations could then be used to calculate precisely the orbit of the meteoroid before it encountered the Earth. During the 1940s, special radar instruments also were applied to the study of meteors generally fainter than those observed photographically.

adiants
ˆ shower
ıeteors

"Showers" of meteors have been known since ancient times. On rare occasions, these showers are very dramatic, with thousands of meteors falling per hour. More often, the background hourly rate of roughly five observed meteors increases up to about 10–50. Shower meteors characteristically have nearly the same radiant. This means they are all moving in the same direction in space. As a consequence, plots of meteoroid trajectories on a star map converge at a single point, the radiant, for the same reason that parallel railroad tracks appear to converge at a distance. The new photographic data fully confirmed the belief that meteors belonging to a particular shower had not only the same radiant but similar orbits as well. In other words, the meteoroids producing the meteor showers move in confined streams around the Sun. The introduction of radar observation led to the discovery of several new meteor streams that were totally invisible to cameras because they came from radiants in the daytime sky.

A fact of great importance, fully confirmed by the photographic data, is the association of many meteor streams with the orbits of observed comets. A list of the more important meteor-stream orbits and associated comets is given in Table 27. The streams with cometary associations represent debris ejected from a comet along its orbit through space. A recently formed stream, the Leonids, tends to appear in great strength every 33 or 34 years, the same as the period of the parent comet, Temple-Tuttle. These meteoroids are clustered in a compact swarm moving in the orbit of the comet. With the passage of 1,000 years or so, the slightly different orbits of the meteoroids will cause them to disperse more uniformly along the orbit of the comet. In such cases, a shower, usually weaker, occurs annually when the Earth's orbit intersects the orbital plane of the meteor stream. After a still longer period, about 10,000 years, planetary perturbations will cause the orbits of the stream meteoroids to disperse into different orbits, and their identity as members of a stream will gradually disappear.

Sporadic meteors

Meteors that do not appear to belong to streams are called sporadic. It is likely that in some sense all meteoroids are, or have been, stream members because the physical processes that release meteoroids from either comets or asteroids do so in great numbers. Sporadic meteors are therefore the result of streams too weak to be distinguished from one another or old streams so dispersed as to be no longer recognizable.

There is one rather strange example of a major meteor shower that is clearly identifiable with an astronomical object that, at least at first glance, does not appear to be a comet: the Geminid shower and 3200 Phaeton, respectively. The latter (formerly designated 1983TB) exhibits none of the usual cometary features, a nebulous halo and tail; it simply looks like a small Earth-crossing asteroid. If the stream is cometary, it means that a comet that produced meteoroids prolifically only a few thousand years ago has now completely ceased its cometary activity and looks more like an asteroid. The orbits of 3200 Phaeton and the Geminids also are unlike those of comets in that their aphelia are at 2.4 a.u., well within the orbit of Jupiter. If 3200 Phaeton came from the Oort cloud of comets (see above), it must at one time have crossed the orbit of Jupiter. Over a span of million of years, it is not out of the question that close encounters with the Earth and Venus could gravitationally perturb a Jupiter-crossing orbit into an orbit of this kind. The observed rate at which matter is lost from comets, however, seems to indicate that their inventory is exhausted in only a few thousand years. Thus, the millions of years required for this orbital evolution does not appear to have been available.

It could be hypothesized that 3200 Phaeton was never a comet at all but simply an Apollo object that strayed from the asteroid belt by the reasonably well-understood resonant perturbations that can cause this to occur. The Geminid meteors would then be explained as fragments produced by an asteroidal collision while 3200 Phaeton is traversing the portion of its orbit that is in the asteroid belt. There are serious problems with this explanation. Quantitative calculations show that an asteroidal collision of the required magnitude during an interval of only a few thousand years is very unlikely. Studies of the historical orbital evolution of the Geminid stream suggest that its orbit is incompatible with a single outburst of meteoroids; it is more like one expected from a body that produced a series of outbursts. Finally, the orbit is not the kind one would expect for an Apollo object perturbed from the asteroid belt. Its perihelion is too close to the Sun. An understanding of the mystery of 3200 Phaeton and the Geminids is likely to contribute much to the understanding of comets, the origin of meteor streams, and the relationship between Apollo objects, comets, and asteroids.

Fireball networks. A very significant development in meteor science occurred during the 1960s. This was the establishment of large-scale networks for photographing very bright meteors, or fireballs. These networks were designed to provide all-sky coverage of meteors over areas of about 10^6 square kilometres. Three such networks were developed: the Prairie Network in the central United States, the MORP (Meteorite Observation and Recovery

Table 27: Principal Visually Observable Meteor Showers

shower	average date of maximum	normal duration (days)	visual strength (Northern Hemisphere)	entry velocity (km/sec)	associated comet
Quadrantid	January 3	1	medium	41	not known
Lyrid	April 22	1	irregular	48	1861 I (Thatcher)
Eta Aquarid	May 3	5	weak	66	Halley
S. Delta Aquarid	July 29	8	medium	41	not known
Capricornid	July 30	3	medium	23	not known
Perseid	August 12	5	strong	59	Swift-Tuttle

Project) network in the prairie provinces of Canada, and the European Network with stations in Germany and Czechoslovakia. The most complete set of published data is that of the Prairie Network, which was operated by the Smithsonian Astrophysical Observatory from 1964 to 1974.

Principal objectives of the networks

An original goal of these networks was to recover a larger number of meteorites for laboratory studies. Other objectives were to determine the orbits of the recovered meteorites and to compare the inferences of meteor theory regarding the density and strength of meteoroids with "ground truth" provided by the study of the same meteoroids in the laboratory. The goal of recovering meteorites had only limited success. Three meteorites were recovered, one by each of the networks. All three meteorites were ordinary chondrites, the most abundant type of stony meteorite. During the operation of the networks, many more meteorites were actually recovered by chance collisions with the roofs of houses.

In spite of this meagre record for meteorite recovery, the networks compiled data that became the basis for a new outlook on meteor science and meteoroid sources. Prior to this effort, there was a tendency to regard the study of meteors and meteorites as independent scientific fields that had little to contribute to each other. Meteors were studied by astronomers and were thought to be associated almost entirely with fragile and low-density "dust balls." On the other hand, meteorites were dense rocks studied by geochemists in the laboratory as samples of the primordial solar system. Little thought was given to why meteor astronomers did not concern themselves with meteorites.

Straightforward application of conventional meteor physics to determine the density of the three recovered meteorites led to the incorrect conclusion that these dense rocks were also low-density objects. This clearly showed that there was something wrong with meteor physics as traditionally applied. A likely, but still not proven, explanation was that the value of luminous efficiency, conventionally used to relate the mass of a meteoroid to the brightness of a meteor, was too low. As a result, the mass of the meteoroid calculated from the luminosity of the meteor was too high. When this large "photometric" mass was combined to measure the cross-sectional area of the meteoroid (using the rate at which it was observed to slow down by atmospheric gas drag) and thereby its radius and volume, a spuriously low density was obtained.

Impact of photographic data on meteor studies

The photographic data from the three fireballs recovered by the networks permitted a more direct empirical approach to the analysis of meteor data. It was found that the atmospheric trajectories of the recovered meteorites, including the end height at which they ceased to be luminous, could be accurately reproduced if the "dynamic mass," determined by the deceleration of the meteor, were used in the theory instead of the photometric mass. It also was found that the ratio of the photometric mass to the dynamic mass was a constant. Laboratory measurements of cosmic-ray effects on the recovered meteorites led to a calculation of the "true mass," which was intermediate between the photometric mass and the dynamic mass. Finally, the light curve (the plot of brightness versus altitude) was similar for the three meteorites.

These results, obtained from the recovered meteorites, could then be used to identify similar objects in the other fireball photographs. Their presence certainly could be expected, because meteorites are produced by fragmentation processes in space similar to those studied in the laboratory. Both experimental and theoretical studies of these processes demonstrate that for every large fragment there must be many small ones.

The recovered fireballs were among the very brightest observed by the photographic networks. Accordingly, there were among the fireball data many objects physically identical to the recovered meteorites. In short, the problem of determining which fireballs were meteorites no longer was dependent on uncertain first principle measurements of density. The empirical data obtained from the recovered meteorites could be used to check the record of each individual fireball, testing quantitatively whether or not the object "looked like a meteorite."

To date, about 30 fireballs have been identified as stony meteorites in this way. The adoption of this approach has increased scientific knowledge of the distribution of meteorite orbits by an order of magnitude.

Application of the same method of analysis shows that fireballs from the Taurid shower, associated with Comet Encke, do not look like meteorites, or at least not like ordinary chondrites. On the other hand, they do not resemble dust balls either but appear to have significant physical strength. The stronger objects of this group have a strength comparable to that of ordinary dirt clods. These physical properties overlap with those of some carbonaceous meteorites. Further analysis of existing data can be expected to shed new light on important questions regarding the relationships between meteoroids of various kinds and their sources. If some way could be found to increase the rate at which fireball networks recover meteorites by about an order of magnitude, the empirical approach, proved valuable for identifying ordinary chondrite sources, could be extended to include less abundant types of meteorites.

METEORITES

As noted above, meteorites are meteoroids that survive passage through the Earth's atmosphere. Any source that can eject such material into interplanetary space should therefore, at least in principle, be thought of as a candidate source of meteorites. There is no fundamental reason why all meteorites must come from similar sources.

Asteroidal origin of most meteorites

It turns out, however, that in practice there are some regions in the solar system that are much more effective in introducing material of substantial strength into Earth-crossing orbits than others. Recent laboratory and theoretical studies fully confirm the older belief that most meteorites are fragments of asteroids. These same studies show that a small fraction, less than 1 percent of the meteorites, come from nonasteroidal sources. The lunar origin of several meteorites is well-established, and it is probable that at least eight others come from Mars. There is evidence from fireball data that a small part of the material in cometary orbits (*i.e.,* with aphelia beyond Jupiter) may possess sufficient strength to successfully penetrate the atmosphere. It is not known if any of this material is present in existing meteorite collections. If it is, the best candidate material would be carbonaceous stony meteorites, probably those of type CI (see below), of which five separate falls have been recovered.

With these few exceptions, it is safe to regard all meteorites as samples broken from outcrops of rock or metal, which until fairly recently in solar-system history were part of asteroidal bodies, mostly in the inner region of the asteroid belt (between about 2.2 and 2.6 a.u.). Like rocks from the Moon, the Earth, or any other similar planetary body, their present state is determined by the total effect of events that occurred on the body throughout the entire history of the solar system. There is no a priori reason why such samples must be pristine samples of a primordial solar nebula from which the present solar system evolved. On the other hand, the principal driving force behind asteroid studies has been the plausible belief that small "primitive" bodies such as asteroids and comets are those most likely to preserve evidence of events that took place in the early solar system. Insofar as this belief is correct, meteorites, samples of these bodies, share this property. Evidence derived from the study of meteorites themselves supports this conclusion.

Types of meteorites. The most fundamental distinction between the various meteorites—no two of which are exactly alike—is the division between chemically undifferentiated and differentiated meteorites. This concept arises from the fact that there is an average chemical composition of the solar system. This average composition must be very close to the composition of the Sun, because the Sun contains most of the mass of the solar system. Spectroscopic comparison of the Sun's chemical makeup with those of other stars shows that its composition in turn is closely related to a cosmic average of the relative abundances of the elements. Important deviations from such average abundances are observed, but these do not invalidate the view that they are deviations from normal abundance ratios determined by the processes by which the chemical elements are formed in stars at various stages of their evolution, returned to the interstellar medium where they are mixed, and then incorporated into new stars and their planetary systems when they are formed.

Since the late 1940s, important advances have been made in the chemical analysis of both meteorites and the Sun. A remarkable result has emerged from this work. Although at one time there appeared to be major differences between the Sun and typical meteorites in the ratios of elements to one another (*e.g.*, iron to silicon), these differences tended to disappear as the accuracy of the measurements improved. It turned out that, for most meteorites and most elements, the solar and meteoritic values of the element ratios relative to silicon (taken as a standard) agreed to within better than a factor of two.

3asic ıgreement ›etween he mete›ritic and olar abunlances ›f the lements

Two kinds of exceptions to this rule were found. Relative to the Sun, the meteorites were deficient in the more volatile elements. For the most volatile elements, hydrogen and the noble gases, the deficiencies were gross—more than a factor of 10^4. For less volatile elements, the deficiencies were smaller; and for the nonvolatile elements, or "refractory" elements, such as iron, magnesium, aluminum, and calcium, the meteoritic and solar abundance ratios were identical within the accuracy of the data.

The other kind of exception to the rule relates to differences between meteorites. For some meteorites, as, for example, those consisting primarily of metallic iron, the similarity between meteoritic and solar abundance ratios fails completely. This also is true for basaltic meteorites, those that appear to have been at one time volcanic magmas and have undergone chemical fractionation of the sort observed in terrestrial igneous rocks.

Undifferentiated meteorites. The meteorites that do obey the rule prove to be of a kind that had already been grouped together on textural grounds—namely, the chondrites. From observed fall rates, this is the most abundant type of meteorite (Table 28). The designation chondrite is based on the occurrence in these meteorites of small (about one millimetre in diameter) spherules called chondrules (Figure 54). In many chondrites, the composition of the chondrules is quite heterogeneous, and the space between the chondrules is filled with a fine-grained matrix material that is richer in volatile elements. In terms of terrestrial rocks, these meteorites seem more akin to sedimentary conglomerates composed of a mechanical mixture of a jumble of components rather than to rocks formed by a process of igneous differentiation.

Not all chondrites contain chondrules of heterogeneous composition. More often, the mixture of heterogeneous chondrules and matrix appears to have undergone a thermal metamorphism that caused the chemical components of the chondrules to come into equilibrium with one another and with the matrix material. This metamorphism was accompanied by the loss of relatively volatile elements. All of these chondrites share one common property: they do not appear to have ever experienced chemical differentiation associated with igneous melting. This shared property is the basis for grouping them all as undifferentiated meteorites even though they clearly differ from one another in the degree to which they have retained volatiles and in various other ways.

Undifferentiated meteorites are classified in two complementary ways. Based on their major element concentrations (Fe, Mg, O), carbon content, and abundance of chondrules, these meteorites naturally cluster into the distinct classes shown in Table 28. In addition, within each of these classes, the meteorites differ according to the degree that they have been thermally metamorphosed or experienced loss of volatile elements. This difference is referred to as the petrologic type (Table 29). For example, the Allende carbonaceous chondrite (Figure 51, top right) is classified CV3, indicating that it belongs to group CV (Table 28) and petrologic type 3 (Table 29).

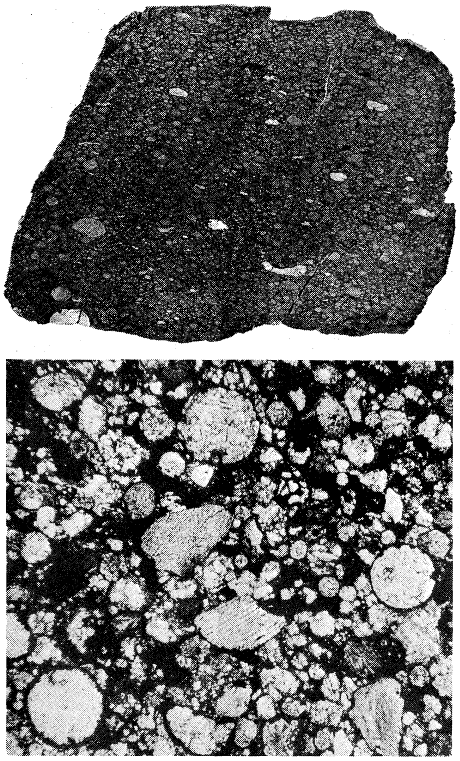

Figure 54: (Top) Sawed and polished section of the Leoville carbonaceous chondrite (CV3; reduced 2.3 X). The small, rounded gray objects are chondrules. The larger, whitish objects are refractory inclusions, similar to those seen in Allende (Figure 51, top right). (Bottom) Microscopic view of a thin section of the Tieschitz (Czechoslovakia) ordinary chondrite (olivine-bronzite H3). The round objects are chondrules, some of which have been fractured by collisions after their formation.

ifferences :tween .ondrite pes

Chondrites obviously differ from one another in several important respects. As has been pointed out, they vary in the extent to which they have undergone thermal metamorphism. Another important distinction is between the more abundant ordinary chondrites (of which there are three principal kinds) and the rarer chondritic meteorites that exhibit significant chemical differences. One of these types is the enstatite chondrite, which is, among other things, chemically more reduced than the ordinary chondrites. Almost all of the iron in these meteorites, for example, is in metallic form. As a result, most of the abundant silicate mineral, pyroxene, is present as nearly pure enstatite ($MgSiO_3$) rather than in magnesium-iron solid solution minerals, such as bronzite and hypersthene, found in the ordinary chondrites. In enstatite chondrites, the readily oxidized element silicon is even found in the reduced state, and calcium occurs as the sulfide mineral oldhamite (CaS) rather than in its more usual silicate forms.

Other very important varieties of chondrites are grouped together as the carbonaceous chondrites. As their name implies, they characteristically contain more carbon (0.5 to 5 percent) than the ordinary chondrites (only about 0.1%). The mineral constituents of the carbonaceous chondrites are less chemically equilibrated with one another than even the unequilibrated ordinary chondrites. In many cases, one finds in the same meteorite carbonaceous material that formed at low temperatures and inclusions of the most refractory minerals—perovskite ($CaTiO_3$), hibonite ($CaAl_{12}O_{19}$), and melilite (solid solutions of $Ca_2Al_2SiO_7$ and $Ca_2MgSi_2O_7$).

CI carbonaceous chondrites

Perhaps the most interesting type of meteorite is the CI carbonaceous chondrite. Strictly speaking, one could legitimately question why such meteorites are called chondrites at all inasmuch as they do not contain chondrules. When compared with solar abundances (Figure 55), however, it turns out that they are the least differentiated meteorites of all, and in making a classification scheme it certainly makes sense to group them with the other undifferentiated meteorites. In accordance with the correlation already observed between chemical undifferentiation and

Table 28: Classification of Undifferentiated Meteorites (Chondrites)

class	group	percentage of observed chondrite falls	total iron (weight %)	Fe—metal / Fe—total (%)	FeO / (FeO + Mg) (mole %)	chondrules (%)	carbon (weight %)

chemical disequilibrium, the constituents of CI carbonaceous chondrites are far from equilibrium. The iron in these meteorites, for example, is highly oxidized, most of it occurring in the ferric iron-bearing mineral magnetite (Fe_3O_4). At the same time, carbon is present as highly reduced complex hydrocarbons. In equilibrium, the carbon would be oxidized to carbon monoxide and carbon dioxide, and the iron would be reduced to metallic iron.

Because CI chondrites are the most undifferentiated meteorites known, it has been speculated that, unlike most meteorites, they are of cometary rather than of asteroidal origin, since comets are believed to represent the most unaltered material in the solar system. There are difficulties in accepting this speculation as being correct. For example, detailed study of these meteorites shows that, in spite of their chemically undifferentiated and unequilibrated nature, they have had a complex chemical and physical history and are not simply a collection of interstellar dust. On the other hand, scientific knowledge about the nature and origin of comets is still limited, so that it would be unwise to dismiss this intriguing hypothesis prematurely.

Differentiated meteorites. Differentiated meteorites exhibit the type of chemical fractionation one would expect to occur on a planetary body that underwent core formation and magmatic differentiation similar to that observed in terrestrial and lunar volcanic rocks. Indeed, at one time it was thought likely that the most abundant type of differentiated stony meteorite, the basaltic achondrites, were actually lunar mare basalts. Their similarities to the lunar basalts subsequently returned by the Apollo missions showed that this was by no means a farfetched idea, but detailed considerations such as oxygen isotope ratios showed that it was not correct.

Iron mete- orites and achondrite

In classifying differentiated meteorites, the major division is made between the iron meteorites and the stony differentiated meteorites, the achondrites ("not chondrites"). In addition, there are a number of stony-iron meteorites that contain mixtures of large masses of nickel-iron metal and

Table 29: Classification of Undifferentiated Meteorites in Terms of Petrologic Type and Metamorphic Grade*

	petrologic type					
	1	2	3	4	5	6

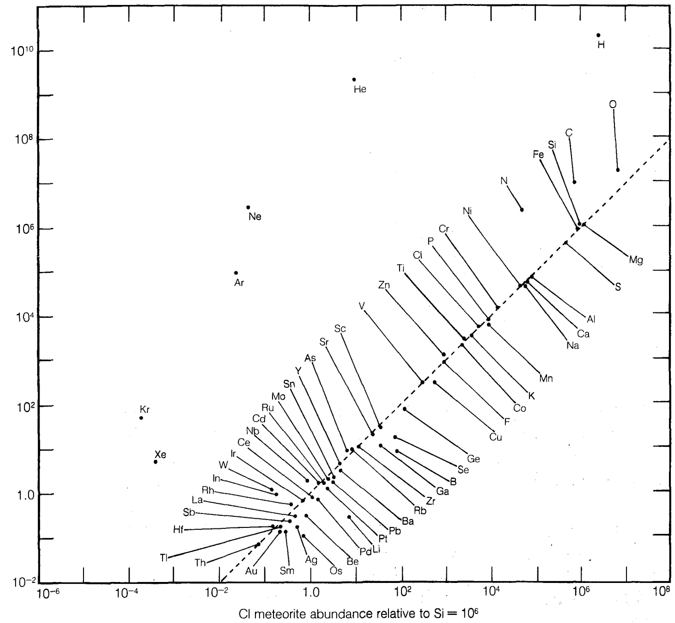

Figure 55: *Comparison of solar and meteoritic carbonaceous chondrite (CI) abundances of elements (relative to silicon = 10^6).* For most elements, the solar and meteoritic abundances are very similar and therefore fall near a line with a slope of 45°. For the most volatile elements (hydrogen, noble gases, carbon, nitrogen, oxygen), the meteorites are highly depleted relative to the solar composition.

Based on data from *Meteorites: Their Record of Early Solar-System History* by John T. Wasson, W.H. Freeman and Company, 1985, and B. Mason, *Handbook of Elemental Abundances in Meteorites* (1971), Gordon and Breach, Science Publishers, Inc.

differentiated silicate rock. The usual classification scheme for differentiated meteorites is given in Tables 30 and 31.

There are compelling reasons for believing that, like the chondrites, all differentiated meteorites, with the exception of those few from the Moon and possibly Mars, are asteroidal fragments. Because asteroids are too small to have experienced the accretional and long-lived radioactive heating that powers igneous processes on the inner planets, this may seem surprising. A partial solution to this enigma comes from radiometric dating, which shows that this differentiation took place very early in the history of the solar system, about 4,500,000,000 years ago. At that time other heating mechanisms may have been available—*e.g.,* heating by short-lived radioactive isotopes such as aluminum-26 (which has a half-life of about 700,000 years) or inductive heating by intense solar activity. It is even possible that asteroids from which differentiated meteorites seem to be derived are fragments of much larger differentiated planetesimals originally present in the inner planet region during the development of the Earth and Venus and which were stored in quasi-stable orbits in the innermost asteroid belt (2.2 a.u.) of the early solar system.

Specific asteroidal source regions for recovered meteorites. There is compelling, even if circumstantial, evidence that nearly all meteorites are derived from the asteroid belt. For scientific understanding of this matter to be complete, it is necessary to know which asteroids are the sources of particular types of meteorites and the mechanisms by which meteorites are transported from the asteroid belt to Earth. It is possible that the ultimate answer will not be found until asteroids are explored by spacecraft. Nevertheless, considerable information relevant to this question is already available.

Orbits of Earth-impacting ordinary chondrites

For the most abundant meteorite type, the ordinary chondrites, there is a fairly large body of evidence that indicates that most of these meteorites strike the Earth while traveling in a rather special type of orbit. Such an orbit has its perihelion just inside the Earth's orbit, as well as low inclination (less than about 10°) and fairly high eccentricity (about 0.6). This has been determined on the basis of the time of day during which meteorites are observed to fall. It has been noted that about twice as many ordinary chondrites fall during the daylight PM hours as during daylight hours before noon. This fact requires that the meteorite must be moving faster than the Earth at the time of impact and, therefore, must be near its perihelion according to Keplerian dynamics. Quantitative consideration of the implications of time of fall data is entirely consistent with evidence obtained by visual observations of meteorite radiants and with about 30 fireballs identified by the Prairie Network as being, at least physically, equivalent to stony meteorites (see above).

This distribution of orbits places strong constraints on the source region in the asteroid belt from which ordinary chondrites can be derived. If meteorites in the kilogram mass range are to be derived directly from the asteroid belt, the mechanism by which they are extracted from the belt and transferred to an Earth-crossing orbit must operate quite rapidly on a time scale of a few million years. Only then can a meteoroid escape destruction by collision while near its aphelion in the asteroid belt. This collisional lifetime is not simply a theoretical result but is measured directly by the cosmic-ray exposure ages of meteorites, as discussed below.

High-energy galactic cosmic rays—primarily protons—have a range of penetration on the order of a few metres in meteoritic material. Any meteoroid of smaller dimensions will be radiated throughout by this proton bombardment. The high-energy protons cause spallation reactions (nuclear interactions that result in the release of many nucleons) on the abundant elements in the meteoroidal target. As a consequence, a large number of otherwise rare isotopic

*Differentiated meteorites of this type consist principally of nickel-iron metal and iron sulfide; they make up 4 percent of all meteorite falls. The classification given here is structural. Another classification is based on the trace element concentrations of iron meteorites, particularly gallium, germanium, and iridium. This classification tends to group the same meteorites that are grouped in the structural classification, but the grouping is not exactly the same. For either classification, a significant number (10–15 percent) of meteorites do not fit well and must be classified "anomalous."

Cosmic-ray exposure age

species, both stable and radioactive, are produced. These include the stable noble gas isotopes helium-3, neon-21, and argon-36, as well as the rare isotope potassium-40 and various short- and moderately long-lived radioactive isotopes, including hydrogen-3 (with a half-life of 12.26 years), beryllium-7 (53.29 days), beryllium-10 (1.6×10^6 years), aluminum-26 (7.2×10^5 years), manganese-53 (3.7×10^6 years), and cobalt-60 (5.272 years). The concentration of the shorter-lived radioactive isotopes can be used to monitor the cosmic-ray bombardment rate, and the accumulation of the stable species (*e.g.,* neon-21) measures the time in the past that this bombardment began—*i.e.,* the time that the meteoroidal fragment was separated from a larger object, that was large enough to have shielded it from cosmic-ray bombardment. For chondritic meteorites, the distribution of cosmic-ray exposure age falls off quite quickly with age. This is to some extent a consequence of the dynamic evolution of the meteoroid orbits but for the most part should be attributed to a "collision half-life" of 5,000,000 to 10,000,000 years.

Mechanisms by which meteorites are transported into Earth-crossing orbits

There are only two processes known that can accelerate meteoroidal fragments into Earth-crossing orbits on this short time scale given by cosmic-ray exposure ages. These processes are direct collisional ejection at velocities of about five kilometres per second and gravitational acceleration by dynamic resonances in the asteroid belt, of which the 3:1 resonance at 2.5 a.u. is of dominant importance. In a hypervelocity collision, some material is ejected at the required high velocity, but the quantity of this material is small and most of it is pulverized by the associated shock pressures. High-velocity ejection is likely to be responsible for the occurrence of meteorites from Mars or the Moon, but it completely fails to provide the observed quantity of meteoroids from the asteroid belt. The resonant mechanisms are therefore of much greater importance. Bodies orbiting the Sun with a semimajor axis near 2.5 a.u. will complete three revolutions about the Sun in the time that Jupiter, a strong source of gravitational perturbations, executes one revolution. The resulting resonant acceleration will cause the orbit of the body to become "chaotic," and its perihelion will become Earth-crossing in about 1,000,000 years.

The calculated quantity of asteroidal material in the meteorite-size range delivered to the Earth from the 3:1 resonance agrees well with the 10^8 gram per year terrestrial impact rate of ordinary chondritic meteoroids. Moreover, this resonant acceleration presents a natural mechanism for concentrating meteoroid perihelia near the Earth's orbit, thereby explaining the special distribution of orbits observed for ordinary chondrites. In fact, as it turns out, meteoroids derived by this resonance acceleration mechanism should be overly concentrated near 1 a.u.; the ratio of afternoon to morning falls should be about 3:1 instead of the observed 2:1. This discrepancy is removed when one takes into account the fact that larger asteroidal fragments (those reaching the size of Apollo objects) will also be accelerated into an Earth-crossing orbit by the same resonant mechanism. Meteorite-sized fragments will be produced as collision debris from these larger bodies, but they will not have the special distribution of orbits exhibited by the smaller asteroidal fragments introduced more directly into Earth-crossing orbits. When the contribution from resonant asteroidal ejecta over the entire size range is averaged, the predicted and observed orbital distribution match rather well.

Orbital statistics are not very well known for other meteorite types. It does appear that the differentiated basaltic achondrites fail to share the special orbital distribution observed for the ordinary chondrites. Basaltic achondrites are most likely the collision debris of Apollo objects that were extracted by another resonance mechanism known to operate in the innermost belt; this mechanism can be shown to be effective only in providing larger Earth-crossing bodies. Although more work remains to be done on this problem, it seems likely that known resonant mechanisms are adequate to explain the dynamical processes by which all classes of meteorites are delivered from their asteroidal source regions into Earth-crossing orbits.

Derivation of meteoritic material from these designated regions of the inner asteroid belt implies that asteroids in such regions have the chemical and mineralogical composition observed in the meteorites. The surface mineralogical composition of asteroids can be determined directly by Earth-based reflectance spectrometry. These measurements have been made for most of the larger asteroids. Although no two reflectance spectra are exactly alike in detail, most asteroids fall into one of two general groups, the S class and the C class. The S-class asteroids have moderate albedos (though comparatively high overall) and contain mixtures of olivine (magnesium, iron silicates), pyroxene (silicates containing magnesium, iron, calcium, and aluminum), and metallic iron. These are the same minerals found in ordinary chondrites and in basaltic achondrites. The C-class asteroids have low reflectance, and their more featureless spectra indicate the presence of light-absorbing opaque minerals. It is plausible to consider these asteroids as candidate sources for carbonaceous meteorites.

Chemical and mineralogical similaritie between the major classes of asteroids and meteorite

When considered in more detail, there are certain difficulties in identifying the required number of S-class asteroids as ordinary chondrite sources. Although qualitatively the mineralogy of these asteroids agrees with that of ordinary chondrites, the proportions of the constituent minerals to one another does not match as well. In particular, the S-class asteroids appear to have, at least on their surfaces, about twice as much metallic iron as the ordinary chondrites. The solution to this discrepancy is not known at present. It may be that the surfaces of the asteroids are not truly representative of their interiors, having been altered by collisional bombardment or exposure to solar radiation and particles. Another possibility is that a systematic change in mineralogical composition occurs during the process of collisional grinding of asteroids into ever-smaller bodies, ultimately to those of meteorite size. There is some indication that the discrepancy is less serious for small asteroidal fragments observed as Apollo objects, which is consistent with this hypothesis.

Meteorites, asteroids, and the early solar system. A prime long-range objective of exploring the Moon and planets by spacecraft is to collect samples of these bodies for detailed laboratory study. With the few exceptions noted earlier, meteorites are samples of asteroids delivered to Earth by fairly well-understood natural mechanisms. It also is believed that samples collected from asteroids will prove especially valuable, because such small bodies are most likely to be "primitive" and thus retain the record of events that occurred during their own formation and that of the solar system in general. The study of meteorites is already providing scientists with much valuable information directly related to this matter.

Isotopic records. Meteorites indicate to investigators that the asteroid belt must always have been a relatively tranquil region of the solar system. Some unequilibrated chondrites have inherited and preserved without complete mixing the remnants of presolar interstellar grains. This is demonstrated by variations of the ratios of the oxygen isotopes oxygen-16, oxygen-17, and oxygen-18 within a single meteorite and between different meteorites. It is well known that the oxygen isotopes are fractionated by natural chemical processes. Variations in the ratio of oxygen-18 to oxygen-16, for example, form the basis for paleotemperature studies of ancient terrestrial sedimentary rocks by making use of the temperature dependence of the isotopic chemical equilibrium between seawater and the calcium carbonate that forms the shells of marine organisms. It is characteristic of this natural fractionation dependent on isotopic mass that the degree of fractionation is proportional to the difference of the masses of the isotopes. Thus, in these marine sediments, the variation in the ratio oxygen-18 : oxygen-16 is twice that of oxygen-17 to oxygen-16. In some unequilibrated chondrites, however, the variations in the oxygen-18 to oxygen-16 ratios are equal to those in oxygen-17 : oxygen-16. It is possible to devise special chemical processes that could produce fractionation of this kind, but it is much more likely that the variations found in the meteorites are caused by nuclear processes that predated the formation of the Sun and solar system. The interstellar grains that were the carriers of these isotope anomalies were probably formed in stellar atmospheres and preserved the signatures of the isotope-formation processes of stars of particular types. These isotopic variations of nuclear origin are found not only in oxygen but also in other less abundant elements, including neon, xenon, titanium, and chromium.

Probable early evolution of the solar system based on meteoritic evidence. The need to provide an environment sufficiently tranquil to preserve this isotopic record, as well as other fragile relics of early solar system events observed in meteorites, places important constraints on the formation of the solar system. If one examines the distribution of matter in the present solar system, it is seen that the density is high both in the region of the inner planets and in the region of the giant planets in the outer solar system but very low in the wide space between Mars and Jupiter. This fact itself is surprising: Why should the solar nebula from which the solar system formed have had a great hole in it? The answer is that it probably did not. In order for asteroids to have formed and developed at all on the time scale of a few million years indicated by the radiometric dating of meteorites, densities more like those in the regions occupied by the giant planets would have been required, as shown by theoretical calculations. It is difficult to escape the conclusion that the quantity of matter in what is now the asteroid belt must have been much greater, perhaps by as much as 10^4 times as is observed there today. Therefore some natural process has to have removed almost all of the material in this region of the solar system after the formation of asteroidal bodies, but in a sufficiently gentle way to have preserved the relics of pre-solar and early solar events found in meteorites.

Although the details are not yet understood, it seems most likely that the formation of the giant planets, particularly Jupiter, quickly resulted in the evacuation of most of the matter from this region of the solar system. This means that Jupiter formed rapidly, before bodies in the asteroid belt had grown to become full-fledged planets. The mineralogical and chemical record of the undifferentiated meteorites is not compatible with their once having been part of a planet even as large as the Moon. Also, the very energetic collisional events that would be associated with the dispersal of large planets in the asteroid belt would preclude preservation of the observed relics.

Planetary
growth and
changes
in mass
distribution
in the
outer solar
system

These constraints, for the most part based on meteoritic evidence, define a conceivable chain of events for the early evolution of the solar system beyond the region of the inner planets. Even though the density of matter was at least as great in the asteroid belt as in the region of Jupiter, planetary growth must have been more rapid in Jupiter's vicinity than in the asteroid belt. (Some suggestions have been made as to how this may be possible, but it remains to be seen if they are satisfactory.) Within about 1,000,000 years, proto-Jupiter(s) began to capture the massive quantities of hydrogen and helium from the solar nebula that constitute most of the giant planet today. At the same time, thousands of large asteroids greater than 100 kilometres in diameter, including some as big as the largest present-day asteroids but not much bigger, had formed. Shortly thereafter, as Jupiter approached its present mass, most of the residual nebular gas was removed by the intense solar ultraviolet radiation characteristic of young stars.

Up until the time Jupiter approached its present mass, the asteroids moved in nearly circular orbits in accordance with the weak mutual gravitational perturbations expected for small bodies. During the final formation of Jupiter and Saturn and the removal of the nebular gas, the changing mass distribution in the outer solar system caused waves of resonant perturbations to sweep through the asteroid belt, increasing the eccentricities and inclinations of the asteroids to the moderate values observed today. Because the asteroids had not grown larger than the asteroids of today, collisions at the relative velocities of about five kilometres per second, associated with their present-day eccentricities and inclinations, would begin to grind down the smaller bodies. This would occur without the shock effects associated with disruption of larger planetary bodies at higher impact velocities.

The foregoing scenario of planetary growth is certain to be wrong in detail and may well be wrong altogether. Nevertheless, without the samples of asteroids provided by recovered meteorites, there would be little observational basis at all for formulating models of this kind. All of the qualitative statements made above should be considered not as established facts but rather as statements of theoretical problems that need to be thoroughly worked out. Their results must be compared with old and new observational data and reformulated and reworked until a satisfactory understanding of planetary formation is achieved.

Thermal evolution of the solar nebula and planetesimals. The available meteoritic evidence is relevant to many other unsolved central questions concerning the early solar system, including some that bear on the way the Sun was formed and its early history. One of these is the question of the thermal evolution of the solar nebula and the planetesimals that formed and grew within it.

As discussed above, the environment of the early asteroid belt must have been a rather "tranquil" one. By tranquil, one actually means thermally, rather than physically, uneventful. The collisions that led to the removal of most of the material from the asteroid belt were highly disruptive, and there is ample evidence of extensive physical disruption in the textures of even the most primitive meteorites. Yet, the preservation of primordial relics, such as the isotope anomalies, argues against widespread heating of the asteroidal region to temperatures as high as 1,000 K.

Low-tempera-
ture origin
of the
asteroidal
region

A relatively cool solar nebula at distances this far from the Sun is in agreement with most current theoretical calculations of the formation of the Sun. In addition to the evidence for an overall low-temperature origin for this region of the solar system, however, the meteoritic record clearly shows the imprint of high-temperature events of major importance, which are not well understood at present. The most apparent of these is the very abundant presence of chondrules in all undifferentiated meteorites except the CI chondrites. Chondrules appear to have once been melted droplets primarily of silicate composition and would have required temperatures of about 1,500 K to have formed.

Formation of chondrules

If chondrules were a relatively rare meteoritic curiosity, one could legitimately consider them an interesting detail to be explained someday but not a matter of central importance. Yet, the fact that chondrules (or their broken fragments) make up most of the mass of the most abundant class of meteorites, the ordinary chondrites, and a major portion of other chondrites, indicates that their formation must have been of major importance in the early solar system. Even if ordinary chondrites formed only within a restricted region of the asteroid belt adjacent to the 3:1 Kirkwood gap (*i.e.,* between 2.44 and 2.56 a.u.), this is still about 10 percent of the entire asteroid belt. It also is likely that other chondrule-bearing meteorites formed outside this region, even though their asteroidal sources may be in that region today.

It seems impossible that chondrules are the product of igneous differentiation because they are of nearly undifferentiated solar composition except for the most volatile elements. Nor does it seem likely that they are impact droplets, such as those found in the lunar soil. The expected low impact velocities of asteroidal planetesimals argue against a ubiquitous high-velocity impact environment. Thus, there seems to be no way by which the chondrules could have formed in or on planetesimals. In all likelihood, they were formed in the solar nebula. At the same time, the evidence for rapid cooling of chondrules argues against their formation by large-scale condensation from a very hot solar nebula. Local, transient heating events appear to have been important on a wide scale in the solar nebula, but the nature and cause of these events remain unknown.

A problem of similar difficulty is that of the origin of the large (up to more than one centimetre in diameter), highly refractory inclusions found in the CV meteorites (see Table 28), especially prominent in the Allende carbonaceous chondrites. Though not as ubiquitous as chondrules, these inclusions are by no means of negligible abundance. Unlike chondrules, they are highly fractionated chemically, apparently as a result of more prolonged heating to about 1,500 K. Because many of the isotopic anomalies are associated with these refractory inclusions, interpretation of this important evidence is limited by a poor understanding of their origin.

Evidence of internal heating in differentiated meteorites

The foregoing thermal events most likely occurred in the solar nebula rather than on growing asteroidal bodies. In addition, thermal effects are observed in meteorites associated with internal heating. The most apparent of these are the differentiated meteorites, which probably represent about 10 percent of the asteroidal region sampled. The asteroids from which these meteorites were fragmented, though probably formed from a relatively cool solar nebula, experienced internal heating, core formation, and igneous differentiation within a few million years of the formation of the solar nebula itself. Clear and detailed evidence for this is based on (1) radiometric dating of the minerals formed by this igneous differentiation, (2) the mineral assemblages of the resulting igneous rocks, and (3) the slow cooling that produced large crystals of differentiated minerals (*e.g.,* the so-called Widmanstätten structure observed in many nickel-iron meteorites). The actual process responsible for this heating is yet unknown, but several good possibilities are being evaluated. These include heating by the short-lived radioactive isotope aluminum-26, heating by electric currents induced by early solar activity, and accretional heating of planetesimals in the terrestrial planetary region, followed by fragmentation and transfer to the innermost asteroid belt.

The ordinary chondrites also experienced heating after the formation of chondritic planetesimals, but not enough to produce melting. As a result, chondritic material, presumably once resembling the unequilibrated ordinary chondrites, was metamorphosed to produce the more abundant equilibrated ordinary chondrites. The time scale for this metamorphism is, within uncertainties, the same as that which produced the parent asteroids of the differentiated meteorites. It is plausible that some of the same heat sources (*e.g.,* aluminum-26) may have been responsible. (G.W.We.)

BIBLIOGRAPHY

General works: GEORGE ABELL, *Exploration of the Universe,* 4th ed. (1982), contains chapters on the solar system written at an elementary level. Popular accounts include: F.L. WHIPPLE, *Orbiting the Sun: Planets and Satellites of the Solar System* (1981); J. KELLY BEATTY, BRIAN O'LEARY, and ANDREW CHAIKIN (eds.), *The New Solar System,* 2nd ed. (1982); and WERNHER VON BRAUN and FREDERICK I. ORDWAY III, *New Worlds: Discoveries from Our Solar System* (1979). See also issues in the University of Arizona Space Science series, including: TOM GEHRELS (ed.), *Jupiter* (1976), *Protostars and Planets* (1978), and *Asteroids* (1979); and JOSEPH A. BURNS (ed.), *Planetary Satellites* (1977). Authoritative reviews are found in *Annual Review of Earth and Planetary Sciences* and in *Annual Review of Astronomy and Astrophysics.* Most original work on the solar system is published in technical journals, including: *Icarus* (monthly); *Astronomical Journal* (monthly); and *Science* (weekly).

(R.L.Ne./G.S.O./D.C.P./Ed.)

The Sun: A large part of modern solar research is published in *Solar Physics,* a monthly journal for solar research and the study of solar–terrestrial relations. Popular works on the Sun's atmosphere include: ROBERT W. NOYES, *The Sun, Our Star* (1982); G. GAMOW, *The Birth and Death of the Sun* (1945, reissued 1976); and E.N. PARKER, "The Sun," *Scientific American,* 233:42–50 (September 1975). Works of a more technical nature include: H. ZIRIN, *The Solar Atmosphere* (1966); G.P. KUIPER (ed.), *The Sun* (1953); and E. TANDBERGHANSSEN, *Solar Activity* (1967). Specific subjects can be found treated in the following technical books: R.J. BRAY and R.E. LOUGHHEAD, *Sunspots* (1964, reprinted 1979), and *The Solar Granulation* (1967); H.J. and E.V.P. SMITH, *Solar Flares* (1963); Y. OHMAN (ed.), *Mass Motions in Solar Flares and Related Phenomena* (1968); N. ROBINSON (ed.), *Solar Radiation* (1966); D.E. BILLINGS, *A Guide to the Solar Corona* (1966); J.W. EVANS (ed.), *The Solar Corona* (1963); A.J. HUNDHAUSEN, *Coronal Expansion and Solar Wind* (1972); R.N. THOMAS and R.G. ATHAY, *Physics of the Solar Chromosphere* (1961); J. MEEUS, C.C. GROSJEAN, and W. VANDERLEEN, *Canon of Solar Eclipses* (1966); K.O. KIEPENHEUER (ed.), *Structure and Development of Solar Active Regions* (1968); M.R. KUNDU, *Solar Radio Astronomy* (1965); A.G. SMITH, *Radio Exploration of the Sun* (1967); S. CHAPMAN, *Solar Terrestrial Physics* (1972), and *Solar and Magnetospheric Science* (1976); V.V. SOBOLEV, *Treatise on Radiative Transfer,* trans. by S.I. GAPOSCHKIN (1963, reissued 1978); I.S. SHKLOVSKII, *Stars: Their Birth, Life and Death* (1975; Eng. trans. from the Russian, 1978); and R.W. NOYES, "New Developments in Solar Research," in E.H. AVRETT (ed.), *Frontiers of Astrophysics* (1976). Atlases of Fraunhofer lines include G. BRUCKNER, *Photometric Atlas of the Near Ultraviolet Solar Spectrum 2988 Å–3629 Å* (1960); O.C. MOHLER *et al., Photometric Atlas of the Near Infra-Red Solar Spectrum λ 8465 to λ 25242* (1950, reissued 1978); L. DELBOUILLE and G. ROLAND, *Photometric Atlas of the Solar Spectrum from λ 7498 to λ 12016* (1963); and M. MIGEOTTE, L. NEVEN, and J. SWENSSON, *The Solar Spectrum from 2.8 to 23.7 Microns* (1956).

(A.K.P./E.A.M.)

Mercury: Nontechnical discussions of Mercury may be found in BRUCE C. MURRAY, "Mercury," *Scientific American,* 233:58–68 (September 1975); J. KELLY BEATTY, "Mariner 10's Second Look at Mercury," *Sky and Telescope,* 48:307–314 (November 1974); KENNETH F. WEAVER, "Mariner Unveils Venus and Mercury," *National Geographic,* 147:858–869 (June 1975); B.C. MURRAY and ERIC BURGESS, *Flight to Mercury* (1977); and B.C. MURRAY, MICHAEL C. MALIN, and RONALD GREELEY, *Earthlike Planets* (1981). An excellent collection of Mariner 10 photographs is available in MERTON E. DAVIES *et al., Atlas of Mercury* (1978). Technical discussions of Mercury may be found in *Science,* 185:141–180 (July 12, 1974); *Journal of Geophysical Research,* 80:2341–2514 (June 10, 1975); *Icarus,* 28:429–609 (August 1976); and *Physics of the Earth and Planetary Interiors,* 15:113–312 (November 1977). See also R.G. STROM, "Mercury: A Post-Mariner 10 Assessment," *Space Science Reviews,* 24:3–70 (1979).

(M.C.Ma.)

Venus: A reference work on Venus that presents the primary results of the Pioneer Venus mission and the current data on the planet is *Journal of Geophysical Research,* 85:7573–8337 (Dec. 30, 1980). A summary article on results of the Venera probe

missions is M.YA. MAROV, "Results of Venus Missions," in *Annual Review of Astronomy & Astrophysics,* 16:141–169 (1978). A general review article on Venus is ANDREW and LOUISE YOUNG, "Venus," *Scientific American,* 233:70–78 (September 1975). A classic paper on infrared temperatures of the clouds is W.M. SINTON and J. STRONG, "Radiometric Observations of Venus," *Astrophys. J.,* 131:470–490 (1960). The greenhouse model as initially proposed is described in CARL SAGAN, "The Radiation Balance of Venus," Jet Propulsion Laboratory Tech. Rep.:32–34 (Sept. 15, 1960). The initial report of the high radio flux from Venus is in C.H. MAYER, *et al.,* "Observations of Venus at 3.15 cm Wavelength," *Astrophys. J.,* 127:1–16 (1958). The discovery of trace gases in Venus' atmosphere by high-resolution spectroscopic techniques is described in P. and J. CONNES *et al.,* "Traces of HCl and HF in the Atmosphere of Venus," *Astrophys. J.,* 147:1230–37 (1967). The first investigation of the clouds by means of Earth-based optical measurements is in J.E. HANSEN and A. ARKING, "Clouds of Venus," *Science,* 171:669–672 (Feb. 19, 1971). An illustrated book with popular descriptions is C. SAGAN and J.N. LEONARD, *Planets* (1966 and subsequent ed.). G.E. HUNT and PATRICK MOORE, *The Planet Venus* (1983), a good introduction to the planet and the space vehicles that have studied it.

(A.S.)

Earth: FRANK PRESS and RAYMOND SIEVER, *Earth,* 4th ed. (1986), an excellent overview of the physical properties and dynamics of the Earth; I.G. GASS, P.J. SMITH, and R.C.L. WILSON (eds.), *Understanding the Earth* (1971), some 25 articles by as many authors who are leading experts (readable, nonmathematical); SCIENTIFIC AMERICAN, *Readings in the Earth Sciences,* 2 vol. (1969), an excellent collection containing 74 offprints of articles that appeared in *Scientific American* between 1948 and 1969—see also current issues of this periodical for further valuable articles; OWEN M. PHILLIPS, *The Heart of the Earth* (1968), introductory for a college science student; FRANK D. STACEY, *Physics of the Earth* (1969), an outstanding text for the advanced undergraduate or beginning graduate student of science with a corresponding mathematics background, including an extensive and carefully selected bibliography; GEORGE D. GARLAND, *Introduction to Geophysics* (1971), a thorough and reliable work that covers several subjects not adequately treated by Stacey; J.A. JACOBS, R.D. RUSSELL, and J.T. WILSON, *Physics and Geology* (1959), a classic text to introduce geology students to the underlying physics with emphasis on those aspects that have direct bearing on large-scale geology; S.K. RUNCORN *et al.* (eds.), *International Dictionary of Geophysics,* 1 vol. and 1 vol. of maps (1967), articles contributed by nearly a thousand authorities, with short bibliographies following the articles. JOHN W. HARRINGTON, *Dance of the Continents* (1983), an introduction to historical geology.

(W.M.E.)

The Moon: BEVAN M. FRENCH, *The Moon Book* (1977); C.W. ALLEN, *Astrophysical Quantities,* 3rd ed. (1973); HER MAJESTY'S NAUTICAL ALMANAC OFFICE, *Explanatory Supplement to the Astronomical Ephemeris and the American Ephemeris and Nautical Almanac* (1963). Works focusing on the motion and rotation of the Moon include D.W.G. ARTHUR, "Selenography," in G.P. KUIPER and B.M. MIDDLEHURST (eds.), *The Moon, Meteorites and Comets* (1963); JACQUES HENRARD, "A New Solution to the Main Problem of the Lunar Theory," in *Celest. Mech.,* 19:337–355 (1979); K. GARTHWAITE *et al.,* "A Preliminary Special Perturbation Theory for the Lunar Motion," in *Astron. Jour.,* 75:1133–39 (1970), the first published use of a numerical lunar orbit, showing the inadequacy of Brown's theory; MARTIN A. SLADE, *The Orbit of the Moon* (1971), including mathematical details of numerical integration of the lunar motion; J. DERRAL MULHOLLAND, "Scientific Achievements from Ten Years of Lunar Laser Ranging," in *Rev. Geophys. Space Phys.,* 18:549–564 (1980) and "How High the Moon: A Decade of Laser Ranging," in *Sky & Telescope,* 60:274–279 (October 1980); J. DERRAL MULHOLLAND, "The Rotation of the Moon," in *Bull. Cl. Sciences Acad. Roy. Belgique,* Ser. V, 55:1088–1113 (1974), a comprehensive overview; STANTON PEALE, "Generalized Cassini's Laws," in *Astron. Jour.,* 74:483–489 (1969), an analysis of the resonance; and ROGER J. CAPPALLO, *The Rotation of the Moon* (1980), which applies numerical integration to the Moon's libration. The use of different kinds of observations is described in R.W. KING, C.C. COUNSELMANN III, and IRWIN I. SHAPIRO, "Lunar Dynamics and Selenodesy: Results from Analysis of VLBI and Laser Data," in *Jour. Geophys. Res.,* 81:6251–56 (1976); J. DERRAL MULHOLLAND (1980, *op. cit.*); and LESLIE V. MORRISON, "An Analysis of Lunar Occultations in the Years 1943–1974 for Corrections to the Constants in Brown's Lunar Theory," in *Mon. Not. Roy. Astron. Soc.,* 187:41–82 (1979). THOMAS C. VAN FLANDERN, "Is Gravity Getting Weaker?" *Scientific American,* 234:44–52 (February 1976), an explanation of the effect of gravity on the Moon's orbit. The mass of the Moon is discussed in A.J. FERRARI *et al.,* "Geophysical Parameters of the Lunar Orbit," in *Jour. Geophys. Res.,* 85:3939–51 (1980). For the gravity field of the Moon, see WILLIAM M. KAULA, *An Introduction to Planetary Physics* (1968); P.M. MULLER and W.L. SJOGREN, "Mascons: Lunar Mass Concentrations," in *Science,* 161:680–684 (1968), which announced the discovery of mascons; and A.J. FERRARI *et al., op. cit.,* which gives an informative description of the harmonic field.

Types of lunar features are covered in GILBERT FIELDER, *Lunar Geology* (1965); ELBERT A. KING, *Space Geology* (1976); JOSIAH E. SPURR, *Geology Applied to Selenology:* vol. 1, *The Imbrium Plain Region of the Moon,* vol. 2, *Features of the Moon,* vol. 3, *Lunar Catastrophic History,* and vol. 4, *The Shrunken Moon* (1944–49); GILBERT FIELDER and LIONEL WILSON (eds.), *Volcanoes of the Earth, Moon, and Mars* (1975); NICHOLAS M. SHORT, *Planetary Geology* (1975); THOMAS A. MUTCH, *Geology of the Moon* (1970); PETER H. SCHULTZ, *Moon Morphology* (1976); ROYAL SOCIETY OF LONDON, *The Moon* (1977); G.P. KUIPER (ed.), *Photographic Lunar Atlas* (1960, with suppl., *Orthographic Atlas of the Moon*); E.A. WHITAKER *et al., Rectified Lunar Atlas* (1963); *The Times Atlas of the Moon* (1969); J.E. BALDWIN, "Thermal Radiation from the Moon and the Heat Flow Through the Lunar Surface," *Mon. Not. R. Astr. Soc.,* 122:513–522 (1961); ROBERT HOOKE, *Micrographia* (1st ed., 1665; 2nd issue, 1667, reprinted 1938); JAMES NASMYTH and JAMES CARPENTER, *The Moon,* 4th ed. (1903); WILLIAM H. PICKERING, "Lunar and Hawaiian Physical Features Compared," *Mem. Am. Acad. Arts Sci.,* 13:151–182 (1908); J.E. SPURR (*op. cit.*); G.K. GILBERT, "The Moon's Face," *Bull. Phil. Soc. Wash.,* 12:241–292 (1893); RALPH B. BALDWIN, *The Measure of the Moon* (1963), and *A Fundamental Study of the Moon* (1965); BRIAN MASON and WILLIAM G. MELSON, *The Lunar Rocks* (1970); G.M. BROWN, "Geochemistry of the Moon," *Endeavour,* 30:147–151 (1971); JOHN F. LINDSAY, *Lunar Stratigraphy and Sedimentology* (1976); ALFRED A. LEVINSON and S. ROSS TAYLOR, *Moon Rocks and Minerals* (1971); TYPHOON LEE, "New Isotopic Clues to Solar System Formation," in *Rev. Geophys. and Space Phys.,* 17:1591–1611 (1979); ALAN H. COOK, *Physics of the Earth and Planets* (1973); S. ROSS TAYLOR, *Lunar Science: A Post-Apollo View* (1975). The results of intensive studies of returned lunar rocks have been published in *Science,* vol. 167, no. 3918 (1970); in the reports of the Lunar Science Conferences held since 1970; and by BRIAN MASON and WILLIAM G. MELSON (*op. cit.*). Discussions on the evolution of the Moon's orbit are found in SIR GEORGE H. DARWIN, *The Tides and Kindred Phenomena in the Solar System* (1898, reprinted 1962), the classic first work on the subject; W.H. MUNK and G.J.F. MACDONALD, *The Rotation of the Earth* (1960), a landmark in the study of dissipation in the solar system; G.D. ROSENBERG and S.K. RUNCORN (eds.), *Growth Rhythms and the History of the Earth's Rotation* (1975), a good summary of the use of ancient fossil records, but with obsolete astronomical discussions; KURT LAMBECK, *The Earth's Variable Rotation* (1980). Theories of lunar origin are dealt with by BRIAN G. MARSDEN and A.G.W. CAMERON (eds.), *The Earth-Moon System* (1966); S. FRED SINGER, "The Origin of the Moon and Geophysical Consequences," in *Geophys. Jour. Roy. Astron. Soc.,* 15:205–226 (1968); WILLIAM M. KAULA and A.W. HARRIS, "Dynamics of Lunar Origin and Orbit Evolution," in *Rev. Geophys. Space Phys.,* 13:363–372 (1975).

(J.D.Mu./G.Fi.)

Mars: Early ideas on the possibility of life on Mars are summarized in H. STRUGHOLD, "Synopsis of Martian Life Theories," in *Advances in Space Science and Technology,* 9:105–122 (1967); post-Viking views are discussed in HAROLD P. KLEIN, "The Viking Mission and the Search for Life on Mars," in *Reviews of Geophysics and Space Physics,* 17:1655–62 (October 1979). The nature of Martian phenomena as understood before 1969, including several enlightening chapters on the possibilities of extraterrestrial life, are discussed in SAMUEL GLASSTONE, *The Book of Mars* NASA SP-179 (1968). The era of space exploration is covered by several books and collections of papers, each dedicated to an exposition of the subject at the conclusion of a project. Mariners 6 and 7 are discussed in N.W. CUNNINGHAM and H.M. SCHURMEIER, *Mariner-Mars 1969: Preliminary Report* NASA SP-225 (1969). An illustrated summary of the results of the Mariner 9 orbiter mission is to be found in *Mars as Viewed by Mariner 9* NASA SP-329 (1974). In addition, *Icarus,* 17:289–561 (October 1972) is dedicated to a collection of original papers by Mariner 9 experimenters. A synthesis of views on the nature of the planet between Mariner 9 and Viking is developed in THOMAS A. MUTCH *et al., The Geology of Mars* (1976). The Viking results are extensive; the original papers describing the results of the mission are to be found in the following entire issues of *Journal of Geophysical Research,* 84:2795–3007 (June 1979), 84:7909–8519 (December 1979), and 82:3959–4680 (September 1977). For an excellent review of the geologic evolution of Mars, see RAYMOND E. ARVIDSON, KENNETH A. GOETTEL, and CHARLES M. HOHENBERG, "A Post-Viking View of Martian Geologic Evolution," in *Reviews of Geophysics and Space Physics,* 18:565–603 (August 1980). An overview of the morphology of surface structures found by Viking and Mariner 9 is MICHAEL H. CARR, "The Morphology of the Martian Surface," in *Space Science Reviews,* 25:231–284 (1980). A detailed account of factual knowledge about the Martian satellites is JOSEPH VEVERKA and JOSEPH A. BURNS, "The Moons of Mars," in *Annual Review of Earth and Planetary Sciences,* 8:527–558 (1980). Knowledge of the meteorology of the Martian atmosphere is described in CONWAY B. LEOVY, "Martian Meteorology," in *Annual Review of Astronomy and Astrophysics,* 17:387–413 (1979). ARTHUR KOESTLER, *The Sleepwalkers: A History of Man's Changing Vision of the Universe* (1959), provides an excellent account of the role of Mars in the work of Brahe and Kepler. Maps of Mars can be obtained from the superintendent of the U.S. Geological Survey, Washington, D.C.

(M.J.S.B.)

Jupiter: A discussion of telescopic observations of Jupiter consisting of descriptions of motions, colours, and transformations observed in the Jovian cloud layers may be found in B.M. PEEK, *The Planet Jupiter* (1958). An extensive compilation of papers on all aspects of the Jovian system through 1975 is presented in T. GEHRELS (ed.), *Jupiter* (1976). The Pioneer missions are described in R.O. FIMMEL, W. SWINDELL, and E. BURGESS, *Pioneer Odyssey: Encounter with a Giant* (1974). An early summary of information about the satellites appears in J.A. BURNS (ed.), *Planetary Satellites* (1977). A later account is given in D. MORRISON (ed.), *Satellites of Jupiter* (1981), which includes a discussion of the Voyager results pertaining to the satellites. Summary articles of other Voyager discoveries may be found in the following journals: *Science,* 204:945–957, 960–1008 (June 1, 1979), and 206:925–996 (Nov. 23, 1979); *Nature,* 280:725–806 (Aug. 30, 1979); *J. Geophys. Res.,* 86 (Sept. 30, 1981), the entire issue being devoted to "Voyager Missions to Jupiter." The Voyager spacecraft and their experiments are described in *Space Science Reviews,* vol. 21, no. 2 and 3 (1977). An overview of this mission is given in D. MORRISON and J. SAMZ, *Voyage to Jupiter* (1980); and many of the results and their interpretation are presented in articles in J.K. BEATTY, B. O'LEARY, and A. CHAIKIN (eds.), *The New Solar System* (1981).

(T.C.O.)

Saturn: A.F.O'D. ALEXANDER, *The Planet Saturn: A History of Observation, Theory and Discovery* (1962, reissued 1980), contains a list of all important papers published up to 1962. For an overview of information gathered by the Voyager space probes, see DAVID MORRISON, *Voyages to Saturn* (1982). See also *Science,* 212:159–243 (April 10, 1981); *Science,* 215:499–594 (Jan. 29, 1982); and ANDREW P. INGERSOLL, "Jupiter and Saturn," *Scientific American,* 245:90–108 (December 1981).

(P.Mo./Ed.)

Uranus: A comprehensive and detailed summary of essentially all the serious work done on Uranus from its discovery through the early 1960s is ARTHUR F.O.'D. ALEXANDER, *The Planet Uranus* (1965). More technical treatments are found in the articles by Brouwer and Clemence, Wildt, and Harris in *Planets and Satellites,* ed. by G.P. KUIPER and B.M. MIDDLEHURST (1961). The mass of Uranus may also be determined by its perturbations on the orbit of Saturn; this technique is summarized by W.J. KLEPCZYNSKI, P.K. SEIDELMANN, and R.L. DUNCOMBE in "The Masses of Jupiter and Saturn," *Astr. J.,* 75:739–742 (1970). Details of the atmosphere of Uranus may be found in "The Atmospheres of the Outer Planets and Satellites," by L. TRAFTON in *Reviews of Geophysics and Space Physics,* 19:43–89 (1981). Findings by the Voyager 2 flyby are reported in several articles in *Science,* vol. 233, no. 4759 (July 4, 1986), including information on the planet's atmosphere, rings, and satellites; and in TORRENCE V. JOHNSON, ROBERT HAMILTON BROWN, and LAURENCE A. SODERBLOM, "The Moons of Uranus," *Scientific American,* 256(4):48–60 (April 1987).

(H.Sm.)

Neptune: B.A. GOULD, *Report on the History of the Discovery of Neptune* (1850), is a classic work that provides detailed accounts. R.A. LYTTLETON, *Mysteries of the Solar System* (1968), includes a chapter on Neptune's discovery, along with a discussion of its orbits. Two articles, with illustrations, for the general reader are D.M. HUNTEN, "The Outer Planets," *Scientific American,* 233:130–140 (September 1975); and M.J.S. BELTON, "Uranus and Neptune," *Astronomy,* 5:6–17 (February 1977). Findings and pictures from the Voyager 2 flyby are included in JUNE KINOSHITA, "Neptune," *Scientific American,* 261(5):82–91 (November 1989); a set of articles in *Science,* vol. 246, no. 4936 (Dec. 15, 1989); and two articles in *Sky & Telescope,* vol. 79, no. 2 (February 1990): "Neptune and Triton: World Apart," pp. 136–145; and KELLY BEATTY, "Getting to Know Neptune," pp. 146–155.

(G.E.T./Ed.)

Pluto: W.G. HOYT, *Planets X and Pluto* (1980), a good account of the history of the prediction, discovery, and subsequent study of Pluto; A.J. WHYTE and H.A. WISE, *The Planet Pluto* (1980), a comprehensive collection of references to, and summaries of, original research reports. Pluto's properties as well as its satellite are described in J.W. CHRISTY and R.S. HARRINGTON, "The Satellite of Pluto," *Astr. J.,* 83:1005–08 (1978); W. BAADE, "The Photographic Magnitude and Color Index of Pluto," *Publs. Astr. Soc. Pacif.,* 46:218–221 (1934); M.F. WALKER and R.H. HARDIE, "A Photometric Determination of the Rotational Period of Pluto," *Publs. Astr. Soc. Pacif.,* 67:224–231 (1955); L.E. ANDERSSON and J.D. FIX, "Pluto, New Photometry and a Determination of the Axis of Rotation," *Icarus,* 20:279–283 (1973); I. HALLIDAY *et al.,* "An Upper Limit for the Diameter of Pluto," *Publs. Astr. Soc. Pacif.,* 78:113–124 (1966); S.J. ARNOLD, A. BOKSENBERG, and W.L.W. SARGENT, "Measurement of the Diameter of Pluto by Speckle Interferometry," *Astrophysical Journal,* 234:L159–L163 (1979). CLYDE W. TOMBAUGH, *Out of the Darkness: The Planet Pluto* (1980), an account of its discovery by its discoverer.

(R.H.H.)

Asteroids: Summary articles can be found in CLARK R. CHAPMAN, "The Nature of Asteroids," *Scientific American,* 232(1):24–33 (January 1975), and "Asteroids," ch. 10 in J. KELLY BEATTY, BRIAN O'LEARY, and ANDREW CHAIKIN (eds.), *The New Solar System,* 2nd ed. (1982), pp. 97–104. See also GEORGE O. ABELL, DAVID MORRISON, and SIDNEY C. WOLFF, "The Asteroids," ch. 19 in *Exploration of the Universe,* 5th ed. (1987). Review and research papers are collected in TOM GEHRELS and MILDRED SHAPLEY MATTHEWS (eds.), *Asteroids* (1979), including three broad review chapters; and C.-I. LAGERKVIST and H. RICKMAN (eds.), *Asteroids, Comets, Meteors* (1983), and *Asteroids, Comets, Meteors II* (1986). International reports of research on asteroids, as well as comets and meteorites, can be found in *Astrophysical Journal* (semimonthly); and *Astronomy and Astrophysics* (34/year).

(E.F.T.)

Comets: General introductory works are FRED L. WHIPPLE, *The Mystery of Comets* (1985, reprinted 1986); and ROBERT D. CHAPMAN and JOHN C. BRANDT, *The Comet Book: A Guide for Return of Halley's Comet* (1984), a historical treatment. More advanced are JOHN C. BRANDT and ROBERT D. CHAPMAN, *Introduction to Comets* (1981); and K.S. KRISHNA-SWAMY, *Physics of Comets* (1986), including a section on spectroscopy. LAUREL L. WILKENING and MILDRED SHAPLEY MATTHEWS (eds.), *Comets* (1982), is a definitive collection of essays covering all aspects at a technical level. See also D.A. MENDIS, H.L.F. HOUPIS, and M.L. MARCONI, "The Physics of Comets," *Fundamentals of Cosmic Physics,* vol. 10, no. 1–4 (1985); and A.H. DELSEMME (ed.), *Comets, Asteroids, Meteorites: Interrelations, Evolution and Origins* (1977). BRIAN G. MARSDEN, *Catalog of Cometary Orbits,* 5th ed. (1986), covers 1,187 cometary orbits, with detailed references and notes; a complementary volume is GARY KRONK, *Comets: A Descriptive Catalog* (1984).

Meteoroids, meteors, and meteorites: Introductory information can be found in ROBERT T. DODD, *Thunderstones and Shooting Stars: The Meaning of Meteorites* (1986); ROBERT HUTCHISON, *The Search for Our Beginning: An Enquiry, Based on Meteorite Research, into the Origin of Our Planet and of Life* (1983); and JOHN A. WOOD, *Meteorites and the Origin of Planets* (1968). More advanced treatments are JOHN T. WASSON, *Meteorites: Their Record of Early Solar-System History* (1985), and *Meteorites: Classification and Properties* (1974); V.A. BRONSHTEN, *Physics of Meteoric Phenomena* (1983; originally published in Russian, 1981); and ROBERT T. DODD, *Meteorites: A Petrologic-Chemical Synthesis* (1981). A descriptive and historical treatment of iron meteorites, including beautiful photographs, is VAGN F. BUCHWALD, *Handbook of Iron Meteorites, Their Distribution, Composition, and Structure,* 3 vol. (1975). H.H. NININGER, *Out of the Sky: An Introduction to Meteorites* (1952, reprinted 1959), provides firsthand experiences of fall phenomena on a nontechnical level. See also D.E. BROWNLEE, "Cosmic Dust: Collection and Research," *Annual Reviews of Earth and Planetary Sciences,* 13:147–173 (1985). A catalog of known meteorites, including data regarding their fall, is A.L. GRAHAM, A.W.R. BEVAN, and R. HUTCHISON (eds.), *Catalogue of Meteorites,* 4th ed. rev. and enl. (1985). There are two journals devoted to papers on meteorites and related bodies: *Meteoritika* (annual), published in the U.S.S.R.; and *Meteoritics* (quarterly). Many papers on meteorites are published in *Geochimica et Cosmochimica Acta* (monthly).

Sound

A human being speaking is said to produce sound, and anyone nearby who has adequate hearing ability is said to hear the sound. The experience is a manifestation of a phenomenon of great significance to all persons, who are immersed in sound stimuli that influence all of their activities.

One suggestion of the importance of sound is the large number of words in every language that are descriptive of the different kinds of sound within human awareness. In nature, the storm thunders, the gale howls, surf roars and pounds, wind whistles and moans, trees whisper, rain patters, and running water ripples and gurgles. The vocabulary descriptive of the sounds of living things is even richer: the barking and snarling of dogs, the mewing of cats, crowing of fowl, roaring of lions, hissing of snakes, lowing and bellowing of cattle, blatting of goats, grunting of pigs, chirping of birds and insects, screaming of gulls, crying and yelling of infants, not to mention the sneezing, wheezing, and snoring of humans.

In addition to the racket all around them, over which they have little or no control, humans are subjected to an almost limitless variety of sounds that they themselves produce. There are the unpleasant blast of an explosion, roar of engines, rumble of traffic, whine of jet planes; the more agreeable if distracting whir of machinery and ticking of clocks; or the melody and harmony of music.

The purpose of this article is to set forth the physicist's explanation of the phenomena of sound, though reference will be made, when necessary, to other disciplines that play a considerable role in human production of and reaction to sound. The branch of physics most concerned with understanding sound is called acoustics, from the Greek word meaning hearing. The various applications of acoustics, including the recording and reproduction of sound and the control of noise, are reviewed.

Inevitably man's major association with sound is through the human ear. Though the anatomical and physiological details of this interesting and important sensory organ are dealt with in the article on SENSORY RECEPTION, a few remarks here will set the stage for the further discussion of sound. The normal human ear is a remarkably sensitive organ, and it has been estimated that as little as 10^{-11} erg or about 10^{-25} kilowatt-hour of sound energy is enough to excite it and produce recognition of the sound.

The ear is built ruggedly enough to tolerate a wide range of sound energy, but hearing becomes painful, and irreversible ear damage may ensue if the amount of sound energy reaches 10^{-11} kilowatt-hour, which is, however, 10^{-14} times that of the minimum audible energy level. These figures must be taken as order of magnitude values and not as specific results of precise measurement. In any case, human ears differ from individual to individual and vary even in the same individual with age and environmental conditions. The noise in large cities takes a heavy toll in physiological damage and psychological impact.

The fact that the human being has two ears enables a hearer to judge the direction from which sound in the open reaches him (the binaural effect) or to separate a signal from ambient noises. A fundamental characteristic of what may be called regular sounds, like musical notes, is their frequency—*i.e.,* the number of cycles per second expressed in hertz (one cycle per second), abbreviated Hz, of the causative vibration. Low-frequency sound is heard as low pitch, and higher frequencies as correspondingly higher pitch (see MECHANICS: *Vibrations*). The normal human ear is sensitive to sound within the range of about 20 Hz to 20,000 Hz, with some variation from individual to individual. Advancing age usually leads to a decrease in the upper limit. Sound of less than 20 Hz is called infrasonic; that of more than 20,000 Hz, ultrasonic. These inaudible sounds are actually of greater interest in modern physics and in their technical application than those in the sonic or audible range.

The article is divided into the following sections:

Historical survey

The fact that a solid object struck in air produces sound must have been observed from the earliest times. The additional observation that under certain conditions the sounds so produced are particularly agreeable to the ear furnished the basis for the creation of music, which must have taken place long before the beginning of recorded history. Thus the germ of the idea that the pitch of a musical sound depends somehow on the frequency of vibration of the sound-producing object is usually attributed to the 6th-century-BC Greek philosopher Pythagoras.

Further, that sound transmission through the air has something to do with the motion of the air was recognized at least by Aristotle, though it is not clear that he grasped the idea that the motion of air involved in sound is a wave motion rather than a streaming of air from the sound source to the listener. The Roman architectural engineer Marcus Vitruvius Pollio of the 1st century BC understood the wave concept and actually drew analogies between sound travelling in air and surface waves in water, but his ideas were more or less forgotten during the Middle Ages, when a corpuscular, or atomic, theory of the transmission of sound was widely held. In the 17th century, a French philosopher and mathematician, Pierre Gassendi, in reviving the atomic theory, attributed the propagation of sound to the emission and transfer of a stream of very small, invisible particles, which, after moving through the air, are able somehow to affect the ear.

Irrespective of the theory of sound transmission, the question of the speed of propagation began to engage attention in the early 17th century. Gassendi in 1635 made one of the first recorded measurements of the velocity of sound in air. His experiments involved firearms and were based on the assumption that the flash of light is seen by the observer instantaneously. Timing the delay between powder flash and the noise of the discharge, he determined a speed of sound the equivalent of 478.4 metres per second (1,569 feet per second, or 0.3 mile per second). This was shown to be too high by other observers during the 17th and 18th centuries. It was about 1750 that the first measurements made in windless, open air that can be considered at all precise were carried out under the direction of the Academy of Sciences of Paris, with a cannon as the source of sound. The result, calibrated for 0° C (32° F), was 332 metres or 1,089 feet per second, or 0.206 mile per second. Careful repetitions during the succeeding two centuries resulted in figures differing from this last result by less than 1 percent.

Velocity of sound in liquids

The first serious attempt to measure the velocity of sound in a liquid, such as water, was apparently made in the 19th century by Daniel Colladon, a Swiss physicist who, with the assistance of a French mathematician, Charles-François Sturm, conducted such studies in Lake Geneva. The average velocity as found by their measurements was 1,435 metres (4,707 feet) per second at 8° C (46° F). It had already been established around 1808 that the velocity of sound in an iron pipe greatly exceeds that in either air or water and in fact is of the order of 5,000 metres (16,000 feet) per second.

Though the wave theory of sound had been in existence in a qualitative way for many centuries, the first attempt to apply it to a theoretical derivation of the velocity of sound was probably made by Sir Isaac Newton, who, on the basis of arbitrary assumptions, reported that the velocity of sound in air (or any gaseous fluid) should be equal to the square root of the ratio of the atmospheric pressure to the density.

Newton's derivation was criticized for giving too low a speed when appropriate pressure and density values were substituted in his equation. This difficulty was resolved by a French mathematician, Pierre-Simon Laplace, who pointed out that the Newtonian formula was based on the assumption that the compressions and rarefactions associated with the propagation of sound in air take place at constant temperature. Laplace felt it to be more reasonable to assume that the compressions and rarefactions in sound propagation do not take place at constant temperature. His assumption led to the correction of Newton's formula by multiplying the ratio of the pressure to the density by that of the specific heats (heat required to raise the temperature of one gram of gas one degree Celsius) of the gas at constant pressure and constant volume, respectively. Thus corrected, the result agreed with that from experiments at ordinary frequencies.

Mathematical analysis of wave motion

In the latter half of the 18th century and the first quarter of the 19th century, many scientists tried to theorize about mechanical waves in continuous media, mainly on the basis of a mathematical expression for wave motion proposed by d'Alembert in 1747. Much of this work was stimulated by the work of two mathematicians, the Swiss Leonhard Euler and Joseph-Louis Lagrange in France. These mathematical considerations made it possible to understand the vibrations of sound sources like strings, rods, membranes, plates, organ pipes, and musical instruments in general. Though earlier work—based largely on empirical or relatively simple mathematical analysis—had been carried out, it required the methods of the calculus to understand in any precise way the behaviour of even the simplest types of sound vibrators.

The ear early attracted scientific attention as the receiver of sound for human beings. A French physicist, Félix Savart, in 1830 attempted to establish the frequency limits of audibility and obtained results not too different from those of modern measurements made with more sophisticated equipment. The corresponding problem of the threshold of audibility was attacked around 1870 by the Viennese physicists, August Toepler and Ludwig Boltzmann, who arrived at the figure 10^{-11} watt (one watt is a unit of power equal to one joule of work per second) per square centimetre, considerably in excess of the modern figure of 10^{-16} watt per square centimetre but indicating, nevertheless, the remarkable sensitivity of the ear as a sound receiver. Further important studies on the ear were made in Germany by Georg Simon Ohm, a physicist, who in 1843 theorized that the ear is able to analyze any complex sound into a combination of simple tones in terms of which the sound may be expressed mathematically by the use of a theorem of a French mathematician, Jean Fourier (see ANALYSIS IN MATHEMATICS). Ohm's work was further extended by Hermann von Helmholtz, a German physicist and physiologist, whose book, *Sensations of Tone,* marked the beginning of physiological acoustics.

Though early scientific work in the production and reception of sound in closed spaces (*i.e.,* room or architectural acoustics) was reported around 1850, the modern quantitative foundation of the subject dates from the work of a United States physicist, Wallace Clement Sabine, who in 1900 found a law to connect reverberation (echo) time in a closed room with the volume of the room and the amount of absorbing material. His finding made applied architectural acoustics possible.

Rayleigh's contributions

In another sense, however, the modern period in acoustics may be said to date from the publication in 1877 by the English physicist Lord Rayleigh (John William Strutt) of *The Theory of Sound,* in which the whole basic theory of all aspects of the production, propagation, and reception of sound was presented in rigorous fashion, together with much of the relevant experimental material. Most of 20th-century acoustics is an exploitation and development of the fundamental ideas in Rayleigh's treatise with the use of more sophisticated equipment.

The nature and properties of sound

THE GENERAL NATURE OF SOUND WAVES

Wave motion, velocity, and intensity. As has been noted, it was early recognized that sound is propagated as wave motion from a sound-producing object. It is important to distinguish this motion from that of such things as automobiles, projectiles, and flowing water. When a person opens his mouth and utters a sound, he moves the air in front of his mouth, but he does not push away all of the air in his vicinity. Instead, the motion is a squeezing one that compresses a small mass of air near his mouth into less than its normal volume. Being elastic, air when compressed tends to expand again when the compressing influence is removed. In expanding, the first mass of air moves some of the air adjacent to it, which is thereupon compressed in turn and in turn expands and pushes against another adjacent bit of air. So the energy of the original compressing motion is passed on in temporal succession through the space surrounding the speaker. When a portion of it is intercepted by a receiver of sound like the human ear, it finally yields up some of itself to the receiver as a stimulus. The response in the case of the human ear is audition or hearing.

A sound wave in air or any fluid medium is thus a compressional wave. The simplest example is the pressure pulse produced by the firing of a pistol or a short speech ejaculation: it takes time for such a pulse to travel through the medium, and hence such a wave has a finite velocity. The velocity of sound in air is about 344 metres (1,128 feet) per second at 20° C (68° F). It increases with temperature in a way that is treated below in the section on the properties of sound waves. It is independent of the pressure or density of the air over wide ranges. Because the velocity of sound in air is so much less than the velocity of light (3×10^8 metres per second), the sound of a distant cannon is heard sometime after the flash or the puff of smoke is seen.

The everyday distinction between loud and soft sounds rests on the differences in the magnitude of the pressure changes involved in sound-wave propagation. In normal conversation the pressure of the air in front of the mouth of the speaker is changed at most by only about one millionth of the normal atmospheric pressure (*i.e.,* by only about one dyne per square centimetre out of 10^6 dynes per square centimetre; the dyne, a unit of force, is that force required to change the velocity of a mass of one gram by one centimetre per second each second). At the same time the accompanying motion that produces the compression corresponds to a fluctuating air-flow velocity with a maximum value of only about 0.02 centimetre per second (about 0.008 inch per second).

A sound wave represents the transmission of mechanical energy. An average rate of transfer of only 10^{-16} watt per square centimetre is enough to produce the hearing of an identifiable sound in a normal young person. This means that mechanical energy of only about 10^{-11} erg or about 10^{-25} kilowatt-hour can produce in the ear an identifiable sound stimulus. The average power transmission in a sound wave per unit area of the medium perpendicular to the direction of the wave is called the intensity. The unit for this quantity is the bel, but in practice it is common to use a unit ten times smaller, the decibel (abbreviated dB). If the intensity of a given sound in absolute units is I and the minimum audible intensity is I_0, the sound is said to be a number of decibels above the minimum audible equal to ten times the logarithm to the base ten of I divided by I_0. The decibel scale is thus relative to some arbitrary level, but the latter is commonly taken as the minimum audible. On this basis, ordinary conversational speech has an intensity of 60 decibels at a distance of about three feet from the mouth. Traffic at a busy street intersection can provide an average of 75 decibels, and a boiler factory can reach 130 decibels.

finition
decibel

As a source of sound in the open, such as an airplane, moves away from the listener, it is heard less distinctly. This is basically a matter of geometry. The intensity of a sound wave from a point source varies inversely as the square of the distance from the source. A point source in the open spreads sound energy in all directions, and the farther from the source, the greater is the spherical area through which the same sound energy flows per unit time. Because the area of a sphere increases as the square of the distance from the centre, the intensity of the wave, which is the average flow of energy per unit area, must decrease inversely with the square of the distance. Actual observation indicates that the falling off of intensity with distance in the open is always greater than this purely geometrical decay. This effect is attributed to a variety of ways in which energy is dissipated—reflection, refraction, diffraction, and scattering—as well as to the absorption of the sound caused by the viscosity and other similar properties of the medium. The diminution of sound intensity from a localized source is further complicated if the source is on the ground or underwater near the surface, and even more so if it is inside a closed room or auditorium.

Frequency, pitch, and wavelength. An air siren produces sound waves by interrupting jets of air at different rates, by means of a rotating disk with orifices in its periphery. The greater the number of separate puffs of air per unit time, the higher is the perceived pitch of the sound. This leads to a consideration of periodic sound waves, which are much the easiest to study analytically (see the section on the properties of sound waves). Waves are called harmonic waves because they result from a source of sound in which the disturbance repeats itself regularly. The simplest periodic sound, a harmonic sound wave, is characterized by a definite frequency. The frequency of the sound is defined as the number of times per second the disturbance at any point in the medium transmitting the wave is repeated.

The relation between pitch, as perceived by the human ear, and physical frequency is more complex in the case of the human voice or ordinary musical instruments than it is for a pure harmonic wave as emitted by a carefully made tuning fork or loudspeaker, activated by an electronic oscillator under precise frequency control. The fork or speaker is said to produce a pure tone of definite single frequency. In such a harmonic wave the time for one complete cycle of pressure change at any point in the medium is called the period of the wave, which is the reciprocal of the frequency, *i.e.,* one divided by the frequency in cycles per second, or hertz.

Meaning
of pure
tone

The sounds of all frequencies are not heard equally well by humans. An object vibrated in air at a frequency of less than about 20 hertz will create a compressional wave that will not be heard as sound by most normal ears. Such waves are said to be infrasonic. An object vibrating at a higher frequency than this will tend to cause audible sound if the intensity is sufficiently great. When the frequency of a compressional wave in air is increased beyond 20,000 hertz (20 kilohertz), the audibility ceases for most people, even if the intensity becomes great, though an uncomfortable nervous sensation is experienced by many. With advancing age of the listener, this upper frequency threshold decreases markedly. These inaudible high-frequency sound waves, commonly called ultrasonic, are periodic stress waves that produce a deformation of the medium through which they are passing. They play an important part in modern acoustical science and engineering. By means of appropriate sources (see below *Sources of sound*) it has been possible to produce ultrasonic radiation of frequency of about 10^{10} hertz. Such waves, however, are rapidly absorbed in fluid media.

Every harmonic sound wave is characterized by a definite wavelength; that is, the distance between identical successive points in a spreading wave at which the disturbance is exactly the same and doing the same thing (*i.e.,* increasing or decreasing the compression of the fluid). At two such successive points the disturbances are said to be in phase with one another. Because the disturbance (*e.g.,* the onset of compression) in a wave travels a distance of one wavelength in one period, the product of wavelength and frequency equals the wave velocity. This important relationship between wavelength, frequency, and velocity, which holds for harmonic waves of all kinds (*i.e.,* sound waves, light waves, water waves, etc.), means that, the velocity of all acoustic waves being constant in any medium, high-frequency acoustic waves in a given medium have smaller wavelengths than low-frequency sounds. Thus, in air at 20° C (68° F), a wave of frequency 1,000 hertz has a wavelength of 0.344 metre (1.128 feet), whereas a wave frequency 10^6 hertz or one megahertz has a wavelength of 0.344 millimetre (0.0135 inch). The corresponding values in water are, respectively, 1.5 metres (five feet) and 1.5 millimetres (0.06 inch).

Few sounds in daily experience are pure tones characterized by a single frequency; most can be considered as arising from more or less complicated combinations of harmonic waves, each with its own frequency. One or more frequencies in such a mixture will often predominate (*i.e.,* have greater intensity) and help give the sound its observed quality.

THE PROPERTIES OF SOUND WAVES

Wave functions. The simplest of all wave motions to imagine are waves that travel along a flexible rope when one end is flicked. This type of wave is called transverse because the disturbance of the medium (in this case the rope) takes place at right angles to the direction of travel of the wave itself. A transverse wave differs physically from a sound wave, in which the disturbance (compression) takes place in the same direction as the wave itself; thus sound waves are called longitudinal. Each particle of the medium through which a longitudinal wave passes is displaced from its equilibrium position along the direction of the wave propagation.

The longitudinal nature of sound waves

Though sound waves are not necessarily periodic, those of greatest interest are characterized by frequency and wavelength (*i.e.,* are periodic). Like transverse waves, these longitudinal sound waves can be expressed in a harmonic equation in which the displacement, or disturbance (ξ), is equal to the amplitude (A) times the sine of two pi (π), times a quantity equal to the frequency (f), times the elapsed time (t), minus the distance (x) from the origin divided by the wavelength (λ), or:

$$\xi = A \sin 2\pi\,(ft - x/\lambda). \qquad (1)$$

The amplitude of the wave represents the maximum value of the disturbance. This equation can be used to determine the size of the disturbance for any value of the time (t) or position (x). In the equation, the quantity inside the parentheses can take successive values of 0, 1/8, 2/8, 3/8, etc., so that the disturbance is equal to the amplitude times the sine of 0, $\pi/4$, $2\pi/4$, $3\pi/4$, etc.; that is, the disturbance is alternately equal to plus and minus the amplitude and passes through zero in between.

Concept of excess pressure

For a harmonic sound wave in a fluid, the displacement ξ is more conveniently replaced by the excess pressure (p_e) produced by the wave. Excess pressure may be defined as the difference between the actual pressure (p) in the medium at any place and time and the normal pressure (p_0) in the originally undisturbed medium. Thus, symbolically, $p_e = p - p_0$. This excess pressure for a harmonic wave varies in space and time like ξ as shown in equation (1).

Velocity of sound waves in fluids and solids. A mathematical study of the propagation of a compressional wave in a fluid (gas or liquid) also shows that the velocity (V) of the wave is equal to the square root of the ratio of excess pressure to excess density:

$$V = \sqrt{p_e/\rho_e}, \qquad (2)$$

in which p_e is the excess pressure in the medium produced by the wave and ρ_e is the associated excess density (difference between the actual and normal, $\rho_e = \rho - \rho_0$). Whenever a fluid is squeezed by the application of extra pressure, the density goes up, and when the excess pressure becomes negative the density goes down. Equation (2) can be used to provide expressions from which the velocity V may be calculated in special cases. Hooke's law of elasticity (see MECHANICS) states that elastic stress is always proportional to elastic strain; that is, stress divided by strain is equal to a quantity B, in which B represents a proportionality constant. In the case of a compressional wave in a fluid, provided these quantities are not too great, one can write:

$$\frac{p_e}{\rho_e/\rho_0} = B, \qquad (3)$$

in which ρ_0 is the average density of the undisturbed medium. The quantity B, called the bulk modulus of the medium, is the coefficient of proportionality between the excess pressure p_e (the stress) and the fractional excess density ρ_e/ρ_0 (the strain). By substituting equation (3) in (2), one obtains the formula for the sound velocity: the velocity is equal to the square root of the ratio, bulk modulus divided by the average density of the undisturbed medium, or,

$$V = \sqrt{B/\rho_0} = \sqrt{1/\rho_0 K} \qquad (4)$$

in which K, called the compressibility, is the reciprocal ($K = 1/B$) of the bulk modulus. For example, the bulk modulus of water has been measured to be (around room temperature) 2.1×10^{10} dynes per square centimetre. Because the density of water under the same condition is about one gram per cubic centimetre, one has a numerical value for the velocity of sound in water under these conditions (from equation [4]),

$$V = \sqrt{\frac{2.1 \times 10^{10}\ \text{dynes/cm}^2}{1\ \text{gram/cm}^3}} = \sqrt{2.1} \times 10^5$$

centimetres per second, which comes out to be 1,450 metres (4,756 feet) per second, a figure in good agreement with the experimentally measured velocity. As a matter of fact, confidence in equation (4) is such that it is commonly used to determine the bulk modulus of liquids from the observed velocity of sound, in place of the static compression method that demands great precision, because liquids are hard to squeeze.

It can be noted from equation (4) that the velocity is expressed in the form of the square root of the ratio of a factor (B) that depends on the elasticity to a specific inertia factor (ρ_0). This type of dependence holds for elastic waves in general (*i.e.,* in solids as well as in gases and liquids). It means that for a given specific inertia factor (such as density), the more elastic a medium is the greater is the sound velocity. It may be that the two factors are interdependent, and then the sound velocity formula can take on a different form. This is true, for example, for gases, as is made clear in the next paragraph.

To use equation (2) for gases requires the so-called equation of state, which connects pressure, density, and temperature. For an ideal gas (see MATTER) the equation of state says that the pressure (p) divided by the density (ρ) is proportional to the absolute temperature, or

$$p/\rho = RT, \qquad (5)$$

in which T is the absolute temperature (Celsius temperature plus 273°) and the constant of proportionality, R, is the ideal gas constant per gram. It can be shown that if the temperature remains constant the ratio of the excess pressure to the excess density is also equal to RT—that is, $p_e/\rho_e = RT$—and therefore that the velocity of sound is equal to the square root of the gas constant times the absolute temperature and also equal to the square root of the ratio of the pressure to the density; *i.e.,* $V = \sqrt{p/\rho}$. As noted above, this is the result obtained by Newton. It does not agree with experiment. If one follows Laplace's assumption that the pressure and density changes that take place in a gas in sound transmission are adiabatic instead of isothermal—that is, the temperature in a gas through which a sound wave passes does not remain constant—one must use the equation in which the pressure divided by the density raised to the γ power is a constant, or $p/\rho\gamma$ = constant, in which γ (gamma) is equal to c_p/c_v, the ratio of the specific heat of the gas at constant pressure (c_p) to the specific heat at constant volume (c_v). Then, the velocity of sound is equal to the square root of gamma times the ratio of the actual fluid pressure to its density, or

Newton's law of sound propagation

$$V = \sqrt{\gamma p/\rho}. \qquad (6)$$

This formula agrees so well with experiment at sonic and low ultrasonic frequencies that it is often employed to determine the value of gamma from measurement of sound velocity. It might at first be supposed that if the sound-induced changes in pressure took place adiabatically at audible frequencies, they would continue to behave adiabatically as the frequency increases. That conclusion would follow from the reasoning employed by Laplace to deduce equation (6). Laplace's reasoning was faulty, however, and at very high ultrasonic frequencies (perhaps of the order of 10^{12} hertz) the velocity of sound follows the Newtonian formula.

For non-ideal gases and vapours—*i.e.,* those that do not obey the equation of state expressed by equation (5)—the simple formula (6) must be corrected, by methods given in advanced treatises.

In any case, for an ideal gas at what may be called ordinary frequencies, equation (6) shows that the velocity of sound does not depend on pressure or density but only on the absolute temperature. Thus equation (6), with the use of the equation of state, states that velocity is equal to the square root of the product of gamma, the gas constant, and the absolute temperature, or $V = \sqrt{\gamma RT}$. This equation can be rewritten in more convenient form. If the velocity of sound in dry air at 0° C (32° F) is denoted by V_0 that at temperature $t°$ C becomes equal to the velocity at 0° C times a factor, the square root of the quantity 1 plus the Celsius temperature divided by 273, or

$$V_t = V_0\sqrt{1 + t/273}.$$

For dry air under standard conditions (*i.e.,* 0° C), $V_0 = 331.3$ metres (1,086.7 feet) per second. For room temperature (20° C or 68° F) the equation then yields a velocity of 344 metres (1,128 feet) per second or 0.214 mile per second.

sence of persion

As the preceding equations indicate, under what may be termed ordinary conditions, the velocity of sound even in an ideal gas and indeed in all actual gases is independent of the frequency—*i.e.,* there is no so-called dispersion (see MECHANICS). If, however, the ratio of frequency to pressure (*i.e.,* f/p) increases sufficiently, the velocity of sound, even in a relatively permanent gas like hydrogen, also shows an increase. In the case of hydrogen, for example, as the ratio of frequency to pressure increases from one megahertz per atmosphere to 30 megahertz per atmosphere, the velocity of sound waves increases by about 8 percent from its standard low frequency value of 1,284 metres (4,212 feet) per second.

In the case of liquids to which equation (4) applies, strictly speaking, the adiabatic bulk modulus or compressibility must be used. For liquids, however, these values as a rule differ little from their isothermal counterparts. Because the dependence of the compressibility of a liquid on the temperature is a complicated affair, it is not possible to derive simple equations to express the dependence of the sound velocity on temperature. Empirical formulas found in advanced treatises show that the sound velocity in water, for example, increases as the temperature rises to 74° C (165° F) and thereafter decreases. For most other liquids, decrease of velocity with increase in temperature is the rule.

Compressional waves in solids are usually considered to be sound waves. Their velocities follow the pattern described in the beginning of this subsection, viz., they are expressible as the square root of the ratio of an elasticity factor to a specific inertia factor. The velocity (V) of a compressional wave in a long solid rod, for example, is expressible in the following way: the velocity (V) is equal to the square root of Young's modulus (the "stretch" modulus of elasticity, Y) divided by the equilibrium density (ρ_0) of the rod material; *i.e.,* $V = \sqrt{Y/\rho_0}$. For most hard solids the velocity here has a range of values from about 1,000 metres (3,300 feet) per second to 6,000 metres (19,800 feet) per second, depending on the elasticity and density. Thus the compressional wave velocity in a steel rod is many times that in a lead rod, as the density of steel is less than that for lead, and the Young's modulus for steel is about 13 times that of lead.

For a three-dimensional solid—*i.e.,* one not in the form of a long thin rod—the compressional wave velocity is similar to equation (4), except that the bulk modulus is increased by a quantity connected with the shear modulus (see MECHANICS). It is $V = \sqrt{(B + 4\mu/3)/\rho_0}$, in which B is as usual the bulk modulus, ρ_0 is the equilibrium density, and μ is the shear modulus.

Wave fronts and rays. It has already been pointed out that an audible sound wave tends to spread out in all directions from the source. It is helpful in describing this situation to introduce the concept of wave front: an imaginary surface of such a kind that at any instant the disturbance characterizing the sound wave is the same at every point of it.

Spherical wave front

An example is provided by a bird radiating a sound wave into the surrounding air. Since the sound wave propagates in all directions at a constant velocity, at any instant the state of compression of the air in this wave will be the same (to a good approximation) on the surface of a sphere with its centre at the bird. This sphere is a spherical wave front. The whole space surrounding the quasi-point source is filled with such wave fronts, each characterized by its appropriate phase of the disturbances. The propagation of the wave can be thought of as equivalent to the spreading of the sphere throughout space as its radius grows larger at a rate equal to the speed of sound in the medium. The expanding ripples on the surface of water produced by a dropped stone provide a clear analogy. A flat plate, on the other hand, vibrating in a direction perpendicular to its surface alternately compresses and rarefies the air and so produces a wave front that, if confined in a tube of uniform cross section, is approximately a plane wave front. Plane and spherical wave fronts are the two most important varieties in the study of sound-wave propagation.

Though wave fronts are an essential element in the description of sound-wave propagation through three-dimensional space, it is often convenient to describe the propagation in terms of rays—*i.e.,* lines perpendicular to a wave front. The ray passing through a particular point at a given instant indicates the direction in which the wave transmission is taking place at that time and place. Sound rays can often be useful, though not so much so as light rays, as it is harder to produce a genuine beam of sound concentrated in one direction because the wavelength of sound is in general so much larger than that of light. At ultrasonic frequencies, however, it is possible to approximate sound beams, and then ray acoustics becomes of value.

Reflection and refraction. The existence of an echo when a sound is emitted in the neighbourhood of a large, hard surface is a manifestation of the fact that sound waves can be reflected when they strike a surface separating media of different properties. Moreover, sound-wave fronts are bent (refracted) when sound crosses such a boundary; *e.g.,* in going from air to water or vice versa.

Huygens' principle of wave propagation

The laws governing the reflection and refraction of sound waves are best understood in terms of a fundamental principle stated by a Dutch scientist, Christiaan Huygens. According to this principle each point on a wave front (F_1 in Figure 1, for example) may be assumed to be the source of a hemispherical wavelet that moves outward from F_1 in the direction of propagation. The new wave front after a short time is the mathematical envelope of all these wavelets—*i.e.,* the surface tangent to them all (see F_2 in Figure 1). A simple but important illustration of Huygens' principle is the establishment of the laws of reflection and refraction of a plane wave at a plane interface separating two fluid media with different densities and different sound velocities. In Figure 2, SS' represents the trace (intersection) in the plane of the page of the plane interface between a fluid medium (I) in which the velocity of sound is V_1 and the mean density is ρ_1, and a medium II in which the corresponding quantities are V_2 and ρ_2, respectively. AB denotes the trace of a plane wave front (perpendicular to the plane of the page) approaching the interface SS' from medium I. If the wave front AB is incident on SS' as CD with angle of incidence i, as in the figure, then AC and BD are incident rays that make an angle i with the normal CN to the interface. The reflected and refracted wave fronts can be constructed by means

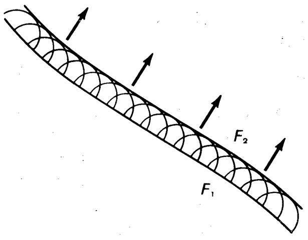

Figure 1: Huygens' construction showing points on wave front F_1 generating wavelets to produce new wave front F_2 (see text).

of Huygens' principle. At the instant the disturbance at one end of the incident wave front has reached C on the interface, the disturbance at the other end is still at D in medium I. In a time equal to the distance DE divided by the velocity (DE/V_1) that it takes the disturbance at D to reach E on the interface, the disturbance will travel out in all directions from C. In particular, in medium I it will traverse a distance equal to DE.

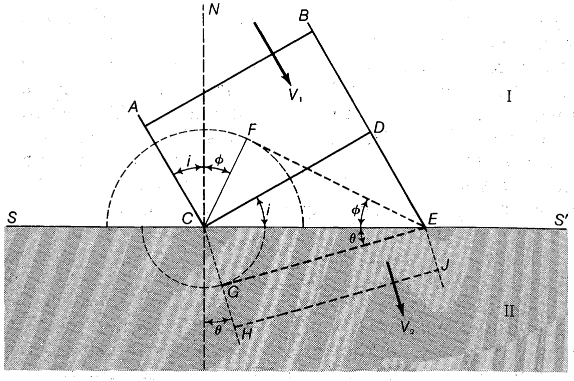

Figure 2: Huygens' construction showing wave fronts *AB* and *CD* that are reflected as *FE* at the boundary between media I and II and refracted as *GE* and *HJ* to give the law of reflection and Snell's law of refraction (see text).

If, with C as centre, a semicircle is drawn in medium I with radius DE and a straight line from E is drawn tangent to this, the result is EF, which makes the angle $\varphi = i$ with SS'. That EF is the trace of the reflected wave front can be confirmed by making a Huygens' construction for other points on the incident wave front. It is seen that the reflected wave front makes the same angle with the interface as the incident wave front. This, combined with the fact that both wave fronts are perpendicular to the same plane (plane of the page), constitutes the law of reflection. Equally well expressed in terms of the incident and reflected rays, this law is the same law that holds for light, namely, that the angle of reflection is equal to the angle of incidence.

The same kind of Huygens' construction shows that, after transmission across the interface, the incident wave front CD is changed to the refracted wave front GE, making the angle θ with SS', such that the ratio of the sine of the angle of incidence to the sine of the angle of refraction is equal to the ratio of the velocity in the first medium to that in the second—*i.e.,*

$$\sin i/\sin \theta = V_1/V_2 = n_{12}. \qquad (7)$$

This is Snell's law for the refraction of plane waves at a plane interface, with n_{12} called the index of refraction of medium II with respect to medium I. A similar law, in somewhat modified form, holds for the transmission of wave fronts through a medium with continuously varying properties. The law as expressed in equation (7) accounts well for the passage of sound waves from air to water, or vice versa, when the media are at rest.

In Snell's law, equation (7), if the velocity in medium I is greater than that in medium II ($V_1 > V_2$), the index of refraction is greater than one ($n_{12} > 1$) and refraction takes place for every angle of incidence. If the velocity in medium I is less than in medium II ($V_1 < V_2$), however, the index of refraction will be less than one ($n_{12} < 1$), and when the incident ray makes an angle i such that $\sin i = n_{12}$, Snell's law gives $\sin \theta = 1$; *e.g.*, the refracted ray just grazes the interface in the second medium—that is, the refracted wave front moves so as to remain perpendicular to the interface. For sin i greater than n_{12}, as may well be possible since the largest value of sin i is equal to one, sin θ becomes greater than one, which is mathematically impossible. The physical result, under this condition, is that no refraction takes place; instead, total reflection ensues. The angle at which this occurs (arc sin n_{12}) is called the critical angle of incidence, and for angles greater than this, all the sound is reflected, analogously to the similar phenomenon in light.

Total reflection

When the two media—*i.e.,* air and water—are moving relative to each other through the action of wind and water currents, the refraction of sound becomes more complicated and so the result will be given only for a relatively simple case in which the velocity of flow of medium I is U_1 parallel to the interface and that of medium II is U_2, also parallel to the interface. Then the law of refraction becomes:

$$V_1/\sin i - V_2/\sin \theta = U_2 - U_1. \qquad (8)$$

If the two velocities are equal ($U_2 = U_1$)—*i.e.,* the two media are moving together with no relative velocity—equation (8) reduces to equation (7). Equation (8) also applies, as more elaborate analysis shows, when the sound velocity and flow velocity vary continuously in a stratified or layered medium in which the flow is parallel to the layers. Then all quantities in (8) vary from place to place in a direction perpendicular to the stratification. Examination discloses that even if velocities V_1 and V_2 are constant, the effect of the motion of the medium is to bend the wave front and ray in the direction in which the motion takes place. Thus, if the wind velocity increases upward from the ground, sound-wave fronts are lifted to windward and depressed to leeward. This tends to decrease the range to windward and increase it to leeward. When the velocities V_1 and V_2 also vary with distance above the ground, as is commonly the case in the atmosphere, the wave-front propagation becomes even more complicated. Nevertheless, many practical cases have been worked out successfully. These considerations are of great importance in sonic gun-ranging.

Energy propagation: intensity of sound. As has already been pointed out, the propagation of sound may be considered as a form of transmission of energy through the material medium. When, for example, a fluid is disturbed at any point, work is done, and energy is expended. The reappearance of the disturbance at a distant point by wave propagation corresponds to the transfer of the original energy across the intervening distance. The average rate of energy transfer per unit time per unit area of the wave front is, by definition, the intensity of the wave. This may also be expressed as the average flow of power per unit area, the practical unit of which is the watt per square centimetre (watt/cm^2).

The intensity in a plane sound wave may be evaluated by finding the time average of the product of the excess pressure (p_e) and the flow velocity ($\partial\xi/\partial t$) in the medium. Inasmuch as pressure is force per unit area, the product just cited is valid as far as the consistency of dimensions is concerned. (The units of pressure times velocity are dyne centimetre^{-2} · centimetre second^{-1}, whereas the units of power per unit area are erg second^{-1} centimetre^{-2}. These are equivalent, as an erg is a dyne centimetre.) It is necessary to take the average of the product in question because both the excess pressure and the flow velocity vary in time and space as the wave progresses. Hence the flow of energy actually fluctuates, and to get a constant effective measure of the flow of energy per unit area, an average must be taken. The appropriate mathematical analysis shows that the intensity of a plane sound wave is given by:

$$I = p^2_{e,\,max}/2\rho_0 V. \qquad (9)$$

in which $p_{e,\,max}$ is the maximum excess pressure in the wave, ρ_0 is the average equilibrium density of the medium, and V is the sound velocity. This expression is independent of frequency. The use of the decibel notation in the representation of intensity has already been described in the section on the general nature of sound waves, and examples were given. It is sufficient to recall here that for ordinary conversational speech, at a distance of about one metre from the speaker's mouth the maximum excess pressure is one dyne per square centimetre (dyne/cm^2). For dry air at 20° C (68° F) and normal atmospheric pressure, the equilibrium density (ρ_0) is 0.001205 gram per cubic centimetre, and the velocity (V) is 344 metres (1,128 feet) per second. Substitution of these values into equation (9) and subsequent division by 10^7 to convert to watts per

Intensity of speech

square centimetre yields an intensity (I) of about 10^{-9} watt per square centimetre, or 70 decibels above the minimum audible intensity of 10^{-16} watt per square centimetre.

From equation (9) it follows that the intensity for given excess pressure depends on the medium and in particular on the product equilibrium density times sound velocity ($\rho_0 V$). The latter quantity is known as the specific acoustic resistance of the medium for a plane wave. For water, for which the specific acoustic resistance is about 3,800 times that for air under standard conditions, it takes an excess pressure some 60 times that for air to produce the same intensity. It will be seen below in the section on sound sources that for given frequency and excess pressure a solid sound source is a more efficient radiator in water than in air.

The intensity of a spherical wave diverging from an effective point source can still be written in the form given by equation (9), provided it is remembered that for this type of wave the maximum excess pressure is no longer constant but varies inversely as the square of the distance from the source. Hence the intensity as given in equation (9) still applies if the maximum excess pressure is the excess pressure amplitude at the place where the intensity is to be evaluated.

Flow of sound energy across a boundary. When a sound wave strikes the interface separating two media of different physical properties (*e.g.,* air and water), as was already seen, some of the wave disturbance is reflected and some transmitted (and in general refracted) through the second medium. The transmission of the sound energy is thus affected by the presence of the boundary.

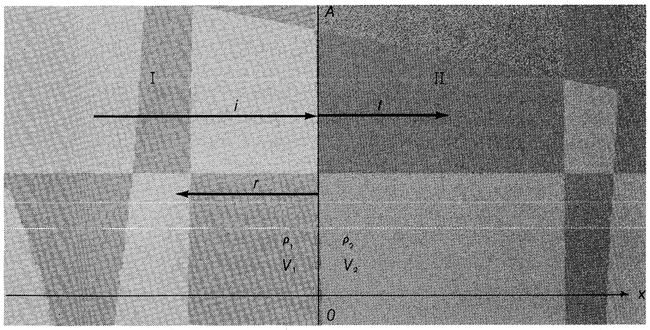

Figure 3: Direction of incident, transmitted, and reflected waves at boundary *AO* between media I and II (see text).

Figure 3 represents a plane boundary *AO,* separating two media I and II, that is perpendicular to the direction of plane wave propagation along the x axis. In medium I the mean equilibrium density is represented by ρ_1 and the sound velocity by V_1. The corresponding quantities in II are ρ_2 and V_2, respectively. The arrow i denotes a plane harmonic sound wave travelling from left to right in medium I in the x direction and striking the boundary at x equal to zero. Similarly, r denotes the wave in I reflected from the interface, whereas t denotes the wave transmitted across the boundary into medium II.

The amplitudes of the excess pressure in the incident, reflected, and transmitted waves may be represented by p_i, p_r, and p_t, respectively. These quantities are not independent inasmuch as the sum of the incident and reflected excess pressure amplitudes must equal the transmitted excess pressure amplitude. There is a similar condition connecting the flow-velocity amplitudes in the incident, reflected, and transmitted waves. The result of applying these two conditions can be expressed by the following two equations:

$$\frac{p_r}{p_i}=\frac{1-\rho_2V_2/\rho_1V_1}{1+\rho_2V_2/\rho_1V_1}, \qquad (10)$$

$$\frac{p_t}{p_i}=\frac{2}{1+\rho_1V_1/\rho_2V_2}. \qquad (11)$$

In the case in which the density times velocity (ρV value) is the same in both media ($\rho_2V_2=\rho_1V_1$), equations (10) and (11) give p_r equal to zero and p_t equal to p_i; in words, all the sound energy is transmitted across the boundary, and none is reflected. This would be realized if the two media were precisely the same: the interface would then of course disappear. It may well be possible, however, to find two different media for which the ρV values are the same and hence secure complete transmission without reflection. Thus there is a certain kind of soft rubber whose ρV value is about the same as that of water. A water tank lined with this material would appear to have no reflecting walls, and this is helpful in the calibration of certain acoustical instruments.

Transmission of sound without reflection

The greater the difference between the ρV values of the two media, the greater is the percentage of reflection at the interface. The actual power-transmission ratio (P_r), which is the ratio of the intensity of the transmitted sound wave to that of the incident sound wave, also depends only on the factors mentioned above. Calculation shows that the power-transmission ratio is given by equation (12):

$$P_r=\frac{4\rho_2V_2/\rho_1V_1}{(1+\rho_2V_2/\rho_1V_1)^2}. \qquad (12)$$

Again from equation (12) it can be seen that when the ρV value is the same in both media, the power-transmission ratio is equal to one, meaning that 100 percent of all the incident sound energy or power is transmitted. The specific acoustic resistance, ρV, is clearly an important criterion for the transmission of plane sound radiation across boundaries.

Formula (12) together with the corresponding formulas for the case of oblique incidence have had important practical application, such as to acoustic transmission in the atmosphere between layers of air at different temperature and humidity and to transmission in seawater with temperature gradients.

Acoustic impedance. The significance of the product ρV in sound transmission prompts further attention to it. Referring to this quantity as the specific acoustic resistance of a plane harmonic wave inevitably suggests the analogy of electrical impedance in alternating electric current, defined as the ratio of the alternating electromotive force to the alternating current (see ELECTRICITY AND MAGNETISM). It has therefore been thought helpful to define the acoustic impedance as the ratio of the excess pressure to the rate of volume flow. The volume flow is obtained from the flow velocity ($\partial\xi/\partial t$) by multiplying by the area (S) of the wave front. Hence the impedance (Z) has a value equal to the excess pressure divided by the product of the area and the flow velocity, or $Z=p_e/(S\partial\xi/\partial t)$. In words, the acoustic analogy of electromotive force is taken to be the excess pressure, and the acoustic analogy of the electric current is the volume flow rate.

In the mathematical theory of alternating currents the impedance is a complex quantity (so called because it involves the square root of minus one, an imaginary number) of which the real part is the resistance of the circuit and the imaginary part (having a factor $\sqrt{-1}$) is the reactance. In the acoustic wave case the quantity Z for a plane wave is real and equal to the density times velocity divided by wave front area ($\rho V/S$). Hence it is taken to correspond to an electrical resistance. The acoustic resistance for unit area of wave fronts (not per unit area) is the product ρV and this is justifiably called the specific acoustic resistance. Analysis shows that the acoustic impedance for a spherical wave has both real and imaginary components, corresponding to resistance and reactance, respectively. The physical meaning of this is connected with the spreading of the wave in all directions. The reactance of a diverging spherical wave turns out to be positive and behaves like an electrical inductance (*i.e.,* an inertia factor), whereas the reactance of a spherical wave converging to a point is negative and thus behaves like an electrical capacitance (*i.e.,* the reciprocal of a stiffness).

Specific acoustic resistance

The impedance notation has the advantage of permitting acoustic transmission calculations to be replaced by analogous electrical computations. Many acoustical effects can be readily estimated in terms of known values of acoustic impedance at strategic points. For example, the effective-

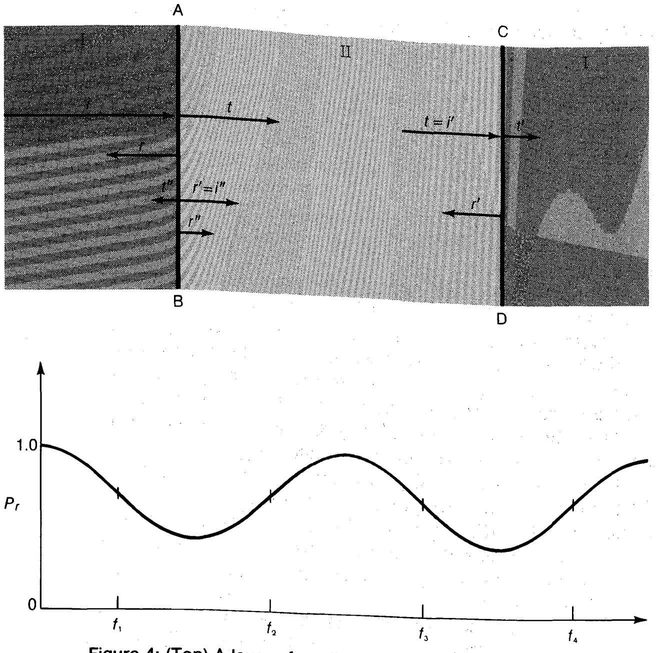

Figure 4: (Top) A layer of medium II situated between layers of medium I (see text). Waves (i, i', i'') incident on both faces AB and CD are reflected (r, r', r'') and transmitted (t, t', t''). (Bottom) Plot of power-transmission ratio (P_r) as a function of frequency (f) transmitted through medium I as above. ($P_r = 1$ represents total transmission.)

ness of a horn (*i.e.*, a tube of variable cross section) as both a receiver and a transmitter of sound waves is directly proportional (for a given volume current) to the value of the acoustic resistance at the horn's throat. The effective acoustic transmission through a tube in which a branch line is inserted at some point can be shown to depend in a relatively simple fashion on the acoustic impedance at the branch point. Problems in room acoustics involving the reflection of sound from the walls of a room can often be simplified by the use of the impedance notation.

Selective transmission: filtration. An important case of the transmission of acoustic energy arises when a finite layer of different acoustic material (medium II) is inserted in a medium (medium I) in which the propagation takes place. A simple example is illustrated in Figure 4 (top). To determine the influence of the layer of medium II on the transmission, a mathematical analysis can be made of the transmission of a plane harmonic sound wave as it passes from medium I through medium II and back into medium I. This yields a power transmission ratio (P_r)—*i.e.*, the ratio of the average power emerging from medium II to that entering it—which is found to depend on the frequency of the sound and the thickness of the layer of medium II, as well as on the ρV value for each layer. The plot of P_r as a function of frequency has the general form shown in Figure 4 (bottom). The transmission in this circumstance is said to be selective with respect to frequency and passes through a succession of maxima and minima as the frequency increases.

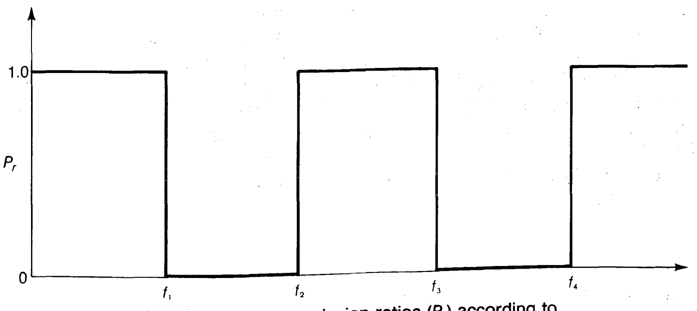

Figure 5: Power-transmission ratios (P_r) according to frequencies (f). Frequencies lying between 0 and f_1, f_2 and f_3, etc., called pass bands, are totally transmitted. Frequencies between f_1 and f_2, f_3 and f_4, etc., called attenuation bands, are totally absorbed.

This suggests the possibility of arranging a collection of media that will act as an acoustic filter—*i.e.*, transmit waves of certain frequencies well, but fail entirely to pass waves of other frequencies. Further theoretical study indicates that this result can be realized approximately by a structure consisting of a sequence of alternating layers of media I and II. As the number of layers increases the transmission ratio approaches more nearly the form shown in Figure 5. Here the power-transmission ratio is equal to one for frequencies lying between zero and f_1, equals zero for frequencies between f_1 and f_2, is unity again for frequencies between f_2 and f_3, etc. A frequency band such as $f_2 f_3$, in which the power-transmission ratio is one, is called a pass band, whereas a band such as $f_1 f_2$, in which the power-transmission ratio is equal to zero, is called an attenuation band. The structure of alternating layers thus acts as an acoustic filter with a series of pass and attenuation bands. Because the first pass band extends from zero to f_1, it is commonly called a low-pass filter.

Attenuation banc

The type of acoustic filter just described depends for its behaviour on the alternation of properties of two different media. This, however, is not necessary to achieve the same general result. Figure 6 (top) represents a succession of cylindrical tubes of cross-sectional areas S_1 and S_2 and lengths l_1 and l_2, respectively. Analysis and experimental tests show that such a structure acts as a low-pass filter for harmonic sound waves passing through it. The transmission pattern of pass and attenuation is indeed very similar to that shown in Figure 5. Here the ratio S_1/S_2 of the cross-sectional areas of the constricted and expanded tubes plays the same role as the ratio of the ρV values of the specific acoustic resistances in the iterated-media filter. The lengths l_1 and l_2 of the section also have a decided influence on the frequency range of the pass and attenuation bands.

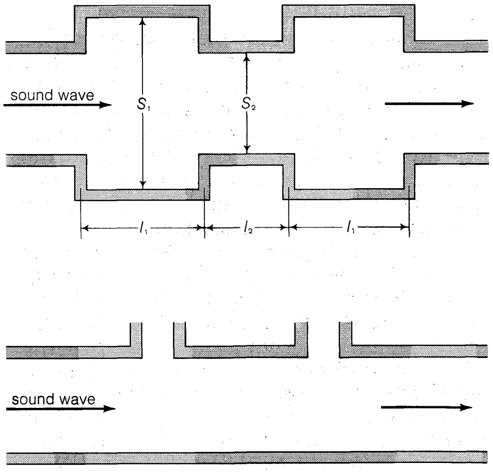

Figure 6: (Top) Low-pass acoustic filter, consisting of a succession of cylindrical tubes, cross-sectional areas S_1 and S_2 and lengths l_1 and l_2, for harmonic sound waves (see text). (Bottom) High-pass acoustic filter through which only high-frequency waves pass.

A tube with equally spaced side orifices, such as are shown schematically in Figure 6 (bottom), also acts as an acoustic filter, but in this case the lowest frequencies are attenuated, and hence it is called a high-pass filter. Many other types of sound filters have been constructed to suppress or silence certain frequency bands in blowers, mufflers, and other equipment producing noise by gas flow. Filters consisting of solid sections have also been constructed. Many musical instruments involve acoustical filtration in their behaviour.

Sound absorption and dispersion in fluids. In the previous discussion of sound filtration no account was taken of the dissipative absorption of sound radiation as it passes through any material medium and its transformation into heat. This leads to a loss in intensity with distance traversed that has nothing essentially to do with the selective transmission just treated. Also, as has already been mentioned, a decrease in intensity of a diverging spherical wave is caused by geometrical spreading. Superposed on this decrease is the absorption due to the interaction between the sound wave and the medium. The properties of the medium responsible for this absorption are shear viscosity, heat conduction and radiation, diffusion, and molecular energy exchange. Shear viscosity is a kind of internal fluid friction that manifests itself in the tendency of parallel moving layers of fluid to have their relative velocity reduced. The coefficient of shear viscosity (usually denoted by η) is a measure of this tendency (see MECHANICS).

To remain correct at all frequencies, the formula for the intensity of a plane harmonic acoustic wave in terms of the distance traversed must take account of the fact that, in propagation through a viscous medium, the sound velocity changes with frequency; *i.e.,* there is dispersion. Unlike the situation in light in which, except for anomalous dispersion, the velocity decreases as the frequency increases, the effect of the viscosity in a medium is to increase the sound velocity with increase in frequency. The effect is a small one, however, even in viscous media like the liquid, glycerin.

ct of
osity
ersion

The medium also produces sound absorption by conducting away heat produced in the compressional disturbance involved in the propagation of sound. For monatomic gases (*e.g.,* helium and argon) the contribution of the heat conduction to the absorption coefficient is about 70 percent of that due to viscosity. For polyatomic gases (*e.g.,* hydrogen sulfide and carbon dioxide) the influence of heat conduction is much less, and in liquids it is generally negligible. The effect of diffusion is also negligible save in mixtures of gases with considerably different molecular weights; *e.g.,* helium and krypton.

Experimentally determined values of the absorption of sound in fluids, especially polyatomic gases, are in general far in excess of those calculated above on the basis of viscosity and heat conduction. The explanation for this disparity has been sought successfully in a closer look at the energy exchanges among the molecules composing the fluid. After all, the propagation of sound is really a molecular phenomenon, which is somehow masked in the usual macroscopic theory of disturbances in elastic media. When a fluid is compressed during the passage of a sound wave, the average translational velocity of the molecules is increased, and it is the transfer of the associated momentum and kinetic energy by collision to the nearby molecules that provides for the transmission of the wave. But this is not all that happens. In a gas made up of polyatomic molecules, the molecules have internal energy of rotation and vibration as well as translational energy of their centres of mass. In the collision of the molecules, this internal energy is continually being exchanged with the external translational energy. When the translational energy is increased by the passage of a sound wave, some of the increase goes into the internal energy states. There is, however, a lag in its return to the translational form. Hence changes in the translational energy fail to keep pace with the propagation of the wave, and some of the original energy of the disturbance is rendered unavailable for transmission during each frequency cycle. It is therefore lost in dissipation and the result is absorption. This type of mechanism, called relaxation absorption, has proved adequate to account for the experimentally determined values. It has led to the establishment of a 20th-century branch of the theory of sound called molecular acoustics, by which sound measurements are able to give insight into the interaction of molecules in fluids.

lecular
ustics

Diffraction and scattering. When a sound wave strikes an obstacle of finite size, some of the sound energy is reflected, some is transmitted into the obstacle, and some gets around the obstacle and is said to be diffracted. It is customary to say that the original beam of sound is scattered by the obstacle. The scattering pattern depends on the relation between the wavelength of the primary incident wave and the dimensions of the obstacle. In the case, for example, of a rigid sphere of radius a as the obstacle, if the wavelength (λ) of the incident radiation is small compared with its circumference ($2\pi a$) the scattered wave on the side of the sphere opposite to the oncoming radiation combines with the latter to produce zero intensity by destructive interference (so called because, being out of phase with one another by 180°, their displacements are annulled). Hence the spherical obstacle forms a shadow that is sharper the smaller the ratio of wavelength to circumference ($\lambda/2\pi a$). This is analogous to an optical shadow in the case of light and justifies the use of sound rays (geometrical acoustics) in place of the propagation of wave fronts. For audible waves (λ in air greater than about two centimetres or 0.8 inch), however, this type of shadow-forming scattering is important only for relatively large obstacles.

At the opposite extreme, if the wavelength is much greater than the circumference ($\lambda >> 2\pi a$), the primary wave is scattered in all directions and there is no distinct shadow. The intensity of the scattered wave is directly proportional to the square of the volume of the scattering particle (in this case a sphere) and inversely proportional to the fourth power of the wavelength. This is the Rayleigh scattering law in acoustics; its optical analogue helps account for the blue colour of the sky (see LIGHT). In the scattered radiation the higher frequencies will produce the higher intensities. Thus it is observed that sound waves scattered by a grove of trees appear to be raised in pitch. A similar phenomenon occurs when underwater sound waves are scattered by air bubbles.

An interesting case of scattering is that in which light is scattered by sound. Optical diffraction by means of a diffraction grating is well-known. A sound wave can serve as a kind of diffraction grating in a material medium (a liquid as well as a gas) and hence diffract light. Study of the light-diffraction spectrum can actually provide a measure of the intensity of the sound.

The fluctuations in density in any material medium (at any temperature above absolute zero) due to molecular motion and ionic vibrations may be considered a form of sound radiation at extremely high frequencies—*i.e.,* about 10^{12} hertz and higher. This is sometimes called the pretersonic, or ultrahigh, ultrasonic range. Such sound waves also scatter light and the result is the so-called Brillouin scattering, which in the 1960s and 1970s showed great promise in the study of material structure, particularly of liquid structure. It has proved advantageous in the study of crystal lattices (a crystal is said to have a lattice structure because its atoms are arranged in an orderly array) to associate a sound "particle" with the ultrahigh-frequency waves travelling back and forth in the solid as a result of the lattice vibration. This hypothetical particle is called the phonon. It plays the same role with respect to ultrahigh-frequency acoustic radiation that the photon, or light particle, plays with respect to electromagnetic radiation.

The
phonon

Another example of the interaction of light and sound is the use of laser light (a narrow beam of coherent light) to stimulate the production of high-frequency sound waves in a crystal. A similar technique can also serve to amplify existing ultrasonic waves.

Waves in bounded media: standing waves in a tube. When sound waves travel in a bounded medium with reflecting surfaces, the superposition of waves travelling in many directions produces important and interesting effects. The simplest case is that of a cylindrical tube of length l and cross-sectional area S, closed rigidly at both ends. A disturbance produced anywhere in the air in the tube will be reflected from both ends and produce in general a series of waves travelling in both directions along the tube. From the geometry of the situation and the constant value of sound velocity, these waves must be periodic with frequencies determined by the boundary conditions at the ends of the tube; *i.e.,* zero resultant air displacement. The allowed frequencies turn out to be a multiple of the sound velocity in the air in the tube divided by twice the tube length, or

$$f_n = nV/2l, \qquad (13)$$

in which V is the sound velocity and n is any integer. These frequencies f_n in which $n = 1, 2, 3, \ldots$ are called the characteristic frequencies or normal modes of vibration of the air column. The fundamental frequency, or first harmonic, is described by an integer value of one and is $f_1 = V/2l$ with the associated wavelength $\lambda_1 = 2l$. The frequency f_2 is called the second harmonic and so on for $n = 3, 4, 5, \ldots$. The harmonics beyond the fundamental are also often referred to as overtones.

End correction for open pipes

Approximately the same set of normal modes holds for a cylindrical tube open at both ends, though the boundary conditions are different. It is assumed that the excess pressure p_e is zero at an open end, since it is open to the surrounding air. The justification of this assumption cannot be easily explained, but it can be confirmed experimentally by placing a probe microphone at the open end. Actually, it turns out that the point of zero excess pressure is never precisely at the open end but somewhat beyond it, producing an effect called an end correction to the normal mode frequencies. Application of the ideal boundary conditions just mentioned to a tube closed at one end and open at the other (the ideal case of a so-called closed organ pipe) leads to an equation for the normal mode frequencies that is similar to equation (13), but the whole integer is replaced by a half integer value:

$$f_n = (n - \tfrac{1}{2})\ V/2l, \qquad (14)$$

in which n equal to one corresponds to the fundamental, and n equal to two to the second harmonic, etc. Because of the open-end effect, however, the length $(2l)$ in equation (14) must be modified by adding a quantity that depends on the tube diameter. Thus, the actual frequencies are

$$f'_n = (n - \tfrac{1}{2})\ V/2\,(l + S/c),$$

in which S is the area of cross section of the tube and c is a quantity with the dimensions of length of about the magnitude of the diameter of the tube. It is called the acoustic conductivity of the open end of the tube. The acoustic conductivity is difficult to calculate theoretically and is often evaluated by the actual measurement of the frequency f'_n.

In an ideal sound-wave disturbance corresponding to a given normal mode in a tube open at both ends, there are positions in the tube, namely, those at distances (x) from one open end that satisfy the equation, $\cos n\pi x/l = 0$, at which the displacement is zero at all times. Such a situation cannot exist in a progressive wave, as shown by equation (1). Hence the resultant wave disturbance corresponding to a normal mode is appropriately termed a standing or stationary wave. The positions of permanent zero displacement are known as nodes, whereas the intermediate positions for which $\cos n\pi x/l$ is equal to one instead of zero are known as antinodes or loops and correspond to maximum displacement. At a node the excess pressure is a maximum, whereas at an antinode it is zero. The distance between successive nodes is equal to a half wavelength of the particular mode. As an example, the fundamental in an open-ended tube is shown schematically in Figure 7 (left) by means of portions of sine waves (the maxima of a wave indicate the positions along the tube where the displacement is greatest). Displacement antinodes are indicated by A_1 and A_2, whereas N (at centre) is a node. In Figure 7 (right) the second harmonic is indicated with antinodes at A_1, A_2, and A_3, and nodes at N_1 and N_2. The latter are, respectively, 1/4 and 3/4 of the length of the tube from the open end at the left. In Figure 8 the corresponding situation is shown for a tube closed at one end and open at the other. In Figure 8 (left) the closed end is node N and the open end is an antinode A. The length of the tube is $\lambda_1/4$. In Figure 8 (right) the closed end is still a node N_1 and the open end an antinode A_2, but there now is another antinode A_1 and another node N_2. For the nodes in the tube closed at one end (at $x = 0$), the analytical condition that exists is $\sin (n - 1/2)\ (\pi x/l) = 0$, in which n equal to one corresponds to the fundamental, etc.

Acoustic propertie of a roon

The preceding analysis can be applied to any confined space as, for example, a room with or without open windows. The reflections of a sound disturbance from the boundaries of the room produce a three-dimensional standing wave pattern that can be analyzed with a set of normal nodes, depending on the shape and dimensions of the room. Some of these nodes may be much more prominent and correspond to more energy flow than others and thus have a good deal to do with the acoustical properties of the room. Here absorption at the walls and in the air of the room plays an important role in diminishing the influence of these normal nodes.

Radiation pressure. For a plane harmonic progressive wave the excess pressure produced by the disturbance as it moves through a fluid is a sinusoidally varying function of time and space and hence vanishes if averaged over the time at any particular place. Associated with a progressive sound wave in any physically realizable fluid medium, however, there is also an excess pressure that does not become zero on the average, thus making a net addition to the static pressure prevailing in the fluid. This is known as the radiation pressure. It arises because the simple linear expressions for displacement and excess pressure, like that in equation (1), hold only for sound of relatively small intensity. For sounds of greater intensity, sine-squared terms and the like enter into the expression for the excess pressure, and it is these terms that, when averaged over the time, give a nonvanishing result, corresponding to the steady radiation pressure. The subject is admittedly a difficult one, and it turns out that there are at least two different kinds of radiation pressure, depending on definition, theoretical calculation, and experimental measurement, but the most practical from an experimental point of view is expressed simply as the ratio of the intensity (I) of the sound radiation to its velocity (V) and has the value $P_{rad} = I/V$. To get an idea of the order of magnitude of the radiation pressure, it is interesting to consider sound in air of intensity 10^{-2} watt per square centimetre, which is about 140 decibels above the minimum audible intensity. This intensity is at about the threshold of pain in the human ear and is equivalent to 10^5 ergs per square centimetre-second. In this case the radiation pressure comes out about three dynes per square centimetre.

Nonlinea acoustics

Radiation pressure is an illustration of what has come to be called nonlinear acoustics, resulting in effects from such large sound intensities that the ordinary linear wave equation no longer applies. Intensities of interest here are about 150 decibels above minimum audible or higher (greater than absolute intensity 1/10 watt per square centimetre). Such sound waves are now referred to as macrosonic. They have become of increasing importance in connection with practical applications of acoustics in industrial processing, as in metallurgy, in underwater sound for communication and detection, and in the biomedical field for the study of individual living cells.

Shock waves. In a macrosonic or high-intensity sound wave, (*e.g.*, that due to an explosion) a disturbance that starts out with a symmetrical profile—*i.e.*, a sinusoidal curve given by equation (1)—will soon develop a steepening of the wave front, which will then take the form of a sawtooth curve if the excess pressure at a given instant is plotted as a function of distance in the direction of the wave propagation. At successive points in this wave there are, ideally, discontinuities in pressure, density, and flow velocity. Empirically, these ideal discontinuities become large changes in these quantities over a very small space interval—*e.g.*, about 10^{-4} centimetre (4×10^{-5} inch). This transition interval travels through the medium faster than the normal acoustic velocity. Called a shock wave, it can result not only from an explosion but is also emitted from an object like a missile or jet airplane moving faster than the velocity of sound. In the case of an airplane breaking the sound barrier, as the phrase goes, it results in the sonic bang or boom on the ground. Such sonic disturbances have produced a serious problem in connection with the flying of supersonic airplanes.

Sound production and perception

SOURCES OF SOUND

Types of sources. Any local change in the density of an elastic medium can serve as a source of sound. This accounts for the great variety of acoustic sources because density changes may be produced in a great many ways, including mechanical, thermal, electrical, magnetic, and chemical actions. The most common sound waves are produced by the mechanical vibrations of solids, liquids, and gases. Solid vibrators include strings and rods, membranes and plates, shells (*e.g.,* bells), as well as three-dimensional extended objects like the Earth itself. Liquid sources are not as common, but the turbulent flow of water or air provides an example. Gaseous sources include organ pipes, whistles, singing flames, and explosions, as well as turbulent airflow.

Methods of producing local density changes in elastic media vary greatly. One of the simplest is the impact of one solid on another, such as the impact of a pile driver on a pile, a piano hammer on a piano string, a drumstick on a drum, a clapper on a bell, or a shoe on a floor. Still another common method is exhibited by the friction associated with the rubbing of two solids together, as in the bowing of a violin string and in the motion of air and other gases past the surfaces of solids, as in the sound of the wind and in aerodynamic noise.

More sophisticated sound sources became technically feasible when mechanical vibrations were made possible by means of magnetic and electrical effects. The attraction of a piece of iron or some magnetic alloy to the pole of an electromagnet is of course the basis for the electric bell and the telephone receiver. The motion of a wire carrying an alternating current in a magnetic field is the basis for the so-called electrodynamic sound source used in radio and television loudspeakers. They are appropriately called electroacoustic devices because they transform electrical oscillations into mechanical vibrations, usually of rods, membranes, or diaphragms.

ctro-
ustic
ices

Still more sophisticated in many respects are the magnetostrictive and piezoelectric sound sources. The former utilize the change in dimensions produced in a magnetic solid, such as nickel, by a changing magnetic field. The latter exploit the fact that many crystals, such as quartz, change their size and shape when placed in a changing electric field. These sources have received wide use in the production of underwater sound radiation and in medical diagnosis and therapy, particularly at ultrasonic frequencies. It is customary to call such sound sources transducers because they involve the transformation of one type of vibratory energy into another. These devices are usually suitable not only for the production of sound but also for its reception as well.

Explosions caused by the rapid combustion of organic materials produce another source of sound usually in the form of noise, as exemplified by the internal-combustion engine.

Mechanical vibration and radiation efficiency. The properties of a sound source depend essentially on the nature of its elastic vibrations. The analytical details will be found in the article MECHANICS. Here the discussions will be confined to general characteristics having to do with the ability of an elastic vibrator to radiate sound energy into the surrounding medium.

When a mechanical system vibrates in a vacuum, it loses energy at a rate equal to a damping factor times the average of the square of the displacement velocity of the vibrator—*i.e.,* $R\overline{\dot{\xi}^2}$ in which R is the damping factor and $\dot{\xi}$ is the displacement velocity. The origin of the damping may be found in the internal frictional forces inherent in the vibrator and its mounting. If now the vibrator is allowed to vibrate in a material medium like a gas or a liquid, it will be found to lose energy at a greater rate because of the production of mechanical radiation, which is transmitted through the medium. The average rate of radiation of energy by the vibrator as a source of sound can be written in the form $R_r\overline{\dot{\xi}^2}$, in which R_r now represents the damping due to the radiation. In order to maintain this radiation energy at a constant average rate, it is necessary to continue to supply energy to the vibrator at the same average rate by whatever is driving it. The radiation damping factor R_r that controls the rate of sound radiation by the source is found to depend on the size and shape of the source, as well as the density of the medium into which the radiation takes place and the velocity of sound in this medium. It also depends on the frequency of the radiation.

Radiation
damping
factor

The analysis of a pulsating, spherical shell, for example, indicates that its radiation efficiency for a given displacement velocity is much greater at higher frequencies than at low and this is one reason for the technological interest in ultrasonics.

A pulsating sphere is not usually a practical sound source. Similar considerations, however, apply to the membrane or diaphragm source in loudspeakers or sonar sources for underwater sound radiation. The mathematical expressions differ in detail, but in every case, other things being equal, the radiation efficiency increases with the frequency. At all frequencies the radiation efficiency depends directly on the density of the surrounding fluid medium. This dependence makes it difficult to get radiation from any source into a medium having a density that is small compared with that of the solid vibrator itself. Such a low efficiency accounts for the often-cited experiment of the difficulty of hearing a bell in an evacuated jar, commonly explained by saying that "sound is not transmitted through a vacuum." Actually, sound waves will still travel short distances without abnormal dissipation through gases at the low pressure prevailing in such an experiment; the difficulty is to get the wave into the gas from the source in the first place.

Sound beams. In view of the relatively long wavelength of audible sound, it is obviously difficult to produce beams of such sound without the use of extremely large acoustical mirrors and lenses. Nevertheless, at ultrasonic frequencies the sound wavelength becomes small enough to make sound beam formation practical, although never with the sharpness of light beams, even at the highest ultrasonic frequencies (*e.g.,* 10^3 megahertz). Such beams are basic to the operation of sonar, the underwater echo ranging system.

Practical simple sources: voice and siren. At the beginning of the section on sound sources various types of sound sources were mentioned; here are presented some specific examples. First to be considered as a source is the human voice (see SPEECH). It operates by forcing air from the trachea to vibrate the vocal cords. This in turn sets into vibration the air in the cavities of the throat and mouth; the resulting disturbance emerges from the lips. The part the vocal cords play in singing and speech has been established by motion pictures of their vibration.

Studies of the acoustical power of conversational speech have shown that in the case of an average speaker the overall level directly in front of the mouth can vary from 81 decibels at 15 centimetres (six inches) from the mouth to 65 decibels at 100 centimetres (40 inches). These decibel levels are relative to a standard reference level of 10^{-16} watt per square centimetre (the so-called minimum audible threshold). The mouth is only an approximate point source of sound emitting spherical waves, for at 100 centimetres directly back of the head, in the case just mentioned, the level is 62 decibels. This effect is due to diffraction by the head and is present to some extent in all practical sound sources of appreciable size.

The power in speech sound waves varies with the sound emitted, being much larger for vowels than for consonants. Ordinary speech involves the superposition of many waves of different frequencies. Moreover, the recognition of speech as mediated by the ear is not as simple as the detection of ordinary sound sources by appropriate electromechanical receivers. In the 1970s researches were directed toward improved methods of speech analysis and machine synthesis of speech. Much attention was also paid to measures of speech perception and intelligibility, as well as to better systems for the transmission of speech. Efforts were made to improve machine recognition of speech—*e.g.*, the phonetic typewriter, which types out spoken dictation. The coupling of sound recognition to computer technology was being developed.

Principle of the siren

The siren is one of the simplest sources of intense sound. In principle it consists of a disk containing a number of small holes placed at regular intervals around the same periphery. If this disk is rotated past an orifice lined up with the holes and compressed air is driven through the orifice, the result will be a succession of puffs of air. If the number of puffs per second (governed by the speed of rotation of the disk) is sufficiently large the result will be a periodic sound wave of frequency equal to the number of puffs per second.

Jet-edge tones and organ pipes. Another standard sound source operated by blown air is the jet-edge system coupled to an air column, as in the organ pipe. In the familiar type of pipe a jet of air impinges on the narrow edge of the bottom of the pipe. The resulting vibrations are coupled to those of the air in the pipe. The natural frequency of the edge tone coupled to the pipe increases approximately linearly with the velocity of airflow, but the coupling forces the fundamental tone of the pipe on the system for small velocities. When the flow velocity reaches the value for an isolated edge tone of frequency equal to the second harmonic of the pipe, the tone emitted rises to this harmonic, and the pipe is said to be overblown. The production of edge tones is associated with turbulence (vortex motion) in the airflow in the vicinity of the edge.

The large noise output of the jet-engine airplane in the 1960s and 1970s stimulated considerable interest in the theory of the generation of sound by airflow. The theory is intricate but leads to the result that the sound-power output of a jet of air is directly proportional to the fifth power of the mach number of the flow. The mach number is the ratio of the air flow velocity (relative to the stationary medium) to the velocity of sound in the stationary medium. Flow with mach number greater than one is known as supersonic.

Electroacoustic sources. The most important sound sources in technological use employ electrical energy. These may be divided into two main classes: irreversible and reversible. In an irreversible source the energy for sound radiation is supplied by a flow of fluid (air or water) under pressure and the electrical energy is used to modulate or control. A variable magnetic field, for example, can produce vibrations in a reed or diaphragm that will control the flow of compressed air through a variable orifice. Such a device can produce extremely intense sound waves with relatively high efficiency.

A reversible electroacoustic source transforms electrical energy directly into mechanical energy and thence into acoustical radiation. As the name implies, such a source can function in reverse to transform acoustical into electrical energy via some mechanical structure. It can therefore function equally well as a receiver of sound. As can be shown, under certain specific conditions, which hold approximately in practice, a good reversible source of sound will act also as a good receiver.

Transducers

Any system that transforms electrical to acoustical energy or vice versa is called an electroacoustical transducer. The important practical characteristics of a transducer used as a source are its acoustical output, its efficiency (ratio of the radiated power to the input power), its directivity, and its departure from linearity. The nonlinearity means the extent to which the mechanical force producing the vibrations leading to radiation is not strictly proportional to the electrical field or voltage applied to the input. Such nonlinearity leads to distortion in the radiated output. The directivity refers to the variation in intensity of the radiation with direction from the source.

To come to detailed examples, in the electromagnetic transducer, an alternating current of the desired frequency is passed through a coil that activates an electromagnet to produce an alternating force on a diaphragm of iron or some magnetic alloy. This is the type that has been employed in the conventional telephone receiver. The electrodynamic transducer is now more common. In this transducer the oscillating current passes through a coil suspended in a permanent magnetic field and undergoes the usual force. The coil, called the voice coil, is fastened mechanically to the sound-radiating surface. In the well-known loudspeaker, the latter is normally a cone attached to the voice coil at or near the vertex. The cone is the acoustical element, radiating directly into the surrounding medium. Various practical devices have to be incorporated in such a source to ensure large output and to diminish the distortion due to the resonant or normal mode frequencies of the cone.

The efficiency of an electrodynamic loudspeaker tends to vary directly with its linear dimensions. The speakers in common use in radio and television sets have efficiencies varying from 2 percent to 5 percent. By the use of an attached flaring horn this figure can be increased to about 50 percent. All these figures depend on the frequency range over which the speaker is driven. For a typical small-cone receiver 10 centimetres in radius, the efficiency is 2 percent only over the frequency range from 75 hertz to 1,000 hertz; at 10,000 hertz the efficiency drops practically to zero. The total acoustical power output of an electrodynamic loudspeaker can have maximum values ranging from 0.5 watt to 150 watts, depending on size and the associated electric circuit. Such a speaker at maximum output risks nonlinear behaviour—*i.e.*, large diaphragm motion that is no longer directly proportional to the applied electrical voltage.

Quartz crystal as an ultrasonic source

For ultrasonic radiation, the most important electroacoustic sources employ the piezoelectric and magnetostrictive effects already mentioned earlier in this section. A plate of quartz cut with its faces parallel to the optic axis of the crystal (a so-called *X*-cut), and used as the dielectric in a capacitor subjected to an alternating electric field, becomes an ultrasonic source with the frequency of the oscillatory field. It will, of course, vibrate with maximum intensity and radiate correspondingly if this frequency matches one of its own natural frequencies of vibration. The various resonance frequencies are inversely proportional to the thickness of the quartz crystal. Higher harmonics of the fundamental frequency of the quartz can be used to provide higher frequencies of radiation without using crystals too thin to be practical.

In practical use, a number of *X*-cut crystals are usually arranged in the form of a mosaic to provide a larger radiating surface. Many types of piezoelectric materials are now available in addition to quartz; these include Rochelle salt, barium titanate, and lead zirconate titanate. With such crystals, radiation of ultrahigh frequency has been achieved. By the mid-1970s it proved possible to reach frequencies of the order of 10^{10} hertz.

Magnetostrictive oscillators have also proved popular as ultrasonic radiators. If an alternating current passes through a coil surrounding a rod of magnetizable material already magnetized in the direction of its length, the rod will vibrate lengthwise with the frequency of the current. If this frequency coincides with one of the natural frequencies of the rod, large amplitudes can be obtained. A nickel rod 10 centimetres (four inches) long, for example, will radiate strongly at its fundamental frequency of about 24 kilohertz. Simple magnetostrictive sources are less efficient than piezoelectric devices, largely because of the loss of energy through the production of eddy currents. Magnetic materials, the so-called ferrites, are also in use in cutting down heating loss in magnetostrictive transducers. These ferrites are ceramic-type materials, such as ferric oxide mixed with nickel oxide and compressed so as to form solid rods.

Magnetostrictive transducers are often used to provide underwater acoustic beams, usually beyond the audible frequency range.

Doppler effect. In the discussion of sound sources it has been tacitly assumed that the source is at rest relative to the medium. Moving sources—*e.g.*, airplanes, submarines, and missiles of various kinds—however, are important in applications. A significant effect of such motion on acoustic reception is the perceived change in pitch in accordance with the Doppler principle. If a harmonic source of frequency f moves with linear velocity v_s with respect to a stationary medium and a receiver is moving with velocity v_r along the same line, the receiver will estimate the emitted frequency as a frequency f' that is given by

$$f' = f(V - v_r) / (V - v_s),$$

in which V is the velocity of sound in the stationary medium. In the formula v_r and v_s are reckoned as positive in the direction from the source to the receiver and negative otherwise. If, for example, the receiver is at rest and the source in motion, the apparent frequency at the receiver is lower than the emitted frequency if the source is receding and is higher than the emitted frequency if the source is approaching. Knowledge of the emitted frequency and measurement of the apparent frequency thus permit the determination of the velocity of the source, a matter of significance in military applications such as sonar.

RECEPTION OF SOUND

To be studied and applied, sound energy must be detected—*i.e.*, transformed to make it perceptible to people or sensible to cybernetic (communication and control) devices. This is the function of a sound receiver. Any reversible sound transducer can be used as a sound receiver.

The ear and hearing. The ear is the most important acoustical receiver in man's environment. Normal people can detect sound intensity as low as 10^{-16} watt per square centimetre and can stand intensities up to about 10^{-4} watt per square centimetre before pain ensues. These are figures averaged over representative samples of the population.

For the description of the structural details of the ear as a receiver of sound see the text article SENSORY RECEPTION. During the 1970s theories of hearing remained in a state of flux, with no one point of view commanding universal assent.

esholds
eeling
.
ring

The threshold values of hearing and feeling as a function of frequency are based on the work of a physicist in the United States, Harvey Fletcher, and confirmed by other investigators (Figure 9). The lower two curves relate minimum audible intensity to frequency. These curves rise at both ends of the audible range and have a minimum at about three kilohertz. The upper curve is the corresponding plot of the threshold of feeling. Intensities greater than those along this curve produce pain. Even so-called normal people show variation in thresholds and the curves represent averages over suitably large samples. Advance in age results in general in hearing loss, appearing in Figure 9 as a rise in the lower curves. The tendency is for the upper-frequency limit to decrease with age.

From *Speech and Hearing in Communications* by Harvey Fletcher (©1953); D. Van Nostrand Company, Inc.

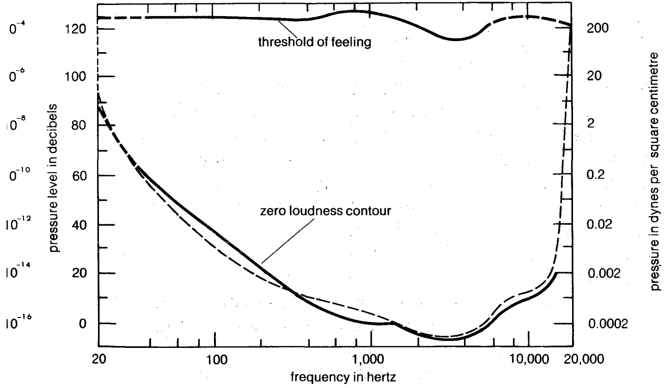

Figure 9: Auditory area between threshold values of feeling and hearing (see text).

Loudness is a sensation related to the intensity of the received sound but not directly proportional to it. Intensity is an objective physical quantity, whereas loudness is subjective and defined in terms of the so-called average listener. It is customary to distinguish between loudness level and true loudness. The former is measured by varying the intensity of a reference tone until it appears to a listener to be as loud as the sound stimulus under test. The number of decibels by which the reference tone has been raised above the minimum audible threshold is said to be the loudness level of the tone under test in phon units. This applies, strictly speaking, only if the reference tone has a frequency of one kilohertz and is placed at a distance of one metre from the head of the listener.

Measurement of true loudness

The measurement of true loudness demands the introduction of a scale such that when loudness of a certain number of units on this scale is multiplied by any arbitrary factor the magnitude of the new auditory sensation then produced will be heard by a listener as equivalent to the corresponding number of units times that of the original sensation. The unit of loudness introduced for this purpose is called the sone. It is defined as the loudness produced by a tone of one kilohertz at 40 decibels above the minimum audible threshold. By a statistical study of experiments in hearing, a loudness scale in sones has been established in which there is a logarithmic relation between loudness (L) in sones and loudness level (P) in phons, $\log_{10} L = 0.03 P - 1.2$, that holds for a reference tone of one kilohertz. This means that subjective loudness is equal to 10 raised to the power $.03P - 1.2$. The loudness level is of course a measure of acoustic intensity on the decibel scale.

Hearing with two ears, the so-called binaural effect, leads to the ability to detect the direction of the source of sound radiation. A source of sound on the right of the plane bisecting the line joining the ears and perpendicular to it will be recognized as on the right. This effect is not due primarily to difference in intensity at the two ears but rather to difference in phase or time of arrival at the two ears. This effect has proved useful in acoustic detectors for gun ranging and underwater sound. It is also of great importance in stereophonic radio broadcasting and phonograph reproduction. Still more important, indeed, than the directionality effect is the ability conferred by the binaural effect to distinguish different sounds; that is, for example, meaningful speech from noise. It seems that the difference between meaningful sound and noise is enhanced, by some means as yet not clear, by the difference in arrival time at the individual ears, so that the nervous system of the listener can make the necessary distinction.

Summation and difference tones

From the fact that the eardrum is an asymmetric vibrator (*i.e.*, its displacement for given applied pressure is not the same in the inward as in the outward direction) it follows theoretically that listeners should be able to hear summation and difference tones. What this means is that if two tones of widely separated frequencies f_1 and f_2 ($f_1 > f_2$) are presented to the human ear, in addition to these tones, the listener detects tones of frequency equal to their difference ($f_1 - f_2$) and equal to their sum ($f_1 + f_2$). As a matter of fact, tones of other combinations of frequency ($jf_1 + kf_2$), in which j and k are small arbitrary integers, have also been detected. If the original two tones, f_1 and f_2, are so close together that their difference is small compared with either, the usual phenomenon of beats is observed—*i.e.*, a periodic rise and fall in intensity with a frequency equal to their difference ($f_1 - f_2$).

(R.B.L.)

Microphones. In modern terminology the word microphone is applied to any electroacoustic transducer used for the detection of sound. Actually, it might legitimately be used to denote a transducer capable of transforming the excess pressure in a sound wave into any other more readily observable physical effect. For example, a sensitive flame formed by burning gas issuing at high speed from a very small orifice and kept just below the point of flaring was an early form of microphone. In the presence of even a rather weak sound wave, the flame makes a perceptible jump. It can be made particularly sensitive to high-frequency, inaudible sound.

Such early microphones have now been entirely superseded by the electroacoustic variety. Such an electroacoustic microphone transforms the excess pressure changes due to an impinging sound wave into alternating electric currents that can be amplified and visualized on an oscillograph.

The conversion, within a microphone, of sound-pressure variations in the air into corresponding electrical waves

Operation of the microphone

occurs in two operations that usually take place simultaneously. In the first operation, the sound wave impinges on a surface, generally referred to as a diaphragm, which is capable of slight movement. Variation of air pressure on this diaphragm causes it to move to and fro in a manner corresponding to the movement of the air particles. In the second operation, the diaphragm by its movement causes a corresponding change in some property of an electric circuit. Thus, for example, the displacement of the diaphragm may cause variations in the resistance of carbon granules or variations in the motion of a coil or conductor in a magnetic field. In each case, motion of the diaphragm produces a variation in the electric current.

Thus, the sound vibrations are first converted into mechanical motion, and then the mechanical motion is converted into variations in electric current. Hence, in studying the operation of a microphone, two things must be considered: (1) the mechanical movement of the diaphragm; and (2) the method whereby this movement sets up the desired variations of electric current. Either part of the process may be taken as a basis for classifying microphones.

The carbon microphone

Any microphone that has its diaphragm exposed to the sound wave on only one side is a pressure-operated type; that is, the displacement of the diaphragm is approximately proportional to the instantaneous pressure of the impressed sound wave. Outstanding among pressure types and of great historical importance is the carbon microphone, used mostly in telephony. Another pressure type, typically consisting of a thin stretched diaphragm separated by about one-thousandth of an inch (0.025 millimetre) from a parallel fixed plate, is the condenser microphone. The diaphragm acts as one plate of a variable capacitor (device for storing electricity) that is connected in series with a resistor and a direct current source. The motion of the diaphragm in response to sound waves varies the capacitance, producing a varying electric current. Condenser microphones are used for sound measurement and for high-quality recordings. Still another pressure type is the crystal microphone, used in hearing aids, sound recording, and office dictating machines. This microphone depends for its operation upon the piezoelectric effect (*i.e.,* the generation of a voltage by the deformation of a crystal by a moving diaphragm). Crystals of barium titanate and Rochelle salts exhibit great piezoelectric activity; they are commonly used in crystal microphones (see also ELECTRONICS: *Piezoelectric devices*).

The dynamic or moving-coil microphone falls within the general class of moving-conductor microphones—*i.e.,* those in which an electric voltage is generated by the motion of a conductor in a fixed magnetic field. In the dynamic microphone a coil is attached to the moving diaphragm; motion of the coil in a fixed magnetic field induces a voltage in the coil. Dynamic microphones are used quite widely in recording, broadcasting, and public-address systems, especially when ruggedness is essential. Among the other types of microphones are the magnetic microphone and the ribbon microphone.

By proper design a microphone can be made to pick up sound from a single direction only, resulting in what is called a cardioid pattern. Such a microphone can be useful in discriminating against reflected and unwanted sounds and noises. Bidirectional microphones, in which the pickup is essentially the same from either front or back but zero from the sides, also are useful for specific applications. Microphones with approximately equal pickup from all directions are called nondirectional or omnidirectional. (E.I.G.)

CRITERIA FOR GOOD HEARING CONDITIONS

Good hearing conditions for an audience listening to speech or music, whether in an auditorium, courtroom, church, outdoor theatre, or living room, depend on four basic conditions. The space must be quiet, the sounds to be heard must have adequate loudness, there must be a good distribution of sound, and the sounds must be properly blended, with adequate separation for good articulation of music or speech.

Absence of noise. Perhaps the single most important factor in providing good hearing conditions is the absence of any interfering noise. Background noise that can be useful in providing privacy and freedom from distraction in the office or apartment has no place in the room in which there is serious listening to speech or music. Not only must the air-handling system be inaudible, but there must be no noise transmitted from other spaces in the building or from outside (see also below *Noise control*).

Adequate loudness and distribution. Obviously, the sounds to be heard should be loud enough and should be uniformly distributed. People sitting in the front of a room should not be subjected to greater volumes of sound than those in the rear. Hot spots, where the sound is too loud, and dead spots, where the sound is too faint, can be as unsatisfactory as seats in which everything is heard twice due to delayed echoes. Adequate loudness and good distribution of sound are determined largely by the shape and surface finish of the room.

Figure 10A illustrates how sound is distributed when an audience is seated on level ground outdoors. In a free field, a sound wave decreases in intensity by a factor equal to the square of the distance from the source. As the sound wave grazes the heads and clothing of the sound-absorptive audience, however, there are additional losses. People seated far back in such an audience receive less sound energy not only because they are far away from the sound source but because some of it is absorbed by the people in front of them. In such a seating area, loudness and distribution requirements are poorly met.

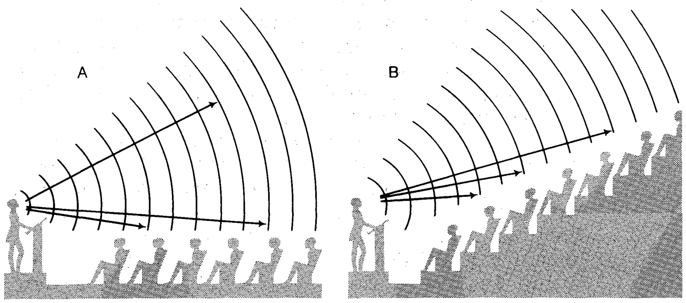

Figure 10: (A) Distribution of sound when audience is seated on ground level outdoors. (B) Distribution of sound in an outdoor theatre of the classical Greek design.

Sound mirror

The ancient Greeks and Romans solved the problem by placing audiences on steep hillsides, which resulted not only in much better sight lines but in significantly smaller losses by absorption of the intervening audience (Figure 10B). Good sight lines almost always mean good hearing lines. An alternative to the steep hillside is to raise the source of sound high above the audience, but this is not usually convenient. A more satisfactory indoor arrangement is to let the ceiling of the room act as a sound mirror, bringing reflected sound down on top of the audience to reinforce the direct sound (Figure 11). In many auditoriums more sound energy is received from the ceiling and other reflectors in the room than directly from the source of sound itself. The ceiling is the most important surface in the room in assuring adequate loudness and good sound distribution. A ceiling in any room that must have good hearing conditions for an audience must always be hard and sound-reflecting, not sound-absorbing. This principle is often overlooked; in fact many auditoriums and other

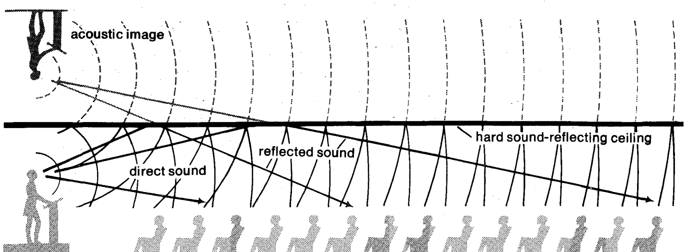

Figure 11: Distribution of sound in a well-constructed auditorium.

buildings for audience use have been deliberately but mistakenly equipped with sound-absorbing ceilings. Such use of sound-absorbing material inevitably produces bad hearing conditions because the room has been deprived of its most useful sound reflector. Sound-absorbing material is useful in rear wall surfaces to control echo and reverberation.

An equally important function of the sound-reflective ceiling is the mixing of sounds that emanate from various parts of a large performing group; *e.g.*, a congregation in a church or an orchestra or a chorus on a stage. Whenever people perform together, it is essential that all members of the group hear each other. An orchestra cannot perform satisfactorily in a conventional stagehouse surrounded by velour draperies, because the various instrumentalists cannot hear each other. Some type of overhead reflector must be used.

If a listener is to receive sound energy by reflection from the ceiling, he must be seated directly under the ceiling; seats in a deep underbalcony area are usually the poorest in the house. The undersurface of such a balcony should always slope upward toward the front, with a sufficient opening to permit the rearmost seats a line of sight to part of the ceiling.

The reflections from ceiling and wall surfaces useful to the listener in improving loudness, clarity, and articulation must arrive at the listener's ear not more than about 30 milliseconds (thousandths of a second) after the initial sound reaches him. This means that the sound will have travelled over a path not more than about 30 feet (nine metres) greater than the distance between source and listener. Reflections delayed longer than this tend to detract from clarity and add confusion. If a reflection is delayed longer than about 70 milliseconds, it begins to be audible as a separate sound or echo.

To provide the members of the audience in the front half of the orchestra, or main floor, of an auditorium with these early reflections, the ceiling near the performing area cannot be more than 30 or 35 feet (nine or 11 metres) above the floor. Ceiling heights of 60 or 70 feet (20 metres) subject much of the main-floor audience to poor sound quality and lack of clarity. In the balconies and toward the rear of the main floor, reflections with a small time delay are received, even if the ceiling is rather high. (R.B.N.)

Sound recording and reproduction

Sound recording consists of transcribing those vibrations in air that are perceptible as sound onto a storage medium such as a phonograph disc. In sound reproduction the process is reversed, and the variations stored on the medium are converted back into sound waves. The degree of accuracy achieved in these two processes is referred to as the fidelity of the sound system and may vary widely with the intended application. For business dictation, and many other purposes where the spoken word is recorded and reproduced, mere intelligibility is sufficient. For full enjoyment of music the fidelity requirement of a sound system may be very high, demanding precision equipment and techniques at every step in the recording–reproduction process.

Over the years a variety of storage media has been used for sound recording and reproduction, but the three principal systems that have survived may be loosely grouped into the mechanical (the phonograph disc), the magnetic (recorded tape), and the optical (sound tracks for motion pictures and the digital Compact Disc, or CD). All three today share a common reliance on electronic circuits, such as amplifiers, but each developed sufficiently independently to warrant treatment in separate sections in this article. Concepts and techniques specific to high-fidelity sound systems and contemporary developments in digital recording and playback techniques are treated in the final two sections.

MECHANICAL SYSTEMS

A phonograph disc stores a replica, or analogue, of sound waves as a series of undulations in a sinuous groove inscribed on a rotating surface by the vibrations of a stylus. When the record is played back, a stylus responds to the undulations, and its motions are then reconverted into sound.

Early history. *The Edison phonograph and its successors.* A precursor of the phonograph appeared in 1857, when the French inventor Léon Scott constructed a device he called the phonautograph. This device recorded the movements of a diaphragm or other vibrating body in response to sound as a wavy line on the smoked surface of a rotating cylinder. The first machine that could both record and reproduce sound was invented in the United States by Thomas A. Edison in 1877. The original Edison recordings took the form of indentations embossed into a sheet of tinfoil by a vibrating stylus attached to a diaphragm. The tinfoil was wrapped around a cylinder that was rotated as the sounds were being recorded. The sound waves were recorded as variations in the depth of the groove, a process later referred to as hill-and-dale recording. For reproduction the groove was again run under the stylus tip, with only enough pressure to maintain contact with the groove bottom.

Edison's phonograph

In 1885 two U.S. inventors, Chichester A. Bell and Charles Sumner Tainter, patented a machine similar to Edison's except that it cut, or engraved, the groove in a cylindrical surface of wax with a sharp tool carried by the vibrating diaphragm. This method gave much better sound reproduction than Edison's indented tinfoil. Another inventor, the German-born Emil Berliner, was responsible for a radical departure in sound recording. During the recording process Berliner's mechanism traced its wavy line as a spiral on a flat disc rather than as a helix on a cylindrical surface. The disc was made of zinc and was coated with a thin layer of a fatty substance that protected it from the action of acid except where the scribe had traced its line. An acid bath then left a groove, the width and depth of which could be controlled by the duration and strength of the acid treatment. Berliner thus obtained a record that could be played on an appropriately designed reproducing mechanism, which he called the Gramophone.

Berliner's Gramophone

Berliner did not use the etched master as the record to be played, however; rather, a negative was made from the master by electroforming (see below *Electroforming*), and the negative was then used to mold records in a thermoplastic material, a procedure that subsequently became standard. Berliner also developed lateral recording, in which vibrations are recorded as sidewise deflections of a groove of uniform depth rather than as variations in the depth of the groove. Starting in about 1900 lateral recording attained wide acceptance both in the United States and in Europe.

As the phonograph and record business grew steadily in Europe and the United States, various technical innovations were introduced that improved the quality of sound reproduction. Methods of molding cylinder records of a relatively hard thermoplastic were introduced in 1901, and in 1908 cylinders made of a new material called Amberol enabled recording grooves to be spaced 200 to the inch, thus doubling the playing time to four minutes per cylinder. In 1912 Edison introduced Blue Amberol, a further improvement in material, and the following year he began making discs and machines to play them. He continued for some years, however, to issue cylinder recordings as well. The 78-rpm (revolutions per minute) record, which virtually replaced cylinders by about 1915, had a playing time of approximately 4½ minutes per side.

The first phonograph machines had to be hand-cranked continually, although some speed-stabilizing effect was provided by flywheels. In one of his early patents Edison stressed the importance of correct and uniform speed, and experiments with battery-operated electric motors were undertaken. These proved sensitive to changes in load and voltage, and various mechanical governors were used to reduce speed variations. The most satisfactory of these governors were those with a friction disk, the friction of which increased rapidly if the speed exceeded the desired value. While Edison was reluctant to abandon the electric motor, he ultimately used a spring-driven governed motor developed by Frank Capps, a pioneer in many phonograph improvements. Spring motors were also developed by the Columbia Phonograph Company and by Berliner, so that by the end of 1896 all three companies were using governed spring motors. Extensive use of electric motors was delayed until radio–phonograph combinations were introduced in the 1930s.

Acoustical horns. The most serious limitation on early phonograph developments was imposed by the need to rely entirely on acoustic methods of recording and reproduction. Performers huddled close to large, clumsy recording horns, and only the most powerful instruments and voices recorded well. At the small end of the horn the sound waves were concentrated onto a diaphragm to which the cutting stylus was attached. During playback only the acoustic output from the stylus–diaphragm combination was available to be fed into the small end of the horn. This severely limited the output volume and led to many attempts to increase the efficiency and improve the tonal quality of phonograph horns.

The easiest horn to construct was of simple conical shape. As experience accumulated, the sizes of horns increased and their shape began to change. In 1906 the Victor Talking Machine Company marketed a machine with the horn contained within the cabinet. This arrangement facilitated increasing the horn size and also made it desirable to keep down the size of the middle part of the horn, thus favouring a shape somewhat like that of an exponential horn. In an exponential horn the cross-sectional area doubles with each increase of x inches in distance along the axis from the small end. If it is a round horn, the diameter doubles with each increase of $2x$ in axial distance. Horns can be bent, or "folded," to conserve space without too seriously impeding their performance, provided the difference between the shortest and longest paths around the bend is not more than about one-third the shortest wavelength.

The exponential horn

After about 1920 the exponential horn became the nearly universal choice of engineers. A theoretical analysis of its characteristics was published in 1919 by a U.S. physicist, Arthur Gordon Webster, and the subject was further elucidated by two U.S. electrical engineers, Clinton R. Hanna and Joseph Slepian, in 1924. It was not until the introduction of the Orthophonic design in 1925, however, that a definitely planned exponential expansion was followed, with considerable increase in length and with an end opening occupying practically the whole front of a large cabinet.

Electrical recording and reproduction. Shortly before World War I the U.S. scientist Lee De Forest invented the Audion (triode) vacuum-tube amplifier, a device that could multiply sound power a thousandfold or more with little loss of quality. Although work toward applications of the Audion amplifier began as early as 1915, World War I intervened, and it was not until the early 1920s that the transition from acoustical to electrical methods took place. With the advent of electrical recording, performers could work under more natural conditions; microphones collected the sound, which was then amplified electrically to the necessary level for recording with an electrical disc-cutting head. The Audion amplifier was also applied in sound reproduction, leading both to the replacement of the acoustical horn by the electric loudspeaker and to the development of the electrical phonograph cartridge.

The vacuum-tube amplifier

Record materials and production processes. Tinfoil and the other earliest recording media were supplanted by materials of two general types: the wax disc (actually a heavy-metal soap with wax gel) intended for subsequent processing and duplication; and the lacquer-coated disc, usually on an aluminum base. The latter was originally intended primarily for instant playback, but improvements in formulations and cutting techniques eventually made lacquer blanks the choice for making master discs suitable for duplication. Since about 1950 electrically heated jewelled styli with precisely ground cutting edges and a special burnishing facet have been used to achieve a smoothly cut, low-noise groove in the master lacquer disc.

Electroforming. To make copies of the master disc, dies must be made whose surfaces are negative replicas of the master-record surface. Electroforming techniques, pioneered by Berliner, are now used to reproduce the surface to an accuracy of better than 0.000001 inch (0.000025 millimetre). In order for this process to be used, the master-record surface is first made electrically conductive by a wet-silvering method similar to that used for silvering mirrors. It is then plated, either with copper or (now more commonly) with nickel, creating a negative mold of the silvered-lacquer master.

After separation from the master record, the electroformed metal master disc can be used directly in a plastic-molding press to produce records if only 100 or so are desired. For records in commercial quantities many pressing masters, called stampers, are required. It has been the practice, therefore, to electroform a metal positive from the metal master. This positive, called a "mother," can be played as a record for quality approval and then used to generate a number of stampers by electroforming. By using a metal master to generate a number of molds and each mold to generate a number of stampers, it is possible to make many stampers, and thus thousands of records, from each master disc. The records themselves are molded by placing a "biscuit" of thermoplastic material between two stampers in a heated hydraulic press that melts the material sufficiently so that it will conform under pressure to the shape of the grooves. The press is then cooled to set the thermoplastic material, and the record is removed for finishing (*e.g.,* removal of the excess material, or "flash," around the edge), packaging, and sale.

The master, "mother," and stamper

Until about 1930 records were made of shellac, a natural thermoplastic, combined with a finely ground filler, usually limestone and clay. This rather abrasive compound served to extend record life, given the heavy weight (100 to 200 grams, or 3.5 to 7 ounces) of early phonograph pickups. These pickups normally used steel needles, which were quickly ground down by the abrasive records to conform to the groove shape. This increased the contact area between the stylus and groove significantly, thus decreasing the force of the stylus per unit area, which reduced record wear. (Steel was later replaced by harder stylus tips, made of sapphire or diamond, which resisted being ground into conformity with the groove, thus increasing record wear.) In the 1930s synthetic thermoplastic resins that used little or no filler material became the choice for record material.

Phonographs and record changers. The advent of commercial radio broadcasts, beginning in 1919 with Pittsburg's KDKA, rapidly captivated public interest and stimulated the next major developments in record-playing equipment. Radios came equipped at first with headphones, and later with amplifiers and electric loudspeakers; they did not need hand cranking, someone else changed the records every 4½ minutes, and, of course, the music was free. For a while inexpensive single-play phonographs that could be plugged into a socket on the back of the radio stimulated the growth of record collections by those who wanted to hear their own choice of music. As collections expanded and longer and longer pieces of music were recorded, however, the need grew for a device designed to permit a stack of records to be played in sequence without human intervention.

While a number of early patents were granted on automatic record-changing devices, very few machines reached the hands of the public until after the mid-1930s. By 1940 many manufacturers were equipping their phonographs with record changers, despite the fact that the edges and centre holes of the heavy 78-rpm records were frequently damaged by the changer mechanisms.

Record changers

The use of electric motors both to turn the phonograph platter and to operate an automatic changer mechanism became extensive with the introduction of radio–phonograph combinations. Typically, a small high-speed induction motor was used, which communicated its rotation to the inner rim of the turntable platter through one or more rubber-edged idler wheels. When the tripping mechanism at the end of the record side was triggered, the motor turned a series of gears connected to a mechanism that lifted the pickup arm above the record just played, returned the arm to the side, dropped the next record down from the stack, and placed the tone arm down on the new record in its lead-in groove.

After World War II many improvements were made in record-changer mechanisms. The use of vinyl record material considerably reduced damage to the record by the selector mechanism. In addition, improvements were made in the turntable drive system, tone arm, phonograph cartridge, and tone arm tripping mechanisms. These, in turn, made it possible to use a lighter tracking force, thus reducing wear on the stylus and record alike.

Modern sound reproduction. *The long-playing disc.* The beginning of the modern era in sound recording and reproduction came in 1948 when Columbia Records introduced the Long-Playing (LP) Record made of Vinylite. Twelve inches (actually, 11⅞ inches, or 30.2 centimetres) in diameter, with a rotational speed of 33⅓ rpm, LPs used fine-groove (often called "microgroove") recording techniques to achieve up to 30 minutes of playing time. Shortly afterward the RCA Victor Company introduced the seven-inch 45-rpm disc with the same groove size, which played for up to eight minutes. These new records offered such improvements in cost, convenience, and performance that they rapidly supplanted the old 78-rpm discs. The necessary accuracy of the recorded groove can be judged by the requirements established for long-playing records: the bottom radius of the groove must be less than 0.00025 inch (0.0064 millimetre) and the top width no less than 0.0022 inch, giving a depth of about 0.00125 inch. The standard also specified a V-shaped groove with an included angle of 90 degrees, a fact that was to become important in the development of stereophonic records.

reo-
ɔnic
tems

Stereophonic phonograph records, with two separate channels of information recorded in a single groove, became a commercial reality in 1958, less than a year after the system had been publicly demonstrated. In a live musical performance the sounds of various instruments and voices come from different directions. Stereophonic systems, by reproducing sound with spatial perspective, produce a far greater sense of realism than single-channel, or monophonic, systems (see below *High-fidelity concepts and systems*). A stereophonic system requires two independent channels, with separate microphones for recording and separate loudspeakers for reproduction. On a stereo disc the outer groove wall contains the left-channel signal, the right channel being recorded on the inner groove wall. The standard stereophonic playback system employs a single stylus with its axes of movement inclined at 45 degrees to the record surface, the pickup being designed to produce two practically independent signals in accordance with vertical and horizontal motion components. Operation at 45 degrees provides a symmetrical arrangement that offers advantages both in the design of disc cutters and reproducers and in quality of reproduction, because the electronic characteristics of the two channels are alike. In addition, good reproduction is possible over a monophonic system because information from both stereophonic channels is contained in the resultant lateral modulation.

Phonograph cartridges. A phonograph cartridge, or pickup, is a device that when actuated by the record groove produces a usable electrical signal proportional to the mechanical signal (music) recorded in the groove. It is typically mounted in a tone arm, which allows its stylus to track the spiral groove on the record. Although steel, and even cactus, needles were used in early phonographs, a great improvement was made possible by the development of jewelled stylus tips that could be ground to precise dimensions.

lus
pe
l
:

For proper tracking it is important that the stylus retain contact with the two sides of the V-shaped record groove, and its "point" should ride above the bottom of the V (where there is no musical information to be extracted, but where there may be grit that can generate noise). Until the development of stereo records (and even today in inexpensive equipment), all playback styli were conical in shape, with a precisely rounded point. For the 78-rpm record a conical stylus with a 0.003-inch (0.076-millimetre) tip radius was desirable and for long-playing records, a 0.001-inch radius. For stereo records a slightly smaller (*e.g.,* 0.0007-inch) tip radius was recommended, but high-quality cartridges today use biradial, or elliptical-shaped, tips that are narrower from front to back (the direction of groove motion) than from side to side (the direction of the groove undulations). The tip dimensions of a biradial playback stylus are typically 0.0002 inch by 0.0007 inch. While sapphire tips were once used, modern styli are made from natural or industrial diamonds. All playback styli are subject to wear, which can create edges that literally chisel away the high frequencies recorded in the groove. A modern diamond stylus should be checked for wear with a specialized microscope after approximately 500 hours of playing time.

Phono cartridge cantilevers, to which the stylus is attached, are usually made of a thin aluminum tubing, although various other materials, such as magnesium, boron, and titanium, are sometimes used. The cantilever must be rigid enough not to bend, twist, or break, but should not resonate at any audio frequency. The effective mass of the stylus tip, cantilever, and generating element(s), together with the compliance of the pivot, contributes to the mechanical impedance of the pickup. Low mechanical impedance has received considerable attention because its attainment permits a low value of stylus tracking force. The less the stylus force, the less is the wear on the stylus and the record groove. Concentrated effort on the part of pickup designers has reduced the mechanical impedance to the point where high-quality pickups can maintain proper contact with the walls of the record groove with only 1.0 to 1.5 grams (0.035 to 0.053 ounce) of stylus pressure.

Modern
phono-
graph
cartridges

To generate an electrical signal from the motions of the stylus–cantilever assembly, phonograph pickup designers have explored nearly every known technique. These include the piezoelectric effect, variable resistance, variable capacity, and variable light-beam photoelectric effects. In general, it is possible to design a pickup using any principle that will produce an electrical signal from a mechanical movement. The most popular types of high-quality phono cartridges employ miniature magnets and coils. In order to produce an electrical audio signal, the stylus assembly either moves the magnet(s) in relation to the fixed coils, moves the coils in relation to the fixed magnet(s), or moves a magnetically sensitive element between the magnet(s) and coils. The purpose in each case is to cause a magnetic flux field to impinge on the coil that varies with the movement of the stylus, which in turn reflects the undulations in the record groove walls.

Stereophonic pickup design follows the same basic principles used for monophonic pickups except that it is necessary to produce two independent signals using a single stylus actuated by the independent signals recorded on the two walls of the record groove. Thus the pickup has two independent electric-generating units connected to and actuated by a common stylus.

Motors and drive systems. Although numerous turntable drive systems have been used since the earliest days of the phonograph, today's quality record players are likely to use either of two systems: a belt drive that couples a high-speed motor to the slow-moving turntable platter; or a direct-drive system employing a special semiconductor-controlled motor whose shaft rotates at the playing speed of the record. In the latter type of system the heavy metal platter that supports the record sits directly on the motor shaft. Precision machining and careful attention to design details are necessary to minimize "wow" and "flutter," low-frequency and high-frequency periodic changes, respectively, in signal frequency that result from momentary variations in turntable speed. "Rumble," a low-frequency noise picked up by the cartridge, is caused primarily by vibrations from the phonograph motor that are transmitted through the motor supports or the drive system (see below *High-fidelity concepts and systems*).

MAGNETIC SYSTEMS

An audio tape deck is an instrument for electromagnetically imposing or detecting varying magnetic patterns, which correspond to sound waves, on a moving magnetizable surface.

Poulsen's
tele-
graphone

Early history. In 1898 Valdemar Poulsen, a Danish inventor, applied for a patent on a device that stored electrical information by means of magnetizing areas of a steel wire. With later improvements his telegraphone, as it was called, was capable of recording continuously for 30 minutes on a length of piano-wire steel that moved at a speed of 84 inches (213 centimetres) per second. The device did not find wide application, however, and for many years interest in magnetic recording was largely confined to the laboratory.

Early attempts at magnetic recording were plagued both by high distortion and noise and by the lack of a suitable medium on which to record. In 1927, however, the scientists W.L. Carlson and G.W. Carpenter patented the use of ac (alternating-current) bias (see below) to reduce distortion and increase the amount of signal that could be recorded in relation to noise. In the same year the first U.S. patent was issued for magnetic tape made by drying a liquid containing magnetic particles on the surface of a strip of paper. A German patent was issued in 1928 for a similar process. In England, Germany, and the United States during the 1930s work progressed on a magnetic recording system to record and synchronize sound with motion pictures. In 1936, at the Berlin Radio Fair, the Magnetophon Company of Germany demonstrated the potential of tape recording by using a Magnetophon recorder and a plastic-base magnetic tape manufactured by BASF to reproduce a performance by Sir Thomas Beecham and the London Philharmonic Orchestra. During World War II Magnetophon machines served the interests of Nazi propaganda organizations, and following the war the machine's principles were imitated and improved upon in the United States and in other countries.

Recording media. Modern recording tapes consist of a plastic-base film coated with magnetic powder that is held in place by a binder. Mylar and other polyester plastics are widely employed as the tape base, which is sometimes "back-coated" with a conductive material to eliminate the buildup of static electric charges and to improve its winding characteristics. For open-reel recording plastic-base films of 1.5 and 1.0 mils (38 and 25.4 micrometres) are commonly used. For cassettes the most common base thicknesses are 0.47 and 0.31 mils.

Common tape materials

The magnetic material most widely used in coating tape is a type of iron oxide, Fe_2O_3, in needle-shaped particles roughly 0.6 to one micrometre (one micrometre equals 0.000039 inch) in length and one-tenth or less that in diameter. The way in which the magnetic powder is prepared, the impurities deliberately introduced or accidentally present, and the physical size and shape of the particles have much to do with the audio characteristics of the finished tape. To meet the demand for extended high-frequency response at the low tape speed of 1⅞ ips (inches per second [4.56 centimetres per second]) used by cassette recorders, Du Pont developed a new magnetic material, chromium dioxide (CrO_2), in the late 1960s. In the mid-1970s TDK introduced a cobalt-adsorbed ferric oxide particle, Super Avilyn, that matched the high-frequency response of CrO_2 but had a higher overall output. Pure metal-particle (nonoxide iron) tape was introduced in 1978 by the 3M Company to provide still better high-frequency response at high recording levels.

The magnetic powder is mixed with a binder, a type of glue that must not only bond the magnetic material to the base material but also hold the particles apart from each other when wet, so that they will remain evenly dispersed throughout the coating. Once dried, the binder must adhere to the base material and retain its flexibility, yet it must not adhere to adjacent layers even when the finished tape is tightly wound and stored at high temperatures. Finally, it must retain its characteristics without change throughout much usage and over many years.

The wet mixture of binder and magnetic particles is precisely coated onto large rolls of the film and passed over an intense unidirectional magnetic field to orient the needle-shaped particles uniformly, and the coated film is then passed through drying ovens. Following this, the tape is pressed between sets of calendering rollers to polish its surface and ensure a uniformly thick coating. Typically, tapes intended for open-reel use may have a magnetic coating thickness of 0.56 mil, while those for cassettes may use a magnetic coating of 0.24 mil. The large rolls of finished tape are then slit to proper widths for their application and are wound onto appropriate reels (see below *Recording formats*).

Recording and playback processes. *Recording.* The electrical signal to be recorded is usually applied to the tape by means of a "head," consisting of a coil wound around a core of magnetic iron, that has a gap at the point where the tape moves across its surface. The current in the coil produces a magnetomotive force across the gap, magnetizing the particles in the tape. The strength and direction of final magnetization of a particular place on the tape is determined by the strength and direction of the magnetic field at the moment that place leaves the influence of the gap. Thus the tape receives a magnetic record containing direction (north or south pole), amplitude, and linear dimension (along the tape) corresponding to the direction (plus or minus), amplitude, and time of the original electrical signal.

In modern ac-biased recording the tape is passed across an erase head before it comes to the record head. Erasure does not remove the magnetism of the tape particles; it simply removes any previous pattern in their north–south or south–north orientation, so that the distribution of north-seeking and south-seeking particles is random. In this condition the sum of the particles' magnetic fields is zero at all measurable points. When the neutralized, or "demagnetized," tape reaches the record-head gap an ultrasonic alternating current is added to the signal current; it is much higher in amplitude than the signal current and several times greater than the frequency of the highest frequency signal to be recorded. While crossing the gap of the record head, the magnetic particles on the tape are subjected to many cycles of the bias current and leave the head with a magnetization that is proportional to the signal. The purpose of the ac bias is to assure low distortion and a high signal-to-noise ratio.

Losses are encountered in recording through eddy current and resistive and capacitive losses in the windings and core of the head. Space between the head and tape causes very large losses, particularly at high frequencies (short wavelengths). The gap must be straight and true, and the surfaces in contact with the tape must be very smooth in order to obtain the best possible transfer of the signal pattern onto the tape. Optical polishing methods are commonly used for finishing the surfaces of the gaps and faces of the head that will be in contact with the tape.

Record-head gap lengths

The gaps used in record heads vary in length (direction of tape motion) depending on their application. For open-reel recording a typical record-head gap length is 100 to 500 microinches (2.5 to 13 micrometres). For slow-speed cassette operation record-only head gaps may be as long as 275 microinches, though cassette heads intended for recording and playback are typically 50 microinches. The tolerances on the trueness of the faces and edges of the gap are usually only a few microinches. The width of the cores and the resulting recorded tracks on the tape may vary from approximately 0.021 inch (0.53 millimetre) for stereo cassettes to 0.25 inch for professional monophonic recording.

Playback. In reproduction the tape is either passed over the same head used in recording (as in most cassette decks) or over one similar to it but with a smaller gap length designed for optimum playback performance (almost universal in open-reel recorders and increasingly used in high-quality cassette machines). The magnetized patterns on the tape passing over the gap in the reproducing, or playback, head cause the magnetic flux in the core to change, generating a voltage in the coil proportional to the speed of the tape and the amplitude and frequency of the recorded signal.

Because the output from the playback head varies with the number of changes per unit time in the magnetic patterns on the tape, its output rises with increasing frequency. For example, there are half as many north–south pole alterations in the octave from 20 Hz (hertz) to 40 Hz as there are in the next higher octave, from 40 Hz to 80 Hz, so the output (given equal recorded levels) from the playback head doubles. This process continues until the gap length of the playback head begins to approach one-half the recorded wavelength of the signal. In order to equalize the frequency response of the playback machine at all frequencies and assure that tapes can be freely exchanged from one recording machine to another reproducing machine, detailed international equalization standards for tape reproducers have been established.

ıyback-
ad gap
ıgths

Maximum playback head output is reached when the gap length (popularly called gap width) equals one-half the recorded wavelength, although some losses have already begun to occur. At one wavelength there is no difference in the magnetic field at the two sides of the gap, so the output from the head is zero. The recorded wavelength (λ) equals the tape speed divided by the frequency. The wavelength of a 20,000-Hz signal at a tape speed of 15 ips (38.1 centimetres per second) is thus 750 microinches (19.05 micrometres), and the requisite playback gap length should thus be significantly less than half of this. At the cassette speed of $1\frac{7}{8}$ ips the same 20,000-Hz signal has a wavelength of 93.75 microinches, so a playback gap length of less than 39 microinches is desirable.

Tape-recording machines. A wide variety of mechanisms has been devised to make use of tape recording in many different applications. These include open-reel machines, which employ 7- or $10\frac{1}{2}$-inch (18- or 27-centimetre) reels of tape, the cassette, and the microcassette. (The once-popular eight-track cartridge format has largely become obsolete.) Each of these is available in a wide variety of equipment, and cassette and microcassette players and recorders are frequently built into home, portable, or automobile AM/FM stereo radios. One of the advantages of magnetic recording is the ability to erase and reuse the recording medium thousands of times with little or no loss in the recording quality. Erasure may be accomplished either with the erase head in the recorder or by subjecting the entire tape to a strong alternating magnetic field provided by an external device and slowly withdrawing the tape from the erasing field. This is called bulk erasing and is similar to the method used by a jeweller when demagnetizing a watch. Professional sound-recording engineers frequently use both methods to make sure all the previous recording has been removed from a tape before it is reused.

The most common drive mechanism found in tape recorders is the capstan drive, in which the tape is pulled forward by the friction between a pinch roller, consisting of a cylindrical piece of rubber, and a motor-driven cylinder (capstan), whose rotational speed and diameter determine the speed of the tape. In many machines both the feed reel, which holds the tape before playing, and the take-up reel, on which the tape winds as it plays, are driven by separate motors to maintain the tape in tension and to permit rapid winding of the tape in either direction. The general mechanisms for magnetic recording and playback described earlier apply to all the formats.

Recording formats. *Open-reel.* High-quality professional-type open-reel magnetic tape recorders are used for recording the master programs for phonograph discs, prerecorded tapes, FM broadcasts, and motion pictures. Such recorders normally operate at 30, 15, or 7.5 ips (76.2, 38.1, or 19.05 centimetres per second) and often use 2-, 1-, or $\frac{1}{2}$-inch (50.8-, 25.4-, or 12.7-millimetre) tape widths to record 24, 16, 12, eight, or four separate tracks on a single reel. A single voice or musical instrument or small group of instruments is recorded on a track. In transfer to a disc, prerecorded tape, or sound motion-picture master record, the material recorded on the tracks is mixed down (combined and rerecorded) onto two or four tracks on $\frac{1}{4}$-inch or $\frac{1}{2}$-inch tape for stereo or quadraphonic mastering.

pe deck
›eds

Consumer open-reel recorders have come to be principally used in semiprofessional applications or where the ability to edit tapes or achieve uninterrupted playing times of longer than 45 minutes is important. Most such tape decks operate at tape speeds of $7\frac{1}{2}$ and $3\frac{3}{4}$ ips, although speeds of 15 and $1\frac{7}{8}$ ips are also available. These machines use $\frac{1}{4}$-inch tape and usually record in a quarter-track or half-track stereo format. While they were once highly popular, tape "recorders" with built-in amplifiers and speakers are no longer generally available; instead, a tape "deck" is connected to the home amplifier and speaker system.

The cassette. Introduced by Philips of The Netherlands in the mid-1960s as a dictation device for business use, the Compact Cassette (usually abbreviated to cassette) has developed so remarkably into a high-fidelity medium that by the early 1980s sales of prerecorded music cassettes exceeded those of phonograph records.

Construction of the cassette

The cassette consists of a feed reel of tape and take-up hub, plus guides and a pressure pad, enclosed in a sealed, roughly rectangular package. The tape is 0.15 inch (3.8 millimetres) wide and travels at a speed of $1\frac{7}{8}$ ips (4.56 centimetres per second). When recording and being played, the tape begins on the feed reel at one side, passes through guides, and then travels across an opening in the cassette shell, where a pressure pad forces the tape into contact with the record–playback head mounted in the recorder. At another opening a rotating capstan and pinch roller pull the tape toward the take-up reel, onto which it is wound after passing through another set of guides. After play is complete, the cassette can be inverted and played in the opposite direction. Cassettes are generally sold in C-60 and C-90 lengths (30 and 45 minutes per side, respectively), though some longer and shorter lengths are available.

For portable use cassette recorders may be battery-powered and are often equipped with a built-in microphone. Most portables also have a low-power amplifier and loudspeaker, and jacks are provided for the use of headphones for private listening. Both stereophonic and monophonic models are available.

Microcassette recorders, using tape $\frac{1}{8}$-inch wide and moving at a speed of $1\frac{5}{16}$ ips in a package only 5.5 by 3.3 by 0.7 centimetres ($2\frac{3}{16}$ by $1\frac{5}{16}$ by $\frac{9}{32}$ inches), have been developed. Once again the design intention is for business dictation, but many models have been improved for music listening. (C.L.S./L.Kl.)

OPTICAL SYSTEMS

Early efforts to produce motion pictures with sound involved attempts to synchronize phonograph recordings with the images on the screen. One inventor actually tied the phonograph to the projector motor through a system of belts and pulleys that ran the length of the theatre from booth to screen. As theatres grew larger, however, it became apparent that amplification as well as synchronization was a problem.

The amplification problem was solved first with the invention of the Audion amplifier (described above) and its application to loudspeakers. De Forest turned his attention to the problem of synchronization and experimented with recording sound directly onto the motion-picture film. By 1923 he had developed techniques for transcribing the varying impulses of sound waves into varying impulses of light that could be photographed on a strip of film. The developed film, when passed between a light source and a photoelectric cell in the projector, could transform these areas of varying density back into electric voltages that could be amplified and converted into sound by a loudspeaker system. Although there were variations in detail, De Forest's methods were fundamentally duplicated by subsequent sound systems in Germany, the Soviet Union, and the United States.

Stereophonic sound tracks

A fortuitous discovery in optical recording was that distortion in the sound-track area of the film could be lowered by recording the light impulses as two separate but identical sets of patterns read simultaneously by a single photoelectric cell in the projector. Thus, when stereophonic motion pictures were produced, beginning in 1976, the sets of optical tracks could easily be converted into left and right channels. In theatres equipped only for monophonic reproduction the two channels are automatically summed into one signal by the existing photocell, while more modern houses with dual-cell projectors can benefit from stereo sound. The sound tracks for stereophonic releases are also normally encoded using the Dolby noise-reduction system (see below *High-fidelity concepts and systems*). The two stereo tracks are also electrically "matrixed," so that in actuality four different sound channels may be obtained. The musical score is heard in full stereophonic perspective, while dialogue emerges from centre front, and special rear effects (*e.g.,* "surround sound") are time-delayed and produced from speakers along the sides and in the rear of the theatre. The rear channel is also reproduced with reversed phase so that it reinforces the perception of reverberation. While the high-frequency response of monophonic optical recording is typically limited to approximately 7,000 Hz, the greater emphasis on sound quality has led to the development of stereophonic optical recorders and reproducers capable of response to 12 or 13 kHz (kilohertz). (See also MOTION PICTURES.)

AUXILIARY EQUIPMENT

A transducer, a device that converts one form of energy into another, is fundamental to all modern sound-recording and reproduction systems. A microphone converts acoustic energy into electrical energy. A phono cutting head converts electrical energy into mechanical energy to drive the stylus. A tape record head converts electrical energy into magnetic energy. Similarly, in the playback process the mechanical motion of the phono stylus or the magnetic variations presented to the playback head are converted into electrical energy and amplified. At the end of the record–reproduce chain electrical power is converted back into acoustic power by a loudspeaker. Amplifiers, frequency equalizers, compressors, noise-reduction systems, and the like, however, all operate within the electronic realm and so are signal-processing devices, not transducers.

Microphones. When sound waves strike the surface of a microphone diaphragm, they cause it to move correspondingly, and this motion causes changes in some property (current, capacitance, or resistance) of an electrical circuit. The electrical variations produced by the microphone are generally very small (in the order of a few millivolts), but they can be electronically amplified to any desired level suitable for recording, broadcasting, driving loudspeakers in public-address systems or earphones in hearing aids, and other uses. The first successful instrument for converting acoustic power into electric power was the electromagnetic telephone transmitter used by Alexander Graham Bell in 1876. The term microphone was first used in 1878 when the concept of the variable resistance of a loose contact was elucidated. In Bell's device variations in sound pressure alternately compressed or expanded the contact between loose granules of carbon in a carbon telephone transmitter, thereby introducing a variable resistance into the circuit controlling the energy delivered by a battery. As a result the sound waves were converted into corresponding but amplified variations in electric current.

Despite their historical importance carbon and crystal microphones (which utilize pressure on a piezoelectric material to generate an electric voltage) are no longer generally used in sound recording. The most common types used in recording music and speech are the condenser, the dynamic, and the ribbon microphones.

Condenser microphones. Used extensively both for studio recording and for laboratory sound measurements, the condenser microphone consists typically of a thin stretched diaphragm separated by about 0.001 inch (0.025 millimetre) from a parallel fixed plate. The diaphragm acts as one plate of a variable capacitor (a device for storing an electric charge) that is connected in series with a resistor and a direct current source. The motion of the diaphragm in response to sound waves varies the capacitance, producing a varying electric current. Condenser microphones require the use of an external power supply (typically a "polarizing voltage" of more than 48 volts [direct current]) and have a small preamplifier built into the microphone case. Because of their high cost they are generally restricted to professional applications.

In recent years a new type of condenser microphone, the electret condenser, has achieved wide use. In this type of microphone the polarizing voltage is permanently stored on a metalized fluorocarbon foil at the time of manufacture, and small penlight batteries are used inside the microphone case for the preamplifier. Electrets are usually far less expensive than their conventional counterparts, and so have found wider application.

Dynamic microphones. Dynamic microphones are used widely in recording, broadcasting, and public-address systems, especially when ruggedness is essential. In a dynamic microphone a coil of wire is attached to the diaphragm, and the motion of the coil within a fixed magnetic field generates an electrical voltage in the coil. This type of microphone is available at a wide variety of prices, depending on the level of quality required.

Ribbon microphones. In this type of microphone a very thin, lightweight corrugated ribbon is suspended in a fixed magnetic field and exposed to sounds coming from either side. The motion of the ribbon in the field generates an electric voltage. The "figure-eight," or bidirectional, response pattern of the ribbon microphone makes it ideal for broadcast interviews, where its rejection of sounds coming from off-axis is important.

Directional patterns. By proper design a microphone can be made to pick up sound from a single direction only, resulting in what is called a cardioid, or unidirectional, pattern. Such a microphone, usually of either the dynamic or the condenser type, discriminates against reflected and unwanted sounds and noises and is the most frequent choice of soloists in popular recording. Bidirectional microphones, in which the pickup is essentially the same from either front or back but zero from the sides, are also used in an X–Y (crossed) configuration or, pointing to the sides and in conjunction with a front-aimed cardioid microphone, for stereophonic music recording of large ensembles. Microphones with approximately equal pickup from all directions are called nondirectional, or omnidirectional, and generally offer more nearly flat frequency response than do cardioids of equal price.

The dynamic loudspeaker

Loudspeakers and speaker systems. Speakers are classified in much the same way as microphones, and their function is exactly complementary. The most widely used type is the dynamic loudspeaker, which was introduced in 1925. An electrical coil of wire is suspended in a fixed magnetic field provided by a permanent magnet. Sound currents (*i.e.,* the electrical impulses into which sound waves have been transformed) flow through the coil. These currents produce a magnetic field that interacts with the fixed magnetic field, causing the coil to move. A cone-shaped diaphragm fastened to the coil alternately pushes and pulls the air in front of it, creating sound waves. Dynamic speakers are normally mounted in an enclosure or against a large baffle to prevent the air compressed by the front surface of the diaphragm from simply circulating around the edge of the speaker to fill the rarefaction created at the back surface, thus neutralizing the acoustic output. This is a particular problem at the low frequencies, where the cone moves back and forth relatively slowly. The performance of a dynamic loudspeaker depends heavily on the enclosure in which it is mounted. An enclosure with a port (an opening to the outside) precisely dimensioned to match the acoustic characteristics of the speaker mounted in it enhances efficiency and bass response, though some find the bass quality "boomy" and unnatural. An acoustic-suspension speaker system is one in which the volume of air within a sealed cabinet, rather than a conventional mechanical suspension, supplies much of the restoring force to centre the cone after its excursions. This type of design is particularly popular in home sound systems because of its relatively small size and smooth bass response.

A single dynamic loudspeaker cannot fully cover the entire frequency range of recorded sound, so it is customary to divide the frequency spectrum into parts that are reproduced by appropriately designed speakers. The low-frequency speaker is called a "woofer" and the high-frequency speaker a "tweeter." In many systems a third, or midrange, speaker is also employed, and in a few there are separate "subwoofers" and "supertweeters" to reproduce the extremities of the audible spectrum.

The electrostatic loudspeaker

The counterpart of the condenser microphone is the electrostatic loudspeaker. In this type of speaker a thin metalized foil is suspended between two acoustically transparent, fixed electrodes and is polarized by a high ac voltage. A step-up transformer feeds the audio signal to the fixed electrodes in a push-pull arrangement. In this way the movable foil diaphragm is alternately attracted and repelled, and its motions are transferred to the air, creating sound waves. Electrostatic loudspeakers are exceptionally well suited for the reproduction of treble frequencies, for their moving mass (in comparison with the coil and cone of a dynamic speaker) is exceedingly small. They are generally less successful in reproducing high-volume bass frequencies, however, as their limit of excursion is small. For this reason they are usually produced as very large panels, permitting a relatively large air mass to be moved by small diaphragm motions. Because of their power requirements and their capacitive nature, electrostatic loudspeakers often require special amplifier circuitry.

Amplifiers. Amplifiers are used at many different points and for various purposes throughout the sound-recording and reproduction process. The output levels of such transducers as microphones, phono cartridges, and tape heads are very small and must be amplified with low-noise, high-gain amplifier circuits. In addition, phono and tape transducers must be "equalized" to obtain overall uniform response in conformity with the standard frequency curves shown in Figure 12, and this process requires an amplifier stage. The midrotation setting of a volume control in an audio system involves inserting a 20-dB (decibel) loss in signal level, and an amplifier following the control is required to restore the loss. Bass and treble controls require still further amplifiers. While all the foregoing amplifier stages operate at low power levels, the signals necessary to drive a loudspeaker system may require very high power, requiring still further amplification.

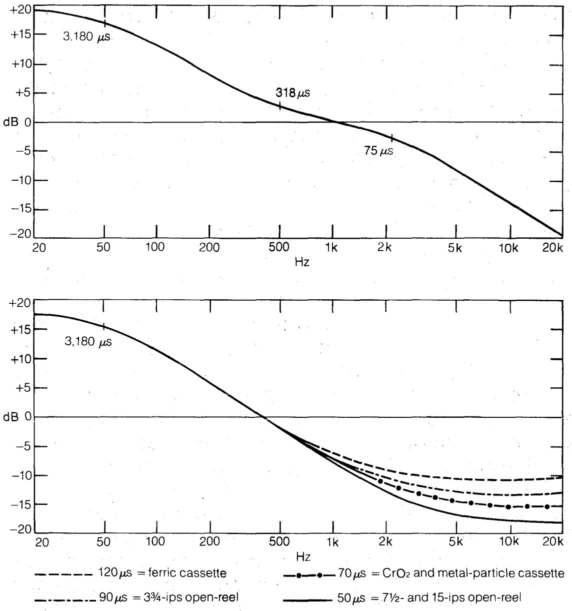

Figure 12: The playback equalization curves for (top) phono and (bottom) tape in the cassette and open-reel formats. Measured in microseconds (µs), playback equalization adjusts both low and high frequencies to obtain overall uniform response.

Amplifiers are not perfect devices. In addition to performing their intended function they also create distortion products, and when it is necessary to link together many amplifier stages, distortion can rise to very significant levels. The principal technique (apart from proper circuit design) used to reduce amplifier distortion is called negative feedback. In a negative-feedback amplifier part of the output signal from the amplifier is fed back into its input, but with reversed phase. Through the use of negative feedback the percentage of distortion can be reduced to negligible proportions, though when used excessively, negative feedback can itself be a source of distortion.

From the days of De Forest's Audion until the early 1960s the vacuum tube provided the only practical means of audio amplification. During the 1960s, however, the transistor gradually took over, and by the early 1970s integrated circuits, each containing a dozen or more transistors, began to be widely used. Integrated circuits are now used not only as amplifiers but also to contain whole circuit sections, such as the noise-reduction circuitry found in nearly all cassette tape decks.

Transistors and integrated circuits

In broadcasting and recording studios amplifier circuits are also used for other forms of signal processing. If the dynamic range (the loud-to-soft ratio) of a sound source is too great to record on a tape or disc or to broadcast, a compressor amplifier is used to reduce the range to a level that can be accommodated. If it is desired that certain portions of the audio spectrum be augmented or cut back, a multiband equalizer amplifier is employed. Popular recording techniques usually involve taping in a "dry" (nonreverberant) studio, so synthetic reverberation devices are used to add a feeling of spaciousness to the sound. Such signal processors all involve some actual or possible loss of fidelity, but they are often considered necessary.

HIGH-FIDELITY CONCEPTS AND SYSTEMS

From the mid-1930s to the mid-1950s the typical home music system consisted of a nicely finished console containing a record changer, AM radio, loudspeaker, and amplifier, augmented in some later models by an FM radio and a television set. For most people music was a form of relaxing entertainment, not a driving passion, and if the sound was pleasant it was good enough.

But a few approached home music reproduction with all the manic intensity of a Toscanini conducting Beethoven's *Ninth Symphony.* They wanted to hear Artur Rubinstein as if he were actually playing in their own living rooms. The LP disc, the FM broadcast, and the rapidly developing art of tape recording were newly at hand and had a music-reproducing potential that was mocked by the poor frequency response, low power, and high distortion of the department-store consoles, whose very brand names became derisive epithets. The enthusiasts of the early 1950s who launched the "hi-fi revolution" did not simply want music to sound good; it had to sound right. This commitment to sonic accuracy is the commitment to high fidelity.

Since the sound waves generated by the original musical source go through a multitude of transformations before they emerge from a loudspeaker, a systematic approach demands examining each link in the reproducer chain. If one manufacturer makes the best phonograph turntable, another the best amplifier, and a third the best FM tuner, it makes sense to interconnect these specific components, however unaesthetic may be their visual appearance together. Moreover, particularly in the early days of high fidelity, improvements were rapid, so it was desirable to be able to change one link in the reproducing chain without disturbing the rest. This dictated a component approach to assembling a home music system. Typically, too, the early audiophiles had at least some background in electronics, usually from training in electrical engineering or from amateur radio. They were not intimidated by, but rather welcomed, the idea of using a soldering iron and a schematic diagram to modify and improve upon a commercially built design.

Component systems

Fortunately, no one today need have the technical orientation of these early hobbyists. The overall quality of high fidelity components (as opposed to prepackaged systems) from established manufacturers in the field has risen to a point where major sonic differences are only likely to be heard between loudspeakers or between systems costing considerably different amounts.

Absolute sonic accuracy would demand that the sound waves arriving at one's ears in the listening room be a facsimile of those heard at a live music performance (minus, perhaps, the noise of the audience). However perfect the electronic part of a high-fidelity system may be, the goal of facsimile reproduction can never be achieved. This is both because microphones do not "hear" selectively (as the ear does) and because home loudspeakers radiate into a much smaller acoustic space than do the instruments in an actual performance. A living room 19 feet 8 inches long by 9 feet 3 inches wide with an 8-foot ceiling (6 by 2.8 by 2.4 metres) has the same dimensional ratios as Boston's Symphony Hall, on a 1:8 scale. For a centrally located listener in Symphony Hall the first reverberant echo from the rear wall arrives 140 milliseconds after the direct sound is heard; in the living room it arrives in only 17.5 milliseconds and can bounce back and forth seven additional times before the first echo is heard in the concert hall. The multiplicity of closely spaced reverberant echoes experienced in home music reproduction seems to give rise to an exaggerated sense of loudness that has been called "echo clutter." With foresight in microphone placement and various tricks (see below) to fool the ear (as the eye is fooled into seeing continuous motion from a series of still pictures in a motion picture) it is possible to create a very plausible illusion of "concert-hall sound" in the home. To do even this, however, demands much of the high-fidelity components.

The requirements for realism. To achieve realism in a sound-reproduction system, at least four fundamental conditions must be satisfied as follows:

First, the frequency range must be such as to include without frequency discrimination all the audible components of the various sounds to be reproduced. Conventionally, the human hearing system is said to extend from approximately 20 Hz to 20,000 Hz, although the ability of the ear to respond to the very highest frequencies tends to diminish with age, particularly among males and those who have had long exposure to high-intensity sounds (*e.g.,* members of a rock group). FM broadcasts are limited to the range from 30 Hz to 15,000 Hz, and a modern FM tuner should be able to cover this range in monophonic or stereophonic modes within ±1 or 2 dB. Very few discs and tapes contain much energy in the lowest musical octave (16 Hz to 32 Hz), and only a few loudspeakers can produce much undistorted output below 40 Hz. At the high-frequency end of the spectrum the weakest link is still the cassette. While many decks can claim a frequency response (±3 dB) to 18,000 Hz and a few go to 20,000 Hz or slightly beyond, the response measurement in this case is made at a low (−20 dB) signal level. At a 0-dB recording level even premium-quality ferric and CrO_2-type cassettes begin to reach tape saturation at about 7,000 Hz; with metal-particle cassettes this high-frequency saturation point is extended nearly an octave higher (14,000 Hz). (It should be noted that, in assessing the claim of any component to reproduce all frequencies from x to y Hz, if no qualifying $\pm z$ dB tolerance is stated the claim is without meaning.)

Frequency range

Second, the volume range must be such as to permit subjectively noiseless and distortionless reproduction of the entire range of sound intensities. A full symphony orchestra or an amplified rock group can produce sound intensities that measure 100 dB or a little higher. Possibly owing to the echo-clutter phenomenon (see above), music reproduced at this level in the home sounds much louder than live music; even during the loudest fortissimo passages in a concert hall one can make a comment to another person nearby without shouting, and this cannot be done in a living room when reproduced music is at so high a measured level. In one's living room the limit of tolerable loudness is probably in the area of 90 dB, with some variations among individuals. With high-powered amplifiers (about 100 watts per channel) and moderately efficient speakers this can be achieved, and the signal-to-noise ratio of a high-quality power amplifier today is adequate to the task.

Dynamic range

The same cannot be said for the sound sources typically available to the audiophile. Few FM broadcasts utilize a dynamic range of more than 50 dB, and if the music exceeds this it is compressed or (worse) limited. New record-cutting techniques such as direct metal mastering (an innovation of Teldec) and direct-to-disc cutting raise the usable dynamic range on discs to perhaps 70 dB or more (justifying turntable manufacturers in reducing their rumble ratings to better that figure). Studio master tapes can be made with the professional Dolby-A noise-reduction system to approach 80 dB, and the consumer Dolby-C system can raise measured signal-to-noise figures for cassettes to about 70 or 72 dB. (A different noise-reduction system, dbx, can achieve a dynamic range of nearly 100 dB, but its incompatibility with the widely available Dolby-B and Dolby-C systems has tended to limit its availability.) The solution to obtaining signal sources adequate to full musical demands probably awaits the wider dissemination of digital recordings (see below *Digital versus analogue recording*).

Third, the spatial sound pattern of the original sound should be preserved in the reproduced sound. The early high-fidelity systems of the 1950s were limited to monophonic reproduction and so could not even begin to project a sense of spatial perspective. Since the arrival of stereo—when careful microphone placement is used—the same order of spatial separation in the reproduced musical instruments and voices can be obtained as in the case of firsthand listening to the live sound sources. Moreover, image-enhancement devices have become available that can yield an astonishing degree of perceived realism in both breadth and depth.

Spatial perspecti

Fourth, the reverberation envelope, or acoustic ambience, of the original sound should be approximated in the reproduced sound. It was expected that the development of quadraphonic sound systems in the early 1970s would solve the final problem in accurate home music reproduction. By feeding separate rear- (or side-) mounted speakers with the reverberant information provided by the hall, it was hoped that the feeling of constricted space often experienced in the listening room could be overcome.

Reverberant sound

For many reasons, including commercial bickering over which matrix four-channel system to adopt for disc recordings and the unwillingness of Philips (the licenser of all cassette machines) to permit four-channel cassettes that could be played on only one side, the quadraphonic idea never captured popular attention, and the medium became dormant. Too few people felt that the benefit was worth the additional cost involved, and demonstrations of the systems tended to be anything but convincing. No one seeking realistic reproduction of music wants, for example, to listen to a string quartet surrounded by the four players.

More promising, however, are reverberation amplifiers that use digital circuitry and time-delay techniques to make the dominant component of the reverberant sound more nearly approximate the ambience invariably present in the concert hall. With good stereo microphone techniques and one of the more advanced "dimensional synthesizers" a very plausible sense of acoustic space can be obtained.

Digital versus analogue recording. The sound-recording and reproducing systems discussed above are all analogue systems. That is to say, they attempt to preserve a complete correspondence between the continuous variations of the sound waves and the methods by which they are stored. The electrical signals from the microphone(s), the undulations in the record groove, the magnetic patterns recorded on tape, and the optical patterns of a film sound track all are types of replicas or pictures, *i.e.,* analogies, of the original sounds. The closer this correspondence is maintained, the greater the fidelity. Since practical devices and storage media are never perfect, absolute fidelity can never be achieved, but in an analogue system closer and closer approximations to the continuously changing sound waves are always possible.

In digital recording, by contrast, no attempt is made to copy all of the infinite number of variations present in even a simple audio tone. Instead, sound waves are sampled at defined time intervals, and the value of each sample is converted into a binary (base-2) number that is recorded on tape as a series of pulses. Each pulse may, for example, be assigned a value of 1, and the absence of a pulse in the sampling sequence be given the value of 0, the two quantities universally used by computers. The 1s and 0s, known as "bits," are grouped into digital "words" to permit larger numbers to be represented. With a 4-bit digital word there are 16 possible combinations, from 0000 to 1111; in general, the highest number that can be represented is 2^n, where n is the number of bits per word. In digital audio recording 16-bit words are used for professional mastering; for consumer applications 14-bit words are nominally standard, although some pressure continues for a 16-bit home format.

Digital sampling

The highest numbers that can be represented in the

16- and 14-bit word formats are 65,536 and 16,384. If each number is used to represent the electrical voltage, or current level, in each sample of the sound wave, the available dynamic range of the professional system is 96 dB and that of the consumer digital system is 84 dB. Both of these ranges far exceed the capabilities of the best available analogue recording and playback machines. Distortion is correspondingly lowered to 0.0015 or 0.006 percent, respectively, again far superior to the performance obtainable in analogue recording.

The frequency-response capability of a digital audio system is determined by the number of samples (the 14- or 16-bit words) taken each second. It can be shown mathematically that any waveform, such as a sound wave, can be reconstructed from samples if the sampling rate is at least twice as high as the highest frequency component in the waveform. To process fully all frequencies in the nominal (20 Hz to 20,000 Hz) audio spectrum thus requires a sampling rate in excess of 40,000 Hz; typically, 44.1 kHz is used for consumer digital audio and 50 kHz for professional recording.)

Figure 13 shows the principal stages involved in a typical digital audio recording. The electrical output from the microphone(s) is amplified to a nominal "line level" of approximately one volt (still in the analogue domain) and passed through a sharp filter that rejects any components above 20,000 Hz. (Without this anti-aliasing filter ultrasonic signals higher than half the sampling frequency can appear within the desired audio spectrum as musically unrelated "aliases" of themselves.) The signal is then processed by an analogue-to-digital (A/D) converter. (Figure 13 shows this "quantization" as a staircase-shaped waveform. In actuality, the various amplitudes shown by the heights of the samples are recorded at the same level, with the pattern of 1s and 0s representing the proper binary number.) After various additional bits are added to correct for any loss of information that may occur in recording or playback from imperfections in the physical tape, the entire pulse code is recorded, or "written," at saturation level onto a tape and stored.

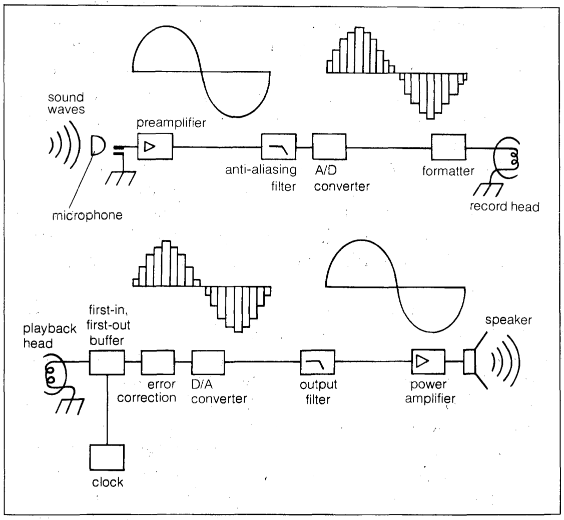

Figure 13: The analogue-to-digital-to-analogue process.

In playback the detected pulses are fed into a "first-in, first-out" buffer memory and are then released at precisely clocked intervals for subsequent decoding. This eliminates the effects of any mechanical wow and flutter, which, to some degree, always degrade the performance of analogue recording and playback systems. After all of the error-correcting procedures have been implemented, the original 14- or 16-bit words are passed to a digital-to-analogue (D/A) converter, whose output passes through a second sharp filter that rejects all signals above 20,000 Hz. In this way the ultrasonic components generated by switching from one bit level to the next are eliminated. A conventional analogue power amplifier and loudspeaker are then used to transform the electrical signal back into sound waves.

By the 1970s a precursor of digital audio had already made its appearance in home music-reproduction systems in the form of digitally mastered recordings converted into conventional, widely acclaimed analogue discs. By the early 1980s more and more master tapes of music performances, particularly in the classical field, were being recorded digitally, even when their public release was in the form of conventional analogue discs and tapes. Further, although intended for a limited market, several companies produced PCM (pulse-code modulation) adaptors for home videocassette decks that recorded and played back audio digitally, and prototypes of digital audio cassette decks were demonstrated. Devices for digital editing, equalizing, and other techniques used in recording studios also became available.

Digital discs

By 1983 fully digital discs and players had been introduced as consumer products in Japan, Europe, and the United States. Developed jointly by Sony (Japan) and Philips (The Netherlands), the Compact Disc (CD), also known as the DAD (Digital Audio Disc), holds approximately 60 minutes of stereophonic, digitally encoded music on one side of a 12-centimetre (4¾-inch) disc. A 16-bit word format and 44.1-kHz sampling rate is used, and the digital information on the disc is detected optically for playback by a laser beam. Technically, these are the finest source of prerecorded sound ever introduced into the home market, for they have an available dynamic range of 90 dB, distortion of less than 0.004 percent, and a frequency response from 5 Hz to 20,000 Hz ±0.5 dB. In one form or another digital technology will play an increasingly large part in all aspects of sound recording and reproduction.

Other applications of acoustics

ARCHITECTURAL ACOUSTICS

The production and reception of sound in closed spaces such as lecture and concert halls, theatres, church auditoriums, school classrooms, and home constitute the subject of architectural acoustics.

The sabin unit

When a sound source is excited in a closed room, the resultant sound intensity at any point depends not solely on the sound waves reaching that point directly from the source but also on the arrival there of sound that has been reflected from the walls and other surfaces of the room. For rooms of the size encountered in ordinary experience the sound intensity builds up rather quickly, and the phenomenon known as reverberation ensues. If the room surfaces were perfect reflectors and the source were to continue to emit sound at a constant power output, the sound intensity would increase indefinitely, except for the attenuation of sound caused by the transmission through the air in the room. Actually, sound is always absorbed to a certain extent by any surface, and this keeps the intensity from building up indefinitely. But if the source stops it takes time for the intensity to decrease so as to render the sound inaudible. The time taken for the average sound intensity in a room to diminish to one-millionth of its original value at the instant the source was turned off is called the reverberation time. It is found experimentally that the reverberation time (*T*) depends directly on the volume of the room and inversely on the absorption of the sound by its various surfaces. If the fractional amount of sound energy absorbed by a surface is called the absorbing power *a*, the total amount of absorption is the integrated value of *a* over all the surfaces of the room. Thus, if 30 percent of the sound energy incident on a particular surface is reflected back into the room, the value of *a* for that surface is 0.7. Each square metre thus acts as the equivalent of 0.7 square metre of a perfect absorber. The metric sabin (after Wallace Clement Sabine, a United States physicist) is the equivalent of one square metre of perfectly absorbing material. The corresponding English unit uses the square foot and is known simply as the sabin. If *a* is the total absorbing power of all the surfaces of the room, then integrating the fractional amount of sound energy absorbed over all the room surface,one gets $a = \int \bar{a}dS = \bar{a}S$, in which dS is the element of surface and S the total room surface. The average absorbing power per unit is $\bar{a}$. The Sabine reverberation law may then be expressed as $T=0.161v/\bar{a}S$, in which T is the reverberation time in seconds, v is the volume of the room in cubic metres, and $\bar{a}S$ is the absorption in metric sabins. The same formula applies if the volume is in cubic feet and the product $\bar{a}S$ is in sabins, though the factor 0.161 then becomes 0.049. Various modifications of the Sabine formula have been proposed to meet the situation posed by extremely high surface absorption ("dead" rooms), and to take account of the absorption in the air of the room.

The optimum acoustical conditions in a room depend on its intended use. For satisfactory reception of speech, a relatively short reverberation time is obviously essential for adequate articulation. With long reverberation time successive utterances overlap, unless the speech is abnormally slow. For auditoriums with volume of the order of 6×10^3 cubic metres to 14×10^3 cubic metres (2×10^5 to 5×10^5 cubic feet), experiments suggest a maximum reverberation time of about 2.5 seconds for satisfactory articulation. For best listening conditions in such rooms the reverberation time should be about one second. These figures indeed assume a low general noise level—*i.e.,* only about 30 decibels above minimum audible. In large rooms (of the order of 3×10^4 cubic metres or more) no speaker's voice can be heard without the use of a public address system, no matter how short the reverberation time. A room used primarily for music requires a longer reverberation time than one used for speech. For concert halls the optimum reverberation time for music is about 1.9 seconds (see Figure 14). Inasmuch as absorption varies more or less directly with the frequency, the reverberation time varies inversely therewith. The above figures are for an average frequency of about 500 hertz.

Sabine's law indicates that the reverberation time for a room of given size can be controlled by appropriate changes in the absorption by the surfaces. Many kinds of acoustic absorbing materials exist to meet a wide variety of needs, both for permanent installation to meet the original design requirements and for portable installations to provide for flexibility in use.

In addition to the overall reverberation, and indeed as a contributing factor to it, the transmission of the sound back and forth between the walls, floor, and ceiling of a room stimulates the development of the normal modes mentioned above. Hence a complicated sound pattern can result in which certain frequencies are accentuated, leading to discomfort and difficulty in hearing. The excitation of the most troublesome normal modes can be materially reduced by the use of absorbing material, and also by introducing slight irregularities in the walls, so as to get rid of parallelism. These precautions break up the regular sound pattern and serve to diffuse the sound energy more equally throughout the space.

Modern architectural acoustics technology uses many special techniques, including the free use of sound-reinforcing systems with loudspeakers placed at strategic points throughout the space. The optimum acoustic design of auditoriums as well as schoolrooms, business offices, residences, etc., reached a high level of efficiency in the 1960s and 1970s. Much of the success of modern room acoustic design is due to the use of computers. A simulated model of a given hall can be introduced into a computer program that will then yield a faithful representation of the acoustical properties of the actual hall. Thus, the modifications necessary to give optimum conditions are relatively easy to determine while the hall is still in the design stage. Acoustic models of this kind will undoubtedly play a role of increasing importance in room acoustics and indeed in applied acoustics generally.

Computers used in acoustic design

MUSICAL ACOUSTICS

Until relatively recent times, acoustical theory had little bearing on musical instruments, even though historically much acoustical theory was developed in the attempt to explain how such instruments work. With the advent of sound recording and reproduction, the attempt to apply acoustical principles to the design of more effective instruments has led to considerable progress.

Conventional musical instruments are complicated examples of coupled vibrating systems—*i.e.,* systems with many degrees of freedom. Many of them, such as horns and woodwinds, function as acoustic filters, emitting only certain frequencies or combinations thereof. The development of electroacoustics has encouraged the invention of many types of electrical musical instruments, such as electronic organs and related devices. Computer-composed music has also attracted considerable attention. (For details see MUSICAL INSTRUMENTS.)

MILITARY APPLICATIONS

The principal military use of acoustics has been the detection of distant objects on the ground or under water. If an impulsive sound wave from a distant source like a gun is received by at least three microphones placed at precisely known intervals along a line (more than three are used in practice), knowledge of the sound velocity in air and the differences in time of arrival of the sound signal at the various microphones is sufficient to yield the bearing of the source and its distance from the microphone range. This is the basis for sound ranging in air. There are, to be sure, many complicating factors, such as the variation of sound velocity due to temperature gradients and wind velocity. Hence meteorological measurements are always important in sound ranging.

Seawater is in general a very good medium for the transmission of sound radiation. Moreover, its acoustic impedance (see the section above on properties of sound waves) matches solid sound sources much better than that of air. Hence sound ranging under water has become a very effective method for the detection of underwater objects such as submarines. Passive detection based on the sound emitted by an underwater vehicle is fundamentally similar to sound ranging in air. Active detection, called sonar, is the more common method. In this, a beam of sound pulses sweeps the water horizontally; when it strikes a solid object, an echo is returned, providing a bearing on the object. The distance may be found from the knowledge of the sound velocity in water. This method is the acoustical analogue of radar. To secure a reasonably sharp beam from a not-too-large transducer surface (employing

By courtesy of Bolt Beranek and Newman Inc.

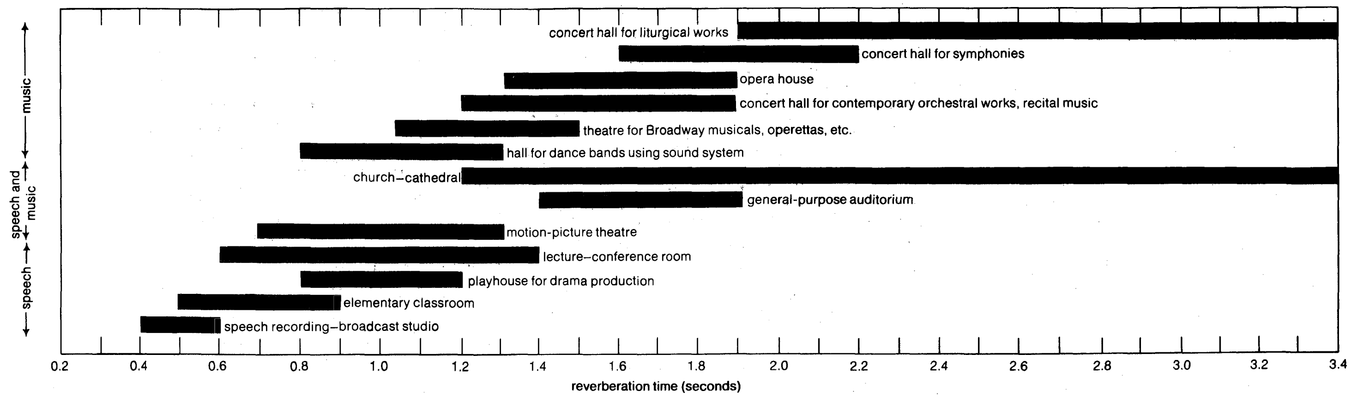

Figure 14: Optimum reverberation time for various types of facilities.

piezoelectric or magnetostrictive elements), a fairly high frequency must be used. On the other hand, because the absorption of sound in seawater increases more or less with the square of the frequency, there are limitations involved. It is usual to employ rather larger transducers with lower frequencies to secure long range. The use of sonar demands many correction techniques to take care of temperature gradients, changes in density, reflection from surface and bottom, and other error-producing effects.

Sonar has become increasingly important not only as a military weapon but as a navigational device and a means for exploring the properties of the sea.

NOISE CONTROL

Noise or unwanted auditory experience was an important aspect of practical acoustics in the 1970s. Noise in human life had reached the level at which it was considered a form of environmental pollution. Noise control then developed into a major branch of acoustical engineering.

Every advance in the efficiency of the transformation of heat energy into mechanical energy has involved a noise problem, and in general this increases with power production. The large-scale turbulence of exhaust gases streaming from a jet airplane is an unusually intense source of sound in which the total acoustic power is proportional to something like the fifth power of the jetstream velocity. The annoyance of this is evident to anyone who lives in the vicinity of an airport. When a plane moves faster than the speed of sound in air, the bow wave formed is shed as a shock wave (analogous to Cherenkov radiation in light), and this leads to the so-called sonic boom, a loud explosion as the shock wave hits the ground. This is one of the serious noise hazards of the supersonic jet plane.

(R.B.L.)

Criteria for noise-control design. The amount of sound energy that reaches the listener depends on the paths by which the sound has travelled, on the distance from the source, the power of the source, and the nature of such intervening barriers as walls, doors, windows, and sound-absorbing ducts. Qualities that characterize a desirable acoustic environment vary widely, depending on how the space is to be used, how particular the users are, and how the specific space involved relates to other parts of the building. A library reading room, for example, should be free of distraction. This objective can be achieved either by keeping the reading room silent or by providing a moderate, continuous, background sound level of unobtrusive, unrecognizable character, sometimes called white noise. Because the background sound hides or masks the minor noises that are unavoidable, the second approach is considered more realistic. In a large business office, a higher degree of background noise might be acceptable, up to the point at which it interferes with conferences and telephone conversations. In general, people usually tolerate a noise conveying no information better than they do one that tells them something, and an expected noise is usually more tolerable than an unexpected one of the same magnitude.

olerable
oise levels

The acoustical character of a space is as important as the amount of sound generated in it or transmitted into it. If a room is finished in hard, sound-reflecting materials, sounds in the room not only persist but seem to come from all directions.

There are optimum ranges for the reverberant character of occupied spaces. An aid to the acoustical engineer is the fact that the acoustical character does not need to be uniform throughout a building; on the contrary, variations may provide a pleasant contrast, from a large, reverberant, monumental space to a smaller, quieter, more intimate space in which communication is easy.

Controlling noise outdoors. The most effective method of noise control outdoors is to separate the source and receiver in space, but because this is not always feasible, some type of barrier is often introduced. Walls and earth banks can be used to control many types of outdoor noise, but the effectiveness of any barrier depends on how well it cuts off the line-of-sight path between source and receiver. A wall to control traffic noise, for example, can be effective at ground level, provided it is near either the source or the receiver, but a low wall constructed in front of a multistory apartment house will do nothing to control noise for those above the level of the wall. Trees and shrubs have little effect.

Controlling noise indoors. When a sound wave strikes a sizable obstacle such as a wall or ceiling, part of it is reflected, part of it is absorbed, and part of it is transmitted to some adjoining space. The relative magnitudes of these three parts of the original sound are determined by the physical properties of the obstacle. A hard-surfaced, dense plaster reflects a great deal of the sound that strikes it, while a soft surface such as a heavy carpet absorbs most sound and reflects little. Absorption and reflection are important only in connection with the space in which the sound originates. More often the problem is the portion of the sound that is transmitted to an adjoining space. Although the mechanisms governing sound absorption and sound isolation are complex, they must be understood in order to predict the resulting acoustical environment in a finished building.

Sound absorption. Useful sound absorption is provided by porous materials such as carpets, draperies, glass-fibre blankets, clothing, and the many specially made, sound-absorbing materials. An essential property of a sound-absorbing material is that it have a porous structure into which the molecules in the air carrying sound energy can dissipate, thus losing energy in the form of heat. Sound energy so dissipated is never recovered as sound. Because it is essential that the interstices of sound-absorbing materials be intercommunicating, a closed-cell foam material is not a good sound absorber. Porous sound-absorbing materials may sometimes be faced with hard-surfaced, refinishable perforated panels, wood strips, or the like, but these facings must be so designed that the sound can penetrate into the porous material behind the facings. In general, the solid parts of the facing material should not be larger than two or three inches (five to eight centimetres) and the openings between these elements to the sound-absorbing material should represent 10–25 percent of the area.

Sound-absorbing materials

When sound-absorbing materials are placed within a room, the reflection of energy is greatly reduced and the sound dies away rapidly instead of being reflected many times by the enclosing surfaces. When the sound dies away quickly, the room has what is called a short reverberation time. If surfaces are highly reflective and sound continues to reflect from surface to surface with almost no loss, the room has a long reverberation time. The "feel" or quality of a space as sensed by the occupants is determined largely by the amount and type of sound-absorbing finish.

When a room has a short reverberation time, sounds seem to come from their point of origin rather than from everywhere, surrounding the listener with many reflections. There is actually some reduction in the level of sound from a source in such a "dead" room when contrasted with a hard, reverberant, sound-reflecting "live" room. A nonreverberant space seems more comfortable, and speech communication is easier because the jumble of successive sounds is absent. The proper use of sound-absorbing finishes can improve the quality of almost any space in which a number of people must work, live, or play together. Large open-plan offices and schools work satisfactorily only when both the floor and ceiling are covered with a sound-absorbing finish.

Dead and live rooms

Sound-absorbing ceilings can be very useful for noise control in factories, but the source of the noise must also be considered. Since a sound-absorbing ceiling affects only the noise level in the overall space, it has no effect on the level of sound reaching the ear of a worker near a noisy machine. In areas where noise is less intense, as in restaurants and college dining halls, a sound-absorbing ceiling is more effective. The potential of sound-absorbing materials in private residences has been largely neglected. A sound-absorbing ceiling in a dining room, for example, can reduce the din at a dinner party (whether the room is carpeted or not) to a pleasant level that permits conversation at ordinary voice level. The kitchen, with its customarily hard finishes, can also be a more pleasant space in which to work if it has a sound-absorbing ceiling.

Sound-absorbing materials are used as linings for air ducts to reduce the transmission of sound from room to room and from the fan. Also, mufflers for internal combustion engines incorporate either resonant or dissipative sound-absorbing materials to reduce the noise transmitted with the exhaust gases.

Sound isolation. While sound-absorbing treatments are useful in the control of the character of occupied spaces and in reducing the magnitude of noise in an enclosure, they are useless as noise barriers. A curtain hung in a doorway or over a wall provides no improvement in sound isolation. Acoustic tiles nailed to the underside of floor joints do not improve the isolation between the living room and a downstairs playroom.

The sound isolation provided by a barrier such as a wall, floor, ceiling, or window, is determined almost entirely by its weight or inertia. Since a sound wave consists of the back-and-forth oscillating motion of molecules in the air, these moving particles, when they encounter an obstacle, tend to make the obstacle oscillate slightly. If the obstacle has a great deal of weight or inertia, it resists this attempt at being moved, but if it is relatively lightweight it may move quite easily. When the obstacle is moved by action of the sound wave on one side, it radiates a new sound wave on the other side. This new sound wave is the transmitted sound, the sound heard in the adjoining space. The sound energy is transmitted from one side of the partition to the other by the direct motion of the partition. The heavier the construction, the less sound gets through. A great deal less sound can be heard through an eight-inch brick wall, for example, than through a lightweight plasterboard partition.

Any construction must be completely airtight if it is to be useful as a sound isolator. An opening in a barrier (such as an open door) transmits much more sound energy than an area of wall of equal size. A wall of porous concrete block or construction with loose joints allows sound energy to be transmitted through the leaks and cracks. Doors and windows work at their best as sound barriers only when they are tightly weatherstripped. Probably the most difficult problem in modern building construction is to make airtight connections between the many dry, prefabricated elements that form the enclosure and subdivision of buildings. Every service penetration for piping, every shrinkage crack, and, in fact, any leaks at all seriously limit the ultimate performance of noise-isolating construction.

Sound-isolating construction

Since it is often impractical to use extremely heavy construction for walls and partitions in buildings, two separated elements, instead of a single heavy unit, are sometimes employed. Two layers of glass, for example, separated by a space of about six inches (15 centimetres), can be as effective as a heavy masonry wall. A double window of this sort is a good isolator provided it is completely weatherstripped. Ordinary sealed double glass, with an air space of 0.5 inch (1.25 centimetres) or less, is not really a double construction from the acoustical point of view, because the air space is too small to permit independent motion of the two pieces of glass. Double plaster walls, using separate framing for each face, are often used for party walls between apartments. This construction can be very effective, but its acoustical effect is seriously impaired by back-to-back convenience outlets or penetrations for heating pipes or plumbing.

Background noise. The amount of acoustical privacy between two spaces is related to the background noise level as well as to the sound isolation provided by the construction. Architects have often been surprised to find that a partition type that worked well in a city office building was far from satisfactory in a quieter location. In such cases, a small amount of white noise may be added to the ambient noise level.

Background noise should be bland, unnoticeable, and continuous. Steady traffic noise of the city or the characteristic sounds of many types of air diffusers are the kinds of background noise that people expect in a typical modern building. When there are no partitions, the background noise becomes even more important in determining privacy. A large, elegant, but sparsely filled dining room is often so quiet that patrons must speak in low tones to preserve privacy, while with a moderate level of conversation throughout an ordinary restaurant, good privacy can be had at comfortable voice levels.

Structure-borne noise and vibrations. Sound is also transmitted in a building when the structure sustains a direct impact or when a vibrating object is in rigid contact with it. The structure then radiates sound energy into the air. For this reason a neighbour's doorbell, if fastened directly to a common wall between apartments, can often be heard as loudly in one apartment as the other. The sound of movements from the floor above is a familiar structure-borne sound, as is the noise from a rigidly attached appliance, or from the great variety of mechanical devices that fill modern buildings. As is the case with airborne sound, the heavier the construction the less sound of impact and vibration is transmitted.

Resilient isolation

Combined with massive construction is the need for resilient isolation. The noise of a footfall overhead is considerably reduced when the floor is covered by heavy carpeting. Footsteps can be made almost inaudible if, during construction, an additional layer of concrete or a wood floor is "floated" on special resilient pads on top of the basic structural floor. A doorbell on a resilient mounting is inaudible in a neighbour's apartment. A garbage grinder, attached to the sink through a rubber collar, is relatively quiet. Water pipes and drains, isolated from walls and floors with resilient materials, perform their functions with little noise. Fans and compressors, mounted so that they are free to vibrate on springs or rubber mountings, create little noise, although in the absence of such mountings, the whole structure acts as a sounding board for these devices.

Not only must moving equipment be properly mounted, but it must also be connected to necessary electrical and plumbing services through flexible connectors. Any rigid ties to the structure of the building nullify the value of resilient mountings.

(R.B.N./Ed.)

APPLICATIONS OF ULTRASONICS

Until about 1910 ultrasonic waves were little more than a scientific curiosity. Following the successful development of the piezoelectric transducer, they were used in an early form of sonar to detect the presence of submerged submarines. Other attempted early applications were as a means of communication, and as light modulators in early experiments with television. Following the development of radar during World War II, ultrasonic techniques were used in such wide-ranging fields as the study of molecular properties of materials, detection of flaws in metals, ultrasonic cleaning, industrial and dental drills, measuring the thickness of the heart walls in man, and determining the presence of fluid in the sac around the heart.

Applications of ultrasonics can be divided roughly into two classes: low energy and high energy. In the former, the amplitude (that is, the height of the wave from its highest point to its lowest point) is sufficiently low so that the wave is not distorted in passing through the medium, and the medium is left unchanged except for a slight rise in temperature. High-energy waves, on the other hand, modify the medium in some irreversible manner, either by the generation of large stresses or high temperatures, which induces physical or chemical changes.

When a low-energy ultrasonic wave travels through a medium, its energy decreases rapidly because of a characteristic of the medium known as its absorption coefficient. Absorption is caused by a medium's viscosity and thermal conductivity, though recently it has been found that the absorption coefficient is often much higher than calculations based on viscosity and thermal conductivity alone would indicate. Much information about the molecular properties of materials has been obtained from studies of the variation of this excess absorption with frequency.

Relaxation effect

Another important factor in dealing with the passage of an ultrasonic wave through a material is the relaxation time, or relaxation effect, a measure of how rapidly the material changes its volume as a result of the pressure changes caused by the passage of the ultrasonic wave. If an appreciable lag takes place between the wave's passage and the completion of deformation, a relaxation effect is said to occur. Whenever the relaxation effect exists, the wave velocity through the material depends on the frequency of the wave.

Propagation of ultrasonic waves. The manner in which ultrasonic waves propagate, or spread, through different media determines their applications. Ultrasonic waves are absorbed in a gas because of its viscosity (resistance to flow) and thermal conductivity (the ability to conduct heat). Relaxation effects, defined above as the measure of how rapidly a material changes its volume as a result of the pressure changes caused by passage of an ultrasonic wave, are also significant. Though liquids absorb for the same reasons as gases, measured values in many cases are greater than would be predicted on the basis of their viscosity and thermal conductivity, indicating that relaxation effects predominate. The thermal conductivity of a solid, like that of liquids and gases, also causes absorption. Thermal conductivity is enhanced in a solid composed of a large number of crystals of microscopic size (microcrystals). In addition, the microcrystals tend to scatter the wave as it passes through. The relation between the fraction of incident energy thus scattered and microcrystal grain sizes is a function of the frequency of the ultrasonic wave, and measurements of scattered energy versus frequency can be employed to determine grain sizes.

mplifi-
ıtion of
ı ultra-
ınic wave

An ultrasonic wave produces strains in a medium as it passes through; if the medium is piezoelectric, the strains generate an electrical field. If the piezoelectric medium is also a semiconductor, the current carriers (if negative) are accelerated by a positive electrical field and decelerated by a negative field. In the presence of the ultrasonic wave the current carriers bunch together and drift through the medium with a velocity dependent upon an applied electrostatic field (voltage). If these bunches drift more slowly than the ultrasonic wave, the latter tends to accelerate the bunches. The energy required for this to happen comes from the ultrasonic wave, which is, therefore, absorbed. If the drift velocity of the bunches exceeds the ultrasonic wave velocity, the opposite occurs and energy flows from the current carriers into the ultrasonic wave, which is therefore amplified. Although amplification factors of 30 have been obtained in cadmium sulfide crystals, there have, as yet, been no practical applications of this amplifying technique.

Lower power applications. *Flaw detection and thickness gauging.* Ultrasonic waves are scattered when they meet an acoustical impedance mismatch—*i.e.,* a point at which the resistance to the passage of ultrasonic waves changes abruptly. This mismatch can occur at a flaw, such as a hole or a crack in a metal casting. The detection of such flaws, vital in metallurgy, can therefore be performed by using an ultrasonic version of radar. In this application, the pulses of the ultrasonic waves are scattered when they strike a flaw in, for example, a metal casting, with some energy returning either to the same or another transducer. By measuring the time required for the ultrasonic wave to pass through the material, be deflected, and return, it is possible to determine the location of the flaw; thickness can be gauged by similar techniques.

Ultrasonic delay line. In certain electronic systems, such as that in the colour separation section of a colour television receiver, it is necessary to delay the passage of an electrical signal from one point to another. This time delay must be precisely controllable, appreciable (that is, greater than a few millionths of a second, or microseconds), and reproducible. One form of delay unit employs two quartz transducers cemented to the sides of a glass polyhedron. Ultrasonic waves emitted by one transducer bounce from side to side of the polyhedron until they reach the other transducer where they are converted back into electrical signals.

trasonic
rsts

Measurement of mechanical stresses. The presence of a stress in a body rotates the plane of polarization of polarized shear waves (a situation in which the particles that propagate the wave are all vibrating in the same direction or plane), and some correlation has been found between the amount of rotation and the magnitude, or physical size, of the stress. When a material is stressed it emits bursts of ultrasonic waves at frequencies up to about 40 kilohertz (40,000 cycles per second) for ductile materials and up to 400 kilohertz for brittle materials. Materials undergoing plastic deformation emit signals of a lower amplitude than when the deformation is such as to produce cracks. The repetition rate of the bursts increases with increasing rates of stain. It is anticipated that the detection of these bursts of ultrasonic waves can provide an early-warning system for incipient mechanical failure.

Ultrasonic image converters. The data presented by the type of flaw detector considered above is essentially one-dimensional; interpretation is difficult and somewhat subjective. For this reason much effort has been devoted to developing an ultrasonic camera equivalent to the X-ray machine.

In the ultrasonic camera a transducer generates an ultrasonic wave in a liquid. This wave passes through the object to be investigated and then strikes the metallized surface of a quartz disk that forms the front plate of a cathode-ray tube. The variation in ultrasonic intensity across the surface of the disk produces a corresponding variation in the alternating charge pattern appearing at the rear surface of the disk. This rear surface is scanned by an electronic beam that converts the charge pattern into a visible image on the face of a television picture tube. The picture on the television tube will then be an ultrasonic "X-ray" of the object.

A hologram is a three-dimensional picture made (without a camera) on photographic film by the pattern of interference formed by laser light reflected from the object; the picture is viewed by passing laser light through the film. In recent years optical holography has appeared as a powerful tool for optical imaging. Some work is being carried out to develop an ultrasonic hologram. In one system, illustrated in Figure 15, two beams of ultrasonic waves at identical frequencies are directed at an angle to the underside of a liquid surface. One of these beams passes through the object to be investigated. At the surface, the two beams interfere to produce an ultrasonic wave pattern containing, effectively, an ultrasonic hologram of the object. This wave pattern is visualized by shining monochromatic (single-frequency) light at an oblique angle onto the liquid surface. The liquid wave pattern behaves like a diffraction grating and the first order diffraction image contains a picture of the ultrasonic cross section. In fact, the light beam is behaving in the same way as the beam used to reconstruct a picture from an optical hologram.

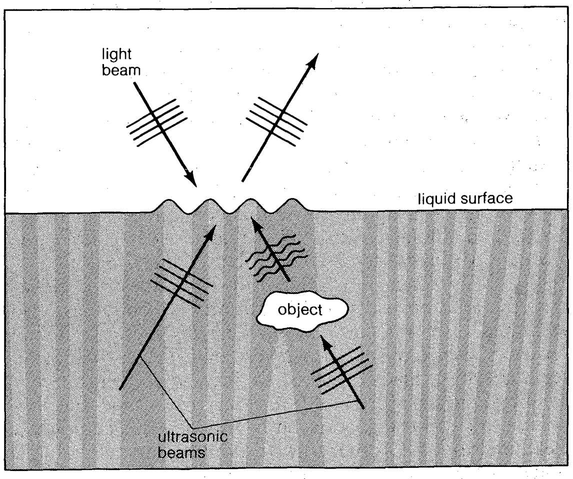

Figure 15: System for production of ultrasonic hologram (see text).

Ultrasonic holography, as so far developed, has a much higher resolving power than the ultrasonic camera.

Underwater applications. Underwater applications of ultrasonic waves are basically flaw-detection systems, in which an object such as a submarine, a shoal of fish, or the seabed acts as the flaw. Ultrasonic waves have been used for short-range underwater communication, but most transducers are so highly directive that their use is of limited value.

Applications in air. The applications of ultrsonic waves in air are similar to those in liquids and solids and are essentially forms of flaw detection. Ultrasonic waves have been used to count objects travelling along a belt, each object breaking the sound beam as if it were an optical beam. In the early 1970s a hand-held sonar blind-guidance device showed promise. In this device an ultrasonic beam is radiated; the presence of an obstacle causes this beam to be reflected, and the reflected beam is indicated by a tone in a headset worn by the operator. The pitch of the tone indicates the distance to the obstacle. Another interesting application is as an intrusion detector, in which a transducer sets up a pattern of ultrasonic waves in a room, producing a specific amplitude at a detector. An intruder alters the ultrasonic wave pattern and therefore alters the ultrasonic amplitude at the detector, setting off an alarm.

Measuring fluid flow rates

Ultrasonic viscometer. The acoustic impedance (resistance to the passage of acoustic waves) of a liquid for transverse or shear waves involves the liquid's viscosity. If the electrical impedance of a shear wave transducer is measured in air (which presents negligible resistance) and then in a liquid, the impedance difference can be related to the liquid's viscosity, enabling the latter to be determined conveniently.

Ultrasonic flowmeter. The apparent frequency of an ultrasonic wave travelling in a medium moving relative to the transducer in a direction parallel to that of the wave, differs from the vibration frequency of the transducer because of the Doppler effect. The frequency shift is directly related to the medium's velocity, and hence, if the frequency shift can be measured, the medium's velocity can be calculated. This principle has been applied to the measurement of fluid flow rates.

Medical applications. The use of X-rays has been well established for many years for medical investigations. X-rays, however, suffer from two defects—it is difficult to delineate soft tissues of the human body with them, and their use is not advisable in the early stages of pregnancy. Ultrasonic waves, however, are reflected by some soft tissues and, as far as is known, cause no harmful effects if the ultrasonic intensity is sufficiently low. In medicine, the main application of ultrasonics has been as a flaw detector in such applications as detecting shifts in the midline of the brain and investigations of the fetus. Fetal echoes are obtainable many weeks before the fetal skeleton is visible by radiography (see also DIAGNOSIS AND THERAPEUTICS).

High-power applications. The effects produced by high-energy ultrasonic waves are normally irreversible and arise from cavitation (see below), intense mechanical stresses, or intense localized heating.

If the ultrasonic pressure exceeds the ambient (normal average) pressure in a liquid, the pressure in the liquid will fall below zero at the ultrasonic wave pressure trough, or point of minimum pressure. If this occurs, a process known as cavitation takes place; the liquid ruptures and forms small cavities, which—if they have a suitable radius—will expand as the pressure rises and then, as the pressure starts to fall, will become unstable and collapse very rapidly. At the end of the collapse, the gas within the cavity will be highly compressed (measurements indicate pressures of several hundreds of atmospheres); these high pressures will be relieved by the radiation of shock waves. These intense shock waves can cause liquids to mix that normally would not do so—such as oil and water; they can break up giant molecules such as polymers, proteins, and viruses; force dirt and grease off surfaces for cleaning purposes; break up cells; and initiate chemical reactions. The violent agitation caused by cavitation has also been used to improve the quality of electrodeposited copperplate and the quality of optical glass by irradiating the glass, when melted, with highpower ultrasonic energy.

The rapid vibration of a gas or liquid under the influence of intense ultrasonic waves causes a net attractive force to develop between particles suspended in the fluid. In addition, small, light particles will take up more of the fluid's motion than large, heavier ones. This difference in motion will increase the chance of collisions between the particles. If the particles coalesce (adhere) on collision, irradiation by ultrasonic waves provides a means of coagulating the suspended particles. This has found applications in the removal of suspended particulate matter, as in the cleaning of factory exhaust gases.

Another useful application of intense ultrasonic waves is the ultrasonic soldering iron. The iron is designed to be a magnetostrictive transducer. The rapid vibration at its tip removes oxide layers from the surface of the metal to be soldered and not only improves the quality of the soldering but also permits the soldering of materials otherwise difficult to solder, such as aluminum.

Ultrasonics in brain surgery

Intense ultrasonic waves have also found an application in medicine, particularly in brain surgery. Four beams of ultrasonic energy are beamed into the brain through holes cut in the skull. The intensity of each beam is insufficient to cause damage, but when combined at some point within the brain the total intensity is sufficient to heat a small region to a high enough temperature to destroy the tissue that the surgeon wants destroyed. This technique has been used successfully in the treatment of Parkinson's disease.

INFRASONICS

Infrasonic waves are those whose frequencies are nominally below the lower limit of human hearing. In recent years, however, evidence has been accumulating that waves with frequencies down to one cycle per second can be detected by human beings, provided the intensity is sufficiently high. The detection process, not yet fully understood, is believed to be a disturbance of the inner ear leading to dizziness. These waves are generated wherever a large high-speed flow of air occurs into, or around, an enclosed box or room. Of particular current interest is their effect on automobile drivers driving with open windows. Some microphones operate down to these frequencies and can be used to detect the presence of infrasonic waves.

Other sources of infrasonic waves of even much lower frequency (sometimes below one cycle per second) are earthquakes and tidal motion. Earthquakes require special detectors that usually consist of a large, well-sprung mass acting as an inertial element, the movement of which relative to the Earth is monitored, either by a pen drawing onto a chart mounted on the Earth or by a light beam falling onto photographically sensitive paper. When the Earth moves, the chart moves with it, but the inertial mass remains stationary and, therefore, the deflection of the trace on the chart indicates the motion of the Earth relative to the stationary mass. For portable use in seismographic surveys, the inertial mass is formed by a well-sprung magnet, between whose poles is situated a coil connected to the Earth. The motion of the Earth relative to the magnet induces a voltage in the coil proportional to the speed of relative motion.

Use in underground exploratio

Underground explosions are used to generate infrasonic waves. From the traces provided by several seismometers of the paths traversed by the waves, the properties of the underlying rocks can be evaluated. This technique is used extensively in mineral and oil surveys. Recently, extremely sensitive seismometers have been employed to monitor infrasonic waves produced by underground nuclear explosions as part of the implementation of the nuclear test ban treaty.

Earthquakes are the main source of naturally occurring infrasonic waves. The main shock is often preceded by smaller shocks; by detecting these preliminary waves it may be possible to develop an early-warning system for large earthquakes. A similar early-warning system has been suggested for volcanic eruptions, which are usually preceded by seismological activity. (G.L.G.)

BIBLIOGRAPHY

General works: LORD RAYLEIGH, *Theory of Sound,* 2 vol. (1877–78; rev. ed., 1926; 1-volume ed., 1945), probably the most famous treatise on sound ever published, has remained an authority on nearly all aspects of theoretical acoustics since its publication. Twentieth-century accounts, particularly recommended, are WALLACE C. SABINE, *Collected Papers on Acoustics* (1922, reprinted 1964), a classic work on the development of the reverberation formula, still in use today, together with a fascinating discussion of solutions to acoustical problems, and a debunking of acoustical myths; F.V. HUNT, *Electroacoustics* (1954), a historical survey of the development of the application of electricity to acoustics; H.F. OLSON, *Acoustical Engineering,*

3rd ed. (1957) and *Music, Physics and Engineering* (1967), two books on various aspects of industrial acoustics, particularly with reference to sound recording and reproduction; R.B. LINDSAY, *Mechanical Radiation* (1960), an advanced treatment of the general principles of acoustical waves; L.E. KINSLER and A.R. FREY, *Fundamentals of Acoustics,* 2nd ed. (1962), a basic text in acoustics for advanced undergraduates; J.N. BRADLEY, *Shock Waves in Chemistry and Physics* (1962), a treatise on the properties and applications of shock waves; R.W.B. STEPHENS and A.E. BATE, *Acoustics and Vibrational Physics,* 2nd ed. (1966), a textbook for advanced undergraduates and graduate students; R.J. URICK, *Principles of Underwater Sound for Engineers* (1967), a practical treatise with emphasis on recent developments; P.M. MORSE and K.U. INGARD, *Theoretical Acoustics* (1968), an advanced and highly mathematical treatise; V.M. ALBERS, *The World of Sound* (1970), modern acoustics, popularly presented without mathematics; ALLAN D. PIERCE, *Acoustics: An Introduction to Its Physical Principles and Applications* (1981), a broad survey; RICHARD E. BERG and DAVID G. STORK, *Physics of Sound* (1982).

Sound recording and reproduction: THE INSTITUTE OF HIGH FIDELITY, *Official Guide to High Fidelity,* 2nd ed. (1978), provides a clearly written discussion of the components of high-fidelity sound systems for the layman. FRITZ WINCKEL, *Music, Sound and Sensation: A Modern Exposition* (1967; originally published in German, 1960), is an extraordinarily perceptive account of the physics and psychoacoustics of music. From a more traditional standpoint many of these topics are discussed by HARRY F. OLSON, *Music, Physics and Engineering,* 2nd ed. (1967). A discussion of some of the problems with facsimile reproduction is contained in CRAIG STARK, "O, O, O That Concert-Hall Realism Rag!," *Stereo Review* (November 1971). For the serious recordist JOHN M. WORAM, *The Recording Studio Handbook* (1976, reprinted with updates 1982), is an excellent manual. The more technical aspects of both analogue and digital recording are covered in CHARLES B. PEAR, JR. (ed.), *Magnetic Recording in Science and Industry* (1967). An insider's view of the development of disc recording and of those who have shaped that industry is contained in CHARLES A. SCHICKE, *Revolution in Sound: A Biography of the Recording Industry* (1974). A standard reference for all aspects of sound recording and reproduction is HOWARD M. TREMAINE, *Audio Cyclopedia,* 2nd ed. (1969, reprinted 1977); JOHN BORWICK (ed.), *Sound Recording Practice: A Handbook,* 2nd ed. (1980).

Applications of acoustics: J. BACKUS, *Acoustical Foundations of Music* (1969), a study of acoustical principles at the basis of music, suitable for students of music; and K.D. KRYTER, *The Effect of Noise on Man* (1970), an important discussion of the modern noise problem; C.M. HARRIS (ed.), *Handbook of Noise Control* (1957), a collection of 40 articles (each with bibliography) on the nature and control of noise in a variety of situations; L.L. BERANEK (ed.), *Noise Reduction* (1960; rev. ed., *Noise and Vibration Control,* 1971), a detailed text and reference work dealing with sound waves and their measurement, principles, criteria, and methods for noise control, and containing an extensive bibliography; *Music, Acoustics and Architecture* (1962), a critical analysis of factors that determine good room acoustics, including detailed drawings, photographs, and discussion of 54 halls in Europe and North and South America; R.B. NEWMAN and W.J. CAVANAUGH, "Acoustics," in J.H. CALLENDER (ed.), *Time-Saver Standards,* 4th ed. (1966), a useful reference covering the basic principles of sound control, data on acoustical properties of common building materials, charts useful in design, and drawings of many details to achieve good acoustics in buildings; W.P. MASON (ed.), *Physical Acoustics,* 6 vol. (1964–70), the most comprehensive survey of the whole field of ultrasonics ever published; G.L. GOOBERMAN, *Ultrasonics Theory and Practice* (1968), a short comprehensive textbook covering most of the theory of ultrasonics with some typical applications; L. BERGMANN, *Der Ultraschall und seine Anwendung in Wissenschaft und Technik* (1954), the classical text (in German) with only an elementary treatment of theory but an encyclopaedic coverage of applications and a complete list of references (two additional lists of references published); T.F. HUETER and R.H. BOLT, *Sonics: Technique for the Use of Sound and Ultrasound in Engineering and Science* (1955), a useful book particularly good on the design of transducers; K.F. HERZFELD and T.A. LITOVITZ, *Absorption and Dispersion of Ultrasonic Waves* (1959), an excellent book although limited to gases and liquids; B. BROWN and J.E. GOODMAN, *High-Intensity Ultrasonics: Industrial Applications* (1965), a good text covering most of the relevant industrial applications of ultrasonics; B. BROWN and D. GORDON (eds.), *Ultrasonic Techniques in Biology and Medicine* (1967), a useful collection of papers dealing with mainly diagnostic applications of ultrasonics in medicine. ARTHUR P. CRACKNELL, *Ultrasonics* (1980), an introduction to the theory and applications. See also HARVEY FEIGENBAUM, *Echocardiography,* 3rd ed. (1981), ultrasonic cardiography. Important journals include the *Journal of the Acoustical Society of America* (1929–); *Acustica* (1951–), the international journal of acoustics; the *Journal of Sound and Vibration* (1964–); and *Ultrasonics* (1963–). *Soviet Physics—Acoustics* (1955–), in English translation, is available through the American Institute of Physics. These journals are mainly devoted to the publication of archival research in acoustics, but most of them contain notes on modern developments of a more popular character as well as news about acoustical scientists and engineers. Useful acoustical data will be found in the chapter on acoustics in the *American Institute of Physics Handbook,* 2nd ed. (1963; 3rd ed., 1972).

South Africa

The Republic of South Africa (Afrikaans, Republiek van Suid-Afrika), the southernmost state on the African continent, has an area of 471,447 square miles (1,221,042 square kilometres). (If the territory of the republics of Transkei, Bophuthatswana, Venda, and Ciskei—all lying within South Africa's borders—is excluded, the area of South Africa is 434,700 square miles.) It measures almost 1,000 miles (1,600 kilometres) from north to south, as well as from east to west; a variety of landscapes, climates, and resources are to be found within its borders.

Of its four provinces, Cape of Good Hope Province, with an area (including the territory of the republics within its borders) of 278,381 square miles, is the largest, followed by the Transvaal (109,622 square miles), the Orange Free State (49,866 square miles), and Natal (33,578 square miles). The administrative capital is Pretoria, the legislative capital is Cape Town, and the judicial capital is Bloemfontein.

The self-administered republics of Transkei, Bophuthatswana, Venda, and Ciskei have been declared independent by South Africa, but they are not recognized by any other national government or by any international organization as being, in fact, independent. Namibia, which is situated to the northwest and has an area of 318,261 square miles, was formerly administered by the South African government, but negotiations held throughout the 1980s resulted in the territory's independence in 1990. Once a German colony, it was mandated to South Africa by the League of Nations; the United Nations, however, challenged South Africa's continuing administration of the territory on the grounds that the League's mandate was terminated, a position confirmed by an advisory opinion of the International Court of Justice in 1971. Walvis Bay, the only useful harbour of Namibia, was administratively attached to the Cape Province (then under British rule) during the latter part of the 19th century and continues to be administered by the South African government as part of the republic. South Africa also possesses two small subantarctic islands, Prince Edward and Marion, situated in the Indian Ocean about 1,200 miles southeast of Cape Town.

South Africa is bordered by Namibia to the northwest, by Botswana and Zimbabwe (formerly Rhodesia) to the north, by Mozambique and Swaziland to the east, by the Indian Ocean to the southeast and south, and by the Atlantic Ocean to the south and west. The Kingdom of Lesotho, a constitutional monarchy in the eastern part of the republic, is surrounded by South African territory.

South Africa's location, almost entirely south of the

Tropic of Capricorn and within temperate climatic zones, contributed to European settlement on a scale unknown elsewhere in Africa. Although South Africa is administered by whites and its political affiliations and most of its economic links are with the Western bloc of nations, its position—3,800 miles from South America to the west, 4,700 miles from Australia to the east, and about 6,000 miles from the markets of western Europe—is a relatively isolated one.

Since World War II, South Africa has been a frequent focus of attention. This attention intensified as the former Portuguese colonies of Angola and Mozambique and the former white-minority-ruled state of Rhodesia, all close to South Africa, gained independence under African majority rule. At the same time, the South African government, dominated by the minority white population, has maintained a policy of apartheid (meaning "apartness"), which maintains separation and separate development of the races and which has evoked vehement opposition from most countries in the world and in the United Nations. South Africa's peoples comprise a diversity of ethnic and racial groups. (A.Ne./D.F.G.)

This article treats the Republic of South Africa. For treatment of the geography and history of the other states of the region, see SOUTHERN AFRICA.

The article is divided into the following sections:

Physical and human geography

THE LAND

Relief. Geologically, South Africa contains some of the oldest rocks in the world. Dominating the topography is a plateau that covers the largest part of the country and is separated from the small coastal strip by what is called the Great Escarpment. The plateau is actually a massive basin reaching heights of 8,000 feet (2,440 metres) in the basaltic Lesotho region, dropping to heights of approximately 2,000 to 3,000 feet in the sandy Kalahari Plateau in the west. The central part of the plateau comprises the Transvaal and Free State Highveld, which is between 4,000 and 6,000 feet in altitude. The Witwatersrand Ridge forms the watershed between the Vaal and Limpopo rivers and their tributaries. The Great Karoo (Karroo) Plateau, south of the Orange River, averages 4,000 feet in height and contains a number of large salt pans such as Verneukpan.

The Great Escarpment

The Great Escarpment, known by a variety of local names, is the most continuous topographical feature in South Africa. Starting in the far northeast, at altitudes of up to 7,000 feet, it is known as the Transvaal Drakensberg ("berg" and "berge," in Afrikaans, meaning mountains). Continuing southward, the mountains become known as the Natal Drakensberg and reach heights up to 11,000 feet. Farther to the south, the mountains become less impressive, ranging from 8,000 feet in the Sneeuberg section to 6,000 feet in the Nuweveldberge and to 5,000 feet in the Roggeveldberge region. In the west the escarpment comprises the Bokkeveldberg and the Kamiesberg (5,600 feet), between which both the plateau and the escarpment are not clearly defined. In the far south is an area of folded mountains that includes ranges such as the Hottentots Hollandsberge, Drakensteinberge, Sederberge, Langeberge, Groot-Swartberge, Outeniekwaberge, Tsitsikamaberge, and the Hexrivierberge, all of which vary in height between 5,000 and 7,600 feet and are geologically older than either the Alps or the Himalayas.

The narrow South African coastal plain is poorly developed; it is less than 500 feet above sea level, and only in northern Natal does it reach a mentionable width—extending about 30 miles along the west coast and broadening to about 80 miles in northern Natal. South Africa has a straight, unindented, and somewhat monotonous shoreline; the only good natural harbour along its 1,836-mile length is at Saldanha Bay, the use of which has been restricted by a lack of fresh water.

Drainage. Because of insufficient and inadequate rainfall, South Africa has no rivers that form navigable waterways, even for short distances. The main drainage system is that of the Orange River, which drains an area of approximately 329,000 square miles; the Vaal and Caledon rivers are the main tributaries. The northern part of the plateau is drained by the Limpopo system, which empties into the Indian Ocean; the Limpopo's main tributaries are the Olifants, Marico, and Sand rivers. From the escarpment a number of smaller and shorter rivers, all of them irregular, flow seaward.

Soils. Three major soil regions may be distinguished. The soil region east of the 20-inch (500-millimetre) isohyet (*i.e.,* a line drawn on a map connecting points having equal rainfall) includes soils formed under conditions of a wet summer and dry winter climate, the more important types being laterite (red, leached, iron-bearing soil) and lateritic soils, unleached subtropical soils, and gley-like (*i.e.,* bluish-gray, sticky, and compact) podzolic soils (highly leached soils that are low in iron and lime). The second major soil region lies within the winter rainfall zone and the southern coastal area with all-season rainfall; gray sandy soils and sandy loams form the main types. West of the approximately 15- to 20-inch isohyet—an area that includes a large part of the interior and all of the western coastal area—the land is semidesert and desert, with rain falling primarily in summer and with a huge annual evaporation rate. The soils of this region as a whole are characterized by a top sandy layer, often a sandy loam, which is underlain by a layer of lime or an accretion of silica.

Climate. The climate is controlled by three main factors. First, South Africa's location between latitudes 22° and 35° S places it—except for a small part in the north—fully within the temperate zone, though it receives a great deal of sunshine. Apart from southwestern Cape Province, South Africa is out of reach of the rainy westerlies and next to a subtropical high-pressure belt of descending air where condensation and rainfall do not readily develop. Most of South Africa thus has a dry climate.

Second, South Africa is flanked on the east by the warm, southward-flowing Agulhas Current, and along the west coast by the cold, northward-flowing Benguela Current. The east coast is comparatively warmer, and the resultant warmer and less dense air rises more readily, facilitating the entry of rain-bearing clouds.

Finally, South Africa's inland plateau greatly tempers the influence of latitude on climate. From Cape Town in the south to the far north, the temperature hardly changes, the increasing intensity of the solar rays being moderated by the increase in altitude.

ıfluences
f the
ıbtropical
igh-
ressure
elt

Because South Africa lies in the subtropical high-pressure belt, the country, as well as the adjoining ocean areas, is influenced throughout the year by descending, divergent upper air masses that circulate primarily eastward, generally causing fine weather and low annual precipitation, especially to the west. During winter (June to August), cold polar air moves over the southwestern, southern, and southeastern coastal areas, sometimes reaching the southern interior of the country from the southwest. These polar masses are accompanied by cold fronts as well as by rain and snow. In summer (December to February) the Atlantic high-pressure system settles semipermanently over the southern and western parts of the country. Local heating of the landmass sometimes causes low-pressure conditions to develop, resulting in tropical air masses being drawn in from the Indian Ocean over the northeastern region and bringing rain.

South Africa is a generally semiarid country where farmers are constantly faced with the problem of a water shortage. About 21 percent of the country is arid, receiving less than eight inches of rainfall annually; another 47 percent is semiarid, receiving eight to 24 inches annually. Abundant rain, amounting to more than 40 inches annually, is received over only 6 percent of the country. From east to west there is a gradual decline in the rainfall. Natal receives more than 40 inches annually, Kimberley approximately 16 inches, and Alexander Bay on the west coast less than two inches.

Temperatures are generally moderate. The summers are moderately warm, with temperatures of between 70° and 75° F (21° and 24° C). Over the western plateau, summer temperatures vary from 75° to 85° F (24° to 29° C); in the Orange River Valley it becomes very hot, with temperatures rising to 90° F (32° C) and higher. South African winters are moderately cool; over the inland plateau July average temperatures fall below 50° F (10° C) and, in places, to less than 40° F (4° C). Along the east coast, in Natal and in the Transvaal Lowveld, even the winters are moderately warm. Influenced by the ocean currents, the temperature also declines from the east coast to the west coast. Durban, on the east coast, has an average annual temperature of 69° F (21° C), while Port Nolloth—on the west coast but approximately on the same latitude—registers 57° F (14° C).

Plant and animal life. In a semiarid country, forests, as such, rarely occur; the small Knysna Forest in southern Cape Province is perhaps the best example. Shrublike vegetation is found in the Karoo region, monotonous grassland with very few trees occurs on the Highveld, and savanna (parklike grassland) is found in a variety of areas such as the Transvaal Bushveld and Lowveld, the Kalahari, the deep valleys of the eastern Cape, and the Natal coastal region.

When the first European settlers arrived in the 17th century, South Africa had an unbelievable wealth of animal life, including lions, elephants, rhinoceroses, and a variety of antelopes; today, however, such wildlife exists only in the most marginal areas, such as the Kalahari. To preserve the larger animal species from extermination, a number of wildlife reserves came into being, of which the Kruger National Park in the northeast is the best known. There is a rich birdlife, and of the more than 100 species of snakes, about one-fourth are poisonous. (A.Ne.)

Settlement patterns. While South Africa could be divided into numerous small regions, known by a variety of local names, these may be grouped more conveniently into 11 large traditional regions.

The veld
regions

Three veld regions may be distinguished in the north. These are the Bushveld in the far northern Transvaal west of the Transvaal Drakensberg; the Lowveld east of the mountains; and the Highveld to the south, including the southern Transvaal, eastern Orange Free State, Lesotho, and an adjoining portion of Cape Province. The Bushveld and the Lowveld are still predominantly rural, but the prairie-like landscape of the Highveld on the eastern interior plateau contains the mining, industrial, and commercial heart of South Africa and the largest urban centres.

To the west and southwest of these veld regions the arid and semiarid landscape consists of three traditional regions. These are the Kalahari in the north, which includes most of Cape Province north of the Orange River but also extends into Botswana and eastern Namibia and which is still only sparsely populated; the Karoo, which lies south of the Kalahari and includes most of the interior of Cape Province and which is inhabited by rural Afrikaans-speaking people and a very few Africans; and Namaqualand, a rugged rural area in the extreme west, immediately south of the Orange River.

The final group includes the more humid regions bordering the South Atlantic and Indian oceans. These are the Western Province in the southwestern corner of the country, the area of the origin of the Cape Coloureds and the oldest white settlement in South Africa; the Eastern Province, centring on the port towns of Port Elizabeth and East London; the Southern Cape Districts (in South Africa itself perhaps better known as the Southwestern Districts), located between the Western and Eastern provinces; Transkei, inhabited by the Xhosa- (Xosa-) speaking people, situated to the northeast of the Eastern Province; and Natal, a garden province, whose character has been shaped by large numbers of English-speaking whites, most of South Africa's Indian population, and the indigenous African peoples.

Almost one-half of the total population still lives in rural areas. There has been a proportional decline, however, in the rural population in recent years. At the beginning of the 20th century, half of the white population was still rural, whereas today the proportion has dropped considerably. The African rural population has also declined greatly.

In the African areas settlement traditionally has taken the form of farming villages; the land belongs to the kraal (village) community, each family receiving from the chief or headman the right to build a home. Pastoral land surrounding the kraal is used communally. Among the whites of South Africa, settlement has taken the form of dispersed farms. The farms are often miles apart in the arid and semiarid regions but are closer together in the better watered parts.

Towns and cities

Urban settlement is much denser in the east and south. All of the largest cities and towns are located in this more humid half of the country. Also located there are the four main urban concentrations—the Pretoria–Witwatersrand–Vereeniging complex in the southern Transvaal; the Cape Peninsula in southwestern Cape Province; the Durban–Pietermaritzburg area in Natal; and the Port Elizabeth–Uitenhage region in eastern Cape Province.

Of these, the Witwatersrand conurbation is by far the largest and the most important for mining, industry, and commerce. Most South African towns originated as centres that supplied services to the surrounding rural areas. Others, such as Grahamstown and Simonstown, originally had a military function, while still others, such as Welkom, Virginia, and Kimberley, began as mining towns, sometimes—as in the case of Kimberley—shedding the mining function at a later stage. Some towns, like Sasolburg, where gasoline is manufactured from coal, developed around a specific industry. Germiston and De Aar are railroad centres, and Durban, Cape Town, Port Elizabeth, and East London are harbour towns. Pretoria is the main administrative centre, and Stellenbosch and Grahamstown are towns where important educational institutions are located. Johannesburg, the economic hub of the Witwatersrand area, is the major city.

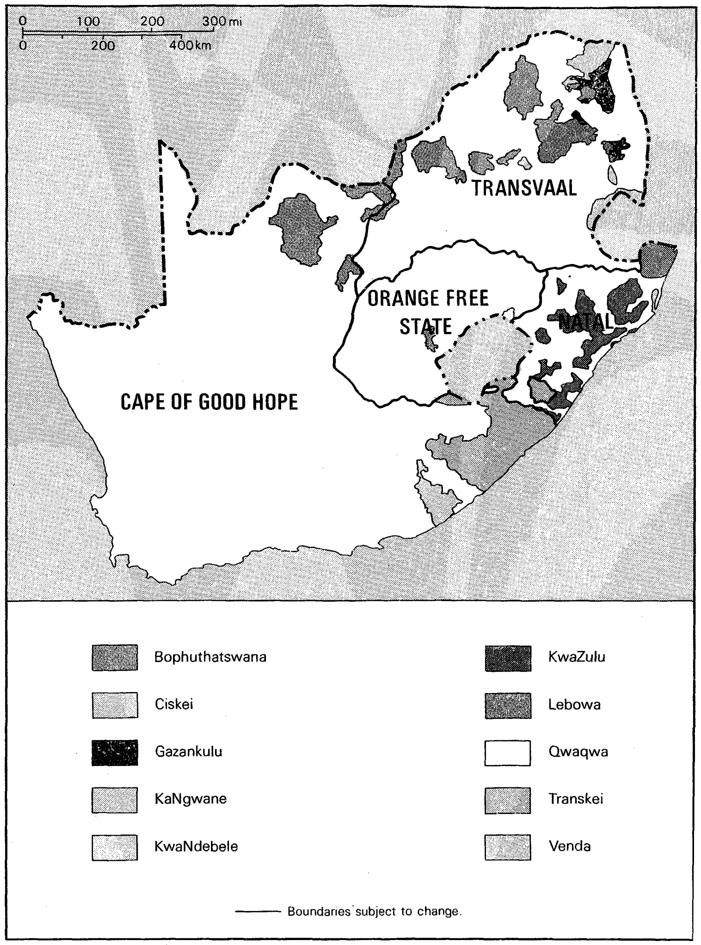
South African cities generally are marked by white residential districts near the city centre and African residential "townships" geographically separated in the outlying areas. Soweto (South-Western Townships), which adjoins Johannesburg, is the largest urban settlement in South Africa. Umlazi is the only town of more than 100,000 population without a substantial white population.

THE PEOPLE

Ethnic distribution. Four racial groups are designated under South African law, and each of these may be further subdivided into different linguistic and ethnic groups. Those classified as whites consist of two main groups—the Afrikaners, who are the descendants of Dutch, French, and, to a lesser degree, German forebears and speak Afrikaans; and the English-speaking group. The Afrikaners comprise more than half of the white population, and the English-speaking make up the remainder. Afrikaans and English are the official languages.

Nonwhites in South Africa outnumber the whites by approximately six to one; they comprise a variety of peoples classified as African, Coloured, and Asian. These classifications are highly arbitrary, however, and sometimes result in legal contestation. The Africans comprise about three-fourths of South Africa's population and have the fastest growth rate of all groups. The South African government emphasizes the ethnic differences among Africans, treating the African population as if it were composed of 10 separate nations, each with its own territory. The Africans more properly can be divided into four main ethnolinguistic groups. These are the Nguni, including the Xhosa, Zulu, Swazi, and Ndebele peoples, who comprise more than half of the African people of South Africa and live mainly in the eastern coastal regions; the Sotho, found mostly in the central and western African areas and constituting the largest minority of the Africans; and the Venda and Tsonga groups, who comprise quite a small percent of the Africans and who are found only in the northern Transvaal. Other Africans form the rest of the total population. At any given time about one-half of the African population is in the republics or the Black States, areas set aside for occupation by blacks, which comprise 13 percent of the country's geographical area. Of the rest, approximately two-thirds are in the cities, and one-third are in the rural areas set aside for white occupation, where Africans work mainly as farm labourers.

The African majority



Republics and Black States within South Africa.

The smaller nonwhite groups are the Coloureds and the Asians—predominantly Indian—of whom the majority live in Natal Province.

South Africa's Coloured population has its roots in the early period (the 17th and 18th centuries) of the Dutch East India Company's regime at the Cape of Good Hope. Children were born of white colonists and sailors and Malay slave women (from the Dutch East Indies) and indigenous Khoisan women, and also of Khoisan women and Malay slave men, especially after the latter were freed in the early 19th century. Varying in skin colour, the Coloureds are culturally closest to the Afrikaners. Most speak Afrikaans and live in the western part of Cape Province, where they form a majority of the population.

The founding of an Asian community began in 1860, when a number of Indians were brought under contract to work on the Natal sugar plantations; the community grew, and by the early 1980s represented a tiny percentage of the population. The original Khoisan people (the Khoikhoin and the San, termed Hottentots and Bushmen by the whites) are almost nonexistent; their few descendants are found in parts of the Kalahari.

Religion. Among the whites and Coloureds, the Dutch Reformed Church has by far the most adherents of the organized religions, including a large number of African

Population density of South Africa.

members. Among the Africans, the independent African Christian churches have the largest membership, followed by the Methodist, Roman Catholic, and Anglican churches. Most of the Asians are Hindu, but many Muslim Malays live in and around Cape Town. There is also a Jewish minority living in South Africa. (A.Ne./D.F.G.)

THE ECONOMY

In the years since World War II, South Africa has had one of the most consistently high growth rates in the world. Its national income is one of the highest in Africa.

The bases of South Africa's economy consist of agriculture, mining, and manufacturing. Mineral resources are extensive. Apart from gold and diamonds, there are nearly 70 other types of exploitable minerals in South Africa. Whites have a well-developed agriculture that embraces a wide range of products. There is a large supply of cheap power; in addition, there are substantial reserves of cheap labour, there is no shortage of entrepreneurial talent, and there is ready access to supplies of domestic and foreign capital.

iamonds ıd gold

Resources. Diamonds and gold are the best-known and historically the most important minerals, but there are many others of growing importance, including copper, iron ore, manganese, asbestos, chromium, silver, beryllium, antimony, tin, and platinum, and some resources have yet to be exploited. The only important exclusion from the country's list of mineral resources is oil, for which an energetic search was begun in and around South Africa in the 1970s. Meanwhile, oil is made from coal, of which there are substantial deposits in Sasolburg.

Gold remains by far the most important mineral. A spectacular increase in the 1970s in the international price of gold allowed gold revenues in South Africa to grow dramatically, though prices subsequently declined. Gold accounts for more than half of total mineral sales. Gold is produced in three main areas—the Witwatersrand, which includes Johannesburg; the Far West Rand and Klerksdorp fields; and the Orange Free State around Odendaalsrus. The centre of the diamond industry is at Kimberley. There is also diamond production in the Orange Free State and the Transvaal. Known coal deposits are quite extensive, with most of the deposits located in the Transvaal. The biggest use of coal is for the generation of electricity. Many companies produce uranium, which is an increasingly important industry.

Agriculture is of major importance to South Africa, but the supply of good agricultural land is effectively curtailed by the climate. The average rainfall for the whole country is about 18 inches, which is less than the world's average and is very little for a subtropical country with a high evaporation rate. Runoff of water from rainfall is only 8 percent. Much of the country receives an even lower rainfall and is thus only marginally useful as agricultural land. Soil erosion is a problem in some areas, and the country is particularly subject to droughts.

Resources of timber are minimal; only a small fraction of the land area is forested. Conifers occupy a little more than half of the forested area; eucalyptus (used mainly for mining timber and pulpwood) covers almost a quarter; and wattle (acacia), which is used for producing tannin bark, as well as in the mining and pulping industries, accounts for about one-fifth. The forested areas are only found in the wetter regions of the south and east.

As a consequence of the low annual rainfall, natural hydroelectric potential is minimal. The government, however, has emphasized several schemes to develop hydroelectricity, the most important being the Orange River Project and the Cabora Bassa Project on the Zambezi River in Mozambique.

Agriculture, forestry, and fishing. Agricultural production, including forestry and fishing, accounts for a small percent of the gross domestic product. It remains important, however, since variations in its output can seriously affect overall growth in the economy and since this sector contributes a substantial proportion of exports. The agricultural sector is also of major importance in employment. White-, Coloured-, and Indian-owned farms are located in the more fertile and better-watered regions, which Africans are not allowed to farm. Among the major products are corn (maize), wheat, cane sugar, peanuts (groundnuts), millet and sorghum, citrus fruits, grapes, tobacco, wool, and meat. Sheep and goats, cattle, and pigs are the most important livestock raised for food. Dairy (including butter and cheese) and egg production are also important.

Major agricultural products

Compared to the vibrant commercial farming sector, the African subsistence sector—confined principally to the homelands areas, which generally lack fertility and are vastly overpopulated—has stagnated since the 1950s. Output has not kept up with population growth, creating pressures for rural Africans to seek work in white areas as migrant labourers. In no area of South African life is the disparity between white and African as visible as it is in agriculture.

Fishing areas lie chiefly off the south and west coasts and off the coast of Namibia. Both shoal fishing (for pilchard and maasbanker) and offshore trawling for a variety of fish, including kingklip, agulha sole, stockfish (Cape hake), and kabeljou, are employed.

Industry. The mining sector continues to be of major importance, and it figures prominently in government economic policy. Gold is the main product, after which bituminous coal is the most important. Next, in order of production, are diamonds, copper, iron ore, manganese, and asbestos. The dramatic increase in the price of gold in the 1970s gave new life to what had been considered a nearly exhausted industry. Gold seams that were previously not economical to mine were put into productive operation.

Manufacturing has been of increasing importance in the last few decades. Manufacturing has become the prime force in South Africa's rapid and sustained growth. Manufacturing also figures prominently in exports, contributing more than one-fourth to the total. This helps to offset the imported manufactured goods, which constitute the largest group of imports. An increasingly significant percentage of the population is employed in manufacturing.

One of the chief reasons for the rapid growth of the manufacturing sector has been the high proportion of the gross domestic product devoted to investment.

South Africa is a major producer and consumer of energy. Lacking its own oil resources, but with substantial reserves of coal, South Africa has been successful in its policy of energy self-sufficiency through a combination of conservation and effective use of its coal resources, including coal-to-oil conversion. Coal output has increased, much of it exported. The Electricity Supply Commission (Escom) takes most of the coal produced for local consumption. South Africa consumes a fraction of its energy in the form of electricity and produces about half of the electricity generated in Africa.

Oil consumption comprises a significant fraction of South Africa's energy. In 1973 the Organization of Petroleum Exporting Countries (OPEC) declared an oil embargo against South Africa, but South Africa continued to receive 90 percent of its oil imports from Iran until 1979. With its sources of oil gone, South Africa is turning increasingly to alternative energy sources.

Finance. South Africa has a well-developed financial system. The central bank—the South African Reserve Bank—is the sole note-issuing authority. It also exercises all the functions necessary for the implementation of monetary policy. There are nine commercial banks, which have strong ties to foreign banks. The banking system also includes a number of merchant banks and discount houses. There are also two specialist state banks—the National Finance Corporation, which was opened in 1949 to develop a short-term money market, and the Land Bank, which, as its name implies, lends chiefly to agriculture.

Second in financial strength only to the commercial banks are the building societies. Installment buying, savings, and general banking are also important, as are private pension and provident funds and insurance companies. There is an active capital market organized around the Johannesburg Stock Exchange.

Trade. Dependence upon foreign trade is relatively high, and the South African economy is thus particularly sensitive to global economic conditions. Precious metals and base metals have been leading exports. Agricultural goods also play an important role in South Africa's exports. The country's major imports are oil, machinery, electrical equipment, and transportation equipment. A number of imports, most importantly oil, have been classified by the government as "strategic materials." Data for these are not available, making it difficult to assess the exact percentages of various import categories. South Africa's main trading partners are the United States, the United Kingdom, West Germany, Switzerland, and Japan. These five countries account for two-thirds of the country's trade. South Africa has moved to diversify its trading partners, increasing its trade with Israel, Taiwan, South Korea, several Latin-American countries, and other African countries.

Trading partners

Administration of the economy. The economy is essentially based on private enterprise, but the state participates in a number of ways. Through the Industrial Development Corporation of South Africa, it controls several public corporations—including the South African Coal, Oil and Gas Corporation (Sasol), which produces oil from coal; the Phosphate Development Corporation (Foskor), which develops phosphates; the African Metals Corporation Ltd. (Amcor), which makes metals; the Iron and Steel Industrial Corporation (Iscor), the major steel producers; and Escom, the main electricity-generating authority. The government also runs the railways, the national airline, harbours, telecommunications, and much of the road transport system. The government sets out targets for development in each industry in an Economic Development Programme, and, by means of a range of official bodies, encourages development of industry through financing, consultations on tariff protection, export promotion, export credit insurance, research, and a bureau of standards.

Direct taxes on individuals consist chiefly of state and provincial income taxes deducted at the source and taxes on dividends and interest. There is no capital gains tax. The main taxes on businesses are income tax and, in some cases, a tax on undistributed profits.

Trade unions for African workers have become a critical issue in South Africa, and there were two periods (1973–74 and 1979) of large-scale work stoppages by African workers. Although African workers had traditionally been denied the right to form unions and participate through them in collective-bargaining efforts, many African trade unions formed. The most important African trade union federations are the Federation of South African Trade Unions (FOSATU); the Trade Union Council of South Africa (TUCSA), with a multiracial membership; and the South African Congress of Trade Unions (SACTU), many of whose leaders are outside of the country. Most organized white workers are members of the South African Confederation of Labour.

The all-white South African Confederation of Labour has opposed the easing of restrictions on African trade unions, and a major point of contention between white unions and nonwhite workers is the practice of reserving the highest skilled jobs for whites only.

The main aim of economic policy has been to maintain the high rate of economic growth. This growth is built upon a base of cheap African labour in low- and middle-level jobs and is dependent largely on the maintenance of a high level of capital investment, a healthy balance of payments, an adequate supply of skilled labour, and the effective control of inflation. In most of these fields considerable success has been achieved, but the labour situation has become increasingly serious. The problem is aggravated by the government's policy of trying to reverse the flow of Africans to the big cities by locating new industry near the designated African areas and by the white trade unions' unwillingness to admit nonwhites to certain job categories. A range of skilled and semiskilled jobs are reserved for whites, but there is an inadequate supply of skilled white labour to fill vacancies in these job areas, and immigration from Europe has proved insufficient to fill the gap. (E.I.U./D.F.G.)

The labou shortage

Transportation. Because South African rivers are unsuitable for navigation, water transport within the country, except for traffic along the coast, is nonexistent. Railroads and roads have been built from the harbours to points of economic and population concentration in the interior.

The South African railway system is state property. The standard gauge, with a few minor exceptions in the Cape and Natal coastal areas, is three feet six inches, and approximately one-third of the republic's railroads are electrified.

South African Railways is the greatest single employer in the country. Of the total quantity of goods transported, coal alone makes up more than one-fourth, other minerals combined accounting for one-third, and agricultural products accounting for one-eighth.

The railroad system is augmented by a network of more than 142,600 miles of roads, of which about 48,700 miles are paved, including more than 1,000 miles of national roads connecting the country's main urban centres.

All South African harbours are state-owned and, together with railways and airways, are administered by the Ministry of Transport. The shipping of the country is served mainly by South Africa's four major ports—Durban, Cape Town, Port Elizabeth, and East London—as well as by the port of Maputo (formerly Lourenço Marques) in neighbouring Mozambique. Durban, which serves the southern Transvaal hinterland, the economic heartland of South Africa, is the main cargo port. Cape Town, the large port nearest to Europe, is the main passenger port. A large new harbour has been developed at Richard's Bay, on the Indian Ocean in Natal, to accommodate giant tankers.

Air servic

Inland air transport services, both passenger and freight, are operated by state-owned South African Airways and by smaller, local private companies. South African Airways also maintains regional services to such neighbouring countries as Lesotho, Botswana, Zimbabwe, Namibia, Mauritius, and Mozambique and flies international routes to Europe, Australia, and New York City via Rio de Janeiro. The air route used by South African Airways to reach European cities must avoid most of the remainder of the African continent because of the antagonism of black African states toward South Africa. Las Palmas, in the Canary Islands, and Ilha do Sal, in Cape Verde, are used as intermediate stopovers. Major foreign air services also are in operation to and from South Africa.

The three international airports are Jan Smuts Airport near Johannesburg, D.F. Malan Airport at Cape Town, and Louis Botha Airport at Durban. Other major domestic airports are the J.B.M. Hertzog Airport at Bloemfontein and those at Port Elizabeth, Kimberley, and East London. (A.Ne./D.F.G.)

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. The republic's original constitution, the South Africa Act of 1909, formed a parliamentary system with the British monarch as head of state. The constitution was revised by the Republic of South Africa Constitution Act of 1961, narrowly approved by the all-white electorate, which transformed South Africa from a monarchy within the Commonwealth of Nations to an independent republic with a president as head of state. This post, like that of the British monarch it had replaced, was essentially honorific, and executive power was held by the prime minister. In 1983 white voters approved a new constitution, enacted the following year, that abolished the post of prime minister and transferred its power to the state president. While the new constitution extended the franchise to Coloureds and Asians, it also introduced a distinction between "general affairs," those pertaining to all racial groups, and "own affairs," those particular to a racial group, that guided the formation of separate government bodies for whites, Coloureds, and Asians. In addition to a strengthened state president, the constitution provides for a cabinet, which includes ministers who head departments of general concern, such as defense; a tricameral Parliament, in which whites, Coloureds, and Asians each have their own chamber; three Ministers' Councils, one drawn from each chamber of Parliament, in which members head departments, such as those for social welfare and education, that administer only for their own racial group; and a President's Council, which settles disagreements between the legislative chambers. Africans continued to be excluded from the national government.

The state president is elected for a term of a maximum of five years by secret ballot of an electoral college consisting of 50 white, 25 Coloured, and 13 Asian members of Parliament designated by their respective chambers. The president appoints ministers to the cabinet, which may include persons outside of Parliament, and to the Ministers' Councils, in which ministers must be members of Parliament or become members within a year of appointment. There is a close working relationship between the cabinet and the Ministers' Councils, and ministers may serve on both. The president, the dominant figure in the South African government, generally wields more power than a U.S. president or a British prime minister.

ıree
ambers
ırliament

Originally a bicameral legislature, Parliament was reorganized as a unicameral body in 1980 and expanded in 1984 to three chambers: the existing House of Assembly, with 178 seats, for whites; the House of Representatives, with 85 seats, for Coloureds; and the House of Delegates, with 45 seats, for Asians. Each house is solely responsible for legislation pertaining to its own racial group, but matters that the president determines to be of general concern must be approved by all three chambers. If agreement is not reached between the chambers, the president may direct the President's Council to make a final decision. The President's Council, which is also an advisory body, is composed of 20 whites, 10 Coloureds, and 5 Asians elected by the respective chambers of Parliament and 25 members appointed by the president.

Members of Parliament are directly elected in single-member constituencies by voters of the racial group they represent, though a small number of legislators are appointed by the president or elected by their respective chamber of Parliament. Members must be South African citizens of white, Coloured, or Asian descent, be at least 18 years old, and have resided in the country for at least five years. Seats for the elected members are allotted to the provinces in proportion to the adult population of each racial group; the electoral boundaries for these seats are delimited by a presidentially appointed judicial commission at intervals of no less than five and no more than 10 years. While members are elected for a five-year period, Parliament can be dissolved by the state president at any time. (Ed.)

Regional, state, and local governments. Where the central government's powers are delegated to regional and local governments, such delegation has been effected within the general framework of a separate administration for each racial group (whites, Coloureds, Asians, and Africans).

The provincial governments began a period of transition after the passage of the 1983 constitution. Each province formerly had a provincial council elected by white voters only, an executive committee of the council, and an administrator appointed by the state president, but in 1986 the councils and the executive committees were abolished and their powers were transferred either to the separate administrations of the three chambers of Parliament or to new executive authorities appointed by the state president and headed by the administrator. By the late 1980s a small number of Coloureds and Asians had been appointed to these authorities.

Each province also had its own system of local authorities, elected by white voters only. Coloureds and Asians had been allowed only advisory positions, while the Bantu Affairs Administration Act of 1971 had completed the process of removing all major aspects of government and administration of Africans from local authorities in white areas to the Department of Bantu Administration and Development, which later became the Department of Development Aid. In the early 1990s local governments were also in a period of transition, and some form of representation for Coloureds, Asians, and Africans was being developed.

The Promotion of Bantu Self-Government Act of 1959 recognized eight African national units, designated Bantu Homelands, that were based upon government-designated tribes. Two others later were created, and the official designation was changed to Black States. Except for Transkei, their areas bear little resemblance to the original areas of African settlement. All but two consist of several land blocks, together comprising more than 200 scattered enclaves. In terms of the official policy of apartheid, all 10 are to evolve into independent republics, although there is no intention of consolidating each into a single geographic entity. The Bantu Homelands Citizenship Act of 1970 made every African a "citizen" of one of these national units, even if he or she did not live or had never lived in the area.

The goal of the separate development policy has been to resolve South Africa's racial conflict by eliminating Africans from the body politic. By the end of the 1980s only four of the Black States had been granted independence as republics: Transkei, October 26, 1976; Bophuthatswana, December 6, 1977; Venda, September 13, 1979; and Ciskei, December 4, 1981. Their governments operate under semiparliamentary systems, with cabinets nominally responsible to partially elected and partially appointed legislative assemblies. While the African areas possess most of the abstract criteria for sovereignty—established boundaries, a settled population, and a functioning government—they have not been recognized by any other government or by any international organization. They also lack potential for economic autonomy, due to their overwhelming economic ties to South Africa. In addition, a wide range of technical, defense, and economic agreements give the South African government powerful influence over the internal affairs of the areas. (M.J.L./D.F.G./Ed.)

The political process. No special qualifications are required for the white, Coloured, and Asian franchise. The voting age is 18 years.

The
National
Party

The all-white National Party has been the dominant national and parliamentary party since it came to power in 1948. Its programs have emphasized the concepts of white South African nationalism and the implementation of the separate-development strategy for dealing with South Africa's racial problems. Other major white parties are the Democratic Party (formed in 1989 of three liberal parties, including the former Progressive Federal Party) and, on the right, the Herstigte Nasionale ("Reconstituted National") Party and the Conservative Party (an offshoot of the National Party formed in 1982). (R.B.Ba./D.F.G.)

South Africa's most significant political developments have stemmed from the implementation of the separate-development philosophy and the response of the nonwhite population. Separate development systematically deprives the nonwhite population of political participation in the conduct of national and provincial affairs in exchange for the establishment of their own political institutions. The last African representation in Parliament (provided by three elected whites) was abolished in 1959 under the Promotion of Bantu Self-Government Act. Prior to the establishment of separate parliamentary chambers for whites, Coloureds, and Asians, the last Coloured representation in Parliament had been in the 1960s, but those four seats were abolished by the Separate Representation of Voters Amendment Act of 1968. The Asian population had never been represented. The Prohibition of Political Interference Act of 1968, which, until its repeal in 1985, outlawed multiracial political parties, forced the Progressive Party to limit its membership to whites; the Liberal Party disbanded rather than do so.

In the 1980s successful boycotts of parliamentary elections resulted in low voter turnout among Coloureds and Asians. Nevertheless, within Parliament the Labour Party and the People's Congress Party emerged as major Coloured parties. Significant Asian parties include the National People's Party and the Solidarity Party.

Black Consciousness movement

The two major national African political parties—the African National Congress and the Pan-Africanist Congress—were banned in 1960 under the Unlawful Organisations Act. In 1990, however, they were legalized, as was the multiracial South African Communist Party, one of the largest Communist parties in Africa. In the 1970s two different forms of political participation emerged among the nonwhite population. On the one hand, the implementation of apartheid led to the creation of a number of political parties in the African areas, oriented toward participation in the new institutions of self-government. On the other hand, especially in the urban areas, many Africans responded to enforced segregation by beginning to assert their racial identity. This tendency, which became known as the Black Consciousness movement, was expressed in such organizations as the South African Students Organisation (SASO) and the Black People's Convention (BPC). The widespread influence of Black Consciousness, especially among young urban Africans, has been demonstrated in periodic unrest, one of the most spectacular examples being the Soweto uprising in June 1976.

In the 1970s the church also emerged as a significant focal point for the expression of the political aspirations of nonwhite South Africans. The South African Council of Churches in particular has played a major role in opposing the policy of separate development. In the period following 1976, there were growing numbers of armed attacks on police stations, banks, and other public facilities, carried out predominantly by the underground guerrilla movement Umkhonto (Umkonto) we Sizwe (Spear of the Nation), a wing of the African National Congress.

Justice. The common law of the republic is based on Roman-Dutch law, the uncodified law of Holland retained after the Cape's cession to the United Kingdom in 1814. The judiciary comprises a Supreme Court with local, provincial, and appellate divisions and the lower courts. The judges, headed by a chief justice, are appointed by the state president. The highest court is the appellate division, which has as many judges as the president chooses. The appellate division hears the appeals of local and provincial divisions, and its decisions are binding on all courts.

The lower courts comprise magistrates' courts and the African court systems of chiefs' courts and commissioners' courts. Most civil and criminal litigation is a matter for the magistrates' courts, each responsible for a magisterial district. Regional magistrates are appointed in populous areas with criminal jurisdiction over a number of districts. The African courts do not have jurisdiction over Africans in criminal cases or where whites are involved. In Transkei, Bophuthatswana, Venda, and Ciskei, courts are under the jurisdiction of their governments, but decisions can be appealed to the appellate division of the Supreme Court of South Africa. (D.F.G./R.B.Ba./Ed.)

Nonwhites in the military

Armed forces. Although the active forces are relatively small, there is a large trained reserve force. South Africa's military traditionally has been white, and there is compulsory military service only for white males. Because of the shortage of manpower, the decision was made in the 1970s to use substantially larger numbers of Coloureds and Asians and to begin to include African soldiers in combatant roles. White women were taken into the services in 1970; their training has been confined to exercises in unarmed combat and the use of light firearms.

The navy has a small fleet consisting of destroyers, submarines, antisubmarine frigates, minesweepers, and auxiliary craft. The air force combat aircraft include light bombers; fighter bombers; interceptor fighters; transport, reconnaissance, and training aircraft; and helicopters.

Police activities are coordinated with those of the defense forces. The police, almost half of whom are nonwhites, bear the responsibility of maintaining internal security. A substantial number have received special training in antiguerrilla activity and have been used to counter guerrilla infiltration in several border areas. South African police assisted the former Rhodesian government in its antiguerrilla activity in the 1960s and 1970s.

The military has played an increasingly important political role in South Africa. In the late 1970s military figures were responsible for the concept of a "total strategy" for South Africa to meet the perils of an increasingly hostile outside world and the threat of domestic turmoil. Part of this strategy has concentrated on nuclear development, considered particularly important in light of South Africa's lack of domestic petroleum sources. The South African Atomic Energy Board (superseded in 1982 by the Atomic Energy Corporation) oversaw the development of two nuclear reactors at Pelindaba, near Pretoria. In 1975 a new plant at Pelindaba began enriching uranium. South Africa has been provided with equipment and training by the United States, West Germany, and France. South Africa has about 17 percent of the world's uranium reserves and has the third largest output among Western nations. It has not signed the Nuclear Non-Proliferation Treaty.

Education. General education issues, such as the establishment of educational standards, are the responsibility of the Department of National Education, headed by a member of the cabinet. Each chamber of Parliament has a Department of Education and Culture, headed by a member of the respective Ministers' Council, that is responsible for providing education to its own racial group. African education at all levels is administered by the Department of Education and Training (formerly the Department of Bantu Education). The 10 African territories each have their own departments of education.

The universiti

For whites there are four English-language universities, five Afrikaans-language universities, and one bilingual university; for nonwhites there are four (including the Medical University of Southern Africa) for Africans, one for Coloureds, and one for Asians. Students who want to attend a university designated for a different racial group must obtain government permission. White schoolchildren are taught in a single language—English or Afrikaans according to their home language. Attendance is free and compulsory between seven and 16 years of age, and books and equipment are provided. For Asians and Coloureds education is free and compulsory where the facilities exist.

Schooling for African children is not free, nor is it compulsory for most. Parents are responsible for some of the books and equipment. The number of Africans who receive some schooling has increased dramatically since the early 1950s; by the late 1970s more than three-fourths of school-age African children were receiving some education. The education available to Africans, however, is far inferior to that available to whites, and the dropout rates in African schools are very high. There is a serious shortage of teachers because the government provides very limited resources for African teacher training. In addition, many of those who teach Africans are not well trained. The per capita government expenditure for whites and Africans enrolled in schools varies drastically.

Health and welfare. The administration of health and welfare is also formed in the context of the government's distinction between general concerns and those of a particular racial group. Formulation and overall coordination of the national health and welfare policy, a general concern, is conducted by the Department of National Health and Population Development, though the policies and standards must be approved by all three chambers of Parliament. The services themselves are not considered a general concern and thus are managed separately for whites, Coloureds, and Asians by the departments of Health Services and Welfare of the three chambers. For Africans, national welfare policy is set by the Department of Development Planning, and health and welfare services are provided by the four provincial administrations. For all four racial groups some powers are variously but separately delegated to regional or local bodies.

Public hospitals and clinics are available free or partly free to the indigent. Voluntary organizations that provide welfare services must register with the government, which subsidizes some of these organizations.

Local authorities have been responsible for public housing, which has been segregated by race and controlled by different departments. The Department of Community Development was established in 1961 to oversee a national policy. By 1970, 50 percent of new housing built by local authorities was being used for resettling Coloured and Asian communities removed from one area to another under the Group Areas Act of 1950; the consequence is a severe shortage of housing for these groups. The Department of Co-operation and Development initiated a program of township development in the African areas during the 1960s, mainly in response to the need to provide housing for those Africans who were removed from white areas in the implementation of the separate-development policy. With few exceptions, Africans have not been allowed to own their own housing outside of these areas.

The regular police are organized nationally and comprise regulars as well as reservists. There are about equal numbers of whites and nonwhites. The Security Police are organized separately. A third police force was established in 1969 in terms of the Public Service Amendment Act and the General Law Amendment Act. These acts established a Bureau of State Security, responsible only to the prime minister and not subject to treasury approval for its spending. The bureau was reorganized in 1978 as the National Intelligence Service. It is an offense in South Africa to possess or publish information about military, security, or police matters deemed prejudicial to state security; in addition, any government minister may issue a certificate preventing evidence from being presented at court.

Many people have served sentences under the various security laws. The number detained without trial is not given officially, but it has been estimated to average several hundred at any given time. The prison population in South Africa increased sharply during the 1960s and '70s. In 1977 the daily average prison population was almost 100,000, one of the highest rates in the world. Of these, the majority were imprisonments for statutory offenses against laws (the so-called pass laws) that define the right of Africans to live and work in white areas and that do not apply to other racial groups.

age dif-
entials

The most obvious feature of social conditions is the difference between the wages and cost of living of whites and of nonwhites. In addition, the vast majority of Africans have remained untouched by the wage advances in the mining and industrial sectors of the economy. In the late 1980s more than one-fifth of the African population was unemployed, and those who were employed were generally in the lowest paying and least prestigious positions.

This pattern of wage differentials partially reflects the composition of South Africa's black population, with its many migrants to industrial and urban areas, but it also is a result of the conscious and systematic effort of the government to control black labour and channel it to the benefit of whites. The Industrial Conciliation Act of 1956, for example, allows for a periodic definition of the levels of employment that members of each racial group may occupy and thus maintains the racial hierarchy in employment. The consequent wage differentials result in income levels below the official poverty line. In the African towns of Soweto, surveys in the 1970s showed that 75 percent of the families lived below the poverty line.

White South Africa has a highly sophisticated public health system, and, while racial bias is not explicitly written into health legislation, health care for nonwhites is invariably affected by the economic and political inequalities of the society. The health status of Africans is generally low. Malnutrition is one particularly important example of this, especially among children. Kwashiorkor, a condition resulting from insufficient protein in the diet, is common among Africans in both urban and rural areas. There is an enormous discrepancy between infant mortality rates; the mortality rate is lowest for whites, then substantially higher for urban Africans, with the highest rate of infant mortality among rural Africans. A similar discrepancy exists in the number of doctors available for whites as compared with Africans. In the late 1970s the South African government opened a facility to train African doctors and other medical workers.

The apartheid policy

It is the purpose of apartheid, the separate-development policy, to segregate the races as far as possible in every aspect of their lives. The country is divided into one white area and 10 African areas. The white area is divided by the 1950 Group Areas Act (as amended) into segregated areas in each of which only members of a designated race may live, own land, or occupy premises. In addition to residential segregation, there is political, social, and economic discrimination, though some apartheid laws have been rescinded. Marriages and sexual relations between the races had been outlawed by both the Prohibition of Mixed Marriages Act of 1949, which was repealed in 1985, and the Immorality Amendment Act of 1950, major portions of which were also repealed in 1985. The Reservation of Separate Amenities Act of 1953, repealed in 1990, forbade persons of different races to use the same public amenities or transport facilities and also gave central or local authorities power to disallow racial mixing in places of public entertainment, cultural institutions, and sporting facilities. These changes, however, have not significantly affected the fundamental economic, social, and political realities of separate development. (M.J.L./D.F.G./Ed.)

CULTURAL LIFE

The 10 or more languages spoken by South Africa's people reflect the country's cultural pluralism. The largest group, the Africans, is the most eclectic in culture. Many have adopted a host of European ways, but the solid core of African cultural traditions of language, music, and dance retains its vitality. The various African societies have rich oral traditions, including imaginative narrative, poetic, historical, and epic forms. These oral traditions, while they remain strong in their own right, especially in rural parts of the country, have exerted a strong influence on the written literatures of the African cultures, which also have been influenced by literary traditions of other parts of the African continent, of the Caribbean and the Americas, and of Europe.

Such writers as Guybon Sinxo (Xhosa), B.W. Vilakazi (Zulu), Oliver Kgadime Matsepe (Northern Sotho), and Thomas Mofolo (Southern Sotho) have been more heavily influenced in their written work by the oral traditions of their cultures than by European forms. Works composed in the indigenous languages have been largely ignored or dismissed as works written for the schools or as works with limited audiences, yet these novels and poems have for years been a primary means of expression for African intellectuals. No matter what the size and composition of the audiences, the works are a significant part of the intellectual history in South Africa.

During the 1970s there emerged in the arts powerful themes of national and multiracial, multilingual cultural patterns, as writers and artists from all groups concentrated on exploring and portraying the crises affecting South African society. Reaction to apartheid and various earlier racial policies had engendered a sense of black culture and history that anticipated negritude as it was manifested in West African, Caribbean, and U.S. movements. The themes of Black Consciousness evident in the poetry and prose of urban writers such as Mothobi Mutloatse and Miriam Tlali, and published in such periodicals as *Staffwriter,* are derived from the literary and oral traditions of African languages in South Africa and in literature by Africans in European languages. The authors Adam Small and Alex La Guma have written vividly in Afrikaans and English, respectively, of the effects of racial discrimination and of the complex and frequently violent nature of relations between the races. Because of the growing international concern with South Africa, many of these black writers, and those white authors who deal with racial themes, have received recognition beyond the borders of the country. Newly recognized writers such as John Coetzee, Sipho Sepamla, and Walli Serote have joined such established figures as Ezekiel Mphahlele, Nadine Gordimer, Alan Paton, André Brink, and Étienne Leroux in bringing South African literary life to the wider world.

Censorship of published works

All published works in South Africa are subject to severe censorship, and many works are banned, especially those with strong political themes or descriptive sexual scenes. A large segment of Afrikaner writers have become alienated from the government; and authors such as Breyten Breytenbach, Dan Roodt, Brink, and Leroux have had their works banned. South African playwrights have responded to the new cultural and political milieu with such innovations as bilingual and multilingual plays and the use of ad-libbing to avoid censorship. Plays by Athol Fugard, Fatima Dike, and Pieter Dirkhuys have been performed worldwide.

The major institutional support for culture comes from the four provincial councils for the performing arts. These councils help fund plays, operas, symphonies, and other events. In the late 1970s the activities of the councils, which are subsidized by the government, were open to South Africans of all racial groups.

The press in contemporary South Africa finds itself increasingly under political and legal constraints. Historically, the strongest elements of the press have been the English-language combines (such as the Argus group). The Afrikaans-language press has come to be more influential, sometimes through government financial support. African readership has also expanded greatly. In recent years several African newspapers have been closed, and individual journalists banned.

Television—introduced in the mid-1970s—and radio constitute important forces in South African society. The government tightly controls both media, which air programs for the different linguistic and cultural groups in the country. The government uses television and radio to communicate its own views and to counter cultural tendencies that it perceives to be threatening to the implementation of separate development. For statistical data, see the "Britannica World Data" section in the current *Britannica Book of the Year.*

(R.V./D.F.G.)

History

For the history of the region before the arrival of European settlers, see SOUTHERN AFRICA.

Whether or not the Phoenicians sailed around Africa as claimed by Herodotus, southern Africa was unknown to the Greeks and the Romans and to Europeans before the 15th century. Then, largely as a result of the patronage of Prince Henry the Navigator, Portuguese mariners steadily pushed down the West African coast until in 1488 Bartolomeu Dias de Novais rounded the Cape of Good Hope and in 1498 Vasco da Gama, in a flagship of 120 tons, 80 feet long, reached the objective, India. Thereafter the Portuguese gained maritime supremacy in the Indian Ocean and used it to exploit the Asiatic spice trade and, less effectively, the East African gold trade. But, though they colonized Angola and Mozambique, they made no settlements as far south as what is now the Republic of South Africa, regarding its resources as negligible and its inhabitants as too primitive for commercial or evangelical effort. Throughout the 16th century, therefore, though South African waters were often traversed by Portuguese fleets, the only civilized people who spent much time ashore were the survivors of the many ships that were wrecked on the coast.

DUTCH FOUNDATIONS

Trading companies. By the end of the 16th century Dutch and English seamen had also begun to trade with Asia by the Cape route. They found it desirable to pause for refreshment (the death rate on the long voyage being often as high as 50 percent), and during the first half of the 17th century they usually stopped at St. Helena, the Cape, or Mauritius. In 1615 the English tried in vain to form a settlement at the Cape with 10 felons reprieved from the hangman's noose, and five years later two English captains made the empty gesture of annexing all Africa for James I; but it was St. Helena that eventually became the main port of call for the English company.

Dutch outpost at the Cape

Meanwhile the Dutch East India Company outstripped all rivals and obtained a virtual monopoly of the East Indian spice trade. For several decades Dutch ships made a practice of putting into Table Bay to take in fresh water and to barter with the Khoikhoin for meat; and to find the latest information about the affairs of Europe or Asia in dispatches they left one another under inscribed stones. Then in 1647 Leendert Janssen was shipwrecked in Table Bay with the crew of the "Noord Haarlem," and after his return to the Netherlands he presented a report advising the company to found a permanent refreshment station at the Cape. Largely because the Anglo-Dutch War of 1652–54 was imminent, the directors eventually agreed; three ships were to take out building materials, seed, and implements, and 90 men were to build a fort and develop a vegetable garden.

Jan van Riebeeck. To command the expedition the directors chose Jan van Riebeeck, a doctor by training, who had already had six years of commercial experience with the company. He landed at the Cape on April 7, 1652, and remained 10 years, during which time droughts, floods, and pests, indiscipline among his subordinates, and thefts by the Khoikhoin often brought the settlement to the brink of disaster. But it survived; a timber-and-sod fort was built, the coastline was charted, the interior was explored, and a belt of land extending about eight miles from Table Bay to Wynberg was brought under cultivation.

However, the Cape did not become the simple outpost the directors had had in mind. At that time Khoikhoin, pastoral nomads loosely organized in small tribes, occupied most of the coastal regions of South Africa as far east as the Great Fish River. The Cape Peninsula had been used by three such tribes, who regarded the Dutch as intruders in their domain, especially when it became apparent that the Dutch intended to stay when they began building fortifications and extending their area of cultivation. The Dutch bartered with the Khoikhoin for sheep and cattle, and from time to time the Khoikhoin stole them back again. Van Riebeeck calculated whether he was strong enough to use force, but when the directors cautioned him to do no such thing he fell back on the idea of confining the settlement within a palisade. Yet even at this early stage in South African history it was not possible to keep the races completely apart, because the Dutch continued to barter with the natives.

Importation of slaves

Van Riebeeck also initiated two experiments that had far-reaching consequences. At first all the work of the station was done by the company's servants, but in 1657 a few slaves were imported and more came in 1658 and thereafter. The second experiment started in 1657 when the company, hoping it would save money if grain were grown and stock bred by unpaid freemen instead of by paid employees, freed nine married men from their contracts and gave them 30-acre farms along the Liesbeeck Valley at Rondebosch. These men, who were known as free burghers, were to produce grain and stock and sell them to the company at agreed prices. So van Riebeeck left behind him an embryonic colony of settlement which used slave labour and was confronted with a "native problem."

Immigration and expansion. In 1662 the Cape settlement numbered about 250 white persons, of whom nearly half were company servants. In the next few years the population increased very slowly. But during the governorships of Simon van der Stel (1679–99) and his son W.A. van der Stel (1699–1707) the company made its one serious effort to encourage immigration. In 1707 a census showed a burgher population of 1,779 men, women, and children, owning 1,107 slaves. This was a slow rate of progress when compared with that of the English colonies in North America.

Nevertheless, the modern Afrikaner people are descended for the most part from those who were enumerated in

1707. Most of them were of Dutch and German stock. There was also a small but significant group of fewer than 200 French Huguenots who, after the revocation of the Edict of Nantes in 1685, went to the Netherlands and then were sent to the Cape. As a matter of policy the company scattered the Huguenots among the other settlers, and within little more than a generation they became fully assimilated, discarding the French language and even pronouncing their names in the Dutch manner.

The area of settlement expanded with the population—to Stellenbosch beyond the sandy Cape Flats (1679) and then to the Berg River Valley. To meet the needs of local administration a general purposes official (*landdrost*) was appointed to Stellenbosch in 1685; sitting with four local burghers (*heemraden*), he was given jurisdiction in minor civil cases. Nearly all the company servants, however, lived in Cape Town, where the governor and his chief subordinates formed a Council of Policy which issued regulations for the colony, subject to the overriding authority of the governor general and council of the Indies in Batavia and the directors in the Netherlands.

From the first the burghers had fretted at many of the regulations, which imposed restrictions and taxes on internal trade. What was particularly galling to the burghers was the tendency of the officials to farm and trade on their own account, using their authority to make sure that their own produce did not remain unsold. This led to an outcry against the governor, W.A. van der Stel, who embarked on large-scale farming operations and cornered the market so successfully that some malcontents, including the Huguenot diarist Adam Tas, sent a petition to the directors, who recalled van der Stel in 1707. But the underlying cause of the discontent—the commercial policy of the company—was not remedied.

Evolution of the Afrikaner people. The company, probably convinced that white settlement led to political agitation, had no vision of a New Netherlands in South Africa and sponsored no immigration schemes after the time of the van der Stels. Nevertheless, during the 18th century a New Netherlands of a sort was arising from the materials present. The white population grew, mainly by natural increase, to about 15,000 in 1795, by which time they regarded South Africa as their only home and spoke a language, Afrikaans, which deviated from the language of the Netherlands. Those who lived in Cape Town—the only port and the only real town in the colony—were mostly traders and innkeepers. In the southwestern part of the colony, near Cape Town, were the grain and wine farmers, some of them proprietors of large estates run by slave and Khoi labour. Beyond them were the Boers, about half the total white population.

The Boers were seminomadic, many of them completely nomadic, pastoral farmers. Most of the land they occupied was unsuitable for cultivation; moreover, the market for agricultural produce was glutted, and slaves did the skilled work of the colony. There was, therefore, nothing to keep the increasing white population in the southwestern Cape and much to encourage them to disperse and become self-sufficient pastoral farmers.

The way was paved by W.A. van der Stel, who, unlike his father, allowed burghers to concentrate on stock farming. Within a few years it became possible for any burgher to take occupation of 6,000 acres or more of land and treat it as his property, paying the company a small annual license. The result was a continuous expansion of the frontiers of white settlement. In the north the Boers were slowed up by aridity and finally stopped near the Buffels River about 1760. In the east they advanced along either side of the arid Great Karoo until in the 1770s the two streams of pioneers began to mingle beyond it in the vicinity of what became Graaff-Reinet, about 400 miles (640 kilometres) from Cape Town.

pansion
white
tlement

Thus a few thousand white persons scattered over an area about twice as large as England and about the size of Colorado. Their simple needs were met by their stock, by hunting, and by travelling traders who bought their sheep and cattle for the Cape Town market and sold them a few imported goods. The company did little for them beyond establishing courts of *landdrosts* and *heemraden* at Swellendam (1745) and Graaff-Reinet (1785). From time to time officials expressed concern that the isolation of the Boers was causing them to degenerate. But although all the Boers were extreme individualists and some were ruffians, most of them contrived to preserve a sound domestic morality, a smattering of literacy, and a respect for their religion, a rather strict Calvinism.

Slaves, Khoikhoin, and San. During the 18th century the slaves, the Khoikhoin, and some of the San were beginning to interbreed with one another and with Europeans to produce the community now known as the Cape Coloured people. Although few slaves were imported, the slave population outstripped the white to number nearly 17,000 in 1795. Negroid types from the west and east coasts of Africa predominated, with Malays from the East Indies forming an important minority. There was a considerable amount of extramarital miscegenation between white men and slave women. Most of the slaves were the property of the agricultural farmers, for whom they formed the main labour supply. Others were owned by the company and the Cape Town burghers, a few by the Boers. The treatment of the slaves, which had at first been fairly mild, tended to deteriorate, and the 1754 slave code was a stiff one.

The nearest approach to a Khoi war had taken place in the 1670s. But it was smallpox that took the heaviest toll of the Khoikhoin, especially a shattering epidemic in 1713. After that, as the Boers advanced into their territories, the surviving Khoikhoin lost their land and their cattle—their only means of an independent existence. Many were reduced to a status not unlike serfdom, forming the main labour supply of the Boers, whose simple demands they were able to satisfy. Others withdrew beyond the frontiers of white settlement to maintain a more or less independent existence until the next century.

There was a certain amount of miscegenation between white men and Khoi women, although intermarriages had been unlawful since 1685. The offspring were usually disowned by their fathers and became known, bluntly, as Bastaards; some entered into service, others retreated before the advancing Boers, leading Boer lives themselves.

The small San were still more primitive than the Khoikhoin. Before white settlement began they had been driven into the more arid and mountainous parts of South Africa by the Khoikhoin and other African tribes. But, though every man's hand was against them, they contrived to make hit-and-run raids to get sheep and cattle for food, and, if cornered, they were able to kill their enemies with their poisoned arrows. As the Boers in turn began to enter San country and to suffer from their raids they organized Boer commandos to hunt them. Toward the end of the 18th century several San bands made a prolonged stand, operating from mountain fastnesses along the northern fringes of the area of white settlement; but the commandos gradually cleared them out, killing 2,500 San and capturing 650 in the decade ending in 1795. Those captured were children, who were taken into service.

San
resistance
to Boer
incursions

Their experience with slaves, Khoikhoin, and San had important and enduring effects on the racial attitudes of the Afrikaner people. Most of the nonwhites they came into contact with were at so low a cultural level that the Afrikaners tended to think of themselves as innately superior. Their response was not merely hostile, however, because they all—Capetonians, agriculturists, and Boers—came to depend on the use of nonwhite servants.

African opposition and economic discontent. Before the last quarter of the 18th century the Boers had not been seriously impeded by human obstacles. Then, however, they came up against formidable opposition.

Bantu-speaking tribes had occupied the the eastern half of South Africa for several centuries. They were more numerous than the Khoikhoin. They had a more complex social and political structure. They cultivated the soil as well as hunting game and herding cattle. They made iron weapons and tools. South of the Limpopo River were two main groups of Bantu-speaking peoples: the Sotho, who lived on the plateau; and the Nguni, in the coastal belt. The westernmost Nguni tribes slowly expanded westward as population increased and tribes split, but the Boers moved toward them more rapidly. Early in the 18th century Boer hunters began to make contact with the Nguni and bartered with them for cattle and ivory. The company vainly tried to prevent such contacts and delay the convergence of the Boers and the Nguni by issuing proclamations prohibiting barter and defining limits beyond which the Boers were not to go. When the governor, J. van Plettenburg, toured the frontier in 1778 he found that Boers were already intermingled with Africans in the vicinity of the Great Fish River.

A long series of frontier "wars" followed—basically struggles for possession of the land. The first fighting took place in 1779–81 and was sufficient to show the Boers that they faced tough opposition. They therefore appealed to the company for aid; although a *landdrost,* M. Woeke, was appointed to Graaff-Reinet in 1785, no troops were sent. Woeke's life was soon made intolerable by the Boers, and in 1793 he was superseded by H.C.D. Maynier. Further fighting broke out in that year, and again the result was inconclusive. The Boers were disgruntled. For nearly a century they had been left by the company to make their own terms with man and nature, and when at length they had asked for help all they received was a government official who not only failed to defeat the Nguni but also allowed Khoikhoin to come to his court with complaints against them. In 1795, on the eve of the British conquest of the Cape, they drove out Maynier and declared Graaff-Reinet to be a republic. But the name "republic" was a euphemism: in fact there was anarchy at Graaff-Reinet. Similar events took place at Swellendam, where another "republic" came into being.

Meanwhile there was trouble in the southwestern part of the colony also. The company had maintained rigorous commercial restrictions, together with a system of government that gave the colonists practically no voice in the determination of policy. The Boers had managed to escape most of the effects, but the restrictions had always borne heavily on the agricultural farmer who had produce to sell and on the Cape Town man who lived by trade. In the 1770s, which were lean years, the discontent came to a head with the organization of the Cape Patriots movement, which had some connections with the anti-Orange Patriot Party in the Netherlands. A petition was drawn up criticizing many of the officials and asking for full burgher representation on the Council of Policy and the right to trade freely throughout the company's possessions. When it was laid before the directors in Amsterdam, their only response was to dismiss the official who was most roundly criticized—the fiscal, W. Boers.

The Cape Patriots movement

In 1784 a second petition was taken above the heads of the directors to the States-General of the Netherlands. This time the burghers were given equal representation with officials on the Court of Justice (though not on the Council of Policy) and the right to trade with the company's possessions—a right that was nullified by the conditions that were attached. By then, however, the disaffection had subsided because the American Revolutionary War had brought a large French garrison to Cape Town to help the Dutch to defend it against the British, and the garrison provided an abnormally large market for Cape produce and brisk business for the traders and innkeepers. In the early 1790s bad times came again as the company, trying desperately to stave off bankruptcy, made a final effort to make the colony pay its way. The garrison was reduced, public works were suspended, and—the last straw—new taxes were imposed. So, when the British invading force arrived in 1795, it found depression in the west and rebellion in the east. The company had never done much for the white colonists and still less for the nonwhite peoples.

SOUTH AFRICA DIVIDES (1795–1870)

British conquest. In the course of the Napoleonic Wars, the Cape was captured by a British naval and military force in September 1795, nominally on behalf of the Prince of Orange, who had taken refuge in England from the Dutch republicans. In their struggle with France the British considered it essential not to let the Cape fall into enemy hands, and until the Treaty of Amiens a hold was kept on it for strategic reasons. The British tried to conciliate the Afrikaners, and by abolishing the restrictions on internal trade and maintaining a large garrison they caused an economic revival in the southwestern part of the colony. On the eastern frontier, on the other hand, the British were no more successful than their predecessors had been. Although the republics of Swellendam and Graaff-Reinet soon submitted to the new government, anarchy developed in Graaff-Reinet again in 1799, after the arrest of a prominent Boer, A. van Jaarsveld, on a charge of forgery. Not only the Xhosa but also many of the Khoi servants of the Boers made the most of the opportunity created by the divisions among the whites and caused havoc as far west as Knysna. The British general F. Dundas patched up a truce; but H.C.D. Maynier, appointed resident commissioner of the two eastern districts, failed to satisfy the Boers, who rebelled again in 1801, when once again their Khoi servants joined with Xhosa tribesmen to harry the farms over a wide area.

The eastern districts were therefore in turmoil when Britain gave up the Cape under the terms of the Treaty of Amiens (1802). By this time the company was defunct, and the Dutch government—the Batavian Republic organized by the French in 1795 after their conquest of the country—succeeded to its charge. J.A. de Mist, the commissioner-general, and Gen. J.W. Janssens, the governor, tried to restore the morale of the Boers and showed a considerable understanding of the problems of the country; but these men did not stay long enough to consolidate their reforms for in 1806 the British sent out another force to recapture the Cape from Napoleon's Dutch allies. Janssens lacked the means to put up much resistance, and once more the colony passed into the hands of the British, whose title was confirmed in 1814 as part of the general peace settlement.

British policy, 1806–36. Until 1823 British policy was cautious and conservative. The governor had autocratic powers, but the Afrikaners were used to that. Moreover, their Roman-Dutch law was retained, and local administration remained as of old in the hands of *landdrosts* and *heemraden,* most of them Afrikaners. These were comparatively prosperous years. The southwestern farmers profited from their access to British markets, where their wine sold well thanks to a substantial tariff preference. Elsewhere, however, extensive pastoral farming remained the norm. Nevertheless, the British introduced some changes in these years. They appointed more *landdrosts.* In 1809 they promulgated a code for the treatment of Khoi servants, who were to be employed only under written contracts registered at a *landdrost*'s office and were given legal protection against ill treatment; on the other hand, they were not to be allowed to leave their employer's farm without a pass signed by the employer. From 1811 onward high court judges, who had previously sat only in Cape Town, made annual circuits to hear cases in the districts.

British reforms

Mild though these reforms were, they caused trouble. There was much grumbling in 1812 when the judges on circuit in the eastern districts tried a number of Afrikaners on charges of ill-treating their Khoi servants. Three years later a Boer, F.C. Bezuidenhout, opened fire on a party that had come to arrest him for repeatedly ignoring his *landdrost*'s orders to answer a charge of cruelty; in the skirmish Bezuidenhout was killed, whereupon his brother proceeded to organize opposition to the government; but the Slachter's Nek Rebellion soon ended when about 60 rebels were rounded up and tried, and five ringleaders were hanged.

The British also brought superior force to bear against the Xhosa on the eastern frontier and thus started the process of the conquest of the African tribes. In 1811 British regular troops and Boer commandos drove the Xhosa back to the eastern side of the Fish River and in 1819 to the eastern side of the Keiskama.

In 1820, 5,000 British settlers were brought out and placed on 100-acre lots in the Zuurveld, on the western side of the Great Fish River. The 1820 settlers did not, however, form the human barrier that was intended, because the land was not suited to agriculture; within a few years most of them had abandoned their lots and become townsmen in Port Elizabeth and Grahamstown. Others became traders among the African tribes to the east. Those who stayed on the land eventually made good by producing wool for export to England, especially when large farms came onto the market at the time of the Great Trek. This was the first subsidized immigration scheme since the 17th century, and the 1820 settlers were the first white immigrants who were not assimilated by the Afrikaner people.

When they had got their bearings the 1820 settlers were dismayed to find that the legal system of the colony was alien to them, the judges were officials without any particular legal training, and Lord Charles Somerset, the governor from 1814 to 1826, was an autocrat who made it impossible for them to publish a newspaper. Their agitation for British liberties and institutions evoked some response. The Charter of Justice of 1827 created a Supreme Court of qualified judges with security of tenure, abolished the *heemraden,* and introduced English rules of procedure and evidence, including the jury system, while it left untouched the Roman-Dutch substance of the law. In 1834 an Executive Council of officials and a Legislative Council of officials and nominated nonofficials were established. By that time the freedom of the press had been won, English had become the official language of the courts, and British teachers had been imported to start village schools in which English was the medium of instruction.

During these years South Africa was attracting the attention of the British humanitarians or evangelicals who were striving to free the nonwhite populations of the colonies from their legal disabilities. They were supplied with severe criticisms of South African conditions by John Philip, South African superintendent of the London Missionary Society, which had established a number of mission stations up and down the country. Philip reached the conclusion that the Khoi code of 1809, with its stringent pass regulations, was unjust; in 1826 he returned to England to appeal to the government and the British public, and in 1828 the House of Commons passed a resolution for the emancipation of the Khoikhoin. Seeing the trend of affairs, Gen. Richard (later Sir Richard) Bourke, the acting governor, had already passed an ordinance, number 50 of 1828, which abolished the pass system and gave "free persons of colour" complete liberty of movement. Meanwhile, with their eyes focussed primarily on the West Indies, the British government had been insisting on improvements in the treatment of slaves; and in 1833 the reformed Parliament passed the Emancipation Act under which all slaves in the colonies became free after a period of apprenticeship, and £20,000,000 was voted as compensation to their owners. When their period of apprenticeship ended in 1838 the former slaves in the Cape Colony stepped into the position of other "free persons of colour." Thereafter the emancipated slaves and Khoikhoin—the Cape Coloured people—became a rural and urban working class in the Cape Colony.

ıe British
nancipa-
ɔn Act

Meanwhile frontier trouble had flared up again. Unrest had developed among the border Nguni tribes for various reasons, including the frequency of military raids on their villages made in reprisal for the theft of stock from white farmers. In 1834 Gen. Sir Benjamin D'Urban arrived as governor with instructions to devise a more equitable policy, but he did nothing about it until large bodies of Africans invaded the colony and did serious damage. D'Urban then reasserted British military superiority and annexed the land up to the Great Kei River, from which most of the Africans were to be expelled (May 1835). But he found it impossible to enforce the expulsion, and the colonial secretary, Lord Glenelg, disapproved; consequently, in 1836 the territory was disannexed, and an attempt was made to pacify the tribes by making treaties with their chiefs. By that time, however, the frontier was no longer a clear line of division between the races; white traders and missionaries were working among the tribes to the east of it, and Africans were working on white farms to the west.

The Great Trek. For several generations the Boers had been left more or less to their own devices. Now, under an alien government actuated by liberal ideals that they did not comprehend, many of their institutions were being transformed. They were short of labour, and they found it difficult to comply with the regulations and get the compensation money for their slaves; their property was being pilfered by wandering Khoikhoin, and they suffered further losses during the African invasion in 1834. Behind all these things they saw the hand of missionaries, who, they considered, misrepresented them in England. The reversal of D'Urban's frontier policy was the last straw that made many of them decide to throw off British dust and find a new home where they could, in the words of Piet Retief, their ablest leader, "preserve proper relations between master and servant." Later, Anna Steenkamp recorded that the British had placed their slaves "on an equal footing with Christians, contrary to the laws of God and the natural distinctions of race and religion, so that it was intolerable for any decent Christian to bow down beneath such a yoke; wherefore we withdrew in order thus to preserve our doctrines in purity." Imbued with this spirit the Voortrekkers, about 12,000 Afrikaners, men, women, and children, left the colony with their sheep, their cattle, their ox wagons, and their Coloured servants between 1835 and 1843.

The
Voortrekkers

In the previous two decades there had been widespread destruction and dislocation among the African tribes, caused by the Zulu under Shaka, and their offshoot, the Ndebele or Matabele, under Mzilikazi (Mozelekatse). By the time of the Great Trek two areas seemed suitable for white settlement—Natal, south of the Tugela River, and the High Veld, on either side of the Vaal. But appearances were deceptive, for these two areas were kept denuded by Zulu and Ndebele impis (regiments). The first Voortrekkers made for the High Veld, where they were attacked by the Ndebele, whom they routed in 1837. Most of them then decided to settle in Natal. Piet Retief and a pioneer group went to the kraal of Dingane (Dingaan), Shaka's successor, to negotiate for a cession of land; and there, in February 1838, he and 70 Boers and 30 Coloured servants were treacherously massacred, while another 300 Boers, mainly women and children, and 200 Coloured servants, were killed in northern Natal. On December 16, 1838, however, Andries Pretorius gained a decisive victory over the Zulu at Blood River. Most of the Voortrekkers then proceeded to stake out farms in Natal. Border troubles ensued, and, when in 1840 a Boer commando expedition made a sortie to the south against the kraals of a chief named Ncaphayi (Ncapaai), his neighbour Faku, who had a treaty with the British, appealed for aid.

Previously the British had been undecided what to do about the Voortrekkers; the Cape of Good Hope Punishment Act of 1836 had made them liable, as British subjects, to trial in British courts for crimes committed south of latitude 25° S, but little had been done to make it effective. Then, however, anxious lest the activities of Natal commandos lead to disturbances on the Cape frontier, the governor, Sir George Napier, sent a small force to Natal, which, after some fighting, became British territory in 1843. Most of the Voortrekkers who had settled in Natal then inspanned their oxen again and trekked back to the High Veld, north of the Vaal River.

Between the Orange and the Vaal, however, the British were drawn in for a while. There was a racial medley in that region; Griquas (of mixed Khoi–European parentage), who had lived north of the Orange River for several decades; Africans, survivors of the Ndebele devastation of the High Veld, who had been rallied by Mshweshe (Moshesh), a Sotho chief, near the Caledon River; and Afrikaners. The British had made a treaty with the West Griqua chief, Andries Waterboer, in 1834, and they made treaties with the East Griqua chief, Adam Kok III, and with Mshweshe in 1843, hoping to use them to keep the peace along the Orange River. Trouble followed when Kok, in accordance with his treaty, tried to hand an Afrikaner over to the Cape authorities for trial under the Punishment Act. The Afrikaners took up arms and were dispersed by troops from the Cape at Zwartkoppies (1845). Two years later Gen. Sir Harry Smith became governor of the Cape Colony and British high commissioner in South Africa. An optimist, he believed that the South African imbroglio would be pacified if the area of British authority was extended. Accordingly, after overcoming further African resistance on the eastern frontier of the Cape, he annexed the land up to the Great Kei River as the province of British Kaffraria (1847) and the land between the Orange and the Vaal as the Orange River Sovereignty (1848). The colonial secretary, Earl Grey, accepted these annexations most grudgingly.

Humanitarian influence was waning in Britain, and the main concern of the Colonial Office was to cut down expenses. Therefore, when further fighting broke out on the eastern frontier and similar difficulties developed with Mshweshe in the Orange River Sovereignty, the British government decided to reduce its commitments in South Africa by recognizing the independence of the Voortrekkers. This was done in two stages. In 1852 the Transvaalers were granted "the right to manage their own affairs without any interference on the part of the British government" in a convention signed at the Sand River; and in 1854 similar arrangements were made with the Afrikaners of the Vaal–Orange area at Bloemfontein.

Independence for the Voortrekkers

South Africa was thus divided into three camps: Afrikaner republics; British colonies; and still-independent African societies.

Afrikaner republics. At the time of the Bloemfontein convention there were about 15,000 white persons engaged in pastoral farming in what then became the Orange Free State. They soon agreed on a rigid constitution, which vested legislative power in an elected council (Volksraad), executive power in an elected president—the voters being the white male adults—and local administration in *landdrosts* and *heemraden* on the old Cape model. The East Griqua question was settled in 1861 when Adam Kok sold his remaining land rights in the Free State and trekked with his people to found a new Griqualand East nearer the coast. The Sotho question was more difficult. The British had abandoned the sovereignty because they shirked the expense of controlling the rivalry between the Afrikaners and the Sotho for the Caledon River valley, which included some of the best arable land in southern Africa.

When fighting broke out in 1858 the Sotho outmanoeuvred the Free Staters, who were glad to accept the mediation of the high commissioner Sir George Grey (first convention of Aliwal North). The Free Staters, conscious of their weakness, then tried to unite with the Transvaal but were stopped by Grey, who threatened to withdraw the recognition of their independence and advised them to federate with the Cape Colony; yet when they expressed a desire to do so, the British government refused. Grey considered that a federation, under the crown, of all the colonies and republics in South Africa would be in the general interest. The British government, however, was averse to any extension of its area of responsibility. Further fighting started in 1864; this time the Free Staters were more successful and were able to dictate terms, by which Mshweshe lost most of his arable land (Treaty of Thaba Bosiu, 1866). But the peace was not kept and Mshweshe asked Britain to annex Basutoland. This was done in 1868, and the next year the frontier line between the Free State and Basutoland was agreed (second convention of Aliwal North).

Britain's annexation of Basutoland

The intervention of the British preserved for the Sotho people more land than had been left to them in 1866; but it gave serious offense to the Free Staters, depriving them of the fruits of their victory. Thereafter the Free State, its frontiers pacified and absolved from the responsibility of administering a large number of Africans, became what Lord Bryce once described as a model republic, under the wise leadership of J.H. Brand, president from 1864 to 1888. The Cape Colony took over Basutoland in 1871, but later got into difficulties in trying to force the Sotho to forfeit their arms and was glad to hand it back to Great Britain in 1884.

Meanwhile the Voortrekkers north of the Vaal River, numbering perhaps 22,000 at the time of the Sand River Convention, preserved their old Boer mode of life. It was not until 1857 that most of them overcame their factional disputes and united to form the South African Republic under the presidency of M.W. Pretorius, son of the victor of Blood River. Their constitution, which created institutions similar to those in the Free State, frankly stated that "The people desire to permit no equality between coloured people and the white inhabitants, either in church or state." In 1863 there was further factional fighting; and Boer expansion frequently led to disputes with African tribes, the weaker of which were broken up, the remnants becoming squatters and servants.

British colonies after the Great Trek. Not more than a quarter of the Afrikaners had left the Cape Colony during the Great Trek, though others went north in later years. Those who remained gradually became accustomed to the more equal order, and in the course of time a liberal tradition developed in the colony, in contrast with the illiberal tradition of the republics. When the colony received representative government in 1853, the only franchise qualifications were low economic ones, irrespective of race or colour; but most of the Coloured people were unable to qualify and the vast majority of the electorate were white men. By that time the loss of population had been offset by further British immigration; and the decline in viticulture caused by the removal of British tariff preferences was remedied by an increase in the production of wool for export.

In British Kaffraria the high commissioner, Sir George Grey, tried to achieve quick results from a policy of civilizing the Africans by encouraging trade, mission schools, medical services, and public works, by bringing in white settlers, and by using white magistrates to undermine the authority of the chiefs. There was a reaction in 1857, when the Africans destroyed their own stock and crops in the superstitious belief that the white man would then vanish from the country. The result was catastrophic: thousands starved to death, and emaciated survivors poured into Cape Colony in search of work. In 1865 British Kaffraria was incorporated in the colony. Soon afterward the British government urged Cape Colony to assume full responsibility for its own affairs, and in 1872 a responsible government bill was carried and J.C. Molteno became the first prime minister.

The first settlement in Natal was established at Port Natal (now Durban) in 1824 by a small party of British ivory traders from the Cape. The population rose with the arrival of the Voortrekkers in 1838 when for a few years to 1842 Natal became a republic ruled by a Volksraad at Pietermaritzburg. British immigrants began to arrive in numbers after 1847, so that its white population became predominantly British and crept up to 9,000 in 1856, when representative institutions were established, and to 50,000 in 1893, when responsible government was obtained. Mixed farming was practiced inland, and sugar was grown in the subtropical coastal belt.

One result of the defeat of Dingane was an influx of Africans from Zululand into Natal, many of them returning to the region from which they had formerly been evicted by Shaka. Thus the African population rose steeply from about 20,000 in 1840 to nearly 500,000 in 1893. They were handled by Sir Theophilus Shepstone, the son of a missionary who had come to South Africa with the settlers in 1820. He placed most of the Africans in a number of reserves or locations, comprising about one-seventh of the total area of the colony. Their tribal laws and customs were maintained, and they were able to preserve their tribal economy for another generation, when they began to suffer from land shortage. Africans subject to tribal law were not eligible for the franchise, but in 1864–65 laws were passed which enabled Africans to apply to be exempted from tribal law and, seven years later, for the franchise. However, the regulations were such that few became exempted and hardly any became voters.

Shepstone' policy for Africans

The colonists were critical of Shepstone's policy, mainly because it did not make the Africans work for them. The coastal sugar planters, in particular, were short of labour, and it was to help them that Natal began to import Indian labourers in 1860. By 1866, 6,000 had arrived, and when their five-year contracts expired most of them chose to stay in Natal, as they were entitled to do. In 1872 the Indian government prohibited further emigration because some of the Indians had complained of ill treatment; but the migration was resumed on a large scale, with a heavy government subsidy, in 1874, and by the end of the century the Indians outnumbered the whites in Natal.

IMPERIALISTIC POLICIES (1870–1910)

Diamonds and gold. After 1870 the South African economy was rapidly transformed. Previously South Africa had been an economic backwater, with most of its inhabitants, whites and nonwhites, engaged in inefficient near-subsistence farming; and it had lacked the means to attract the capital and the skilled personnel to create the facilities of a modern country. In 1867 diamonds were found along the Orange and the Vaal rivers; in 1870 the dry diamond diggings began to be worked at Kimberley; and in 1886 the gold rush to the Witwatersrand began to eclipse all previous gold rushes. The effects were remarkable. The sum of South Africa's imports and exports rose from £49,000,000 in the decade 1861–70 to £128,000,000 in 1871–80, to £179,000,000 in 1881–90, to £357,000,000 in 1891–1900, and to £700,000,000 in 1901–10. In the last of these decades gold (59 percent) and diamonds (19 percent) accounted for 78 percent of South Africa's exports; and by 1910 £121,000,000 had been invested in the Witwatersrand gold-mining industry and dividends totalling £77,000,000 had been paid by it.

Immigration raised the white population from about 328,000 in 1875 to 1,117,000 in 1904. Railway construction was even more striking: in 1870 there were only 69 miles of railway track in all South Africa; by 1886 there were 1,800 miles and the line from Cape Town had reached Kimberley; by 1895 there were 3,600 miles and Johannesburg was connected with five ports—Cape Town, Port Elizabeth, East London, Durban, and Lourenço Marques (Portuguese East Africa).

Thus South Africa at last entered the world economy and acquired a special place in it as the source of about a third of the world's annual supply of gold and of more than half its diamonds.

e Beers onsol-ated ines id Cecil hodes

The control of these great industries became concentrated in a few hands. The digger phase on the diamond fields was short-lived; companies forced out individuals and then the companies amalgamated until in 1891 De Beers Consolidated Mines controlled the entire South African diamond industry. The digger phase of the gold fields was even shorter, but there the process of concentration never reached quite the same finality; companies became organized into groups or corporations, and the groups became associated in the Chamber of Mines for certain purposes only, notably for the recruitment of African labour. Thus great financial power came to be exercised by a few men, above all by Cecil Rhodes, who went to South Africa for his health in 1870 and became the most successful of all the mining financiers, controlling both De Beers and the Consolidated Gold Fields, one of the strongest gold corporations.

The skilled work in the mining industries was done by whites, mainly immigrants at first, who drew high wages. The unskilled work was done by low-paid Africans who went to the mines from all over southern Africa, especially from Portuguese East Africa, to work for limited periods during which they lived in closed compounds, separated from the ordinary life of the community. In 1898, for example, the Witwatersrand gold-mining industry employed 9,476 whites at an average monthly wage of £26 and 67,797 Africans at an average monthly wage of £2 9*s.* Previously many Africans had been employed as farm labourers in return for squatting rights or low wages. Now the agrarian pattern of race relationships was being adapted to the mining industries.

The discovery of diamonds led to a serious controversy. The Transvaal claimed part of the diamondiferous area and the Orange Free State claimed the rest of it, while David Arnot, a white attorney, claimed it all on behalf of his client Nicholas Waterboer, the chief of the West Griquas. Arnot managed to persuade the British Colonial Office that the Griquas had the best case; therefore when a new high commissioner, Sir Henry Barkly, reached South Africa in January 1871 he had instructions to take a strong line. Barkly persuaded M.W. Pretorius, the Transvaal president, to submit his case to arbitration by R.W. Keate, the governor of Natal. When Keate discovered that Pretorius had unwittingly placed great reliance on a forged document, he decided against him. Although this award did not directly affect the Free State claims, which were the strongest, Barkly, failing to understand their merits, annexed to the crown the entire area claimed for Waterboer in the same month (October 1871). Five years later a land court decision exposed the fallacies in Waterboer's claim to sovereignty over the diamond fields; whereupon J.H. Brand, the Free State president, went to London and exacted £90,000 compensation from the imperial government. In 1880 Griqualand West was incorporated in the Cape Colony.

Annexation and retrocession of the Transvaal. Lord Carnarvon, colonial secretary in Disraeli's 1874 ministry, hoped that the South African states and colonies might unite in a self-governing federation under the British crown. The following year he summoned a conference to discuss the project in London, but it was a failure. The Free State, smarting under the recent annexations, would have nothing to do with the project; nor would the Cape, whose ministers' dignity had been ruffled by the conduct of the historian J.A. Froude, who had toured the colony on behalf of Carnarvon urging federation. Federation from the south having failed, Carnarvon turned his attention to the north and found that the South African Republic was ripe for plucking.

That republic, unlike the Free State, had never acquired stability. Pretorius was bundled out of the presidency after the annexation of Griqualand West, and the Transvaalers chose as his successor Thomas François Burgers, a Cape colonial preacher of the Dutch Reformed Church. But in Burgers they had more than they had reckoned for; he was critical of Transvaal backwardness and proposed to remedy it by social, educational, and religious reforms. He also borrowed money, intending to build a railway to Delagoa Bay to free the Transvaal from its dependence upon British trade routes; but not a single track of the railway was laid, whereas the loan strained the meagre resources of the republic and alarmed the Cape and Natal merchants whose interests it threatened. When in 1876 Burgers personally waged an unsuccessful campaign against the Pedi (one of the Sotho peoples) in the northern Transvaal, he was totally discredited. The Afrikaners, including Paul Kruger, were plotting against him, and the traders were conniving with the Cape and Natal merchants to bring in the British. Carnarvon heard their cries and commissioned Shepstone to annex the Transvaal. Entering the republic in January 1877 with 25 police and a staff of seven, Shepstone annexed it in April in a proclamation that promised "the fullest legislative privileges compatible with the circumstances of the country and the intelligence of the people."

British annexation of the Transvaal

But British rule in the Transvaal was neither efficient nor tactful, and the elected legislature did not materialize. Then the Zulu War revealed the weakness of British arms: the Zulu, their martial spirit revived by Cetshwayo, routed a large British force at Isandhlwana in 1879 before they were vanquished in the following year. By that time the Transvaalers, who had passively acquiesced in the annexation, were moving toward open rebellion under the leadership of Paul Kruger, Piet Joubert, and M.W. Pretorius, and in 1881 they, too, wiped out a British force at Majuba. Gladstone's ministry, which assumed office in Britain in 1880 but failed to reform the Transvaal administration in time to avert the rebellion, then gave the Transvaalers a qualified independence (Pretoria Convention, 1881). Three years later they allowed the republic full internal autonomy, while maintaining British control over its relations with foreign states, other than the Free State (London Convention, 1884). Carnarvon's project had completely miscarried, and his permissive act for the unification of South Africa (1877) was stillborn.

The Rhodes–Hofmeyr alliance. In the Cape, which remained the most civilized of the South African states, the advent of reponsible government and the series of British annexations prompted a group of Afrikaners to form a political organization, the Afrikaner Bond, in 1879. At first the Bond's program was crudely sectional, but three years later Jan Hendrik Hofmeyr gained control and turned it in the direction of Anglo-Afrikaner cooperation, with a British South African federation, which should include the republics, as the ultimate goal. Meanwhile Cecil Rhodes had entered the Cape Parliament and, as his vision of British expansion in Africa was reconcilable with Hofmeyr's, he was able to form a ministry with Bond support in 1890.

Meanwhile, although it had washed its hands of Basutoland in 1884, the Cape Colony by 1894 had annexed all the land below the mountain escarpment as far east as the Natal border at the Umzimkulu River. The Nguni inhabitants of these Transkeian territories remained in occupation of most of their lands after their political autonomy had been extinguished; but steps were taken to prevent them exercising much influence over the colonial Parliament. Laws were passed providing that land occupied on tribal tenure should not satisfy the economic requirement for the franchise (1887) and raising the economic qualification and introducing a simple educational test (1892). A start was also made in encouraging African communities to adopt individual land tenure and to elect local administrative councils (1894). Thus the Cape government drew a line between "tribal" and "civilized" Africans, treating tribal Africans as minors and giving civilized Africans the same rights as white men in theory, though in practice not many Africans got the vote. By 1895, therefore, the Rhodes–Hofmeyr alliance was bidding fair to heal Anglo-Afrikaner tensions in the Cape Colony, without destroying the prospect of a constructive relationship with Africans.

British clash with the Transvaal. During the late 19th century the Bantu-speaking tribes of South Africa, which had previously maintained their autonomy north of the Vaal River, came under white control as a result of Boer expansion and the intervention of Germany and Great Britain. In 1884 Germany took over South West Africa, and Transvaalers began to encroach westward toward it, setting up the republics of Stellaland and Goshen. This expansion, which seemed likely to cut off the British from access to central Africa via the Cape, was checked, largely on the insistence of Rhodes, in 1885, when Great Britain, after a display of force, proclaimed a protectorate over northern Bechuanaland and annexed southern Bechuanaland as a crown colony. Transvaal efforts to keep their north clear of the British were also foiled by Rhodes, who secured a prospecting concession from the Ndebele chief Lobengula in 1888, obtained a royal charter incorporating the British South Africa Company to exploit the concession in 1889, and dispatched a pioneer expedition to occupy what became known as Rhodesia in 1890. Finally, the Transvaalers tried to push toward the east in order to get a port on the Indian Ocean, but, although they incorporated fresh territory, including Swaziland, they did not reach the coast, as Britain annexed Zululand in 1887 and Tongaland, the last gap, in 1895. The Afrikaner republics were thus encircled by the colonies of Great Britain and its oldest ally, Portugal—hemmed in a kraal, as Paul Kruger complained. Southern Bechuanaland was taken in by the Cape Colony in 1895; Zululand and Tongaland by Natal in 1897; but northern Bechuanaland remained a British protectorate.

Paul Kruger as president of the Transvaal

In 1883 Paul Kruger was elected president of the Transvaal. His character had been molded in the hard school of the Great Trek and of commando fighting against Afrikaner factions and African tribes; and recently he had led the opposition to President Burgers and the British. His policy was to regain complete independence for the republic and to preserve Afrikaner control of it. In 1885 he was constrained to suggest a customs union with the Cape, whose government rejected the offer. Soon afterward his financial difficulties were solved by the gold discoveries and he proceeded to use the mining industry as a milch cow, imposing heavy taxation and granting monopolies of essential materials, such as dynamite.

The growth of such an industry in the heart of his republic, however, posed serious problems. The Afrikaners became outnumbered by the newcomers who poured in from all parts of the world, most of them British subjects. To give these uitlanders ("outlanders"), as they were called, an effective vote seemed like suicide; to withhold such a vote was bound to cause trouble with the British. Kruger and the Volksraad never hesitated: they progressively raised the franchise qualifications until by 1894 no uitlander could vote in presidential elections, and only those who were 40 years old and had lived 14 years in the Transvaal, during 12 of which they had been subject to an oath of allegiance, could vote in Volksraad elections. In short, on the one hand the government got most of its revenue from the uitlanders and denied them political rights; on the other hand the uitlanders continued to swarm into the republic where many of them prospered exceedingly. Such a situation required patience. Although Kruger was reelected for a third term in 1893, his majority over the more moderate Piet Joubert was small and a change seemed likely in 1898.

But Rhodes was not patient. Finding that Kruger stood between him and a British South African federation, he planned to overthrow him. Kruger nearly played into Rhodes's hands in 1895 when, contrary to the London Convention, he tried to injure Cape trade with the Transvaal and the Cape railways that were competing with the Delagoa Bay line by making the rates over the Transvaal sector of the Cape line prohibitive and by closing the Vaal drifts to prevent the carriage of goods by wagon. But he gave way when the colonial secretary, Joseph Chamberlain, agreed to support the Cape ministry's protests, by force if necessary.

The Jameson Raid

Rhodes then pushed ahead with his conspiracy: the uitlanders were to rise, an armed force under Leander (afterward Sir Leander) Starr Jameson was to go to their assistance, and the high commissioner was to hurry to Pretoria to "restore order." Chamberlain knew of Rhodes's plans when he provided a suitable jumping-off place for Jameson's force by ceding to the British South Africa Company a strip of land along the Transvaal border of the Bechuanaland Protectorate, but he later withdrew his support when he learned that the uitlander rising would not take place to give the invasion an air of respectability. Therefore, when Jameson, contrary to Rhodes's last-minute instructions, rode into the Transvaal from Pitsani near Mafeking on December 29, 1895, he was disowned by the colonial secretary and the high commissioner. Four days later he surrendered to Transvaal commandos at Doornkop.

Outbreak of the South African War. The raid fiasco cleared the decks for the South African War. Rhodes had to resign the premiership of the Cape Colony, where, in 1898, W.P. Schreiner became head of a ministry that relied upon the support of the Afrikaner Bond, now deeply suspicious of British designs. In the Orange Free State, which had opposed the Transvaal in the drifts crisis, M.T. Steyn was elected president and formed a military alliance with the Transvaal. While Steyn and the Bond were not uncritical of the Kruger regime, Kruger's anglophobia seemed to have been vindicated in the Transvaal, where he won the 1898 presidential election by a large majority. In England, on the other hand, a parliamentary committee failed to probe Chamberlain's dealings with the raiders, a telegram from the German emperor congratulating Kruger turned Jameson and Rhodes into popular heroes, and the press paid much attention to uitlander grievances.

As the tension mounted, Chamberlain, taking the high ground of British paramountcy in South Africa, claimed to be competent not merely to control the foreign relations of the Transvaal (a right expressly granted by the London Convention) but also to intervene on behalf of the uitlanders. If the right to intervene existed, there were grounds enough for exercising it. The tendency of the Volksraad to give sweeping powers to the president was exemplified in the judges' crisis: in 1897 Chief Justice John (afterward Sir John) Gilbert Kotze delivered a judgment that meant the greater part of the laws of the Transvaal had been enacted unconstitutionally and were null and void, whereupon the Volksraad deprived the courts of the testing power and gave Kruger the power to dismiss any judge who disagreed; and the next year Kruger dismissed Kotze. In 1898 an Anglo-German agreement removed the likelihood of German intervention in the event of war in South Africa, and Chamberlain and the high commissioner, Sir Alfred (afterward Viscount) Milner, proceeded to apply the screw. In so doing they brushed aside several attempts by the Cape government and the Afrikaner Bond to avert a catastrophe.

The central issue was the Transvaal franchise. In June 1899, in conference at Bloemfontein, Milner proposed a simple five years' franchise, Kruger refused, and the negotiations collapsed. The last chance of peace was lost in August when Jan Christiaan Smuts, Kruger's young state attorney, offered a five years' franchise and Chamberlain rejected the conditions that were attached to the offer. Milner had long since made up his mind that war was "inevitable," and in September Chamberlain arranged for 10,000 British troops to be sent to augment the meagre British forces in South Africa. The republicans, who had been arming furiously for several years, replied by issuing an ultimatum that expired on October 11, 1899.

(L.M.T./R.J.Da./Ed.)

South African War. The forces were unequal from the beginning. British military strength in South Africa reached nearly 500,000, whereas the Boers were never able to muster more than about 65,000. The British, however, were hampered by their ignorance of the rough terrain. The Boers put their knowledge of the countryside to good effect and attacked the British on two fronts—from the Transvaal into Natal and from the Orange Free State into the northern Cape. The northern districts of the Cape Colony rebelled against the British and joined the Boer forces. In the course of Black Week (December 10–15, 1899) the Boers beat the British in a number of major engagements and besieged the key towns of Ladysmith, Mafeking, and Kimberley. Large numbers of British reinforcements were being landed but before the siege of Ladysmith could be relieved, the British suffered another reverse at Spion Kop (January 1900).

The British began to take the offensive under Maj. Gen. Herbert Kitchener (later Lord Kitchener) and Field Marshal Sir Frederick Sleigh Roberts. The besieged towns were relieved and the Boer armies were beaten in the field. Bloemfontein was occupied in February 1900, and Johannesburg and Pretoria were taken in May and June. Kruger left the Transvaal for Europe. But the war, which until then had largely been confined to military operations, entered upon its most destructive phase. For 15 months Boer guerrillas, under the leadership of generals Christiaan Rudolf de Wet and Jacobus Hercules de la Rey, harried the British army bases and communications; large rural areas of the Transvaal and Free State (which the British annexed as the Orange River Colony) were out of British control.

Kitchener responded with brutal retaliation against the noncombatant civilian populations and initiated a scorched-earth policy. The farms of Boers and Africans alike were destroyed, and the families of Boer guerrillas were rounded up and placed in concentration camps. More than 20,000 Boer women and children died in the carelessly run and unhygienic camps.

he Peace
ereeniging

To contain the guerrillas' actions, Kitchener's troops installed blockhouses and barbed-wire barriers along the railway lines in the Free State and later in the Transvaal. The barriers were extended across the countryside to form zones of fortification. The guerillas continued their attacks, many of them deep into the Cape Colony, Gen. Jan Smuts leading his forces to within 50 miles of Cape Town. But Kitchener's drastic and brutal methods slowly paid off. The Boers unsuccessfully sued for peace in March 1901; finally, they accepted the loss of their independence by the Peace of Vereeniging in May 1902. But the divisions and hatreds exacerbated by this war would affect South African politics for more than half a century.

(Ed.)

Reconstruction and union. After the Peace of Vereeniging, Milner, high commissioner and governor of the crown colonies—the Transvaal and the Orange River Colony—concentrated on their material reconstruction from the ravages of war. The gold mines resumed large-scale operations, and the Afrikaners were returned to their land from the prison and concentration camps and supplied with food, stock, seed, and implements, no less than £10,000,000 being spent by Great Britain on their rehabilitation. Milner also prepared the ground for political union by bringing all the colonies into a South African customs union and by amalgamating the railways of the Transvaal and the Orange River Colony.

All this work was well done by Milner and his band of able young men, who were dubbed the "kindergarten." But the opportunity was not used to emancipate the nonwhite inhabitants of the crown colonies from their legal disabilities, which remained much as they had been during the republican regime. Nor did Milner gain the confidence of the Afrikaners: they disliked him as "the man who made the war," who openly supported an agitation for the suspension of the Cape constitution in 1902, who imposed an English educational system on the crown colonies, and who was responsible for bringing Chinese labourers to the Witwatersrand gold mines in 1904. For the importation of Chinese labourers there were, indeed, strong economic reasons, because the supply of African mine labour had temporarily fallen off; but in Britain the decision played a large part in the fall of A.J. Balfour's Conservative government in December 1905, and the change of government was followed by a radical change in the distribution of power in South Africa.

Sir Henry Campbell-Bannerman's Liberal ministry, anxious to make amends to the Afrikaners for a war that had been brought about by its predecessors, decided to give the new colonies responsible government, with exclusively white electorates. The Liberals defended this decision by referring to the Treaty of Vereeniging, but it did not, in fact, debar them from allowing Coloured and Asian people to vote. Consequently in March 1907 Louis Botha, former commandant general of the forces of the South African Republic, became premier of the Transvaal, with Smuts as his right-hand man, and in December 1907 A. Fischer became premier of the Orange River Colony. The swing of the pendulum was finally completed in February 1908, when J.X. Merriman's South African Party, consisting largely of members of the Afrikaner Bond, ousted Jameson's Progressives from office in the Cape Colony.

The move
toward
union

The high commissioner, Lord Selborne, who succeeded Milner in 1905, argued the case for union in a memorandum published in July 1907, and, once in power, the three Afrikaner parties took it up enthusiastically, with the support of their oppositions. White public opinion in South Africa moved steadily in favour of union, partly out of an idealistic feeling that it was best to bury the hatchet and make a new start on a basis of white equality, and partly because an African rebellion in Natal in 1906 led many to think union essential for white security; some, moreover, saw in union the best way of guarding against any further British interference in South African affairs. There were also compelling economic reasons for union: the four colonies were interdependent and yet, without political union, their material interests were so divergent that the customs union seemed almost certain to collapse.

Accordingly a national convention, comprising 30 members appointed by the four colonial parliaments and three nonvoting members from Rhodesia, met in 1908 and 1909 under the chairmanship of Sir (afterward Baron) John Henry de Villiers, chief justice of the Cape. A constitution was drafted and unanimously approved by the convention and it was carried with scarcely any dissentients in the parliaments of the Cape Colony, the Transvaal, and the Orange River Colony, and by a three-to-one majority of the electorate in a referendum in Natal. It was enacted by the British Parliament in September 1909, substantially as it had been submitted to the British government by delegates from South Africa. The South Africa Act came into force on May 31, 1910, and the four colonies became the provinces of the Union of South Africa.

The convention, except for the Natal members, wanted a close union and complete flexibility, and they were largely successful; the principal feature of the South African constitution was the grant of power to Parliament to legislate on practically every subject by simple majorities in each house. Nevertheless, on two subjects they did not grant

Parliament such extensive powers. First, the Afrikaner members wanted special protection for the section which gave Dutch (to which Afrikaans was added in 1925) equal status with English as an official language of the Union. Second, the convention could not agree on a uniform franchise for the Union, the Cape delegates favouring a colour-blind franchise and the others a rigid colour bar. Eventually a compromise was reached whereby the franchise qualifications were to remain as they were in each province and the established franchise rights of the Cape nonwhites were specially protected. Accordingly, the sections on language equality and the Cape nonwhite franchise were to be amended only with the approval of two-thirds of the members of both houses of Parliament in a joint sitting. The act also made it possible for Rhodesia to join the Union on terms to be approved by the Privy Council and for the High Commission Territories of Basutoland, the Bechuanaland Protectorate, and Swaziland to join on terms laid down in a schedule, but only with the consent of the imperial government, which had special commitments to their African inhabitants.

THE UNION AND THE REPUBLIC

The race issue. The dominating factor in the history of South Africa has been the exceptionally complex character of the population. In 1910 there were nearly 6,000,000 inhabitants, of whom 21.5 percent were whites, 67 percent Africans, 9 percent Coloureds, and 2.5 percent Asians. By 1960 there were 16,000,000 of whom 19.3 percent were white, 68.3 percent Africans, 9.4 percent Coloureds, and 3 percent Asians. In 1910 the whites included an Afrikaner majority, mainly rural, and a British minority, mainly urban. Between them they owned most of the land and the capital, did most of the skilled work, and possessed 93 percent of the votes.

Living conditions of Africans

The Africans were still predominantly tribal rather than modern in culture, but, as a result of their conquest and of white missionary activity and economic enterprise, there was already a distinct trend toward the disintegration of tribalism. Although most Africans still had homes of sorts in the reserves, those were scattered lands that amounted to only one-fourteenth of the area of the country and by no means provided them all with a livelihood; consequently, many Africans went out to earn wages on white farms and in the towns. Moreover about 1,000,000 Africans had long been established as squatters on white farms and a few were already completely urbanized. The Africans were subject to pass laws, which restricted their movements outside the reserves, to Masters and Servants laws, which made breach of contract a criminal offense in many types of employment, to special taxation, and to other special laws. These laws varied from province to province, and in the Cape about 7,000 African voters were exempted from some of them.

The Coloureds were European in culture. Most of them lived in the Cape Province, where their legal status was that of the whites, and about 14,000 were voters, whereas in the other provinces they were subject to discrimination.

The Asians were mainly the product of the indentured Indian immigration scheme to Natal, where they outnumbered the whites and were subject to special laws, including a £3 tax. They were excluded from the Orange Free State, but about 11,000 had settled in the Transvaal, where, too, they came under special laws.

The policies of South African governments differed on many important issues; but all, being responsible to a predominantly white electorate, stood more or less explicitly for "the maintenance of white supremacy," a task that became increasingly difficult as a result of the rapid tempo of economic development in South Africa and the change in the balance of power and the climate of public opinion elsewhere.

The Botha–Smuts regime (1910–24). In 1911 the Afrikaner parties of the former colonies merged to form the South African Party, which, under Botha and Smuts, governed the country until 1924. Botha and Smuts had been zealous fighters for republican independence so long as there was a chance of success, but they were realistic enough to accept the inevitable at Vereeniging and imaginative enough to see great prospects for South Africa when the hot mood of British imperialism had spent itself. By 1910 they hoped for the coalescing of the British and Afrikaner elements into a white South African nation that would freely cooperate with the British Commonwealth in peace and in war. The ideal went too far, however, for the more conservative Afrikaners, who were concerned with preserving their group identity, and not far enough for the more self-conscious nonwhites, for whom it implied a permanently inferior status.

The government wished to keep most of the Africans in the reserves to prevent the whites from being swamped, and to use African manpower as the unskilled base of all forms of economic enterprise—objectives that involved certain contradictions. As the Africans became more accustomed to a money economy, some of them were liable, unless checked by law, to compete successfully with the less efficient whites. This was already happening in the gold-mining industry, and laws were passed in 1911 to preserve the racial hierarchy in that industry. Such competition was also happening in some rural areas, where Africans were pooling their resources to buy more land; a Natives Land Act was passed in 1913 to limit the areas within which such purchases could be made. Neither of these acts was wholly effective. In 1916 a commission reported that if the policy of territorial segregation was to be carried out the reserves should be substantially increased in size, but little was done about it because the whites were not prepared to make the necessary sacrifices.

Gandhi's nonviolent resistance against £3 tax

The Asian question had reached a more crucial phase. Already before union Mohandas K. Gandhi had organized nonviolent resistance against the Transvaal government, and after union he resumed the struggle against the £3 tax in Natal. As a result the Indian government stopped the importation of indentured Indian labourers in 1911 and the £3 tax was removed in 1914. By that time the pattern of later disputes had developed: the Union government regarded the Indians as temporary visitors and tried to persuade them to return to India; and most of the Indians regarded themselves as permanent residents and demanded full rights of citizenship.

The conservative Afrikaners had found their leader in J.B.M. Hertzog. Although he had joined the Botha Cabinet in 1910, Hertzog regarded his colleagues' policy as liable to cause the Anglicization of the Afrikaner people, and he publicly advocated a different, "twin-stream" policy, which led to his exclusion from a reconstituted Cabinet in 1912 and to the foundation of the Nationalist Party. When in 1914 the government unhesitatingly took the part of Great Britain in World War I and Parliament voted funds for the conquest of German South West Africa, a number of former republican generals, some of whom held appointments in the South African defense force, came out in rebellion to avenge Vereeniging. After mastering the revolt, Botha took command of the South West African expedition and forced the Germans to capitulate on July 9, 1915. South African volunteer contingents also fought in East Africa and on the Western Front in Europe and many individuals joined British units. Smuts, after serving as commander in chief in East Africa, did notable work in the British War Cabinet. In July 1919 he and Botha, on behalf of South Africa, signed the Treaty of Versailles and the covenant of the League of Nations, under which South West Africa became a Union mandate. Back in South Africa Botha died before August was out, and Smuts, succeeding to the premiership, faced the discontents caused by thwarted Afrikaner nationalism, a steep rise in the cost of living, and industrial troubles.

Smuts as premier

As early as 1907 Smuts had intervened on the side of the employers in a strike of white workers on the Witwatersrand, and in 1914 he had ended another strike by declaring martial law and illegally deporting nine strike leaders. After the war there was a serious crisis. In December 1921 the Chamber of Mines, faced with rising costs and a fall in the price of gold, decided to organize the industry more rationally by using Africans for semiskilled work. There was a violent reaction by white labour, which Smuts suppressed at a cost of 230 lives. The result was that, although the threat to relax the colour bar was not carried out, the Labour Party, representing the aggrieved white workers, made an electoral pact with the Nationalists. In the hope of redressing the political balance Smuts wooed the Southern Rhodesian electorate to accept incorporation in the Union, but when a referendum was held on the issue in 1922 they preferred to remain separate. Two years later the South African Party was heavily defeated at the polls and Hertzog became premier of a Nationalist–Labour coalition.

Hertzog's nationalist policy (1924–33). Hertzog's main objectives were to complete the emancipation of South Africa from imperial control and to provide greater protection for the whites from the Africans and for the Afrikaners from the British. He played a notable part in the events leading to the Balfour Report (1926) and the Statute of Westminster (1931), which gave statutory definition to the established convention that the British government could not exert authority over a dominion. South Africa's sovereign status was also asserted by the adoption, after a long and bitter controversy, of a distinctive national flag (1927), by the appointment of ambassadors to Italy, the United States, and The Netherlands (1929), and by the separation of the office of governor-general, the head of the South African government, from that of high commissioner, the representative of the British government in South Africa (1931).

Economic nationalism was fostered by the foundation of a state-controlled iron and steel works at Pretoria, by increased protection for agriculture and industry, by a reduction in imperial preferences, and by a commercial treaty with Germany. White supremacy was bolstered by the provision of sheltered employment for "poor whites" in state enterprises; by a Mines and Works Amendment Act (1926), which was more effective than its predecessor in shutting Africans out from skilled mining trades; by a Native Administration Act (1927) and a Riotous Assemblies Act (1930), which gave the executive wide powers over individuals; and by franchise acts (1930–31), which extended the vote to all white men and women, while they left the Cape nonwhite vote as before, restricted to men who possessed property and educational qualifications. Hertzog's legislative program was still incomplete when the world depression undermined the prosperity of the country and the popularity of the government, which continued to cling to the gold standard after Great Britain had abandonded it in 1931. After the government, yielding to pressure from some of its own supporters, left the gold standard in December 1932, there was a fairly rapid economic recovery, but political confusion continued until, in 1933, Hertzog and Smuts formed a coalition government that secured overwhelming support from the electorate.

Hertzog–Smuts regime (1933–39). The coalition was based on a great deal of common ground between Hertzog and Smuts. Consequently, in 1934 the two major parties fused to form the United Party; but Hertzog failed to carry with him a small group of Afrikaner irreconcilables, led by D.F. Malan, who formed the Purified Nationalist Party, while C.F. Stallard at the other extreme dissociated himself from Smuts and formed the Dominion Party. By then the constitutional settlement had been completed by the Status Act and the Seals Act (1934), which secured, so far as words could do, that South Africa was master in its own house. The government then proceeded to complete Hertzog's segregation legislation. A Representation of Natives Act (1936) removed the Cape Province African voters from the common roll and gave them the right to elect three white members to represent them in the lower house, gave the Africans throughout the Union the right to elect four white senators, and created a Natives' Representatives Council with advisory powers. A Native Trust and Land Act (1936) provided for a considerable increase in the size of the reserves. A Native Laws Amendment Act (1937) authorized the executive to prevent more Africans from entering the towns and to compel municipalities to segregate African from white residents. It was Hertzog's hope that the enlarged reserves would become capable of maintaining almost all the African people, so that those who worked for whites could be regarded as temporary visitors from the reserves. But it is notable that he saw the need for consultation with an African council, and that he did not try to discriminate against the Coloureds. Moreover, his government expanded the social services not only for the whites but also for the nonwhites; there was, for example, a considerable increase in government grants for education.

gregation
gislation

Nevertheless, Africans, Asians, and Coloureds were becoming disturbed by the great contrast between their living standards and those of the whites and by an accumulation of laws that caused 500,000 Africans to be convicted of statutory and municipal offenses in a year. As tension began to mount, the Nationalists claimed that "white South Africa" would not be safe unless the restrictions on Africans were increased and the Coloureds were also segregated from the whites. Though Hertzog strongly disagreed, the Nationalists were able to profit from the celebrations held to mark the centenary of the Great Trek in 1938, when they appealed to all Afrikaners to remain true to the principles of the Voortrekkers and of Paul Kruger, placing special emphasis on their race attitudes.

World War II. The outbreak of World War II caused a crisis in South Africa. Although Hertzog and Smuts had cooperated successfully, they differed widely on foreign affairs. Hertzog took an indulgent view of Nazi Germany, believed that its expansion was no concern of South Africa, and moved in the House of Assembly, on September 4, 1939, that South Africa should remain neutral. Smuts, keenly aware of the wider implications of Nazism, maintained that it was the interest and the duty of South Africa to support Great Britain, and he won the crucial division by 80 votes to 67. On September 5 Smuts formed a ministry with the support of the Labour Party, the Dominion Party, and the majority of the United Party, and war was declared on Germany.

South
Africa's
support of
the Allies

The Smuts government concentrated its energies on the war. About 200,000 white men (more than half of them Afrikaners) and 125,000 nonwhites (mainly Africans and Coloured men) joined the forces, and many of them served with distinction in the Ethiopian, Mediterranean, and Madagascan theatres of war. The nonwhites were not allowed to bear arms but were distributed among the combatant units, for whom they performed vital work as stretcher-bearers, labourers, etc. Industry was efficiently switched to the production of munitions and clothing for military purposes. Smuts himself remained in close contact with Winston Churchill and watched carefully the strategy of the war, often leaving his able lieutenant, J.H. Hofmeyr (1894–1948), to carry a lion's share of the burden of administration.

South Africa's achievements were impressive, considering the strength of the opposition to the war. Fortunately for the government, the opposition splintered into fragments during the most critical period: J.F. van Rensburg's Ossewabrandwag (Guard of the Ox Wagon) and Oswald Pirow's New Order, accepting the racial doctrines of the Nazis and their contempt for parliamentary government, patently hoped to profit from a Nazi victory; the Malanites expounded the ideal of an Afrikaner republic in which, as in Kruger's republic, the British would not necessarily have political rights; while the Hertzogites stood firm by their principle of equality among the whites. In the first flush of his disappointment, indeed, Hertzog led his defeated minority from the United Party to join hands with Malan and form the Reunited Nationalist Party, but the reunion was not a happy one and before the end of 1940 Hertzog had been driven out for his tenderness toward the British. His colleague, N.C. Havenga, subsequently founded the Afrikaner Party to maintain his ideals.

The general election of 1943 was a victory for Smuts in that his prowar coalition secured a majority of 67 seats in a lower house of 153; but it was also in a sense a victory for Malan's Nationalists, who won all the 43 opposition seats. Thereafter, as the prospect of a Nazi victory faded, the Nationalists consolidated their position as the political instrument of self-conscious Afrikanerdom, absorbing elements from the Ossewabrandwag, the New Order, and the Afrikaner Party, and drawing support from a variety of cultural and economic organizations, including the Broederbond, a secret group of Afrikaner elite.

As the war drew to a close Smuts drafted the preamble to the United Nations Charter signed at San Francisco in 1945 and returned to mold postwar South Africa along the lines of a generous demobilization scheme, an expansion in the social services for all races, a planned development of agricultural, mineral, and industrial resources, and large-scale white immigration.

Industrial expansion in South Africa. Subsequent events can be understood only in relation to the fact that from about 1938 onward South Africa was experiencing an industrial expansion as intense as the British industrial revolution of the early 19th century, with the added complication of racial differences between the unskilled workers on the one hand and the skilled workers, the capitalists, and the majority of the electorate on the other. The way had already been paved by the rise of the mining industries and by the foundation of many manufacturing industries during World War I and the 1930s; the rate of expansion increased during and after World War II. In the 24 years between 1936 and 1960 the total population increased by 67 percent. In the 28 years between 1935 and 1963 the geographical national income at current prices increased more than eightfold (the value of mining production fivefold, of agricultural production sixfold, and of manufactures thirteenfold). In the same period the price index increased by two and a half times; so that, even allowing for the change in the value of money, the growth of manufacturing industries was remarkable.

The gold-mining industry continued to play an important role in the South African economy, especially in easing the balance of payments problem. Fears that the supply of gold would soon be exhausted were removed by the opening up of new mines on the Far West Rand and in the Orange Free State, where production started in 1951. Nevertheless, gold production did not increase as rapidly as other industries and the relative importance of gold mining decreased as the economy became more diversified. The mining industries continued to be organized on racial lines, and the manufacturing industries adopted a similar basis. Skilled work remained virtually a white monopoly and was well paid; most of the unskilled work continued to be performed by nonwhites for low wages.

Relative importance of gold mining

As a result of this expansion more than four-fifths of the white population were townsmen by 1960, the "poor whites" were absorbed by industry, and the earlier economic distinctions between the Afrikaners and the British inhabitants became blurred. Industry also attracted many nonwhites. More than 3,500,000 Africans (nearly a third of the total African population) were in the towns at the time of the 1960 census. Into some of these towns the influx was so rapid that housing and other amenities were grossly inadequate and there was much crime. But in spite of low wages and squalid living conditions, the urban Africans earned far higher incomes than the rural Africans did.

The 1948 election. As the 1948 election approached, disturbing facts were becoming known in South Africa. Although the reserves had been enlarged under the 1936 act, only 40 percent of the African population was to be found in them at the time of the 1946 census. The Social and Economic Planning Council reported that the quality of the reserve lands was deteriorating; and early in 1948 a commission revealed that many Africans were becoming permanent inhabitants of the towns. These facts did not square with the argument that the Africans had adequate homes in the reserves and could therefore be treated as inferiors elsewhere. Moreover the Natives' Representative Council was frustrated because the government ignored its advice, and the African National Congress, which had been cautious since its foundation in 1912, was now demanding the removal of discriminatory laws in terms of the ideals of the United Nations. This raised the question of whether white supremacy, which had developed in the simple pastoral economy of the 18th century, could be maintained in the industrial economy of the 20th century.

Demands of the African National Congress

The Smuts government continued to profess adherence to the segregation policy but tried to deal with practical grievances in a conciliatory spirit, while Hofmeyr went further than his colleagues on occasion, feeling toward a policy that might be acceptable to all races. But Asians were protesting vigorously against legislation that prevented their buying or occupying new premises in Durban, and the Indian government attacked South Africa in the United Nations General Assembly. Consequently, when Smuts tried to persuade the assembly in 1946 to allow the Union to incorporate South West Africa, he met with a rebuff, and the assembly passed the first of a series of resolutions condemning racial discrimination in South Africa.

The Nationalist leaders wished to reduce South Africa's links with Britain, the Commonwealth, and the United Nations, to advance the power of the Afrikaner people, and, above all, to preserve white supremacy by every possible means. They expressed horror at the "liberalism" of the United Party, declared it would cause the "suicide" of white South Africa, and proclaimed a policy of apartheid, according to which whites, Coloureds, Asians, and Africans would be separated from each other and each race would be able to "develop along its own lines in its own area." Though as far as the Africans were concerned this was little more than Hertzog's segregation policy in a new dress, it was presented to the electorate as something new and dynamic. The Nationalists also exploited the discontents caused by wartime controls and were assisted by the fact that the electoral system favoured the rural voters. The result was that in May 1948 Malan, with the assistance of Havenga's small Afrikaner Party, was able to form a government, with a majority of five in the House of Assembly. This result, which was a surprise to Malan as well as to Smuts, was decisive for South Africa.

Nationalist Party policy from 1948. After the 1948 election the Nationalist Party consolidated its power, absorbing the Afrikaner Party and gaining strength in the House of Assembly in each election—from 73 seats in 1948 to 94 in 1953, to 103 in 1958, to 105 in 1961, and to 126 (in a larger House) in 1966. The process was promoted by legislation and administrative action: Smuts's immigration scheme was scrapped; British immigrants, like others, were required to wait several years before they could vote; the white people of South West Africa were given six seats in the House of Assembly; the voting age was lowered to 18; and the Coloured voters were given separate and limited parliamentary representation and the representatives of the Africans were removed from Parliament. Nationalist power was also promoted by the strong leadership of the prime ministers Malan (1948–54), J.G. Strijdom (1954–58), and H.F. Verwoerd (1958–66). The United Party, led by J.G. Strauss after the death of Smuts in 1950 and by Sir D.P. de Villiers Graaff from 1956, remained the main opposition party, but it lost seats at each election and suffered from secessions on both flanks. Several new parties were founded, including a Liberal Party and a Progressive Party, but they had little success at the polls and the former party has since been disbanded. The first indication of possible change came in 1970 when the Nationalist Party lost nine seats in a general election. The Nationalist Party, however, still retained more than 70 percent of all seats in the assembly (117).

The Nationalist governments enacted a mass of racial legislation to preserve white supremacy. They created a population register to fix the racial category of every South African. They made marriages and unions out of wedlock between whites and nonwhites unlawful. They systematically divided the towns as well as the rural areas into zones in which members of only one race could own or occupy property or conduct business. They assumed control over African and Coloured school education, eliminating the mission schools. They excluded nonwhites from the established universities and founded separate colleges—one each for Coloureds, for Asians, for Xhosa, for Zulu, and for Sotho. They intervened in the labour-union movement to separate white from nonwhite. They gave officials sweeping powers to remove "undesirable" Africans from towns. They extended the practice of reserving particular types of jobs for whites. They enforced segregation where it did not previously apply, as in buses, trains, post offices, libraries, motion-picture houses, and theatres in the Cape Peninsula. White and nonwhite South Africans could thus rarely meet, except as masters and servants or rulers and subjects.

Nonwhites were almost totally excluded from the authoritative political system. After a long struggle the Cape Coloured voters were removed from the common voters' roll and given the right to elect four whites to represent them in the House of Assembly. At first the government lacked the two-thirds majority laid down in the South Africa Act for such legislation and, therefore, in 1951 attempted to pass it through Parliament by the ordinary simple-majority procedure. It was declared invalid by the Supreme Court. Under a further act the Nationalist members of Parliament then sat as a high court and reversed the judgment, but the Supreme Court held that the "high court of Parliament" was itself invalid. Eventually the Senate was enlarged and its composition changed to give the Nationalists 77 seats out of 89 in 1955. Coloured voters were then removed from the common roll by the necessary two-thirds majority in a joint sitting of both houses.

In 1959 the representatives of the Africans were removed from both houses of Parliament and the Cape Provincial Council. The House of Assembly then contained 156 whites elected by the white voters of the Union and South West Africa and four whites elected by the Cape Coloured voters. In 1960 the Senate contained 43 whites elected by white electoral colleges and 11 nominated by the government. All provincial councillors were whites elected by white voters, except two in Cape Province who were elected by Coloureds. Thus the compromise embodied in Hertzog's 1936 legislation was destroyed.

The only nonwhites who had any say in the composition of the Parliament or of the Provincial Councils were the Coloured people of Cape Province, and their say was meagre. Instead, nonwhites were given various types of segregated subordinate institutions. For the Africans there was a system of "Bantu authorities" in the Bantu areas, consisting mainly of chiefs, councillors, and their nominees. In the Transkei, the largest Bantu area, a Legislative Assembly, with a majority of chiefs ex officio and a minority of members directly elected by Africans, and a cabinet and prime minister responsible to the assembly were established in 1963. Such bodies had powers in defined fields, subject to the overriding authority of the government of South Africa. In the towns some Africans could elect members of Bantu urban councils. An advisory Coloured Persons Representative Council with an elected majority was established in 1964.

The Nationalists were able to transform South Africa into a republic after a national referendum in 1960 narrowly approved a new constitution that reflected the change. In March 1961 Verwoerd asked a Commonwealth prime ministers' conference whether South Africa might remain a member of the Commonwealth when the change took place, but he withdrew his request when other members of the conference criticized his government's racial policies. Consequently when South Africa became a republic on May 31, 1961, it left the Commonwealth. The republican constitution was substantially the same as the constitution of the Union, except that an indirectly elected state president replaced the British monarch and the governor-general as head of state.

Internal opposition to Nationalist rule. In spite of all the separatist laws the peoples of South Africa were becoming more and more interdependent as a result of the economy's continuous growth, and many South Africans, white as well as nonwhite, opposed the government's racial policies.

African opposition was more serious. The leaders of the African National Congress (ANC), with the cooperation of Coloured and Asian congresses and small white groups, organized a series of campaigns to elicit the support of the African masses and to intimidate the government into making concessions. In 1952–53 several thousand people, mainly Africans, deliberately courted arrest by "passive resistance to unjust laws." For 10 weeks in 1957, 45,000 Africans walked many miles each day to work in Johannesburg and Pretoria rather than pay increased bus fares. There were also intermittent riots and clashes with the police in many parts of the country. These reached a high point in 1960 when the Pan-Africanist Congress (PAC), a radical offshoot of the ANC, organized demonstrations against the pass laws; at Sharpeville, near Johannesburg, the police opened fire against demonstrators, killing 69 Africans and wounding 178. Blood was also shed in Cape Town and elsewhere. Between 1959 and 1961 there was a revolt against the Bantu authorities system in the Transkei.

Parliament enacted many laws to help the executive break the revolutionary opposition. The nonviolent resistance campaign of 1952–53 was called off in the face of harsh new penalties for protest actions, and in 1960 order was restored by the declaration of a state of emergency. The Transkei revolt was handled under proclamations giving extraordinary powers to chiefs and white officials. General Law Amendment acts allowed the executive to outlaw any organization and to ban persons from attending meetings or publishing statements and to arrest and hold them incommunicado without trial. The ANC and the PAC were banned in 1960, and by the end of 1964 all known revolutionary leaders were in prison or exile, and all known revolutionary organizations had been outlawed.

Foreign opposition. The governments of the newly independent African states wished to complete their revolution by destroying the last strongholds of white supremacy in Africa. Although they had the diplomatic support of the Asian and Communist countries, they did not have the resources to coerce South Africa without the cooperation of South Africa's principal trading partners—Britain, western Europe, and the United States. They therefore tried to use the United Nations as an instrument of coercion. The General Assembly had condemned South Africa's racial policies since 1948; the Security Council since 1960. In 1962 the assembly, by majority vote, called on member states to apply economic sanctions against South Africa and to break off diplomatic relations; in 1964 the Security Council set up an expert committee to consider the feasibility of sanctions. Britain, France, and the United States, although subscribing to many resolutions criticizing apartheid, did not commit themselves to coercion. In the mid-1960s, when the UN was financially weakened and the major powers were distracted by the conflict in Vietnam, the prospect of a UN blockade of South Africa diminished. By then South Africa had well-equipped and well-trained military forces, consisting of about 125,000 white men, who could be rapidly mobilized and who were capable of overcoming any but a very large-scale attack.

UN call for
economic
sanctions
against
South
Africa

In October 1966 the UN General Assembly voted to revoke South Africa's mandate over South West Africa. The UN Council for South West Africa voted in 1968 to rename the territory Namibia. Renewed pressure on South Africa to relinquish its administration of South West Africa came with a ruling of the International Court of Justice against South Africa in 1971.

(L.M.T./R.J.Da./Ed.)

South Africa since the mid-1960s. Verwoerd, the prime minister, was assassinated in September 1966 and was succeeded by B.J. Vorster, a member of the Nationalist Party's extreme right wing. Under Vorster, restrictions against the nonwhite populations were tightened, and segregation was even more strictly enforced. This led to increasing unrest among the Asians and Coloureds as well as Africans, who saw even the small rights they possessed being stripped away. The UN moved repeatedly to isolate South Africa from the world community. Vorster further alienated world opinion by his deployment of South African troops to fight the Soviet-backed Popular Movement for the Liberation of Angola (MPLA) in the Angolan civil war.

In mid-June 1976 the worst race riots in South African history broke out in Soweto (South-Western Townships), the residential area reserved for Africans near Johannesburg. The riots began when African students marched in protest against a new rule that made Afrikaans the compulsory language of instruction in African schools. The police responded with tear gas and made mass arrests, and fighting erupted. After nearly three weeks of constant battle, massive destruction of property, and increasingly repressive police action, the riots were finally suppressed.

Along with increasing internal dissent, South Africa faced further conflicts on the question of independence for

Namibia. A main point of contention with Namibia was control over Walvis Bay, which was finally conceded to South Africa on September 1, 1977. But as independence talks continued without any tangible results, the South West Africa People's Organization (SWAPO), representing Namibia, conducted guerrilla raids into South Africa. In March 1990 Namibia gained its independence. (For further treatment of Namibia, see SOUTHERN AFRICA.)

P.W. Botha, a prominent Nationalist, became prime minister in 1978 upon Vorster's retirement. The decision to draft a new constitution that would extend the franchise to the Coloured and Asian population caused a split in the National Party, resulting in the formation of the new Conservative Party, which objected to alterations in the current system. The new constitution was enacted in 1983 and implemented in September 1984. In addition to extending the franchise, it created a tricameral parliament, each house being elected separately by the white, Coloured, and Asian voters. Criticism of the constitution came from both the right and the left; the right objected to the relinquishing of complete political control, while the left asserted that the constitution further entrenched apartheid and failed to provide representation for the majority black population. The United Democratic Front, a coalition of some 30 multiracial organizations, organized boycotts against the elections of the Coloured and Asian parliaments, and voter turnout was less than 31 percent for both elections. The implementation of the constitution sparked riots and killings in the black townships. Conflict intensified until a state of emergency was declared in July 1985. Violence continued, however, and except for a short period in 1986, the state of emergency was maintained throughout the rest of the 1980s. Many countries enacted economic sanctions against South Africa to condemn the government's actions, and the lack of confidence abroad caused the rand to fall and investment to slacken.

The constitution of 1983

In 1989 Botha, after suffering a stroke, resigned and was replaced by Frederik W. de Klerk, a former minister of finance. Leading the National Party in the September 1989 elections, de Klerk campaigned for negotiations on a new constitution with leaders of all racial groups, including those of the African community. While the Nationalists held onto a majority in the all-white House of Assembly, they lost significant support to the Conservative Party and the newly formed liberal Democratic Party. In early 1990 de Klerk announced that the Separate Amenities Act, as well as prohibitions and restrictions on more than 60 political organizations—including the ANC, PAC, and the South African Communist Party—would be rescinded. Nelson Mandela, the leader of the ANC who had been in jail since 1962, was released and began negotiations on political change with the government.

Cape of Good Hope

PHYSICAL AND HUMAN GEOGRAPHY

Cape of Good Hope, or Cape Province—officially Kaapprovinsie in the Afrikaans language—is situated on the southern extremity of the African continent and is the largest of South Africa's four provinces. The name Cape of Good Hope, while specifically referring to the promontory about 30 miles (48 kilometres) south of Cape Town, officially applies to the entire province. Occupying the southern and western region of the republic, the province has an area of 278,381 square miles (721,003 square kilometres), including the territory of the three republics, Transkei, Bophuthatswana, and Ciskei, within its borders and the exclave of 434 square miles around Walvis Bay on the coast of Namibia. In addition, 1,476 square miles of territory were transferred from Griqualand East to Natal Province in 1978. Cape Town, the provincial capital and the legislative capital of the republic, is the largest city.

The land. *Relief.* Most of the province lies at an altitude of between 3,000 and 5,000 feet (900 and 1,500 metres) above sea level, occupying part of the great interior plateau of southern Africa. The edges of the plateau form conspicuous escarpments that trend southward from the Namaqua Highlands in the northwest to the Roggeveldberg in the southwest and from there eastward as the Nuweveldberge, Sneeuberg, and Stormberg mountains until the southern end of the Drakensberg escarpment is reached. These escarpments separate the plateau from a coastal zone with a varied relief in the west and from the broad basins of the Doorn Karoo and the Great Karoo plateaus to the southwest and south. Across the southern part of the province a series of sandstone ranges of equal height enclose the elongated basin of the Little Karoo, running approximately parallel to the south coast. At the western end of these ranges, a complex of similar ranges runs northward from Cape Hangklip, southeast of Cape Town, to the Bokkeveld, about 200 miles to the north. Lowlands, between the mountains and the coast, are narrow and discontinuous, apart from a strip 10 to 50 miles wide between Mossel Bay and Cape Agulhas (the southernmost tip of the African continent) and an area 20 to 60 miles wide between False Bay (immediately south of Cape Town) and St. Helena Bay (about 100 miles to the north).

Climate. Maritime influence on the climate is restricted to the coastal fringe. Over most of the province the mean annual precipitation is less than 15 inches (380 millimetres), and large areas in the northwest receive less than 5 inches. Years of drought are common. Only the southwestern and southern margins receive more than 25 inches of precipitation, mostly in the form of rain resulting from winter cyclones in the southwest, and summer rain resulting from easterly winds beyond Mossel Bay on the south coast. In the interior most of the rain is from summer thunderstorms; the occasional winter rains and the rarer snowfalls are associated with the passage of cyclones. Solar radiation is intense at all seasons, because of the latitude, the elevation, and the usually clear skies; inland mean daily maximum temperatures usually range from 65° F (18° C) in winter to 90° F (32° C) in summer. Frost occurs on more than 60 nights a year; the frostless season lasts for less than 240 days on the southern margin of the Upper Karoo. Snow occasionally mantles all the higher mountain peaks, and only the coastal zone is frost-free.

Droughts

Plant and animal life. The vegetation is predominantly xerophytic (adapted for growth under dry conditions). Thornbush savanna (parklike grassland) occurs in the north, while low-growing Karoo bush vegetation, typified by many species of plants adapted to semidesert conditions, occurs south of the Orange River. Desert shrub and succulents (juicy plants) are found in Namaqualand in the northwest. In the southwestern region, where winter rainfall occurs, the sclerophyll bush (characterized by plants with thickened hardened foliage) is extremely rich in endemic species. Indigenous forest, predominantly evergreen, is found only on the south coast between Mossel Bay and Algoa Bay and on the southern slopes of the Amatole Range, to the northeast of Algoa Bay, where rain occurs at all seasons; farther east it passes into grassland and, in the coastal zone, into xerophytic low forest and bush.

Immense herds of springbok and other antelope, wildebeest (gnu), and zebra formerly ranged the interior, while hippopotamuses were found in all the perennial rivers, and elephant and rhinoceroses roamed the coastal zone from Natal in the east to the Olifants River in the west; lion, leopard, and other carnivores were ubiquitous. Though many local place-names recall this rich and varied animal life, today, apart from the smaller species, it has mostly disappeared except in a few scattered game reserves, in some sparsely settled areas where a few springbok still roam, and in some remote mountain areas where the rare leopard preys on the few surviving baboons. Birdlife, however, remains numerous and varied. Along the coast, particularly in the west, cormorants and other seabirds abound, while inland each vegetation zone is associated with its own characteristic birds, including, in summer, great numbers of migrants from the Northern Hemisphere.

The people. The government recognizes four population groups: Cape Coloureds (of mixed descent, principally

Khoi, white, and Indonesian), Africans, whites, and Asians (mostly Pakistanis and Indians). About three-fourths of the population lives in the urban areas of the four largest cities: Cape Town, Port Elizabeth, Kimberley, and East London. Most of the province is sparsely populated. The highest rural population densities are in a coastal zone from St. Helena Bay to East London and in a few irrigated areas inland, notably along the Vaal and Orange rivers.

frikaans, nglish, hosa, and otho

Official languages are Afrikaans and English. Afrikaans, a derivative of Nederlands (the official name of the Dutch language), is the first language of more than half of the whites and provides a powerful cultural bond for Afrikaners. It is also the first language of nearly 90 percent of the Coloureds; the remaining whites and Coloureds are English-speaking. Xhosa is the language of 80 percent of the Africans, Tswana (mainly in the northern interior) and Sotho of most of the remainder.

More than half of the whites and a third of the Coloureds belong to the Nederduits Gereformeerde and allied churches (Dutch Reformed churches); about a fourth of these groups belong to Anglican or Methodist churches. Malays, constituting about 10 percent of the Coloureds, are adherents of Islām. Two-thirds of the Africans are Christian, more than a fifth being Methodists and lesser numbers members of independent churches.

The economy. *Resources.* Mineral resources are extensive, but mining employs relatively few people. Copper has been mined in Namaqualand since 1852, and diamonds in Griqualand West since 1870. Since 1928 diamonds also have been recovered in Namaqualand from deposits on coastal terraces and, more recently, from submarine deposits offshore. Blue asbestos is mined in a zone extending northward from Prieska to beyond Kuruman. Enormous reserves of manganese and high-grade iron ores also are found in Griqualand West; in 1976 a 540-mile railway was completed from Sishen to a new iron-ore-loading terminal accommodating 250,000-ton vessels at Saldanha Bay.

Agriculture and fishing. Although the economy is fairly diversified, farming remains of paramount importance. In a normal year, of South Africa's total farm production, two-thirds of the wheat and wool, 70 percent of the alfalfa (lucerne) hay, most of the mohair, the deciduous fruit, and the grapes, and all of the wine are produced in the Cape. Sheep are raised in the Karoo and cattle in the thornveld north of the Orange River. Alfalfa, sultanas, and cotton are grown under irrigation along the Orange River near Upington; alfalfa and peanuts (groundnuts) are grown in the Harts Valley. Ostriches still graze in the Little Karoo, but alfalfa seed, hay, fruit, tobacco, wool, and mohair have long surpassed ostrich feathers in importance. In the winter rainfall region the lowlands are given over to grain cultivation, sheep raising, and dairy farming, the foothills to vineyards and orchards, and the upland basins to deciduous fruits. These activities support a lively export trade in fresh fruit, table grapes, wine, brandy, and canned goods. In the higher rainfall areas, particularly between Mossel Bay and Humansdorp on the south coast, extensive timber plantations have been established; farther east, citrus fruit is grown under irrigation in the valleys of the Gamtoos, Sundays, Great Fish, and Kat rivers. Chicory and pineapples are produced between Algoa Bay and East London.

Rich fishing grounds lying offshore from the Agulhas Bank to Namibia are actively exploited by South African and foreign vessels, supplying an important fish meal and canning industry.

Industry. Industries include food processing, marine engineering, ship repairing, and the manufacture of textiles, clothing, footwear, motor vehicles, tires, agricultural fertilizers, pesticides, mining explosives, and pharmaceuticals.

Transportation. Harbours and public rail, road, and air transportation services are operated mainly by the South African Railways and Harbours Administration and its subsidiary, South African Airways. Ships drawing up to 40 feet can berth at Cape Town and Port Elizabeth, and ships drawing up to 35 feet at East London; there are two graving docks at Cape Town (one more than 1,000 feet long) and another at East London. Port Elizabeth has ore-loading facilities for iron and manganese, and there are grain elevators at Cape Town and East London. There is an extensive railroad and highway system. South African Airways operates air services linking the port cities and Kimberley to Bloemfontein, Johannesburg, Pretoria, and Windhoek and also international services to Europe, Australia, South America, and the United States.

Administrative and social conditions. *Government.* Administrative authority is shared by the province and the republic, though most functions are discharged by the republic. Until the late 1980s an administrator appointed by the state president and a council of 55 members chosen by the provincial white electorate directed the administration of primary and secondary schools and teacher-training institutions, as well as of hospital, public health, library, and conservation services. The provincial council, however, was abolished in 1986, and its powers were transferred to the three chambers of Parliament and to a new executive authority appointed by the state president and headed by the administrator. In the early 1990s the provincial government was still in a process of transition.

Tribal territories

The area east of the Great Kei River, formerly consisting of tribal territories that were given a considerable degree of local autonomy in 1894, was formed into a semiautonomous territory for Xhosa-speaking peoples within the republic in 1963. This region, Transkei, is now administered as a republic with a president and a legislative assembly of paramount chiefs, tribal chiefs, and members chosen by the African electorate, with executive authority invested in a cabinet of ministers. Bophuthatswana, consisting of an area in the north of the Cape of Good Hope, together with areas in the provinces of Transvaal and Orange Free State, was similarly constituted as a republic for Tswana-speaking peoples in 1977. It is administered by a president and an elected legislature. Ciskei adopted a republican form of government in 1981.

Health and welfare. Both birth and death rates are considerably higher among Coloureds than whites. The higher Coloured death rate is attributed to high infant mortality, as well as greater incidence of diseases such as gastroenteritis, pneumonia, and tuberculosis that are associated with lower standards of living and hygiene. Meaningful data for the African peoples, among whom registration of births and deaths is not required, are unavailable.

Free hospital services are provided for lower income groups by the administration and by charitable health services. Smallpox is no longer a hazard, but immunization against poliomyelitis is compulsory and free to all.

School attendance is compulsory for all white and Coloured children from 7 to 16 years of age. Among most Africans attendance is optional, and educational facilities for them still lag behind population growth. As late as 1970 more than half the economically active Africans had received no formal schooling, although most urban and many rural Africans over age 15 were literate in at least one language. By 1980 an estimated three-fourths of the Africans of school age, about one-fifth of the total African population, were attending school. Universities have been established for all population groups: for whites at Cape Town, Grahamstown, Port Elizabeth, and Stellenbosch; and for Coloureds and Asians at Bellville. A university for Bantu-speaking peoples is located at Fort Hare in Ciskei.

Colonial artifacts

Cultural life. The South African Library (founded in 1818), Museum (1825), and National Gallery (1871) are located in Cape Town. There are noteworthy museums in all the larger urban centres and numerous smaller museums in towns such as Graaff-Reinet, Swellendam, and Tulbagh that foster interest in cultural history, including the work of Cape silversmiths and other colonial artifacts. The colonial heritage is also manifest in traditional country dances and folk songs and the largely indigenous Cape Dutch architecture of many farmhouses in the western part of the province. The provincial library operates branches in most towns and serves rural areas with mobile libraries.

There are several performing arts organizations, especially in Cape Town, where the city's orchestra has presented regular concerts since 1914 and the university has operated a theatre since 1931 and a ballet school since 1934. The Eoan Group, a Cape Coloured organization, fosters operatic talent through amateur productions of professional standard. Since the establishment of the Cape Performing

Arts Board in 1963, government subsidies have enabled it to send touring companies to perform outside Cape Town. Since 1971 the board has staged professional ballet, operatic, and theatrical productions throughout the year in its new complex in Cape Town.

HISTORY

Dutch settlement

The first European settlement in southern Africa was located in what is now Cape Province. This was the refreshment station established in 1652 by the Dutch East India Company at Table Bay, 30 miles (50 kilometres) north of the promontory that the Portuguese navigator Bartolomeu Dias de Novais had named Cabo da Boa Esperança (Cape of Good Hope) in 1488. In 1814 the Cape settlement was ceded to the British and became the Colony of the Cape of Good Hope. In 1910 the colony was constituted a province of the Union of South Africa (since 1961 the Republic of South Africa).

As the early agricultural ventures of the Dutch East India Company proved inadequate to supply the garrison and ships in transit, lands were assigned to independent settlers in 1657 and, to supplement their labour, from 1658 slaves were imported, at first from West Africa and later in larger numbers from Madagascar, Ceylon, and the East Indies. As the amount of livestock obtainable from the nomadic Khoikhoin (called Hottentots by the Dutch) to supply ships also proved insufficient, the company itself began to raise stock and later to encourage settlers to do so. At first the paucity of grazing during the summer dry season necessitated the establishment of pastoral outposts in well-watered localities in the immediate hinterland; later, however, colonial pastoralists moved inland seasonally in search of good grazing, as had the Khoikhoin.

By 1700 grain, wine, and fruit farms were scattered along the eastern foot of Table Mountain (which overlooks Table Bay) as well as along the western foot of the Hottentots-Hollandsberge and Drakenstein ranges 30 to 40 miles to the east, while pastoral farmers ranged as far as 100 miles to the north and east of Table Bay. To this encroachment the Khoikhoin offered no sustained resistance, withdrawing before the colonists or accepting service with them as shepherds, guides, and interpreters; in the smallpox epidemic of 1713 thousands died. The survivors fled, and by 1730 no tribal remnants remained within 250 miles of Table Bay. Concurrently, the growing volume of shipping and the consequent demand for livestock provided the incentive for the spread of colonial sheep farmers northeastward beyond the Roggeveldberg and Hantamsberg and eastward through the Karoo (a plateau region) until, by 1779, they were in contact and conflict with Bantu-speaking peoples along the Great Fish River.

Stock thefts and reprisals subsequently resulted in a series of frontier wars; the introduction of some 3,500 settlers by the British in 1820 between the Dutch settlers and the Africans failed to establish an effective buffer settlement, and pacification was achieved only after a series of annexations had by 1894 advanced the frontier to the Mtamvuna River, the southwestern border of the colony of Natal. All the tribal territories east of the Great Kei River were thus reduced to the status of tribal reserves under colonial administration.

The gradual northward diffusion of pastoralists across the Upper Karoo meanwhile had led to the discovery of diamonds in 1867–68 where the trail to Bechuanaland—followed for half a century by traders and missionaries—crossed the Orange River.

The diamond rush

The discovery of diamond-bearing intrusions north of the river precipitated a rush of immigrants. It also led to the annexation of Griqualand West by Cape Colony in 1871, despite conflicting claims by the Orange Free State; to the extension (between 1873 and 1884) of the small Cape Town-to-Wellington railway more than 600 miles inland to Kimberley; and to the construction of railways inland from Port Elizabeth and from the port of East London. The fortuitous discovery of diamonds was particularly timely, since the opening of the Suez Canal in 1869 threatened to bankrupt the colony. The era that followed was one of unprecedented population growth and economic activity that attracted capital from overseas. The attention paid to the potential, although then still unknown, mineral wealth of the hinterland gave impetus to expansion. Political manoeuvring culminated in 1885 in the proclamation of a British protectorate over the area extending north to 22° south latitude, and in 1895 the section south of the Molopo River, the present boundary with Botswana, was incorporated within the Cape Colony. (W.J.T./Ed.)

Natal

Natal, the smallest of the four provinces of the Republic of South Africa, is bounded on the east by the Indian Ocean, on the south by Cape Province, on the west by Lesotho, the Orange Free State, and Transvaal, and on the north by Swaziland and Mozambique. Its area, which includes Zululand and Tongaland, is 33,578 square miles (86,967 square kilometres). It was given its name by Vasco da Gama, who, on Christmas Day 1497, sighted the entrance to the harbour of Port Natal, today called Durban. Its capital is Pietermaritzburg. The province attained its present extent by 1902.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Natal is generally hilly or mountainous, especially along its western border, and rises from the coast to over 11,000 feet (3,353 metres) at the Drakensberg Escarpment (the edge of the interior plateau of South Africa and of Lesotho). The slope, however, is not gradual and is converted by various outcrops into steps of undulating land separated by escarpments. The lowest step is the coastal plain, less than 500 feet above sea level, widening to the north; then follow surfaces at 2,000 to 2,500 feet and at 3,500 to 4,500 feet (parts of which are referred to as the Midlands). Beyond the province, to the west, lies the Highveld, or high plateau. The continuity of these steps is often interrupted by spurs extending from the Drakensberg and by rivers—notably the Tugela—that cross the province in troughs hundreds of feet below the surrounding countryside.

Relief and drainage

Climate. The climate is generally related to major relief features. Rainfall decreases from more than 50 inches (1,270 millimetres) annually along parts of the coast to 30 to 40 inches inland, and then increases to well over 60 inches in the Drakensberg. About 60 percent of the coastal rainfall and 85 percent in the west falls in the summer months, October to March, often as heavy afternoon showers associated with thunderstorms. Temperatures decrease with altitude from the frost-free coast (January 70° to 75° F [21° to 24° C], July 60° to 65° F [16° to 18° C]) to the west (January 60° to 65° F [16° to 18° C], July 40° to 45° F [4° to 7° C]). There are significant day-to-day changes in weather and innumerable local climates due to minor differences in relief. In sheltered valleys or basins annual rainfall is often below 25 inches, and temperature inversions occur in winter (April to September); sea-facing slopes receive higher rainfall, while in the Midlands, mist belts often form in summer along escarpments and hot mountain winds blow from the interior occasionally. In general, summers are hot with occasional rain, and the humidity is high near the coast; hence, the Drakensberg mountain resorts are well patronized at this season. The warm, dry, and sunny winters have made the coast the principal holiday playground of southern Africa.

Plant and animal life. The natural vegetation, where it has not been modified or destroyed, falls into several belts according to altitude and climate. Tropical forest or bush, mangrove-fringed in the north, occurs in patches on the more open land along the coast. Farther inland in the north is bushveld, or savanna (grassy parkland), while farther south, in the river basins and valleys, cactus-like euphorbias (spurges) are characteristic. The Midlands and southwest sustain temperate forests, but these now exist only in relict patches. Open country, studded with thorn trees, covers the western half of the province; with true grassland occurring only at the high altitudes.

Game and nature reserves

The province, especially its coastal margin, is regarded as a transitional corridor along which tropical and more temperate animal life and vegetation have spread and intermingled. Measures for conservation are taken. The

Natal Parks Board controls 34 parks or game and nature reserves, with a total extent of 527,000 acres (213,277 hectares), which provide facilities for wilderness trail hiking. The larger reserves are situated in two different environments—along and behind the Zululand coast and in the Drakensberg. In Zululand, rhinoceros, buffalo, hippopotamus, and crocodile are characteristic varieties of animals. Fishing owls and fish eagles are also found, while vegetation includes the fever tree and the crane flower. In the Drakensberg are found the eland (a large African antelope) and the baboon, the martial eagle, and the lammergeier (bearded vulture). Vegetation includes tree ferns and ground orchids. Trout are found in the rivers of the interior, while along the coast, fish catches range from shad to sharks; in winter, sardine or pilchard shoals attract many game fish.

The people. The people of Natal form a mosaic of different ethnic groups living together within a complex social structure. As elsewhere in South Africa, the main distinction is between two composite groups, white and black, who, in accordance with the government's policy of apartheid (separate development), live in different but coexistent worlds. The whites are mainly of British or Dutch descent, while the nonwhites (according to South Africa's classification system) include an African majority, a number of Asians (Indians), and a group of Coloureds who are the product of interbreeding. Most of Natal's people live along and behind the coast (except in the north) or in the centre of the province; the extreme west and northeast are lightly populated. The Africans are especially concentrated in many fragmented areas (formerly referred to as Bantu Homelands, later called Black States), which, in 1970, were designated as the Zulu Territorial Authority and granted some autonomy. These homelands cover about a third of the province, and—except in the northeast—consist of broken rugged country. Whites own about two-thirds of the land in Natal although they compose only one-fourth of the population. Most whites live in or near Durban, in the towns along the route running west to the Witwatersrand ridge on South Africa's central plateau, or along the coast. The vast majority of South Africa's Asians live in Natal, and the Asians and Coloureds have a distribution similar to that of the whites.

Urbanization is proceeding apace. The towns are a European innovation, superimposed upon a previous rural settlement pattern, but they have proved increasingly attractive to the other population groups who live in separate residential areas within them, and few towns now have a majority of whites. Durban and to a lesser extent Pietermaritzburg dominate the urban scene. The other towns are few in number and are considered small in size.

Each population group has a cultural identity reflected in its religion, language, and customs. Most of the whites have English as their basic language, most of the remainder speak Afrikaans, and many whites speak both languages. The whites are mainly Christians; the Coloureds have a close affinity to the whites and have a similar culture. The Asians, on the other hand, have adopted many elements of the Western culture, but they retain an identity and a diversity by maintaining much of their own cultures. Some 70 percent profess Hinduism, 20 percent are Muslims, and the remainder are largely Christians. Most are fluent in English, but most speak various Indian languages at home. The Africans have not been culturally assimilated to the same extent as the other non-whites. They have retained their identity through their use of Zulu, a Bantu language, which is the language of the overwhelming majority of the Africans, and through a rich heritage of folklore, ceremony, and customs that reflect the diversity of tribal allegiances. The rest of the Africans speak cognate languages.

The economy. Natal has two coexistent economies. One is the subsistence economy of the Black States based upon pastoralism (largely cattle raising) and cultivation (mainly of corn [maize] grown in small plots) and supplemented by migrant labour. The Black States have poor resources, although considerable effort is being directed toward their development; their economy is supplemented by the earnings of Africans who work elsewhere in South Africa. The other is the advanced commercial economy pursued by the whites, with the assistance of nonwhites, elsewhere in the province. It is through this economy that most of the considerable and varied resources of the province are being developed.

Resources. The mineral wealth of Natal consists essentially of coal, which is mined in the Newcastle–Vryheid–Dundee–Utrecht area of the northwest; 85 percent of the output is high-grade bituminous coal, much of it of coking grade. This coalfield is South Africa's chief source of coking and semi-anthracite coal.

Agriculture and forestry. The most important agricultural area lies along the coast, where sugarcane is the major crop. Sugar growing is now of increasing importance in the Midlands. Refining for domestic and export requirements is mainly carried out at Durban. Plantations of pine and eucalyptus provide raw materials for sawmills and for paper, hard and soft board, and rayon pulp mills. Subtropical fruits, especially pineapples and bananas, are also grown. Durban is also the base for an important whaling industry. In the Midlands, plantations of pine, eucalyptus, poplar, and especially black wattle cover large areas. A tanning agent, of which South Africa is the largest world producer, is made from the wattle bark.

Dairying is important. Milk is produced near Durban and Pietermaritzburg; butter and cheese are produced inland. The northwest is largely devoted to cattle raising and maize cultivation, although the Drakensberg Escarpment cannot be used for agriculture because of its rough terrain. The northeast coastal plain is also unproductive, but projected irrigation schemes may provide the impetus for a final movement of the economic frontier of the province to the Mozambique border.

Industry. The products of mining, farming, forestry, and fishing, together with imported materials, support important manufacturing industries. Most are established in the towns, with the number of factories and output values roughly proportional to urban populations. Rural industries are generally restricted to those where processing takes place on the spot, although since 1960 decentralization in the form of the establishment of border industry (industry located just outside the Black States) has been in progress, notably at Elangeni (Hammarsdale), between Durban and Pietermaritzburg.

Rural and border industries

Durban, with nearby Pinetown, is the economic heart of the province and its industrial centre. It possesses most of Natal's factories, and—with more than 10 percent of those of the republic—is South Africa's second or third most important industrial region. Its factories are associated primarily with shipping, food processing, chemicals, sugar, and oil refining. An oil pipeline connects Durban with the southern Transvaal. Pietermaritzburg has a number of industries, including an aluminum plant, several footwear factories, and food-processing establishments. The northern coalfield has not yet developed industrially, but plans for the development of the Tugela Basin and a recent decision to establish a large steel plant at Newcastle may engender considerable industrial growth.

Transportation. A railway network consists of a main electrified axis from Durban, northwest through Pietermaritzburg to the Witwatersrand, a line along the coast, and various branch lines. The roads parallel the railways and also serve more remote areas; main roads are tarred, country roads have gravel or earth surfaces. Aircraft fly from Durban's airport to South African cities, and to Mozambique and Zimbabwe, and—via Jan Smuts Airport (Johannesburg/Pretoria)—to world centres; other towns have smaller airfields.

A completely new port and industrial growth point is being developed at Richard's Bay, 100 miles (160 kilometres) north of Durban; dredging began in 1972, and the port was expected to open in 1976. An aluminum smelter was already in production in the early 1970s. In the meantime, however, Durban remains Natal's only port. It serves much of the interior of southern Africa and is South Africa's main cargo port. It has shipping links with the world, and its importance was considerably increased by the closure of the Suez Canal.

Administrative and social conditions. The constitution of the republic formerly provided for provincial administration from Pietermaritzburg, through an administrator (chief executive officer), a provincial council, and its executive committee. The province, under the aegis of the central government, imposed duties and granted certain rights to local government authorities. In 1986 the council was abolished and was replaced by a presidentially appointed executive authority, headed by the administrator. Many of its powers were also transferred to Parliament. In the early 1990s the provincial government and local administrative units were in a period of transition.

The provincial administration, the administrations of the three chambers of Parliament, local authorities, voluntary bodies, and a range of welfare authorities cooperate in caring for health and welfare. Medical facilities are largely concentrated in the towns but are supplemented by many outlying clinics and health centres. Medical training for doctors is available for nonwhites at Natal University, Durban. Diseases that especially affect the Africans include tuberculosis, bilharzia (a parasitic disease of the blood), and kwashiorkor (malnutrition resulting from severe protein deficiency).

Education below the university level is provided for whites at some 360 schools, two technical colleges, and three teacher-training colleges; and for nonwhites at about 1,200 schools, nine technical colleges, and 10 teacher-training colleges. The University of Natal, which was founded in 1909 as a constituent college of the University of South Africa and assumed university status in 1949, is the chief institution of higher education. It is located partly in Pietermaritzburg and partly in Durban. Higher education for Asians is available at the University of Durban-Westville—established in 1960—and for Africans at the University of Zululand, located at Kwa Dlangezwa, near Empangeni, established in 1957.

Universities

Cultural life. The people of Natal have a rich cultural heritage drawn from their differing backgrounds. Generally speaking, that of the whites and Coloureds is of the West, the Asians of the East, and the Africans of Africa, although non-Europeans are becoming increasingly Westernized. Cultural institutions include botanic gardens, parks, museums, libraries, art galleries, cinemas, theatres, music societies, and agricultural and industrial exhibitions in many centres, notably Durban and Pietermaritzburg. Of particular importance is the recently established Natal Performing Arts Council.

HISTORY

The area was occupied centuries ago by the Nguni branch of the Bantu-speaking peoples, who entered in strength from the north. The first European settlers established the trading post called Port Natal in 1824, but little attempt was made to develop the interior, whose inhabitants had been decimated by the Zulu chief Shaka by 1820. This apparently empty land was entered by the Voortrekkers, Afrikaners who left Cape Colony, via the Drakensberg passes in 1837. After the defeat of the Zulus by the Afrikaners at Blood River in 1838, the Afrikaners established the Republic of Natal. When Natal was annexed by the British in 1843, many of the Afrikaner inhabitants left for the interior and were replaced by immigrants, mainly from Britain. From 1860 onward, increasing numbers of Indians entered to work as labourers in the sugar plantations on the coast. The colony was extended by successive acquisitions—notably that of Zululand (the area north of the Tugela River), which was added after the Zulu War of 1879, fought between the Zulu and the British. The lands north of the Buffalo River were added in 1902. During the South African War (1899 to 1902), when the British fought the Boers, the Afrikaner descendants of Dutch settlers, Natal was invaded by the Boer forces who were checked by the British defense at Ladysmith. In 1910 the colony became a province of the Union of South Africa and in 1961 of the republic. (O.W./Ed.)

European settlement

Orange Free State

The Orange Free State—Oranje Vrystaat in the Afrikaans language—is the second smallest of the four provinces of the Republic of South Africa. It has an area of 49,866 square miles (129,152 square kilometres) and a population of which three-fourths is black and less than one-fourth is white. Landlocked, the province is bordered to the north by Transvaal Province, to the east by Natal Province and by the independent state of Lesotho, and to the south and west by Cape Province. The administrative capital is Bloemfontein, which is also the judicial capital of the Republic of South Africa.

More than three-quarters of the white population is Afrikaner, and the state is a stronghold of Afrikaner culture. While its undulating plains produce up to 40 percent of South Africa's corn, a quarter of its wheat, and a quarter of its wool, the Orange Free State also contains the most productive of South Africa's seven principal goldfields, from which uranium is also obtained. As South Africa's central province, the state is the focus of its transport network.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* The Orange Free State is situated on the Highveld, a high plateau that rises to 6,000 feet (1,829 metres) on its eastern boundary, sloping down to the west to almost 4,000 feet. Its surface is formed by beds of sandstones and shales (laminated rock form of clays) and is extremely even, except where it is broken by the occurrence of dolerite (coarse basalt) intrusions (inflows of formerly molten rock) or by the occurrence of mesas. This general evenness results in low gradients for river courses; coupled with the semiarid climate, it also produces a peculiar type of wind-eroded pan (depression) in the west that is filled with water during the rainy season.

Drainage. The province is entirely drained by two rivers—the upper Orange River, which, as mentioned, forms the southern boundary of the province, and the Vaal River, which forms part of the northern boundary, together with their tributaries. The largest of the tributaries is the Caledon River, which flows into the Orange from the Drakensberg mountains in neighbouring Lesotho. The Wilge River, which drains the northeast, is the principal tributary of the Vaal. An interesting geologic feature is the Vredefort Dome, a series of incomplete circular ranges enclosing a mass of old granite partly eroded by the Vaal River.

Soils. The eastern part of the province is covered by claylike, heavy, and somewhat acidic soils. Farther to the west are alkaline soils that can be impervious to water. The northwestern region forms the so-called Sandveld, on which good crops are obtained only in years of high rainfall. The west is covered by sandy soil resembling that of the Kalahari, where successful cultivation is possible only under irrigation.

Climate. The climate varies from a warm and temperate type with an annual rainfall of 40 inches (1,016 millimetres) in the east to a semiarid type with a rainfall of 15 inches in the far west. Mean annual surface temperatures gradually increase from about 58° F (14° C) in the east to 62° F (17° C) in the west. Frost is common over the entire province from May to September, while dust storms normally occur during drought-stricken summer periods. Whirlwinds are common during warmer days; and hailstorms, sometimes destructive, occur on an average about seven times a year in the east but only three times a year in the west. Because rainfall is unreliable, long periods of drought are frequent each year. Thunderstorms, almost exclusively a summer phenomenon, are the normal sources of precipitation, occurring between 60 and 100 days a year. Sunshine is abundant; there are only about six days a year on which Bloemfontein has no sunshine. The rate of evaporation is consequently high. Because rainfall is sporadic, much reliance is placed on underground supplies of water and on storage dams.

Rainfall and temperatures

Plant and animal life. From west to east the vegetation consists of four successive zones—desert shrub, sweet grassveld, mixed grassveld, and sour grassveld. In most of the province, animal life, like the vegetation, has given way to crop cultivation and human settlement. Many animal and plant species are now protected by legislation. At Willem Pretorius Game Reserve, Highveld game animals, including herds of such species of antelope as blesbok and springbok, are plentiful; zebra and giraffe are also to be found. Golden Gate Highlands National Park was developed to restock the area with antelope species—such as black wildebeest and blesbok—and other animals and to establish a habitat for a wide variety of birds. Several of the smaller reptiles and snakes, such as adders, ringhals (venomous spitting snakes), and tree snakes, are still to be found over the entire province. The rarely observed freshwater fishes of the Orange and Vaal river systems include yellowfish, carp, and barbel.

The people. *Ethnic composition.* The ethnic pattern is revealed by the home language spoken. Among the white population, the vast majority are Afrikaans-speaking; a small percentage speak English; and the remainder speak German, Dutch, or other European languages. Historically, the Afrikaners, whose ancestors came from the preindustrial Netherlands, tended to be farmers; while the English, who came from an industrialized Britain, tended to be city dwellers. Today, most whites live in towns and cities. In general, the rural white population increases from south to north, with Bloemfontein and the northwestern goldfields being the most densely populated regions. The African population was originally largely confined to the northern and eastern districts, adjoining Lesotho, but today their numbers are rapidly increasing in the goldfield area. More than half belong to the South Sotho (also known as Sotho proper or Basuto) tribe. Various other tribal groups include the Zulu to the northeast, the city-dwelling Xhosa (Xosa), and the Tswana. African densities also increase in a northerly direction. The Coloureds, almost without exception, speak Afrikaans; slightly more than half of them live in towns and cities; the remainder increase in number toward the southwest.

frican
bal
oups

Religion. Throughout the province, church buildings are dominant in towns. The Provincial Council begins the day's work with solemn prayer, and, in the distant farmhouse, divine worship is part of the family's evening activities. The three main Afrikaans churches (Nederduits Gereformeerde, Nederduits Hervormde, and Gereformeerde) account for about three-fourths of white church membership, and the three main English churches (Anglican, Methodist, and Presbyterian) for a smaller fraction. Many white Christians engage in missionary activity. The Coloureds are almost entirely Christian. The Africans of the Orange Free State are more Christianized than those of the neighbouring Transvaal.

The white population is dispersed over the country on individually owned farms and single homesteads. New discoveries of gold since World War II in the northwest have resulted in a maize and cattle country being turned into a mining and industrial belt. New towns, including Welkom, Virginia, and Odendaalsrus, have sprung up. Welkom, the second largest town, has grown rapidly since 1950 and provides an example of modern planning, in which residential suburbs radiate from the town centre with green wedges of open spaces between them. Bloemfontein, the largest city, was the province's administrative, transport, educational, and cultural centre. It is also developing industrially. Kroonstad is the third largest town, while Sasolburg has a burgeoning chemical industry. Most of the remaining towns are small.

The economy. *Resources.* The Orange Free State is not as rich in mineral resources as the neighbouring Transvaal. The gold resources of the Welkom district are the most important. Diamond production totalled 220,000 metric carats in 1968 alone. Estimated coal reserves of 3,400,000,000 tons are worked in the north and are mainly used in the coal-to-oil project at Sasolburg that supplies about 10 percent of the nation's gasoline requirements. Salt is derived from the pans of the semiarid region, and bentonite (a moisture-absorbing clay) is mined from a large deposit near Parys on the Vaal River.

Agriculture. The province forms part of the country's grain belt. The undulating plains afford excellent grazing, and stock farming is important. The province produces almost one-quarter of South Africa's wool output, and its cattle are mainly located in the wetter northeastern districts of Harrismith, Vrede, and Bethlehem.

Water is the province's most essential resource. Apart from several storage dams—like the large Allenmanskraal, the Erfenis, and the Kalkfontein—the region will benefit enormously from the vast Hendrik Verwoerd and Van der Kloof dams, part of the great Orange River Project.

Transportation. The state-owned railways and highways provide internal provincial transportation. The J.B.M. Hertzog Airport at Bloemfontein is the largest in the province and is of growing importance. Post-office and telecommunication services expand from year to year to meet an increasing demand. The South African Broadcasting Corporation broadcasts to the province in English, Afrikaans, and several Bantu languages. There is a radio station at Bloemfontein.

Administrative and social conditions. Until the late 1980s the Orange Free State was administered by a provincial council, in which members were elected every five years, and an administrator appointed by the state president. The council had jurisdiction on such matters as taxation to provide revenue for white education, hospitals, roads, and nature conservation. The council, however, was replaced by a presidentially appointed executive authority, and many of its powers were transferred to Parliament. In the early 1990s provincial government, as well as the local governments, was in a period of transition. Forty-nine magisterial districts control the administration of justice.

There are several provincial hospitals. Apart from the leper, mental, and tuberculosis institutions, there are provincial and private hospitals and clinics. The province and the administrations of the three chambers of Parliament provide a wide range of health services. Increased attention to health has led to a decline in infant mortality over the last decades.

Education

Schooling, when available, is free for all and is compulsory for whites between seven and 16 years of age. Where demand justifies the establishment of facilities, Coloureds between seven and 16 years are also compelled to attend schools. The University of the Orange Free State, located in Bloemfontein, is the institution of higher learning for whites. Administration of primary and secondary education and the training of teachers, as well as the administration of the university and higher technical training, are under the central government's Department of National Education and the separate Departments of Education and Culture of the three chambers of Parliament.

The Parliamentary administrations and the provincial authorities, in cooperation with private organizations, undertake a wide variety of welfare services, including care for the aged, workshops and housing for the blind, and the provision of housing for the Africans in larger urban centres.

Cultural life. The cultural life of the whites resembles that in Western countries. As the Orange Free State is predominantly a rural province, the more austere and moralistic aspects of the Afrikaner character are probably more in evidence here than elsewhere. The well-known hospitality, a general trait of white South African life, is a result of the stimulus of a mutual dependence that developed in an earlier era when life on the trekker's frontier was hard and sometimes dangerous. African culture is still strongly influenced by tribal life; the supremacy of the chiefs is recognized, and the heritage of traditional animist religion is still in evidence, despite the influence of Christianity. The sunny climate influences all aspects of life, from clothing to food and drink and from literature to architecture. Cultural institutions such as museums and theatres are to be found in the principal towns.

HISTORY

Before the arrival of Europeans, the region was the home of seminomadic Bantu-speaking tribes. In the 18th century, Europeans first crossed the Orange River, which forms part of the state's southern border, to enter the area. In the early 19th century, Boers began to settle the area. After 1836 came the Great Trek, a migratory movement in which Boer farmers seeking freedom from British rule also moved north across the Orange River. From 1848 to 1854 the British administered the territory as the Orange River Sovereignty, after which the British withdrew, and the Boer settlers formed the independent Orange Free State. The constitution of the new state combined traditional Boer institutions with Dutch and United States constitutional theory. During the first few years of the state's existence, it was much harassed by raids from Basuto (Sotho) tribesmen from the east; the Basutos were, however, at length conquered, and part of their territory was annexed. During the South African War (1899–1902), the Orange Free State fought against the United Kingdom by the side of its sister state the South African Republic (now the Transvaal), with which it had a defensive alliance. The two Boer republics won some victories against the British army but could not finally prevail. In 1900 the Orange Free State was annexed by the United Kingdom as the Orange River Colony. Self-government was restored in 1907, after which, in 1910, the colony became the Orange Free State Province of the Union of South Africa. In 1961, when the Union of South Africa became the Republic of South Africa, the province remained unchanged in form and administration. (J.N.S./Ed.)

Transvaal

The Transvaal is the northernmost and second largest province of the Republic of South Africa. With an area of 109,622 square miles (283,917 square kilometres), it is bordered by Botswana and Zimbabwe to the north, Mozambique and Swaziland to the east, the provinces of Natal and the Orange Free State to the south, and Cape Province to the west. About three-fourths of the population is black and less than one-fourth is white. Many of the whites are descendants of the Afrikaners who in the earlier 19th century migrated north over the Vaal River, which now forms part of the province's southern boundary, thus giving the province its present name—Transvaal, "across the Vaal."

Rich in mineral resources, including gold and uranium, as well as in power resources, the Transvaal is South Africa's industrial heartland and also an important agricultural region in its own right. Pretoria, the provincial capital, is also the administrative centre of the republic. The province also contains Johannesburg, the largest city in South Africa.

PHYSICAL AND HUMAN GEOGRAPHY

The six regions

The land. *Relief.* There are six distinct physiographic regions in the province—the Highveld, the Bushveld Basin, the Waterberg Plateau, the Pietersburg Plain, the Limpopo Valley, and the Lowveld. In the south, the altitude of the Highveld ranges between 4,000 and 6,000 feet (1,219 and 1,829 metres), declining slightly from east to west. The eastern area is covered by horizontal sandstones and shales (laminated clays) that produce gray, claylike acidic prairie soils with a leached upper layer that merges into lateritic (leached, reddish, iron-bearing) soils farther to the north and west. The relief is undulating but changes into a rugged landscape in the vicinity of the Witwatersrand Ridge, where older rocks have been bared. To the west of Johannesburg, the Highveld is monotonously even, being composed of water-bearing limestone and lavas. The region is drained by the Vaal River and its tributaries.

The central part of the province is occupied by the Bushveld Basin, formed by a large substratum of rock that has been solidified from the molten state. The peripheral ridge-and-valley landscape is composed of quartzites and intervening shales that dip toward the centre. These ridges are known as the Western Bankeveld around Pretoria and the Eastern Bankeveld near the Drakensberg Mountains. North of Pilgrimsrest, water erosion on the Eastern Bankeveld has created the spectacular canyon of the Blyde River. The black clays of the basin are associated with norite (a granular, mineral-bearing rock solidified from the molten state) and basalt and are of exceptionally high fertility, as they are at the Springbok Flats.

The Waterberg Plateau rises from 3,500 to nearly 7,000 feet in altitude to the northwest of the basin. Few of its grass- and bush-covered sandstone areas are suitable for cultivation. To the northeast the Pietersburg Plain is almost entirely composed of a granite surface. It is bounded by the Strydpoort Mountains in the south and the Soutpansberg Mountains in the north.

Soils. The Limpopo Valley forms the northern border with Zimbabwe. It cuts mainly into old granite in a bushy area covered by the sandy soil of the nearby Kalahari, and a red-brown unleached subtropical sandy soil to the east. Farther east, this sandy soil extends into the Lowveld, a bush-clad plain, generally below 2,000 feet in altitude, that gently slopes toward the Lebombo Mountains on the Mozambique boundary. On the slopes of the Great Escarpment—the ridge that separates the plateau from the Lowveld—thick, red, iron-bearing earths support dense plantation growth. The whole of the northern, and most of the eastern, Transvaal is drained by the Limpopo River and its tributaries, which include the Crocodile, Mogalakwena, Letaba, and Olifants rivers.

Climate. Temperatures are directly related to the altitudes of the region. Rainfall is unreliable and varies from year to year. Almost exclusively a summer phenomenon, it normally arrives as thunderstorms and showers. Hailstorms that frequently are destructive may be expected about five times a year, while the great amount of sunshine results in extensive evaporation.

The Highveld is warm and temperate, with mean annual surface temperatures of 57° F (14° C) in the east and 65° F (18° C) in the southwest. Rainfall varies from 40 inches (1,016 millimetres) in the east to 18 inches in the west. Frost is common from mid-May to mid-September, but its duration decreases to the north and east. North of Pretoria, the climate becomes subtropical and semiarid, with an annual average rainfall ranging from 28 inches on the Waterberg Plateau to 16 inches in the Sand River Valley, which is the driest part of the Transvaal. The subtropical Lowveld is warm and oppressive except during the winter. The mean annual surface temperature is 74° F (23° C), and rainfall increases from 19 inches in the northeast to more than 72 inches on the Drakensberg slopes, where mist and drizzle are frequent.

Plant and animal life. The natural vegetation of the Highveld and part of the Bankeveld consists of successive sweet, mixed, and sour grassland toward the east, the extent of each zone depending upon the climate and type of soil. The whole of the Lowveld and the greater part of the country to the north of the Bankeveld carries a parkland type of vegetation, with acacia types predominating and tall grasses and scrubs forming the undergrowth. Where rainfall is high in the mist belt, true timber forests with dense undergrowth are found, but they have suffered severely from the hand of man.

Kruger National Park

Animal life has been severely decimated, except in conservation areas. Kruger National Park—covering some 8,000 square miles in the eastern Lowveld—supports a wide variety of primates such as monkeys and baboons; insect-eaters such as hedgehogs and ant bears; carnivores such as lions, cheetahs, jackals, and hyenas; and hoofed animals such as rhinoceroses, hippopotamuses, giraffes, buffalo, kudus, blue wildebeests, and impalas. There are many species of birds. Crocodiles and several species of snakes are found, as well as freshwater fish.

Settlement patterns. Because of large, individually owned farms, rural settlement among whites is dispersed, with long distances separating neighbours. The pattern in the African areas differs totally because African communal ownership and communal land use result in the appearance of rural villages separated by open stretches of cultivated and grazing lands.

South Africa's urban heartland

Towns are generally small and few in number, having evolved as mining, marketing, or administrative centres. Although the towns were founded by whites, they are numerically dominated by the Africans. The highly built-up Witwatersrand region covers about 200 square miles. Johannesburg, Pretoria, and the Vereeniging–Vanderbijlpark complex—in fact, the whole of the southern Transvaal—forms the mining, industrial, commercial, and financial heart of South Africa. In the west the gold-mining complex of Klerksdorp–Stilfontein–Orkney, and in the east the Witbank–Middelburg coalfields and industrial area, are important. Other important centres are Pietersburg, Nelspruit, Ermelo, and Lichtenburg.

The people. *Ethnic composition.* There are four main population groups in the Transvaal, the Africans, whites, Coloureds, and Asians.

More than half of the white population is Afrikaans-speaking and one-third is English-speaking. The balance are of German, Dutch, and other European origin. Most of the whites are urban-centred, being concentrated in the Pretoria–Witwatersrand–Vereeniging metropolitan complex. The Afrikaners, once overwhelmingly engaged in farming, live increasingly in the cities; now the vast majority is urbanized.

The African population, in spite of a broad cultural solidarity, is diversely grouped in numerous tribes and clans. The main groups are the Sotho, Nguni, Tsonga, and Venda. Since few members of the main groups can understand each other's language, a lingua franca called Fanagalo has developed, especially among the African gold miners. The majority of the Africans live in rural areas.

The Coloureds are urbanized and are concentrated mainly in the Witwatersrand area and in the larger towns. They speak both Afrikaans and English. The Asians are also predominantly urban; they consist mainly of Indians, although there is also a Chinese minority.

Religion. More than half of the white population are members of the three Afrikaans churches—the Nederduits Gereformeerde and the Nederduits Hervormde (both Dutch Reformed churches), and the Gereformeerde (Reformed Church of South Africa)—and about one-fourth are members of the three main English churches—Anglican, Methodist, and Presbyterian. There is also a small Jewish community. Because of strong missionary activity, the vast majority of the Coloureds are Christian. Many of the Africans have accepted Christianity, but they tend to form independent sects; a significant fraction of the Africans belong to more than 1,000 separatist churches. The Asian community has retained its affiliation with Hinduism and Islām.

d
monds

The economy. *Resources.* The Transvaal contains one of the greatest known concentrations of mineral deposits, both in variety and quantity. Producing large quantities of gold and uranium, the mines of the Witwatersrand, Klerksdorp, and eastern Transvaal have stimulated the growth of a large complex of industries and economic activities. Gold purchased for industrial purposes had by 1968 reached the level of total world output of newly mined gold. Diamond output amounted to 2,550,000 metric carats in 1968. Enormous reserves of platinum, as well as of chromite, tin, and nickel, are associated with the Bushveld. Reserves of coal are estimated at 75,000,000,000 tons. Other mineral deposits include iron ore at Thabazimbi, copper at Messina and Phalaborwa, asbestos, vermiculite (a micaceous mineral), antimony, corundum (crystals used industrially as abrasives), and limestone. An ever-growing need for explosives for mining has resulted in the development of a large chemical industry.

Agriculture. Agriculture is productive, having adopted modern methods of conservation, irrigation, and fertilization. Products include corn (maize), wheat, peanuts (groundnuts), sunflower seeds, cotton, sugar, tobacco, and potatoes and other vegetables, as well as a wide variety of fruits. Beef and dairy cattle are important, and there is some sheep ranching. Huge plantations of eucalyptus and coniferous trees in the mist belt comprise a large fraction of South Africa's total acreage of plantations.

The demand for water for mining, industry, power stations, and irrigation has exceeded the supply available from the Vaal River, virtually all of which is already in use. Planners are seeking supplementary supplies from the Tugela River of Natal and from the desalinization of seawater.

Transportation. Railways, as well as a vast highway network, cover the province. An underground pipeline from the port of Durban in Natal Province conveys petroleum products to the Witwatersrand over a distance of 450 miles. South Africa's main international airport, Jan Smuts, is situated near Johannesburg. Post-office services and the telecommunication system have expanded steadily to cope with increasing demands. There are national radio broadcasting stations at Johannesburg, Pretoria, and Pietersburg. The Voice of South Africa transmits to other countries from Bloemendal in 10 languages. Radio Highveld broadcasts continuously in Afrikaans and English.

Administrative and social conditions. *Government.* Until the late 1980s provincial authority was delegated by the Parliament of South Africa to a provincial council, in which members were elected every five years, and an administrator appointed by the state president. Taxation for provincial purposes was under the council's control. The council, however, was abolished in 1986 and replaced by a new executive authority appointed by the state president and headed by the administrator, and many of its powers were transferred to the three chambers of Parliament. In the early 1990s the provincial government and the local governments were in a period of transition. There are 62 magisterial districts with responsibility for the administration of justice.

Health and welfare. There are provincial and private hospitals. There are also mine hospitals and hospitals for leprosy, mental illness, and tuberculosis. The government maintains field services to combat malaria, plague, typhus, tuberculosis, trachoma, and other diseases. Indigent whites and most nonwhites receive free medical attention from the provincial hospitals. A major hospital specializing in the treatment of a wide range of diseases is Baragwanath, a hospital for nonwhites near Johannesburg.

Education

Elementary and secondary education and the training of teachers are administered by the central government. Schooling is compulsory for whites between the ages of seven and 16 and, where the demand justifies the establishment of facilities, for Coloureds between seven and 16 and Asians between seven and 15. Six universities—the universities of South Africa, Pretoria, the Witwatersrand, Potchefstroom, Rand Afrikaans University, and the University of the North for the Africans—are subsidized by the federal government but remain autonomous.

Welfare activities are undertaken by voluntary organizations, the departments of Health Services and Welfare of the three chambers of Parliament, and the provincial administration. From 1960 onward, in order to clear the so-called squatters' camps that resulted from a rapid industrialization that was accompanied by an unprecedented influx of Africans into urban areas in the southern Transvaal, more than 100,000 houses were built; provision was also made for schools, parks, community halls, and other facilities.

Cultural life. The Transvaal's population diversity has resulted in a variety of different cultures. "White" Transvaal is culturally comparable to any Western country. Its well-known hospitality can be traced back to the rough environment and hard life of past decades, which stimulated mutual dependence and a close family life. There is a strong desire to preserve objects of historical significance; Afrikaner attachment to national tradition is symbolized by the Voortrekker Monument near Pretoria, which honours the first pioneers.

The Transvaal has attained international recognition for its contributions to art, music, and ballet. Opera is presented regularly, and the Aula at Pretoria and Johannesburg Civic Theatre are well-known cultural centres. A wealth of literature and folk song has accumulated, but there is little if any traditional architecture.

Among the Africans, tribes are normally composed of a number of clans whose members are related. A strong recognition of the power of the tribe's chief prevails, and traditional medicine has considerable influence. The Africans are renowned for their music and dancing, of which the "Domba," or snake dance, of the Venda is an example.

The climate lends itself to outdoor living, and sports are extremely popular. Motoring vacations over large distances are common, and an exodus to the beaches of Natal is a holiday phenomenon at all seasons.

HISTORY

In the early 19th century the land between the Vaal River in the south and the Limpopo River, which today forms the northern border, was inhabited by tribes of agricultural Bantu-speaking peoples who were skilled in metalwork-

Settlement by the Voortrekkers

ing. They became unsettled in the 1820s and 1830s by invasions of refugee Bantu tribes fleeing south and west from the warring Zulu. Between 1837 and 1838 seminomadic pastoral Afrikaner farmers, the Voortrekkers, moving northward to avoid British rule, crossed the Vaal River and entered the area, where they settled in isolated farms. More white settlers arrived when the United Kingdom annexed both Natal and the Orange River Sovereignty in the 1840s. In 1852 the independence of the Afrikaners in the Transvaal was recognized by the United Kingdom with the conclusion of the Sand River Convention. In 1857 the new Transvaal state was formally proclaimed as the South African Republic; its authority, however, was virtually limited to the southwest of the present Transvaal. In 1877 the republic was annexed by the United Kingdom, but the Afrikaners resorted to arms to maintain their independence, which they regained—subject to certain provisos—in 1881 after the British forces had been overwhelmed at the Battle of Majuba Hill. The discovery of gold in the Witwatersrand area in 1886 resulted in a tremendous influx of fortune seekers, primarily English and German, which caused new problems for the Afrikaner republic. Tension with the United Kingdom increased when an English adventurer, Leander Starr Jameson, led an abortive raid across the frontier of the South African Republic in an attempt to provoke an internal uprising. War between the republic and the United Kingdom subsequently broke out in 1899. Defeated by superior arms and numbers, the republic, together with its ally the Orange Free State, lost its independence when peace was concluded in 1902, after which the Transvaal became a British crown colony. In 1907 it regained self-government and in 1910 became a province of the Union of South Africa, a status that was maintained when the Union became the Republic of South Africa in 1961. (J.N.S./Ed.)

South America

South America is situated between longitudes 35° and 80° W and latitudes 12° N and 55° S. It is the fourth-largest of the continents, having an approximate area of 6,874,200 square miles (17,814,400 square kilometres), or about one-eighth of the land surface of the Earth.

Politically, the continent and its adjacent islands are divided into 12 sovereign republics and two dependencies. The republics are Argentina, Bolivia, Brazil, Chile, Colombia, Ecuador, Guyana, Paraguay, Peru, Suriname, Uruguay, and Venezuela; the dependencies are the Falkland Islands (owned by Britain but also claimed by Argentina as the Islas Malvinas) and French Guiana (Guyane Française).

South America is compact and roughly triangular in shape, being broad in the north and tapering to a point in the south at Tierra del Fuego. It is bounded by the Caribbean Sea to the northwest, the Atlantic Ocean to the northeast, east, and southeast, by Drake Passage to the south, and by the Pacific Ocean to the west. In the northwest it is joined to North America by the Isthmus of Panama, which forms a land bridge narrowing to about 50 miles (80 kilometres) at one point; to the north, the islands of the West Indies roughly form a chain running from Trinidad to Florida. At the continent's southernmost extent are the small Islas Diego Ramírez, about 60 miles (100 kilometres) southwest of Cape Horn.

In relation to the area of the continent, the coastline, which is 15,803 miles in length, is exceptionally short—one mile of coast for every 435 square miles of area.

An important feature of the continent is its dissymmetry. Because the Andes border the Pacific, the gigantic backbone that they create divides the continent into two parts differing greatly in both size and character. This unequal division has had profound effects on climate, wildlife, and even human settlement.

No other continent has a greater latitudinal extent or penetrates so far to the south. Though its northern part is crossed by the Equator and 80 percent of its landmass is located within the tropical zone, South America also extends into the subantarctic. Because of the high altitudes and wide extent of the Andes within the tropics, extensive zones of temperate or cold climate exist in the vicinity of the Equator—a circumstance that is unique. These conditions produce a great range of climates; the unrivalled diversity of ecological zones is probably the most prominent characteristic of South American geography.

Some parts of the continent are now industrialized, but most regions still follow an agricultural way of life. The possibilities of development, offered by the wealth of mineral products and renewable resources, are considerable. The human devastation of nature and of natural resources has nevertheless reached alarming proportions. Ecologists find this development particularly disconcerting because the human population is increasing at a rapid rate throughout the whole continent. Despite the wealth of the continent's resources, the trend could prove to be an obstacle to optimum development of most South American countries.

This article treats the physical and human geography and the history of South America, followed by discussion of geographical features of special interest. For discussion of individual countries of the continent, see specific articles by name, *e.g.,* ARGENTINA, BRAZIL, and VENEZUELA. Other South American countries are treated in the article CENTRAL AMERICA. For discussion of major cities of the continent, see the articles BUENOS AIRES, CARACAS, LIMA, RIO DE JANEIRO, and SÃO PAULO. For discussion of the indigenous peoples of the continent, see the articles AMERICAN INDIANS and PRE-COLUMBIAN CIVILIZATIONS. Related topics are discussed in the articles LATIN AMERICA, THE HISTORY OF; and LATIN-AMERICAN LITERATURE. For further references, see also the entries for these topics in the *Index.*

The article is divided into the following sections:

PHYSICAL AND HUMAN GEOGRAPHY

Geological history

The geological history of South America is complex and to some extent still unknown. The present geological structure is the result of the movement that uplifted the Andean mountain ranges.

BASIC STRUCTURAL UNITS

The five structural units

The geological structure of South America is dominated by five geotectonic units (structural rock masses of the Earth's crust), the history of which can be traced from the end of the Precambrian Era (570,000,000 years ago). The five units are the continental shields (stable masses of Precambrian rock), the epicontinental basins (*i.e.,* those situated on the continental plateau), the insular shields, the belt of pericratonic basins (*i.e.,* the basins surrounding large relatively immobile parts of the Earth's crust), and the Andean Geosyncline (*i.e.,* the gigantic linear trough in which sediments accumulated and which runs from north to south on the western side of the continent).

The continental shields consist of three old landmasses that together form the vast Guiana-Brazilian Shield that constitutes the greater part of northeastern South America. The complex, as a whole, is of crystalline rock, and—unlike the Andes—has long been quiescent. Its three parts are, firstly, the Guiana Shield, situated between the Orinoco and Amazon rivers; secondly, the Central Brazilian Shield, between the Amazon, the Parnaíba–São Francisco Basin, and the Paraná Basin, together with a long spur extending to central Paraguay; and, thirdly, the Eastern Brazilian Shield, covering eastern Brazil and Uruguay.

The epicontinental basins consist of three huge basins—the Amazon, Parnaíba–São Francisco, and Paraná basins—situated in weaker areas between large and relatively immobile masses. They have great unity of structure and have undergone uniform sedimentation, having been at first invaded by seas of the Paleozoic Era (from 570,000,000 to 225,000,000 years ago), then filled with continental sediments and volcanic deposits. Only tectonic movements resulting from volcanism have changed their structure.

The Amazon Basin is about 540,000 square miles in area and consists mostly of marine sediments from 280,000,000 to 570,000,000 years old, which underlie continental deposits. The Parnaíba–São Francisco Basin, in northeastern Brazil, is filled with sediments almost 10,000 feet deep; the oldest of these are marine limestone deposits, covered by sandstone, conglomerate deposits from rivers, and continental sediments which accumulated during the Mesozoic Era (from 225,000,000 to 65,000,000 years ago), together with some marine deposits in the north. The Paraná Basin, more than 500,000 square miles in area, is filled with sediments about 6,500 feet thick and with up to 5,000 feet of basaltic lava. Continental sediments of sand and silt, from 190,000,000 to 295,000,000 years old, are covered with lava deposits which extend over an area of more than 460,000 square miles.

The insular shields, which lie to the east of the Andes, are Precambrian massifs (mountainous masses) situated in Argentina; they include the Pampine Sierra and the Patagonian and Deseado massifs and may extend along the continental shelf as far as the Falkland Islands.

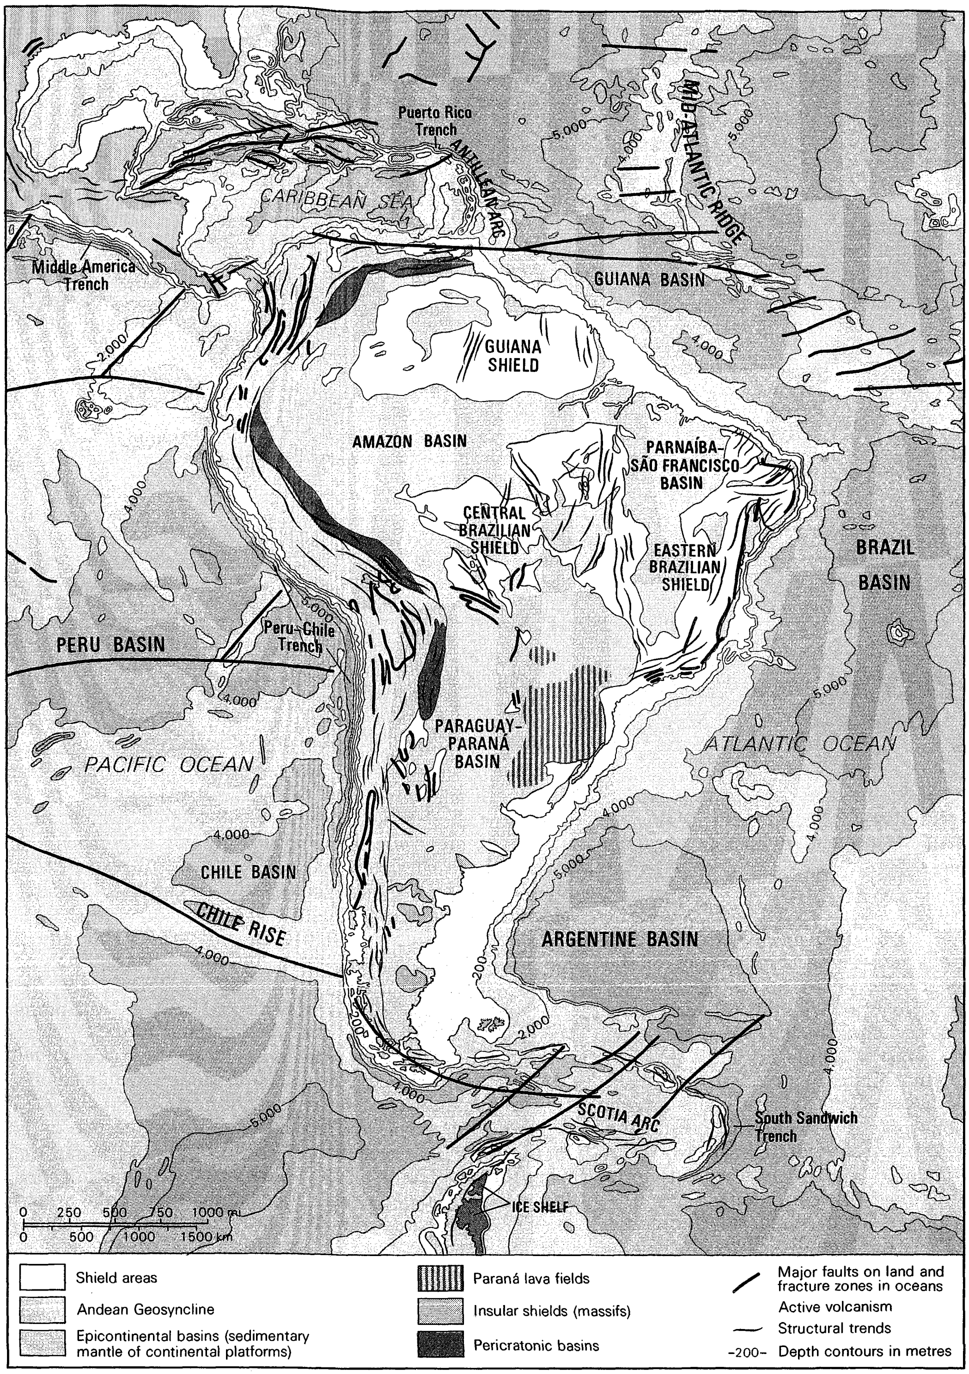
The belt of pericratonic basins lies along the western edge of the Brazilian shields and has a tendency to subsidence. It is long and narrow and runs from north of the Orinoco through Acre, Beni, and Chaco to south of the Río de la Plata. From the Precambrian Era to the beginning of the Mesozoic Era (about 225,000,000 years ago), seas invaded this slowly sinking region, depositing sediments, which slowly merge with continental strata on the east.

The Andean Geosyncline

The Andean Geosyncline occupies a zone stretching from the island of Trinidad on the northern coast to Tierra del Fuego in the extreme south. The original geosyncline contained sediments from the western highlands and from a continental mass that has now subsided under the Pacific, as well as of marine deposits that accumulated from the Late Precambrian Era onwards. Rapid and persistent subsidence was counterbalanced by the occurrence of extensive sedimentation. Movements of the Earth's crust began in the Paleozoic Era and were accompanied by intense volcanic activity, but the main activity began in the Early Mesozoic Era, reaching a maximum during the Middle and Upper Tertiary Period (from about 26,000,000 to 2,500,000 years ago). Movements continued up to the Pleistocene Epoch (from 2,500,000 to 10,000 years ago). Intense volcanic activity occurred from the Jurassic Period (from 190,000,000 to 136,000,000 years ago) to the Tertiary Period (from 65,000,000 to 2,500,000 years ago). Plutons (bodies of rock formed beneath the Earth's crust by solidification from a molten or partly molten state), running from Colombia in the north to Cape Horn in the south, form the bases of many cordilleras (groups of mountain ranges) and the summits of important massifs.

GEOLOGICAL DEVELOPMENT

The Precambrian Era is divided into early and late periods. The Serra do Mar and the "sugar loaf" formations



Structural features of South America.

in the Baía de Guanabara (Bay of Guanabara), both in southern Brazil, belong to the early period; the so-called Minas series (a long belt of metamorphosed sediments located in the State of Minas Gerais, Brazil), on the other hand, which contains valuable minerals, belongs to the late period.

During the Cambrian Period (from 570,000,000 to 500,000,000 years ago) marine deposits accumulated in the Andean syncline and in the Amazon region of Brazil. Continental deposits of glacial or fluvial origin were laid down in various other districts, including northern Paraguay and the Brazilian Mato Grosso.

During the Ordovician Period (from 500,000,000 to 430,000,000 years ago) only the Brazilian shields were not beneath the sea, which covered the Gran Chaco region, the Paraguay Basin, and the whole of Patagonia. Thick beds of shale (laminated sediments consisting mostly of clay) and sandstone were consequently scattered from Huánuco, Peru, to La Rioja, Argentina.

Those parts of the geosyncline that extended from Tierra del Fuego to central Peru and from Quito in Ecuador to the Orinoco Basin were uplifted during the Silurian Period (from 430,000,000 to 395,000,000 years ago). Between these two ranges the sea invaded the Amazon Basin, and even the Parnaíba–São Francisco Basin. A geosyncline extended from Bolivia to the mouth of the Río de la Plata and to northeastern Argentina. During the late Silurian Period the sea regressed from almost all the land, except the Andean Geosyncline.

During the Devonian Period (from 395,000,000 to 345,000,000 years ago) the sea again invaded the whole Andean Geosyncline and later joined Amazonia and the Parnaíba Basin to Patagonia. During the later part of the period it regressed once more when mountain-building movements occurred in the Andean region. Much sedimentation occurred during this period, with sands being deposited in the Andean Geosyncline, sandstones in Amazonia, and conglomerates and sandstones in the Parnaíba Basin.

The Carboniferous Period

During the Carboniferous Period (from 345,000,000 to 280,000,000 years ago) the sea was at first restricted to Chile, western Argentina, central Colombia, and part of the Parnaíba Basin but later invaded a large area from west of Lake Titicaca to Venezuela, depositing deep layers of sandstone in the Amazon Basin and limestone and shales in Peru and northern Colombia. Glaciation occurred south of a line from Lake Titicaca to São Paulo, as a result of which glacial sediments and moraines (deposits of boulders, gravels, sands, and clays left by glaciers) were laid down in the Paraná Basin.

During the earlier part of the Permian Period (from 280,000,000 to 225,000,000 years ago) a shallow sea invaded Bolivia; later in this period, however, the sea withdrew from the entire continent. Red beds (red coloured sedimentary rocks) and continental sandstones were deposited on the border of a geosyncline which extended from Peru to northern Argentina. In Peru, volcanic activity resulted in the depositing of volcanic detritus that had been explosively ejected from volcanic vents. The Andean region of the continent as a whole was subjected to movements of the Earth's crust that permitted basaltic or andesitic magma (mobile rock material of volcanic origin) to flow out.

South America was free from invasion by seas during the Triassic Period (from 225,000,000 to 190,000,000 years ago); red beds were deposited from Colombia in the north to Patagonia in the south, sometimes attaining thicknesses of almost 10,000 feet. In the later part of the period, the Paraná Basin became a huge desert; sandstones deposited at this time are at least partly of windborne origin and now cover more than 500,000 square miles.

During the Jurassic Period (from 190,000,000 to 136,000,000 years ago) the continent was generally not covered by the sea, although it periodically invaded some districts in the Andean region, depositing limestone beds containing ammonites (one of a large extinct group of mollusks) in many places from Colombia to Patagonia; the Chilean coastal plain (associated with the Andean Geosyncline because of the downward warping of the western section of the Chilean Andes) also remained maritime. There was much volcanic activity on the east side of the geosyncline; in Peru and western Chile it resulted in the depositing of lava and tuffs (rocks formed of compacted volcanic fragments) from about 30,000 to 60,000 feet thick, forming one of the largest volcanic masses on Earth. Volcanic activity continued to the end of the Mesozoic Era, when it reached its greatest extent, notably in the Paraná Basin where lava flows about 5,000 feet thick occurred, as well as along a lengthy belt from Venezuela to the lower Amazon and to the Parnaíba Basin. At the end of the Jurassic Period the rise of the Andes began.

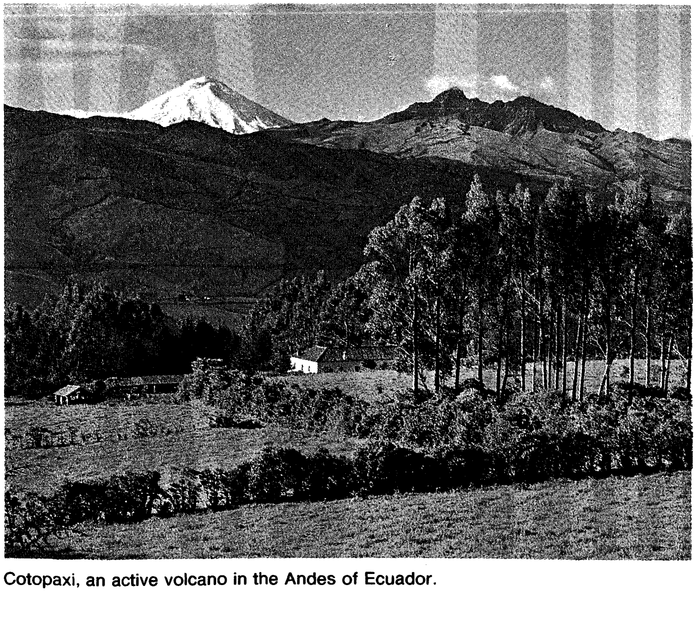
Beginning of the Andes

During the Cretaceous Period (from 136,000,000 to 65,000,000 years ago) seas invaded the larger part of the continent, with the Precambrian shields remaining as islands. The northern part of the Andean Geosyncline was still sinking rapidly, as indicated by the deposits of limestone about 46,000 feet thick that are to be found in Colombia. Continental sedimentation was active in the Amazonian, Paranaiba, and São Francisco basins, while layers of calcareous sand were deposited over the Brazilian Shield.

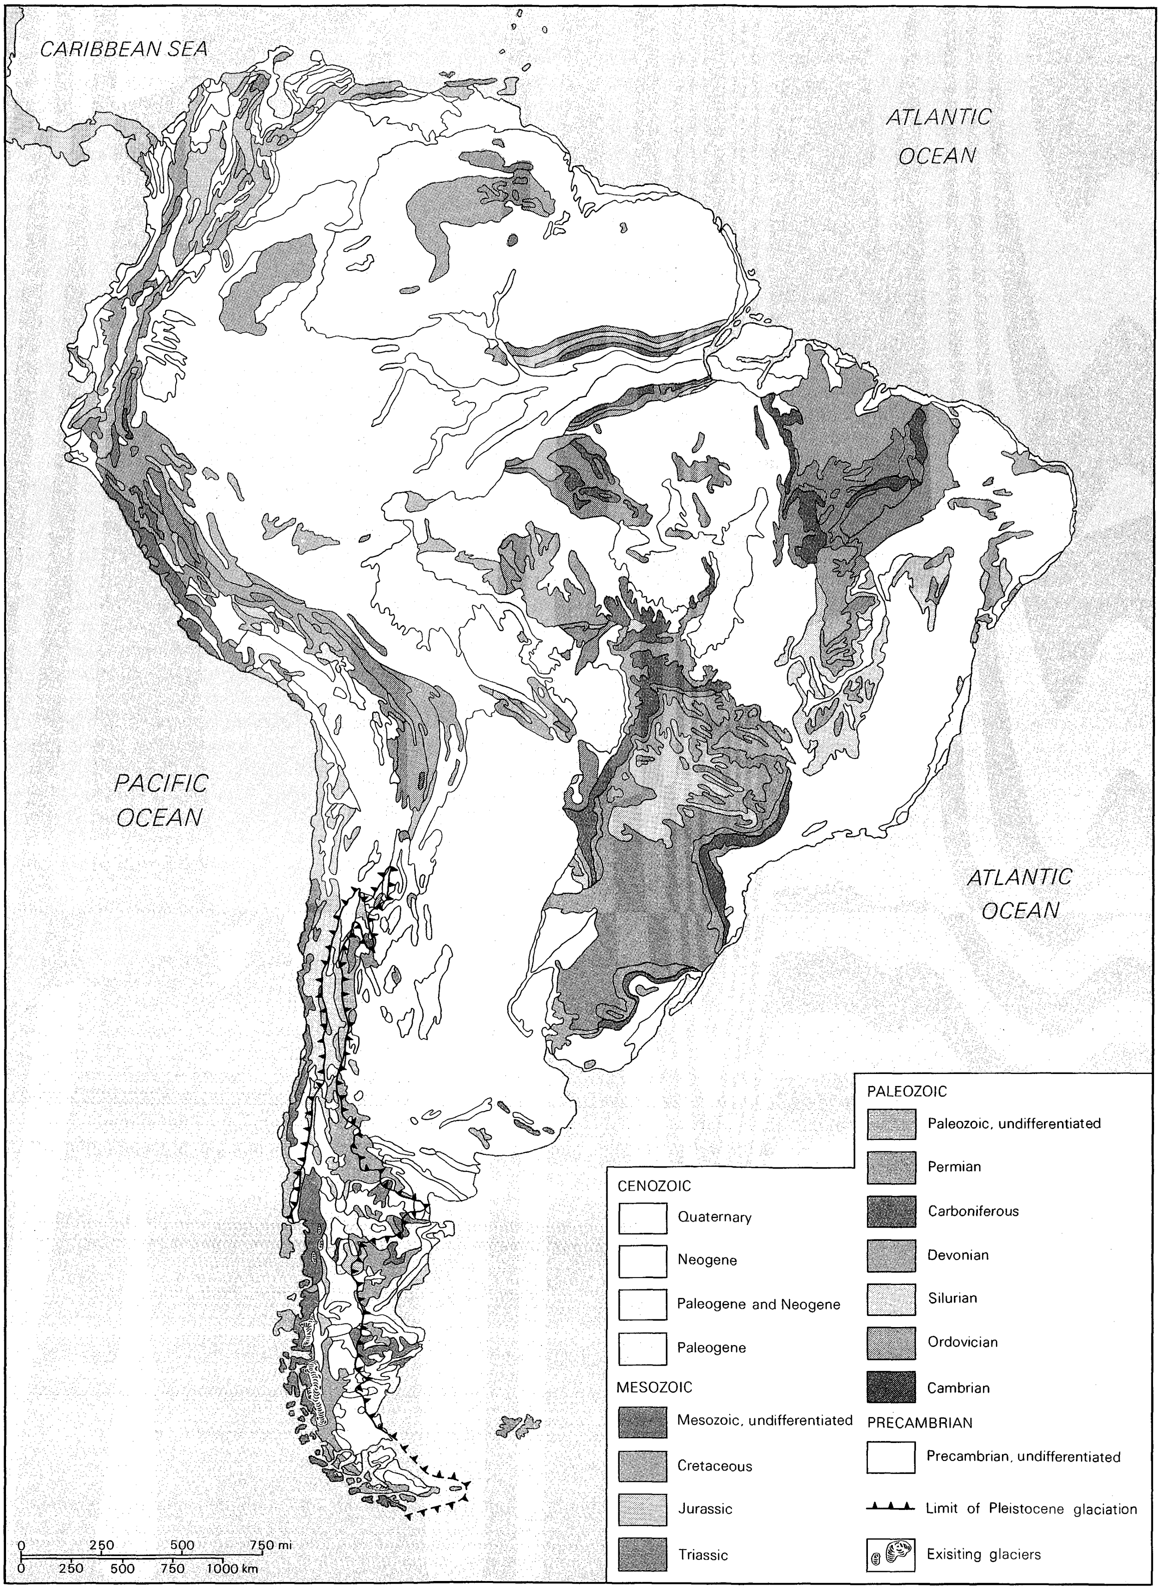
During the final part of the Cretaceous Period, the rise of the Andes reached its first maximum of activity with the uplifting of the Cordillera Central of Colombia, the Cordillera of Ecuador, the Cordillera Occidental of Peru, and the main ranges of Chile and Argentina. Mountain-building activity was strong along the length of the western Andes, and many intrusive rocks coalesced to form large and complex batholiths (very large masses of intrusive igneous rock), which are visible from Peru to Chile. Volcanic activity continued, and erosion resulted in continental sedimentation occurring in Peru, Bolivia, and Argentina (including the depositing of sandstones with abundant dinosaur remains in Patagonia). The sea regressed from the Amazon Basin at this time.

During the Eocene Epoch (from 54,000,000 to 38,000,000 years ago) of the Tertiary Period (from 65,000,000 to 2,500,000 years ago), great changes occurred. The sea

Shostal—EB Inc.



Cotopaxi, an active volcano in the Andes of Ecuador.



Geological structure of South America.

regressed almost everywhere, except in the northwest and in the centre of Patagonia between the Deseado massif and the cordilleras.

During the Oligocene Epoch (from 38,000,000 to 26,000,000 years ago) the sea returned, invading eastern Peru. The main event during the Tertiary Period was, however, the persistent uplifting and folding of the Andes, which assumed their present form in the Miocene Epoch (from 26,000,000 to 7,000,000 years ago). From this time onward the range formed a huge barrier and the gate between the Amazon region to the Pacific via Ecuador was finally closed. The Amazon Basin at first formed a huge freshwater lake but later drained into the Atlantic. At the same time the uplifting of the Andes determined mountain-building movements on their eastern border; nappes (laterally displaced, faulted, and overturned folds), sometimes more than 3,000 feet thick and several hundreds of miles long, were projected eastward against the Brazilian plateaus. Basins became filled with sediments eroded from the surrounding mountains, and much volcanic activity occurred.

evelopments n the leistocene poch

During the Pleistocene Epoch (from 2,500,000 to 10,000 years ago) sedimentation continued and the general uplifting of Patagonia occurred. The Pleistocene Epoch was mainly marked by important glaciation. Ice caps covered the Andes from Tierra del Fuego to Ecuador as many as four times, reaching the Atlantic in the south where moraines are to be found today in Patagonia; glacial terraces covered the plateaus at these times. Much loess (a loamy deposit, formed by the wind) deposition took place, particularly in the Argentine Pampas (grassy plains), which are almost entirely covered by a thin layer of continental deposits of the Quaternary Period (the last 2,500,000 years). Deposits from rivers or lakes covered more than 38,000 square miles in the Pantanal (the marshy plains in the Paraguay River Basin). Volcanic activity continued, especially in the Andes. Thick deposits of volcanic ash were laid down in the inter-Andean trough extending from Chile to Ecuador. Climatic changes following the last glaciation produced laterization (the formation of reddish residual soil, leached of silica and containing concentrations of iron and aluminum hydroxide) and large-scale soil modifications in Brazil and the Guianas (Guyana, French Guiana, and Suriname). Gigantic lakes formed in the Andean region as the ice melted included Lake Ballivián, which covered the area now occupied by Lake Titicaca, as well as others in Argentina and Paraguay.

The land

RELIEF

South America has two major mountain systems of unequal mass. The young cordilleras of the Andes in the west extend down the entire continent from north to south, bordering the Pacific. On the eastern side are the ancient Guiana and Brazilian highlands, which are much less high and slope gently to the west; further south are the Patagonian plateaus. Lowlands—the Orinoco, the Amazon, and the Paraguay basins and the Pampas—divide the highlands from one another. The relief of the whole continent shows an imbalance; a drop of rain that falls only 100 miles east of the Pacific will flow down to the Atlantic, 2,500 miles away.

The Andes. The Andes mountain ranges, about 5,500 miles long and second only to the Himalayas in average height, constitute a formidable and continuous wall with many summits more than 22,000 feet high. Near the southwestern frontier of Colombia and through Ecuador they form a single mountain mass, from which three distinct massifs—the Cordilleras Real (Oriental), Central, and Occidental—branch out. The valley of the Río Magdalena, between the Oriental and the Central ranges, and the valley of the Río Cauca, between the Central and the Occidental ranges, are in fact huge rifts. An overall view of the Andes in Colombia shows, within relatively short distances, a succession of hot lowlands and high ranges with a cold climate.

he olombian ndes

In Peru the Andes form two parallel cordilleras, one along the Pacific and the other descending eastward toward the valleys of the Ucayali and Urubamba rivers. The western range is the highest, particularly in central Peru where it splits into two chains; its impressive snowclad peaks include Huascarán (22,204 feet). Between the two cordilleras extends the Altiplano—a vast complex of high plateaus between 12,000 and 15,000 feet high and sometimes as much as 125 miles wide. This Altiplano forms a maze of valleys, hills, and vast plains without equivalent except in Tibet. Water accumulates in closed basins to form marshes and lakes, one of which is Lake Titicaca. This huge massif has been dissected by rivers such as the Marañón, Huallaga, Apurimac, and Urubamba, all of which have cut spectacular gorges down the eastern slopes.

In the south, the Andes form a single but very complex chain with many peaks; one of which—Aconcagua—at 22,834 feet (6,960 metres), is the highest mountain in the Western Hemisphere. In Patagonia, a part of the cordillera runs beneath the sea, forming innumerable islands with steep slopes. The Andes have also been deeply carved by glaciers, which still occupy about 1,900 square miles, constituting an ice cap with long terminal tongues running into lakes or into the sea.

The Andes are studded with volcanoes that form part of the so-called "ring of fire"—the vast circle of volcanoes that border the Pacific. Earthquakes are frequent; almost every city has at one time been totally demolished, even along the coastal plains, where clear signs of recent vertical movement are visible.

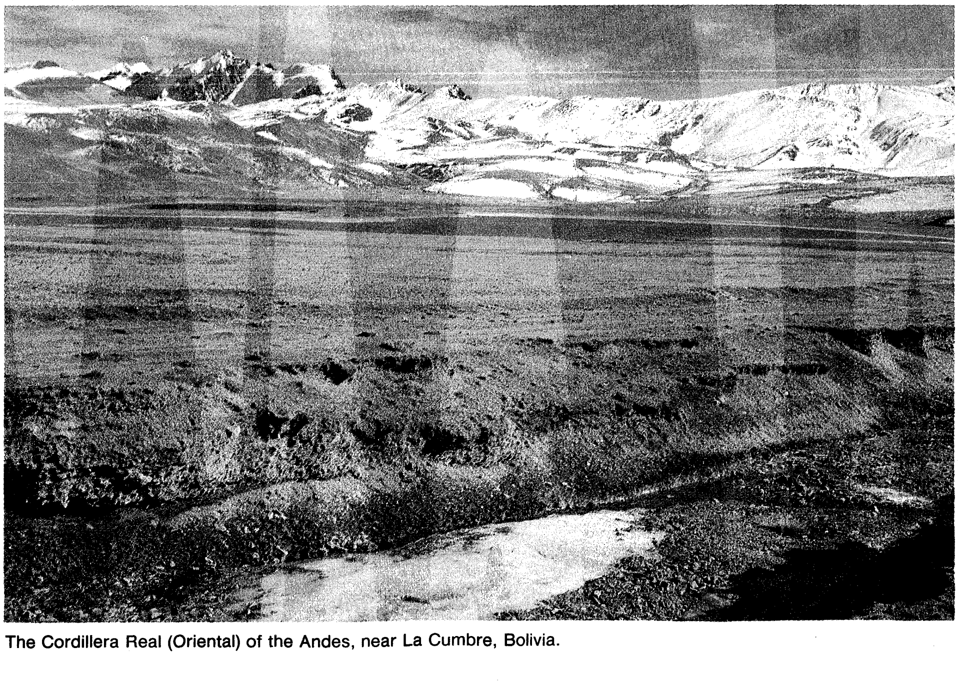
Detailed discussion of the Andes can be found at the end of this article.

The eastern plateaus. To the east, the Guiana Highlands and Brazilian plateaus consist of very old crystalline rocks, most of them greatly worn down. The Guiana Highlands are a monotonous expanse, about 800 feet high, forming a series of small hills which are separated by marshy depressions and are surmounted by dome-shaped granitic inselbergs (steep-sided residual hills), some 2,000 feet high. The southern edge rises abruptly to a mountain chain, the Tumucumaque, and to some high tablelands, such as Mt. Roraima (9,094 feet) and Mt. Duida (7,859 feet).

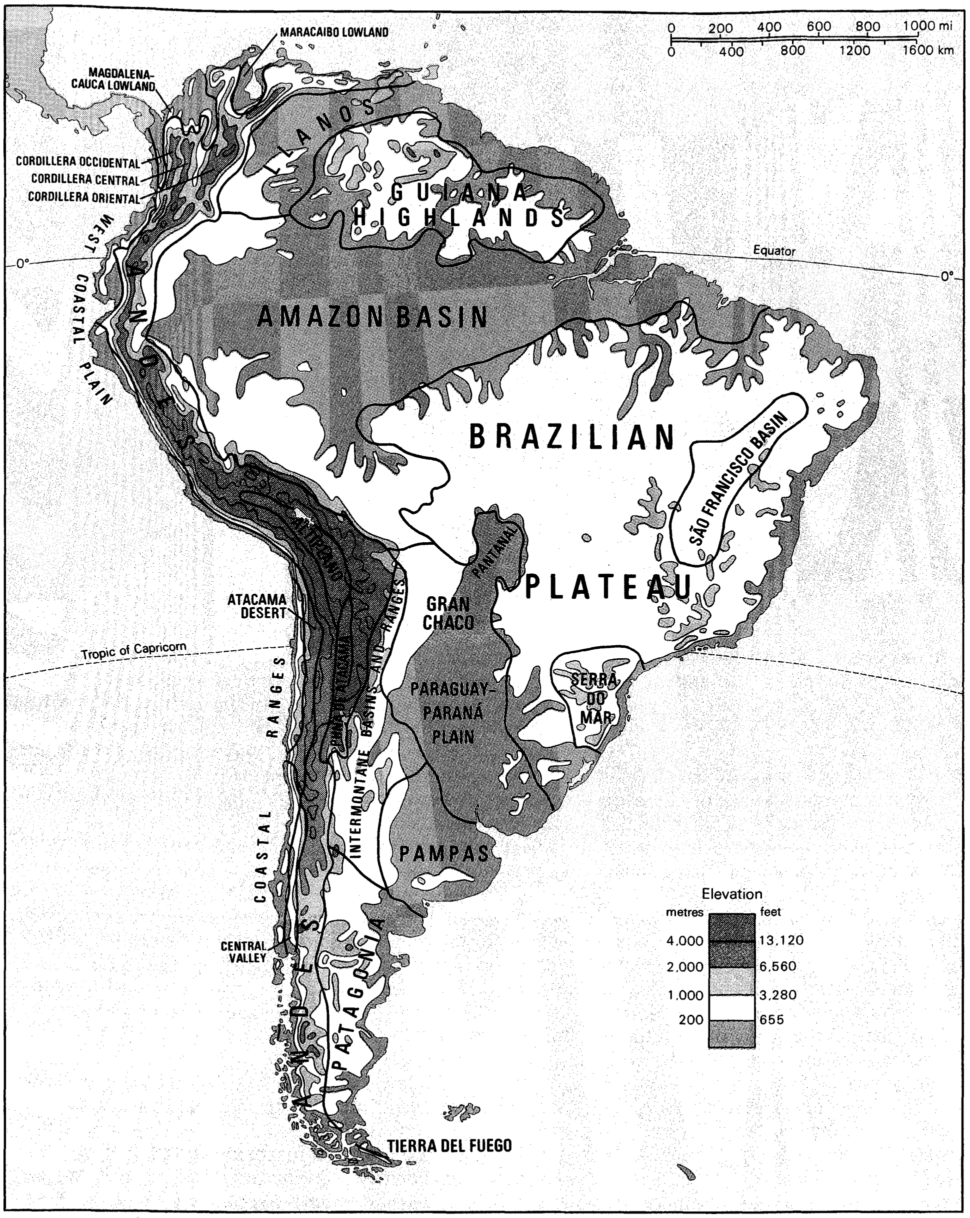
The Brazilian Plateau

Covering an area of about 580,000 square miles, the Brazilian Plateau (also called the Brazilian Highlands)

Shostal—EB Inc.



The Cordillera Real (Oriental) of the Andes, near La Cumbre, Bolivia.



Physiographic regions of South America.
Adapted from *Odyssey World Atlas*, © General Drafting Co. Inc.

rises to about 3,000 feet and is crowned by short ranges of hills; the São Francisco River has cut deeply into it. In the north the plateau slopes gently down to the sea, but in the east it drops abruptly down, sometimes as much as 2,600 feet. Skirting its southern edge, the Serra do Mar has summits of more than 7,000 feet—such as the Pedro do Sino (7,365 feet). The sea has partly invaded the original coastal ranges; there rocky masses, such as the Pão de Açucar, or Sugar Loaf (1,279 feet), and the Pico do Corcovado (2,309 feet), have been isolated by the sinking of surrounding land.

Eastern Patagonia constitutes a series of gigantic tablelands covered with rounded pebbles and crumbling sandstones. Volcanic eruptions have also spread layers of basaltic lava flows and have dotted the sedimentary plateaus with volcanic cones.

The lowlands. The Orinoco Basin, which is also called the Llanos, extends between the coastal ranges of the Venezuelan Andes and the Guiana Highlands and is covered with alluvia which has been brought down by the Andean torrents.

The Amazonian depression, the largest river basin in the world, forms an enormous drainage area of 2,722,000 square miles, bounded by the Andes to the west, the Guiana Highlands to the north, and the Brazilian plateaus to the south. The ancient platform of primary rock that underlies the Amazonian depression is covered with layers of alluvial sand and clay, so that it forms an immense plain of low undulations, the general incline being extremely slight. Iquitos, in Peru, is at an altitude of only 384 feet, while Manaus, in the heart of the basin, has an altitude of 144 feet.

The basin of the Paraguay River, between the Bolivian highlands in the west and the Brazilian plateaus in the east, consists of a series of vast alluvial plains drained by a complex network of rivers interspersed with marshes. These plains, called the Pantanal, are only a few hundred feet above sea level and are subject to annual floods; they form an immense swamp during the rainy season.

The Pampas, covering almost 300,000 square miles, consist of an immense accumulation of loose sediments brought down from the Andes. These deposits, 1,000 feet deep at Buenos Aires and much deeper at some other places, have completely buried the ancient features of the land. The landscape is monotonous and seems perfectly level, though in fact it rises imperceptibly toward the west—rising from an elevation of 66 feet near Buenos Aires to 1,640 feet at Mendoza. Some hills, such as the Córdoba and San Luis ranges, stand out from the plains like islands.

Detailed discussion of the Gran Chaco, the Patagonian Desert, and the Llanos can be found at the end of this article.

CLIMATE

As South America extends over a vast range of latitudes, it is hardly surprising that it has a great variety of climates. Although it is the only southern continent to reach such a high latitude, it nevertheless has its broadest extent in the equatorial zone, so that tropical conditions prevail over half of the continent.

ir
rculation
atterns

Factors influencing climate. The circulation of air over the continent is influenced by winds related to the great anticyclones (circulation of winds around central regions of high atmospheric pressure) of the Atlantic and Pacific oceans. Trade winds blow from the northeast in the Northern Hemisphere and from the southeast in the Southern Hemisphere. Another southern high-pressure region is located off the west coast, so that strong westerly winds blow toward the continent. Two low-pressure centres—one situated over the south polar region, the other extending from northeastern Brazil to the Gran Chaco region of Argentina—affect wind patterns inland.

Landforms largely influence specific circulation patterns. Above all, the Andes prevent winds from the South Pacific anticyclone from reaching the interior of the continent.

Ocean currents have a strong influence, particularly the so-called Peru (Humboldt) Current, which in effect is a series of upwellings along the steep Pacific coast, which result in cold water being carried to the latitude of southern Ecuador, where the flow turns westward. Average surface temperatures vary from about 58° to 64° F (about 14° to 18° C)—about 18° F (10° C) lower than is usual in such latitudes. The east coast is washed by the cold Falkland Current in the south and by the warm Brazil Current in the north.

Finally, altitude plays an important part. Wide areas located within the tropical zone were uplifted by the rise of the Andes.

Climatic regions. South America can be divided into several well-marked climatic regions, as determined by the factors already mentioned. Four major types of climate occur—tropical, temperate, arid, and cold.

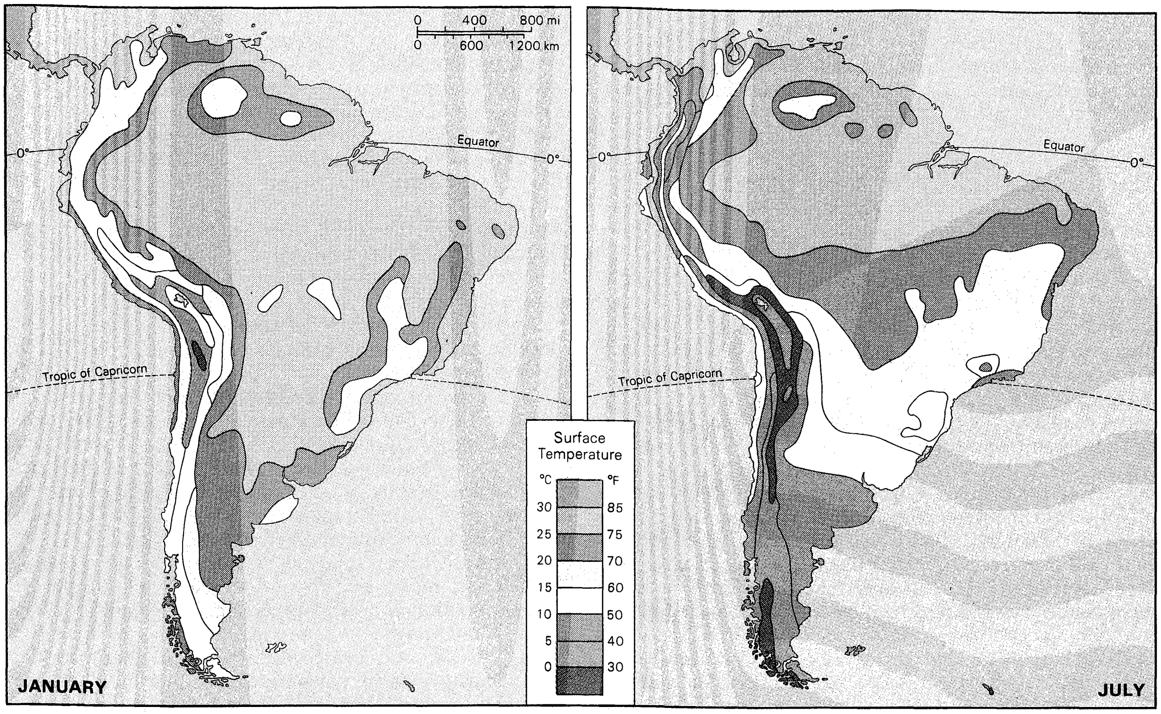
Among the tropical climates, the tropical rain forest type occurs on the Pacific coast of Colombia, in the Amazon Basin, and on part of the coast of Brazil. The average temperature is around 86° F (30° C), with monthly and annual variations of less than about 5° F (about 3° C); heavy rainfall, evenly distributed all the year round, averages about 98 inches (2,490 millimetres) in Pará, about 108 inches in Iquitos, 71 inches in Manaus, and 354 inches in the Chocó region of Colombia—one of the most watered zones in the world, where it rains more than 300 days a year. In the Amazon region, rains do not fall regularly all over the basin. The southern part receives rain especially during the southern summer (from October to April), while the northern part has its rainy season during the northern summer from May to September. The "dry" season is neither lengthy nor noticeable; humidity is always high.

The second type of tropical climate—the savanna (grassy parkland) type—is characterized by high temperatures (with monthly minimum temperatures above 64° F, or 18° C) but receives less precipitation and experiences a definite dry season. It is found around the rain-forest belt, in the Orinoco Basin, on the Brazilian Highlands, and in part of western Ecuador. Temperatures are still high and annual variations small, but average daily temperature extremes are greater, ranging from 42° to 63° F (6° to 17° C). There is a prolonged dry season.

Temperate climates, characterized by lower winter temperatures, are found south of the Tropic of Capricorn (in Paraguay, parts of Bolivia, Brazil, Argentina, and Chile) and in the Andes, where, in their rainfall pattern, they resemble tropical climates. On the Atlantic side, temperatures in the warmest month average 77° F (25° C), but cold-month averages vary from 63° F (17° C) in the north (Asunción, Paraguay) to 50° F (10° C) in Buenos Aires; rainfall is greater than one and a half inches each month in the east but decreases to the west. In central Chile, between latitudes 32° and 38° S, the features of the climate are similar to those of the Mediterranean, with mild winters and winter rains; summers are, however, cooler (69° F, or 21° C, in Santiago, Chile, in January—19° F, or 5° C, cooler than in the Mediterranean). In southern Chile, winter temperatures are lower, but not as low as the latitudes would seem to indicate. The islands and channels have a relatively uniform climate throughout the year, and winters are much less severe than in Labrador, which is at a comparable latitude north of the Equator. The presence of glaciers is the result of cold and cloudy summers during which ice does not melt. Rainfall is very high (102 inches in Valdivia, Chile, and probably twice this figure on the western slopes of the mountains), while the coast is one of the most heavily watered regions in South America. A short distance inland, rainfall decreases considerably (20 inches at Ushuaia, Argentina, which is protected from the westerly winds). Thus, in Patagonia there are surprisingly greater differences in climate from west to east than from north to south. Winds are very violent.

Arid zones

Arid climates are found in four areas. Patagonia east of the Andes is in the rain-shadow zone, and rainfall is low (about four inches in San Juan, Argentina). The annual range in temperature is more than 36° F (20° C)—the



Average temperatures for January and July for South America.

highest in South America—and is caused by warm summers and cold winters. Another arid zone is found in a narrow coastal strip along the Pacific coast between latitudes 5° and 31° S. The cold seas (the Peru, or Humboldt, Current) and the proximity of the high Andes produce an inversion of normal atmospheric temperatures, as air in contact with the water cools more rapidly than the upper strata of air. The result is a cloud layer about 1,200 feet thick, lying at altitudes varying between about 1,000 and 3,000 feet, that prevents the warming of the air near the ground. Temperatures are consequently low: Lima has an average annual temperature of 64° F (18° C), ranging from about 72° F (22° C) in February to about 59° F (15° C) in August. The coast of Peru is thus the cloudiest desert in the world, with no sunshine for at least six months of the year. It almost never rains, except under abnormal circumstances, but condensation of fog (called *garúa* by the Peruvians) provides some humidity. Another desert extends from northeastern Colombia to Venezuela, covering a zone where rains are scarce and droughts prolonged.

Finally, an arid zone occurs in northeastern Brazil, between the Parnaíba and São Francisco rivers. The interior highlands act as a wedge separating the sea winds from the northeast and those from the southeast, all of which carry their moisture beyond the region. Average annual rainfall is less than four inches, and the dry season may last as long as seven months. The worst feature of the climate is the irregularity of the rainfall, as a result of which severe droughts plague the region.

Cold climates, with average annual temperatures of less than 50° F (10° C), occur in the southernmost parts of Argentina and Chile and in the high Andes above about 11,500 feet. Mean temperatures are relatively low, but daily variations are wide. There is a marked difference in humidity between the northern and southern parts of the upper Andean zone. In Colombia and Ecuador the climate at such altitudes is cool and damp. Temperatures, always low, may on the average vary daily from 54° F (12° C) during the daytime to 28° F (−2° C) at night. Rainfall is high and well distributed throughout a good part of the year. Clouds and mist are dense, and sun shines only for short periods. From central Peru to Bolivia and Chile, temperatures are still lower. Near Lake Titicaca, the average annual temperature is only about 34° or 36° F (1° or 2° C); November is the warmest month, with a temperature of 41° F (15° C), while the coldest month, July, has an average of 28° F (−2° C). Daily variations are considerable; the daily maximum of 68° F (20° C) drops to a nocturnal minimum of 5° F (−15° C). Annual rainfall varies from 24 to 56 inches but is concentrated during the southern summer, from November to April. The dry season is long and is characteristically accompa-

Average annual precipitation in South America.

nied by drought. Winds are constant and often violent, accelerating the coldness and the dryness of the climate, which produces a harsh and hostile environment. As in any mountainous region, climate varies largely according to local conditions.

DRAINAGE

Rivers. Drainage has been deeply affected by the dissymmetry of the continent. The largest basins are found on the east side, and the main rivers run to the Atlantic Ocean.

'he ›mazon :iver

By far the largest river is the Amazon River, which, with a length of 4,000 miles, is second only to the Nile; the volume of water carried, however, surpasses that of all other rivers, comprising a fifth of all the flowing water of the world. About 6,350,000 cubic feet (179,800 cubic metres) of water per second is emptied into the Atlantic by the Amazon—10 times more than the Mississippi. The Amazon drains more than three-tenths of South America and has more than 1,000 tributaries, seven of which are more than 1,000 miles long. The source of the Amazon (although not the most distant of its headwaters from the sea) is in a small lake (Lauricocha) at an altitude of 15,875 feet (4,840 metres) in the Cordillera Huayhuash, near the Cordillera Blanca, Peru. It is named the Marañón in its upper course; after being joined by several rivers, it escapes from the Andes through narrow canyons. It is from the source of one of these rivers, the Ucayali, that the Amazon's length is measured. Below Iquitos, Peru, the river—often called Río Solimões—is joined by the Río Napo, which flows out of Ecuador; further on, near Manaus, it is joined by the mighty Rio Negro, which drains a large part of northern Brazil. The Amazon, then at full strength, winds through the low plains to pass between the Guiana Highlands and Brazilian Highlands before emptying into the Atlantic.

As rains do not fall regularly year round all over the basin, the river has two annual floods in its upper course, which is subject to the alternate influence of the tributaries that descend from the Peruvian Andes (where rains fall from October to January) and the tributaries on its left bank, which descend from Ecuador (where rains fall from March to July). This pattern of alternation disappears further downstream, the two seasons of high flow gradually merging into a single one, which progresses slowly downstream in a gigantic wave from November to June. The height of the floods is lower further downstream. At Tefé, the difference between the high and low water mark is 50 feet and, at Óbidos, Brazil, only 25 feet. The width of the river likewise varies; exceptional floods may extend more than 60 miles beyond the main river bed. Because of the low gradient of the basin, tides are perceptible as far as Óbidos, 600 miles from the Atlantic coast.

The Paraguay, Paraná, and Uruguay system

The second important drainage system, variously estimated to cover from 1,600,000 to 1,700,000 square miles, is formed by the Paraguay, Paraná, and Uruguay rivers, which empty into a vast expanse of the water, the Río de la Plata—actually not a river but a gulf. About 2,800,000 cubic feet of water per second flow from the common mouth of these rivers. The Paraguay River, with a length of 1,584 miles, rises in the Bolivian hills; it is a river of the plains, flowing across a wide stretch of marshes (the Pantanal) in its middle course; its lower course is, however, drier. The Paraná River, with a length of 2,485 miles, flows mainly among high plateaus.

The Orinoco River, 1,337 miles long, is the third largest drainage system, covering about 365,000 square miles. It flows west and then north; plunging down a series of steep slopes, it then flows along an almost flat basin. Near the ocean, it divides into a series of distributaries that form the Delta Amacuro, which has an area of about 5,000 square miles. The rainy season from April to October causes annual floods, which at Ciudad Bolívar, Venezuela, reach a height of 60 feet in July. By means of the Casiquiare Canal, it communicates with the Amazon system through the Rio Negro.

The São Francisco River, with a total length of 1,800 miles, rises in the State of Minas Gerais, Brazil, and flows northward for 1,000 miles before curving eastward to the Atlantic. The river has been an important artery of communication since colonial times and is now the location of large hydroelectric projects in operation since 1955, at Cachoeira da Paulo Afonso (Paulo Afonso Falls), and at Três Marias, north of Belo Horizonte.

Jacques Jangoux

Lake Titicaca, the world's highest large lake, located between Peru and Bolivia. The Cordillera Real of the Andes rise along the northeastern shore of the lake.

Among other important rivers are the Río Magdalena in Colombia (navigable in two sections separated by rapids at Honda), and the Essequibo, Maroni, and Oyapock rivers in the Guianas.

Drainage to the Pacific is different because of the proximity of the Andes from the Pacific coast and the scarcity of rains from southern Ecuador to northern Chile. The rivers are consequently very short, and few convey any large quantity of water. The only important rivers are the Río Guayas in Ecuador, on which the port of Guayaquil is located, and the Río Santa in Peru. Some torrents had great importance since early times, when good water management permitted ancient civilizations to develop. In central Chile the valleys of Río Aconcagua and Río Bío-Bío are very fertile.

Detailed discussion of the Amazon River, the Orinoco River, the Rio de la Plata system, and the São Francisco River can be found at the end of this article.

The Andean lakes

Lakes. Most of the lakes are mountain lakes located in the Andes or along their foothills. Because of the complex topography, water has accumulated in closed basins. Among permanent lakes, the largest is Lake Titicaca, which lies at an altitude of 12,500 feet (3,810 metres) between Peru and Bolivia; the lake measures 110 by 35 miles and was much wider in the past. Lago de Junín in central Peru; Lake Sarococha, also in Peru, between Puno and Arequipa; and Lago Poopó in Bolivia also rank among the larger Andean lakes. These create uniform physical conditions throughout the year in terms of temperature and percentage of dissolved gas; up to an altitude of 16,000 feet they never freeze. In consequence, the climate of their shores is temperate.

Another type of lake is to be found in Patagonia where, in the wake of melting glaciers, lakes have formed, such as Lago Buenos Aires, Lago Argentino, and Lago Nahuel Huapí. Their eastern parts, which stretch to the end of the Argentinian plateau, generally have gently sloping banks bordered by low mountains, while their western parts form a series of narrow arms, like fjords, lying between steep slopes.

Marshes and swamps. Marshes are to be found in depressions in many parts of the continent. One of the widest marshy areas is the Pantanal, in the middle valley of the Paraguay River; it is subject to flooding in December, reaching its highest watermark in June, when it becomes an immense swamp; similar habitats are to be found in the Orinoco Basin.

Swamps of another type are found in rain forests, mostly in the Amazon region and in northwestern Colombia. The ground is inundated or very marshy throughout the year or else only at the time of the annual flood.

Finally, the mouths of the Orinoco and of the Amazon

rivers form wide marshy deltas, while mangrove swamps of various types are to be found from southern Ecuador to Santos in Brazil.

SOILS

As a consequence of its geological history, geomorphology, and climate, no less than 26 soil regions, many of which are split into several subdivisions, can be distinguished in South America. They consist of three major groupings, which correspond to the continent's three major geographical components—the lowlands, the uplands, and the Andes.

Low natural fertility is an outstanding feature of South American soils. About 50 percent of the continent's soils are made up either of unconsolidated and nutrient-poor sediments (such as china clays and quartz sands) in the river basins, latosols (red residual soils, also called laterite, leached of silica and containing concentrations of iron and aluminum hydroxides), red-yellow podzols (highly bleached soils that are low in iron and lime), and regosols (azonal soils consisting chiefly of imperfectly consolidated material and having no specific morphology). About 20 percent of the continent is covered by desert soils of various types in which agriculture is hazardous because of lack of water. Other regions, representing about 10 percent of the total area, suffer from poor drainage, the soils being gleys (layers of soil in which the material is blueish grey, generally sticky, and often structureless, due to excessive moisture), groundwater laterites, grumosols (soils formed of granules), and planosols (a type of soil found in humid climates in which soluble salts and minerals are leached out of the upper layers and are cemented or compacted at a lower level). In the Andes, slopes are often steep, and lithosols (soils with no clear morphology, consisting of imperfectly weathered masses of rock fragments) abound, accounting for about 10 percent of the continent's surface. In the inter-Andean valleys and on some of the foothills, nevertheless, eutrophic soils (deposited by lakes, and containing much nutrient matter, but often shallow and subject to seasonal oxygen deficiency) can be found.

ıe fertile
il
gions

Fertile soils extend over only about 10 percent of the surface of South America. The most important of these are brunizems (any of a zonal group of deep dark prairie soils, developed from loess; *i.e.,* unstratified loam deposited by the wind), chestnut soils, ferruginous tropical soils, red latosols, and reddish-brown lateritic soils. On the low coastal ranges and in the foothills of the western Andes and on the nearby plains and terraces of Colombia and Ecuador, the soils consist mainly of red-yellow latosols, podzols, and alluvial soils. Soils in southern Brazil and Uruguay are not uniform and consist of brunizems, reddish prairie soils, and planosols. The Argentinian Pampas, the largest fertile area on the continent, is uniformly covered with the so-called pampean loess, which is calcareous, rich in minerals, and partly of volcanic origin. Other rich soils are found in the uplands of northeastern and central Brazil; they consist of sandy regosols in the north and red latosols in the south.

The agricultural development of South America reflects exactly the distribution of soils according to their fertility. It is mostly confined to the eastern temperate plains, in which is concentrated the production of wheat and corn and the grazing of cattle; to the subtropical and temperate parts of the Andes, from Colombia to Chile, where grazing takes place and a variety of crops are cultivated; and to eastern and southeastern Brazil, where coffee, cacao, and sugarcane are grown, while the interior plateaus are devoted to cattle grazing. The Amazon Basin is still a region of elementary agriculture, though it produces cacao and rubber.

Soil erosion has ravaged a large part of the continent. According to some estimates, in several countries up to 50 percent or more of the presently arable land has been severely affected or ruined by bad land use. In the Andes, land that once produced up to 25 bushels of wheat to the acre is now abandoned; mountain forests are still cleared for cattle grazing and cultivation, which ruins the soil of the region for years after. Soil damage has been slight in the areas in which the topography is relatively smooth. Campaigns for soil conservation or restoration are now in progress in most countries.

PLANT AND ANIMAL LIFE

South America, with its distinct vegetation and animal life, is the very heart of the neotropical region (that part of the Americas that extends from the Tropic of Cancer southwards). With Australia it is, because of its isolation from the rest of the world during the Tertiary period, the landmass with the strongest biological originality.

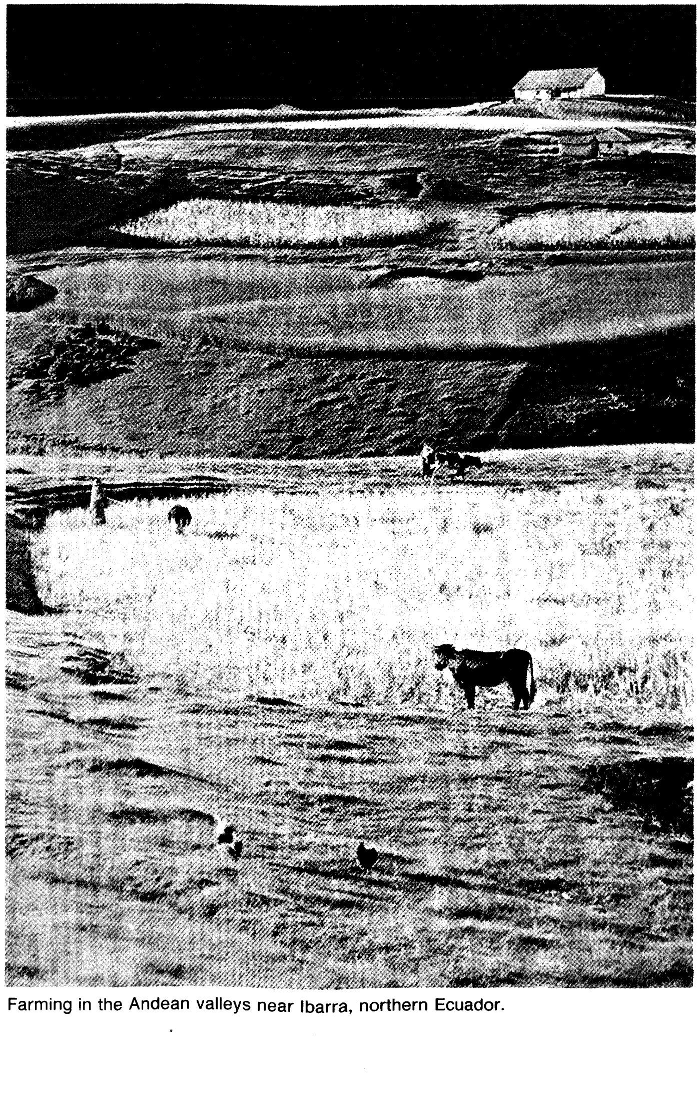
Vegetation and animal life are a mixture of elements of various relationship. Ancient groups of plants and animals including mollusks, chilopods, some fishes, reptiles, and amphibians show affinities with the animal life of Africa, Australia, and New Zealand. More recent elements migrated from or through North America during the late Tertiary Period and the Pleistocene Epoch; most of these are vertebrates.

The pattern of distribution within the continent is much diversified because of the variety of climatic and ecological zones. The northern tropical regions are the richest, while the southern part and the Andean highlands are much impoverished, despite some differentiation.

Vegetation. The origin of South American vegetation is much diversified, as is shown by the relationship of its components. The proportion of endemic plants is very high, even at the family level. Among angiosperms (plants having seeds enclosed in an ovary) no less than 25 families and 3,500 genera are endemic in the neotropical region. Others are related to African plants or belong to southern plant groups also distributed in Southern Africa and in Australasia.

Vegetation is by no means uniform all over the continent; its distribution is determined by climatic, geographic, and

Reflejo—EB Inc.



Farming in the Andean valleys near Ibarra, northern Ecuador.

soil differences. The main geographic plant zones are as follows:

Tropical and subtropical rain forests. Rain forest covers the largest part of the Amazon region, most of the Guianas, southern and eastern Venezuela, the Atlantic slopes of the Brazilian Plateau, and the Pacific coast of Colombia and northern Ecuador. The huge Amazon region is the largest and probably the oldest forest area in the world; it also ascends the slopes of the Andes until it merges with subtropical and temperate rain forest. On its southern border it merges with the woodlands of Mato Grosso, with galleries of its trees extending along the rivers. Consisting of enormous trees, some exceeding a height of 300 feet, it is composed of an almost incredible number of species growing side by side in the greatest profusion and arranged in different strata. In the region of Manaus, 1,652 plants belonging to 107 species in 37 different families were found on about 1,900 square feet. Amazonian trees number about 2,500 species.

The Amazon rain forest

The forests of the *igapós* (swamps, where the ground is inundated or very marshy throughout the year) cover the lowlands. Characteristic trees are, among others, jacareúbas (*Calophyllum brasiliense*), which is a tall tree with hard reddish-brown wood used for heavy construction, araparis (*Macrolobium acaciaefolium*), abiuranas (*Lucuma* species); piranheiras (*Piranhea trifoliata*) and louros-do-igapo (*Nectandra amazonum*). Undergrowth is dense.

The *várzea* regions are those that are inundated only at the annual flood. Trees are higher and quite diversified; they include oeiranas (*Alchornea castaneifolia*), a euphorbia (having a milky juice) of the chestnut family, and imbaúbas (*Cecropia* species), a rapid-growing tree of the nettle family with a light wood. Palms and hevea (a kind of rubber plant) grow in these forests. The forests of the nonswampy areas are rich in hardwoods, of which acapu (a tree with dark-chocolate-brown wood), pau-amarelo (*Euxylophora paraensis*), pau-santo (*Zollernia paraensis*), massaranduba (a Brazilian tree with light-reddish-brown wood that yields a milky juice), jarana (a tree with hard, heavy, durable wood), and matamatá (a tree with hard, heavy, durable wood, used for pilings) are the best known. Caucho (a wild rubber tree) and the castanheiro (*Bertholletia excelsa*) are characteristic of these forests where spiny palms cover the ground.

Epiphytes (nonparasitic plants that grow on other plants, deriving moisture and nutrients from rain and air) are very numerous, mostly Bromeliaceae (a species having leaves that are often spiny, and spiny flowers), orchids, and ferns. Lianas abound, particularly in drier forests.

Tropical deciduous forests. These forests, dominated by trees of moderate height, notably of leguminous species, are found widely dispersed through northern South America, where the climate is characterized by a prolonged dry season, notably in Venezuela, Colombia, and in the Brazilian Plateau.

Caatinga. Caatinga (white forest) is stunted and somewhat sparse. Thorny vegetation and trees that are leafless for long periods, and able to resist drought, are characteristic of the dry interior of northeastern Brazil, particularly in the basin of the São Francisco River. Dominant species are leguminous trees, particularly catingueiras (*Caesalpinia*), juremas (*Mimosa*), and joazeiros (*Zizyphus joaseiro*), Euphorbiaceae (a family of herbs, shrubs, or trees with usually milky and often poisonous juice), crotons (herbs and shrubs of the spurge family), and Bombacaceae (a family of tropical trees with palmate leaves and large, dry, or fleshy fruit). Undergrowth consists of thickets, bromeliads (plants with basal, often spiny leaves), and innumerable cacti, among which is the xiquexique (*Cereus gounellei*), the complicated intertwinings of which cover the soil.

South Brazilian forests. These parklike forests, sometimes very dense but interspersed with savanna, occupy vast expanses from the border of the Amazonian rain forest to the marshes of the Upper Paraguay River. The typical landscape is a grassland strewn with smaller trees. In effect, it includes a mosaic of associations, from hygrophilous (living or growing in moist places) to xerophilous (adapted to life in the presence of minimal amounts of water) forests and even desert.

Notable is the Paraná pine forest (*Araucaria angustifolia*), which covers a vast area between the Río Paraná and the Atlantic Ocean, stretching from Curitiba, Brazil, to northern Argentina. These trees dominate a dense forest of numerous species including hardwoods, Podocarpus, and the yerba maté (*Ilex paraguariensis*), or South American holly.

Xerophytic associations. Thickets of small trees and shrubs, often very thorny, among which prosopis (a genus of tropical or subtropical branching shrubs or trees), acacia, and mimosa predominate, cover regions that experience alternate dry and relatively wet seasons; these regions particularly include coastal Venezuela, northeastern Colombia, southwestern Ecuador, and northern Peru.

In Peru this association merges with the desert, which extends along the coast to northern Chile, having a width of from 50 to 100 miles. Only a few shrubs and some terrestrial (as distinct from epiphytic) bromeliads grow in this area, which becomes greener only in the Andean foothills, where cacti and other xerophytic plants are to be found, and along the valleys of rivers flowing down from the Andes. In some areas, called *lomas* by the Peruvians, winter mists bring some humidity, and a specialized type of vegetation, consisting of annual and bulbous plants, grows for a short period.

Subantarctic beech forests. Temperate rain forests—similar to those found in British Columbia and in the northwestern United States—grow in southern Chile at low and moderate altitudes, thanks to very high rainfall. The most typical trees belong to the genus *Nothofagus* (timber trees found in the cooler parts of the Southern Hemisphere), the northern species of which are evergreen, whereas the southern species are deciduous. Various conifers, notably the larch and araucarias, mingle with the leafy trees. A dense undergrowth of shrubs, lianas, bamboos, ferns, mosses, and epiphytes grow in the northern districts but disappear toward latitude 49° S. In southern Chilean Patagonia, forests consist of twisted, creeping trees merging into a kind of heath.

The temperate rain forests

Savannas. True savannas are found mostly in Venezuela where the plains known as the Llanos of the Orinoco Basin are covered with tufts of grasses and sedges. Trees and some palm trees are fairly abundant, especially along the rivers.

Pampas. The flat plains called Pampas, which constitute the greater part of eastern Argentina, are covered with grasses. The Pampas were originally covered with trees, but man has acclimatized various species, including pines, eucalyptus, oaks, and poplars.

To the south the Pampas merge with the Patagonian steppe, where grasses are mixed with rosette and cushion plants; the vegetation becomes much poorer as one proceeds south.

Mountain vegetation. In the high Andes, a temperate zone extends from the upper limit of the subtropical rain forest, around 6,000 feet, up to the timberline, which occurs at an altitude of between 10,500 and 12,500 feet. This zone is very humid on the Amazonian side, where both the epiphytes and the undergrowth are dense.

The upper zones have a peculiar vegetation that reaches the snow line. In the wet northern Andes in Colombia and Ecuador, Alpine meadows called *páramos* consist of grasses and of herbaceous plants, often with bright flowers; these are surmounted by taller plants, especially good-sized plants called *Espeletia,* or frailejones, which are 15 to 20 feet high and are crowned by enormous bouquets of long, lanceolate, hairy leaves.

In the south the *páramos* merge with the *pajonal de puna*—a typical steppe vegetation consisting of rough grasses, between which grow a variety of herbaceous, cushion, and rosette plants, shrubs, and cacti. Vegetation extends to the limit of permanent snow but becomes very scarce at higher altitudes where soil is often barren.

Human activity has transformed the original vegetation cover to a large extent throughout South America, particularly in forested areas. The forests of eastern Brazil were ravaged in the process of clearing the ground for sugarcane plantations as well as to grow other crops. The forests of *Araucaria* (a genus of tall trees of the pine

family) in the southern states of Brazil have been rapidly vanishing. The slopes of the Andes have also been severely deforested. New roads have been cut through the Amazon region, which is no longer the enormous inviolate mass it once was. In Patagonia the practice of burning to convert forest into pasture steadily increases. Animal herders have destroyed grasslands through overgrazing, notably in the Venezuelan Llanos and in the high Andes. The process of the destruction of habitats continues to accelerate alarmingly throughout the continent, where previously primeval conditions had remained stable for centuries.

Animal life. South American animal life is particularly rich and well diversified as a result of the wide range of habitats. A number of animal groups well distributed over the rest of the world are nevertheless missing, because of South America's lengthy isolation. Many animals belong to exclusive groups, and even at the family level the percentage of endemic forms is very high. Speciation has reached a much higher degree when compared to other parts of the world—a phenomenon that makes attempts to establish systematic classification difficult in South America. Neotropical animal life nevertheless evidently consists of several well-defined elements.

Freshwater fishes are very numerous, numbering about 2,700 species, though deriving from only a few ancestral groups. Amazonian fishes may approach 1,500 species in number. Characins (800 species), which are tropical fishes with deep scaly bodies and strong jaws; gymnotidae, South American cyprinoid fishes that include the electric eel; catfishes; cyprinodonts, a large family of small scaly-headed soft-finned fishes; and cichlids (a family that consists chiefly of fishes that have a resemblance to sunfish) are the dominant groups. Amphibians are well represented by caecilians (small wormlike, burrowing amphibians), salamanders, toads, and a number of varieties of frogs, including clawed frogs, the most aquatic of all; the tree frogs, arboreal amphibians, are particularly abundant through the Amazon Basin, and are very different from their African and Asian counterparts, although the frog faunas of Australia and South America are often surprisingly alike. Reptiles include a great variety of turtles and tortoises, crocodiles, caimans, (endemic crocodilians), geckos, many iguanas, teiids (a family of mostly tropical American lizards), amphisbaenids (a genus of harmless, limbless lizards) and many snakes, including boas, colubrids (a very large family of nonvenomous snakes), coral snakes, and vipers. Birds are represented by 89 families and about 2,700 species—a much higher figure than in Africa or Asia, which justifies the application of the name bird continent to South America. Twenty-five families

Savanna vegetation in the Guiana Highlands of eastern Venezuela.
Jacques Jangoux

are endemic to the neotropical region, including rheas (large, tall, flightless birds that resemble ostriches), curassows (large arboreal birds distantly related to the domestic fowl), hoatzins (a brownish crested bird, having claws on the digits of the wing when young), oil-birds, motmots (bright-coloured birds related to kingfishers), jacamars (small, bright-coloured, clamatorial birds), toucans, manakins, cotingas (related to manakins), and many passerine birds. Hummingbirds are differentiated in the neotropical region, where parrots, pigeons, cuckoos, tyrants (a kind of flycatcher), woodhewers, and orioles are among the dominant groups. Remarkably, the nonpasserine birds are more numerous in proportion to passerine birds than in other parts of the world.

Mammals include types that immigrated to the continent before its complete isolation in the early Tertiary Period. Among these are marsupials (pouched animals), sloths, anteaters, and armadillos; other kinds, now extinct, persisted until the Pleistocene Epoch. More recent elements include hystricomorph rodents (a suborder including porcupines and guinea pigs) and monkeys among the oldest arrivals, and tapirs, deer, carnivores, and bats among the newer arrivals.

Animals are distributed according to the pattern of vegetation zones and several well-defined communities can be distinguished. They include regions as diverse as the Amazonian forests and the high Andes.

The Amazonian and Guianan forests. The most diverse community is found in the Amazonian and Guianan forests where abundance of water and trees makes life easy. Rivers are the realm of large numbers of invertebrates and fishes, such as pacu (*Metynnis*), which is a big brownish flat fish, the meat of which is highly appreciated; coumarou (*Curimato*), which is a vegetarian fish without teeth resembling the marine mullet; electric eel (*Electrophorus electricus*); arapaimas, or pirarucu, which attain a length of 15 feet and a weight of 200 pounds; and piranhas that are provided with teeth so sharp that they can cut through flesh like a razor, as well as a wealth of small fishes, many of which are vividly coloured. The manatees (a chiefly tropical, aquatic, herbivorous animal with a broad tail) and the inia, a primitive dolphin-like cetacean (an order of completely aquatic mammals), frequent the larger rivers of the region. Arraus (*Podocnemis expansa*), a water turtle, is still extraordinarily numerous. There are large populations of crocodiles and caimans inhabiting the main waterways.

Arboreal forms of the Amazonia forests

Amazonian forests constitute an environment to which most animals responded by becoming arboreal. Tree frogs can move across the surface of the leaves thanks to adhesive pads; lizards have very elongated fingers; monkeys, sarigues (a close relative of the opossum), and kinkajous (a kind of nocturnal, arboreal, carnivorous mammal) have prehensile tails. Birds are numerous and,

because of the enormous amount and variety of available foods, well diversified. Antbirds, tyrants, cotingas, tangaras (brilliantly coloured birds related to the finches), hummingbirds, toucans, woodpeckers, barbets (loud-voiced tropical birds closely related to honey guides), parrots, and tinamous (quail-like terrestrial birds) are the dominant groups. Many of them never leave the forest canopy, where they display their brilliant colours, which contrast with the more modest plumage of those birds that live in the undergrowth. Mammals are represented by a number of terrestrial or half-aquatic species, such as very small deer; some large rodents (including the agouti, paca, and capybara); tapirs; and carnivores (including the jaguar). Monkeys range from pygmy marmosets to larger douroucoulis (small, round-headed, stocky-bodied, bushy-tailed monkeys), woolly monkeys, spider monkeys, and howler monkeys. Bats are also numerous, including fruit bats. Sloths feed on the leaves of certain trees among whose branches they remain much of their lives. The predators are represented by carnivorous mammals, a series of snakes—including anacondas and boas—and large raptors (birds of prey), such as the great harpy eagle, the most powerful bird of prey to be found in the world. Insects, including a great variety of butterflies and ants, are innumerable.

The Brazilian Plateaus. The Brazilian Plateaus have an impoverished animal life, from which species that are strictly adapted to the dense forest are excluded. The plains of Uruguay and the Gran Chaco have a varied animal life that includes some particular species, such as the maned wolf. The marshes are inhabited by a wealth of waterfowl, as well as by a species of lungfish (*Lepidosiren paradoxa*) that is related to its African and Australian counterparts.

imal
e of the
mpas

The Argentinian Pampas. The Pampas of Argentina are inhabited by a very limited number of indigenous animals such as rheas, a series of smaller birds, including the popular ovenbird (*Furnarius rufus*), the name of which comes from its globe-shaped nest made of mud, and mammals such as the mara (*Dolichotis patagona*), a long-legged, long-eared rodent; the plains vizcachas (*Lagostomus*), a burrowing rodent related to the chinchilla; guanacos (*Lama guanacoe*), a South American mammal related to the camel but resembling a deer; and Pampas deer (*Blastoceros campestris*). The restricted number of the larger herbivorous mammals is quite remarkable and illustrates the scarcity of recent mammalian types in the neotropical region.

The southern Chilean forests. The forests of southern Chile are inhabited by a specialized animal life, with a high percentage of endemic species. Parakeets and hummingbirds are found as far south as Tierra del Fuego. A marsupial, the rincolesta of Chiloé (*Rhyncholestes raphanurus*), is one of the most primitive mammals still in existence.

The high Andes. The high Andes have been settled by a very impoverished animal life, which had to adapt to the harsh and cold environment, to the scanty vegetation, and to low oxygen pressure. The great quantity of lakes in the region has attracted numerous aquatic birds, including flamingoes, which nest up to 16,000 feet in northern Chile, and amphibians such as the giant toads of Lake Titicaca, which spend their entire life in water. Mammals are represented by guanacos, vicuñas (wild ruminants related to the domesticated llama), deer, and numerous rodents, including vizcachas, chinchillas, and guinea pigs. Predatory species include foxes, pumas, and many birds of prey, notable among which is the condor, the giant of living birds, with a wingspan of more than 10 feet.

The arid west coast. The arid coast of Peru and northern Chile is inhabited by a terrestrial animal life impoverished when compared to its rich offshore marine life. The zones washed by the Peru Current, cold and rich in salts, are swarming with life, from plankton to fishes, including an anchovy (*Engraulis ringens*); these small forms of life provide food for higher levels of the marine community, represented, for example, by sea lions and birds, many of which are endemic to the area. Bird life includes a penguin, many species of gulls and terns, shearwaters, petrels, cormorants, pelicans, and boobies (a kind of gannet). Three kinds of these birds—the guanay (*Phalacrocorax bougainvillii*), the variegated booby (*Sula variegata*), and the brown pelican (*Pelecanus occidentalis*)—nest by the millions on small islands off the coast, where their droppings accumulate to form guano, a highly prized source of fertilizer.

Protection of wildlife. Overhunting and the destruction of habitats have wrought great harm to South American animals. Until the mid-20th century South America had suffered less from these problems than had the rest of the world, but since that time the situation has changed very rapidly. Many kinds of animals are on the decline, and some even appear to be threatened with extinction. Destruction of the Amazonian forest, which in recent years has reached significant proportions, could be disastrous for its animal life.

National
parks

In order to remedy the situation, a number of nature reserves and national parks have been established throughout the continent. Argentina was indisputably the pioneer in wildlife protection in South America. Nahuel Huapí National Park, the original nucleus of which was established in 1903, preserves a part of the Andes, featuring glaciers, beech forests, and many animals. Two national parks, one on the Argentinian, the other on the Brazilian side, protect the Iguaçu Falls and the surrounding rain forest. Many national parks and reserves, including the Itatiaia National Park, are maintained in Brazil. In Venezuela the Henri Pittier National Park, in the coastal cordillera, is famous for its subtropical forest, bird life, and migrations of birds and butterflies. Other reserves and parks have also been established in Ecuador, Peru, and Chile in order to preserve representative areas of the habitats of the Andean slopes and plateaus. (J.P.D.)

The people

ETHNIC ORIGINS AND MIGRATIONS

Four main components have contributed to the present-day population of South America—the American Indians (Amerindians), who were the pre-Columbian inhabitants; the Iberians (Spanish and Portuguese who conquered and dominated the continent until the beginning of the 19th century); the Africans, imported as slaves by the colonizers; and, finally, the postindependence immigrants from overseas, mostly Europeans.

Indians. During the epoch of European discovery and conquest in the early 16th century, Indian societies existed at three different cultural levels; this to a large extent determined the composition of the population during the colonial period and afterward.

Andean civilization

Andean society, a civilization of archaic type, comparable to Egyptian, Mesopotamian, and other Old World pre-Greek civilizations, existed on the Pacific coast with its focal centre in Peru. It is estimated that agriculture (based on corn [maize]) had been developed in this area from at least 2500 BC, while the beginnings of the formative period of Andean civilization date to the 1st millennium BC. At that time the agricultural village was the basic community; different arts and crafts were also developed, and, toward the end of the period, religious–ceremonial buildings began to appear.

The culture of the Classic Andean period (approximately from AD 1 to 1000) reached a higher refinement in the architectural arts; palaces and elaborate multiroom buildings were constructed, metallurgy (the smelting of copper and gold alloys) was developed, and agricultural techniques, such as terracing and irrigation, were evolved. Urbanization, which is to say the emergence of inhabited cities, as distinct from religious–ceremonial centres, also came into existence during the Classic period. With a relatively high level of political and military organization, these civilizations established several kingdoms. Neither the Classic nor the post-Classic Andean civilizations, however, had a written language. The post-Classic phase, moreover, was marked by further extension and centralization. The Inca Empire of Peru, for example, expanded from its homeland in Cuzco both to the north (to the area occupied by present-day Colombia, with its relatively advanced Chibcha cultures), and to the south (present-day Chile, with its primitive Araucanian tribes). The Incas began their conquests around AD 1200, but the expansion of their empire was greatly accelerated after 1400, until the process was halted by the Spaniards in 1536.

The remaining South American societies—among which lower and intermediate levels could at the same time be distinguished—had not evolved beyond the earlier phases of social development. The lower level occurred in the Guanaco area, inhabited by nomadic hunting tribes. It was located on the present-day territory of Argentina and Uruguay and included the extreme south (Tierra del Fuego and Cape Horn). The intermediate level occurred in the Manioca area, which covered the Amazon Basin to the Atlantic coast, occupying part of the present-day territory of Brazil. Although the intermediate level was mainly represented by hunting people, they also practiced agriculture, using the slash-and-burn technique (*i.e.,* cleaning ground for temporary cultivation by cutting and burning the vegetation). Andean civilization and the peoples dominated or influenced by it included perhaps one-half of South America's indigenous population and also covered the most densely settled areas of the continent. Elsewhere, the population was sparse, and large areas remained deserted.

The contemporary Indian population

The number of Indians at the time of the conquest is uncertain: estimates vary from 8,000,000 to 100,000,000 for North, South, and Central America combined (for the Incas, from 3,000,000 to 32,000,000). Some authorities assign to South America 6,800,000, of which a little less than half belonged to the Inca Empire or were under Inca influence. Other more recent estimates that put South America's preconquest population at about 14,000,000 seem more realistic.

Equally controversial is the origin of South America's Indians. Most anthropologists believe that they arrived in America from Asia, in successive waves, from about 25,000 BC onward—probably across the Bering Strait, which separates the extremities of northeastern Asia and northwestern North America.

Iberians. Until the end of the era of their domination, only the Spanish and Portuguese were admitted to their South American colonies. The rigid exclusion of all other foreigners had but few exceptions, though a small number of other Europeans settled as a result of illegal or tolerated immigration. The Iberian ethnic background itself was, however, highly diversified. Apart from the Romans themselves, many pre-Roman peoples—Visigoths, Jews, Arabs, Berbers, and Moors—contributed to form both the Spanish and Portuguese population. Most of the Spaniards came from Castile and the southern regions. Very little is known about the principal regions from which the Portuguese came. It is estimated that the total number of *licencias* (authorizations to emigrate) granted by Spain was about 150,000 for the whole colonial period, which lasted from the 16th to the 19th century; it is possible that the number of illegal immigrants also come to this number. Of these, no more than two-fifths of the emigrants went to South America.

Africans. A few African servants accompanying their Spanish or Portuguese masters were the first slaves to enter the continent. Larger-scale importation of slaves from Africa developed two or three decades later: the slave trade was authorized by Spain for the first time in 1518, though reliable quantitative information is lacking. An idea of their demographic contribution may be given by some estimates: 4,000,000 for Brazil, and 3,000,000 for all Spanish America, of which only a minority went to the Andean region and an even smaller number to the southern cone (consisting of present-day Argentina, Uruguay, and Chile). Paradoxically, the slave trade was supported by the defenders of the Indians. African slaves were also considered to be more efficient than American Indians, particularly for working on tropical plantations. Most of the slaves imported into South America were from West Africa, including Angola. The slave trade ceased in the early 19th century.

Postindependence overseas immigrants. With the attainment of independence by most of the South American countries in the early 19th century, the legal exclusion of foreigners came to an end. Mass immigration to the continent, however, did not begin until the late 19th century, acquiring momentum in the last three decades of the century and continuing until 1930, when it decreased abruptly. Some 11,000,000 to 12,000,000 people arrived in South America; the great majority of these went to Argentina (more than 50 percent) and Brazil (about 37 percent). Although many later left, the demographic and sociocultural impact of this influx was tremendous in Argentina and (to a lesser extent) in southern Brazil. Immigration to other countries was numerically insignificant (although socioculturally meaningful), except in Uruguay, where because the preexisting population was not numerous, the percentage of the foreign born was high—18 percent in 1908, and even higher in the 19th century. In Argentina this proportion reached nearly one-third of the total, and stayed at that level for many years. In both cases the contribution of post-independence immigration was proportionally much higher than in the United States at the peak of mass immigration.

Sources o immigration

The great majority of the immigrants were Europeans—Italians (forming nearly one-half of the immigrants in Argentina, one-third of those in Brazil, and probably the majority of immigrants in Uruguay), the Spaniards (one-third in Argentina), and the Portuguese (30 percent in Brazil). Other small but socially relevant immigrant streams arrived from central and eastern Europe. This source of immigration became more important after the turn of the century and especially during the 1930s and 1940s, when it included more middle class and educated people, among whom were many Jews and other refugees. After World War II another smaller wave of immigration arrived from Europe, directed mostly to Venezuela and Argentina.

POPULATION AND ECOLOGICAL DISTRIBUTION

The present population. The present population of South America is the result of four centuries of race mixture among these four components—Indians, Iberians, Africans, and overseas immigrants—and their mixed descent. Race mixture began when the first Iberians touched South America. Their own previous traditions and their basic values and attitudes, coupled with other characteristics of their conquest and colonization, facilitated intermixing not only with the Indians but in general among all the various racial and ethnic groups even although its intensity, extent, and frequency varied both among different groups and at different epochs.

Legal marriage between Iberians and Indians was tolerated, often permitted, and even, in some special circumstances, promoted. It was possible—and in certain epochs easy—to recognize mestizo (generally, mixed European and American Indian) children, though often a mestizo was considered automatically illegitimate. With regard to mixing between Europeans and Africans and between Africans and Indians and their offspring, such social permissivity did not exist—a fact that nevertheless failed to prevent generalized race mixture. This prolonged process created a great variety of physical types, resulting in the emergence of a complex terminology to describe them.

The more important types are the mestizo (called caboclo in Brazil); mulatto (European–African), zambo (African–Indian), and cholo (mestizo–Indian). When the postindependence European immigration occurred, other national groups contributed to race mixture. As a result, Argentina and Uruguay completely modified their ethnic composition.

ıe three
ɔlogical
ȝions

Ecological distribution. For these ethnic groups, three regions of ecological distribution may be distinguished—Indo-America, Mestizo-America, and Euro-America.

Indo-America consists of the highlands from north to south on the western side of the continent. It corresponds roughly to the territory of Venezuela, Colombia, Ecuador, Peru, and Bolivia, where—together with a minority of white or "whitish" groups (mostly of Spanish origin)—mestizo and Indian groups are predominant. Mestizo-America is situated in the lowlands of tropical and subtropical South America. Both on the eastern and western coasts, the African influence is strongest; the area is then characterized by European groups (mostly Portuguese in Brazil), many of them with various proportions of black ancestry, as well as by Africans and mulattos. Euro-America, or the temperate zone, consists of southern Brazil, Argentina, Uruguay, and central Chile. There the Europeans are overwhelmingly predominant, and there is little African or Indian influence (with the exception of Chile, where the original Indian contribution was much more significant, although it is not any more visible from the cultural or even the somatic point of view). Geographical, historical, cultural, and socioeconomic factors account for this ecological distribution.

Indo-America. It must be remembered that the Indo-American zone was the site of the higher civilization in South America and was the most densely settled at the time of the conquest. There the social and economic organization of the Spanish empire could be founded on the relatively advanced institutions of the pre-Columbian cultures, and, at the same time, Indian labour could be easily exploited. Although the original Indian population suffered what has been called a demographic disaster (during the first century of Spanish domination the Indian population of this area decreased by at least 30 to 60 percent), a substantial Indian population survived, and race mixture was intense; the Indians subsequently began their demographic recovery at about the end of the 17th century. The new nations in this area did not receive substantial European immigration in the 19th and 20th centuries, so that the European component in the population comes mostly from the colonial period.

Mestizo-America. In the lowlands of Venezuela and Colombia, however, and much more especially in Brazil, African slave labour was important. There the sparse indigenous tribes were much less well adapted to work efficiently; they also resisted enslavement and were decimated by disease and warfare. Indians were therefore replaced by imported Africans, mostly for the purpose of cultivating plantation crops. European–Indian mixture became less frequent, and the African racial and cultural influence became significant, particularly in Brazil where the Negroid (*i.e.,* African and mulatto) population constitutes perhaps 30 to 40 percent of the total. The other two South American countries with a substantial proportion of blacks (or with black components) are Colombia (no more than 30 percent black and mulatto) and Venezuela, where the black or Negroid proportion of the population is probably smaller.

Euro-America. In the temperate zone, the indigenous tribes, already scarce, were destroyed or reduced to an insignificant size, and the mestizo population was mostly overwhelmed by the avalanche of European immigration.

Another factor in the ecological distribution of ethnic groups in South America is the degree of urbanization. People of European origins, who were white or "whitish," tended to be more urban than rural and to live in larger cities rather than smaller ones. This pattern, however, was being blurred in the middle and later years of the 20th century by internal migrations. In effect, from World War II onward, these internal population movements, as well as some inter-American migrations (mostly between contiguous states and mostly from the less to the more developed states) represented a new contribution to the South American melting pot.

Racial
criteria

Sociocultural factors. As a general comment on the foregoing discussion, it must be remembered that racial criteria in all of Latin America are sociocultural (that is, generally based on language, clothing, and behaviour patterns) and not genealogical (that is, based on descent, as in the United States, South Africa, and elsewhere). In Latin America, "passing" may be no more than a question of buying a European dress and moving elsewhere. This does not mean lack of prejudice, discrimination, and exploitation—which indeed characterize the whole history of South America—but it involves significant differences for the life chances of the individuals. "Race" classification becomes in any case very subjective, being based also on the particular social status of the person. (The higher the social class, the "whiter" the person is considered to be.)

Linguistic patterns. The linguistic diversity and multiplicity of South America is said to be unmatched anywhere in the world. Thousands of languages and dialects have been cataloged, including all those existing since the conquest. Classification systems vary a great deal—from more than 100 "linguistic families" and many unrelated languages at one extreme to an extremely simplified scheme including four main families and a few subfamilies at the other.

There is also considerable disagreement on the composition of these "stocks" and how many languages should be classified. Most are now extinct, either because the tribes who spoke them have disappeared or because of acculturation into a European language or, in some instances, into another indigenous tongue. Relations between the South American languages and other New and Old World languages are still highly controversial. There are limited evidences of ties between some southern Colombian languages and one large North American linguistic family. Hypotheses have been advanced about connections between South American Indian languages of the Pacific coast and the Malayo-Polynesian languages, but linguistic and cultural evidences fail to support them.

The
surviving
Indian
languages

The survival of Indian languages follows the same pattern as the ecological distribution of the population and is equally determined by the level of civilization. Quechua and Aymara (both languages of the Andean highlands, the former being spoken originally by the Cuzco Incas) are the most diffused languages; they are used by an estimated 60 percent of the population in Bolivia, 40 percent in Peru, and a sizable proportion in Colombia and Ecuador (where both Quechua and Jíbaro are spoken). Another important tongue is Guaraní, which, together with Spanish, is diffused most of all in Paraguay, where it is also spoken by the non-Indian population. Contrasting with this, the languages of the lower level Indian cultures have in general disappeared or remain only as scanty remnants. African dialects have been wiped out, although they did exercise some influence on Portuguese and Spanish—as also was the case with both existing and extinct Indian languages. Such countries as Argentina and Chile, therefore, have only a small segment of the population still speaking an indigenous language. A higher proportion speak such languages in Brazil, and perhaps 10 percent do so in Venezuela.

Sociological changes. All or most legal discrimination against the Indians and other ethnic sectors of the population was nominally abolished at the time of independence, or during the 19th century. The real conditions of the Indians (and to a certain extent of the Africans after the abolition of slavery in Brazil in 1888), however, remained the same or became worse, since, on one hand, liberal legislation tended to eliminate all communal property and the legal existence of the Indian communities, while, on the other, various forms of exploitation continued unchanged. These de facto conditions were also reinforced by 19th-century biological doctrines, which held Indians and Africans to be inferior races.

In the 20th century, however, a complete change in intellectual attitudes resulted in a series of public and private initiatives toward ameliorating the conditions of these groups. Illustrations of this change in attitude are to be seen in the creation by Latin American governments of the Instituto Indigenista Americano (1940); in the (formal) restoration of the "legality" of the Indian communities, in Peru (1919); and in the many projects of agrarian reform, as well as in other legal and administrative innovations discussed and sometimes approved in different countries, even though these are seldom seriously enforced. Institutions such as the Serviço de Proteção ao Indio (Protective Service for the Indians) in Brazil, as well as missions, centres, and the like were established with the purpose of providing educational, sanitary, and other social services to the Indians. Special areas were established as reservations, particularly for tribal Indians, although these received little attention of any kind from the governments. At present, two types of situation may be distinguished—that of the Indian tribes and that of the Indian communities.

The status of Indian tribes

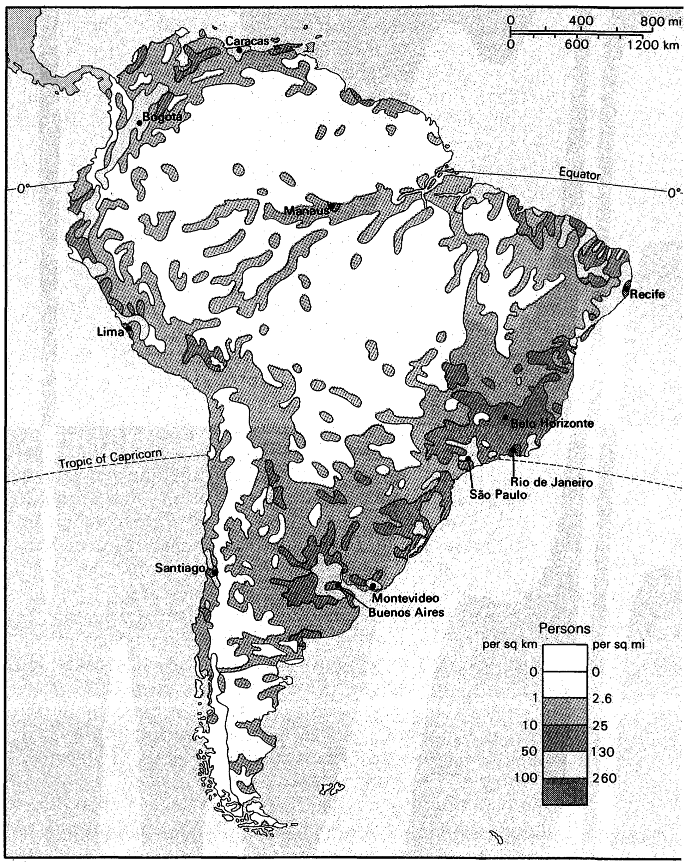
Although the Indian tribes should nominally be under the "protective" regulations existing in several Latin American countries, they must nevertheless be considered as totally or mostly marginal to the life of the national societies. Statistically, they represent an insignificant proportion of the total population (between 30,000 and 200,000 where they exist at all). They can be found in the Gran Chaco and Amazon regions and also in the selva (tropical rain forest) and mountain regions of Peru and Bolivia. Some Indian tribes are also located in Chile, Colombia, and Venezuela. These groups are disappearing—in most cases either through physical extinction, caused by poor living conditions, illness, or violent death, or through absorption into some sector of the national society.

The Indian communities (as distinct from tribal Indians) are related to the pre-Conquest communities belonging to the higher cultures but have been deeply modified by colonial domination and Hispanic culture. They can be found mostly in Peru but also exist in smaller proportions in the other areas influenced or formerly dominated by the Inca, such as parts of Bolivia, Colombia, or even Venezuela. These communities—some of which in Peru were recognized by the state—are nominally under the formal national bureaucracy but sometimes maintain their traditional Spanish-Indian authorities, such as alcaldes (mayors) or *regidores* (council members). Those that maintain more strongly their identity and traditional nature have been characterized as "corporated" (*i.e.,* incorporated) communities (in the sociological, not the legal, sense of the term). Often, however, the communities are (or were) de facto tributaries of the haciendas—the large landed estates that until recently exercised quasifeudal dominion over the Indians. This situation, however, has been in the process of rapid transformation, particularly since the Bolivian revolution (1952) and since the social movements and political changes that have taken place in Peru. (G.Ge.)

DEMOGRAPHIC PATTERNS

South America is at the peak of a phase of demographic transition, a modernizing process that includes three main stages. The first of these is the traditional stage, in which the population balance is maintained by both high birth and death rates; second is the transitional stage, in which decreasing mortality combines with a stable high fertility (or else with a delayed or slow decline, or both) to generate a high growth; finally is a modern stage, in which low mortality and low fertility produce a small demographic increase. Areas that developed earliest underwent the same process, but with two differences: they experienced first a lower fertility rate in the traditional stage and, second, a slower or delayed decline, or both, in the mortality rate.

It must nevertheless be remembered that some 60,000,000 Europeans emigrated overseas. Natality in Europe's preindustrial phase rarely exceeded 30 to 35 per 1,000; in South America it has been 25 to 40, with a number of exceptions. Argentina and Uruguay have been at the modern stage since the 1930s, and Chile has had declining fertility since the 1920s. Mortality decline in Europe often took 100 to 150 years. In 1900 the South American average life expectancy at birth was 25 to 30 years (not including Argentina and Uruguay). By the late 20th century it was estimated at a little more than 60 years. The great change occurred in all countries (except the two "first comers," Argentina and Uruguay) between 1920 and 1940 and is continuing. Mortality declined spectacularly in 40 or 50 years, and, in Chile, in 20.



Population density of South America.

The fertility rate. The population explosion is the result of a traditional type of fertility rate (among the highest ever known), combined with a quasimodern mortality rate. The reason for this discrepancy in comparison with the rest of the Western world lies in the fact that while mortality can be reduced through the relatively fast diffusion of sanitary and medical innovations a spontaneous fertility decline requires complex social transformations (in social stratification, and in urbanization, mobility, family, and life-style) correlated with psychological changes. These demand much time. It is also possible that cultural values peculiar to the Latin and Indian societies produce additional obstacles to spontaneous limitation of fertility. Government-sponsored policies to induce family planning have met two ideological obstacles: the attitude of the Roman Catholic Church and that of the political parties toward birth control. Though resistance has declined in the church, politicians have remained indifferent or hostile to birth control. The fact that the region is underpopulated disguises the enormous strain imposed on the economy by too rapid a rate of demographic growth.

ɔstacles
family
ınning

Spontaneous changes are nonetheless taking place. As in Europe, birth control is initiated by the urban population and by the middle classes. In South American cities the average number of live births per married woman becomes lower with increased education. Because of the large rural population and the limited size of the educated group, however, the overall impact of the differentials is not yet reflected in national fertility rates. The process, if left to its own spontaneous evolution, may require several decades to take place, while mortality is meanwhile expected to decline further in various countries. If fertility is not curbed or economic development is not accelerated, the operation of Malthusian laws (that when population outstrips its means of subsistence further growth will be checked by disease, famine, or war) would seem to ensure that the mortality decline would be interrupted or reversed. In this case the expected growth would be reduced.

Effects of rapid population increase. Rapid population increase has important demographic and social effects. Two examples are especially illuminating.

At the peak of population growth, the proportion of children tends to be very high, while in the third stage it is low. In South America the proportion of the population under 15 years is relatively high. As a consequence, the working-age group is greatly reduced. This high ratio creates a heavier burden for the working group, while the economy is not able to raise the productivity needed to compensate for it.

pulation
ɔwth in
ꞔ cities

Another crucial consequence is the so-called urban explosion. Argentina and Uruguay are among the most urbanized countries in the world, but their urban growth has been due to mass foreign immigration. The dramatic increase in urban concentration began approximately in the 1930s. In all of Latin America, urban centres with more than 10,000 inhabitants increased from one-fourth in 1950 to an estimated one-half 20 years later.

South America is one of the most urbanized regions in the world, following the industrially advanced areas. Although the rate of growth in larger cities has decreased since 1950, the urban population continues to be concentrated in the bigger cities: a large proportion of the urban, and in some cases of the total, population lives in a single urban centre. This situation prevails in Uruguay, Argentina, Chile, Paraguay, and Peru.

Demographic growth has both a direct and an indirect influence on the urban population explosion. Contrary to widespread opinions the principal component of urban growth on the continent is natural increase, not internal migration. This is the case in Venezuela, Chile, and other countries. Internal migration, nevertheless, remains important in South America; the demographic influence is indirect and operates in conjunction with other factors—such as unfavourable conditions in the countryside, including the concentration of land ownership in a few hands and the rejection by the rural population of the resulting extremely low standard of living.

High urbanization is coupled with a very low population density in South America as a whole, with variations among individual countries that ranged from a very low density in such countries as Suriname and Guyana to an extremely high density in Ecuador and Colombia. The averages disguise the existence of sharp internal inequalities in density. High density is found in South America only in urbanized areas—that is, in large cities or metropolitan areas and their immediate hinterland. South America is increasingly coming to resemble a vast desert ocean, dotted with a few scattered densely populated islands. Though geographical and physical environmental factors play a role, high concentration is largely the consequence of uneven internal development caused by international and domestic factors. The trend in South America continues to be toward an even higher imbalance, although in several countries the state has begun to intervene in an attempt to achieve a more rational use of the national territory. (Ed.)

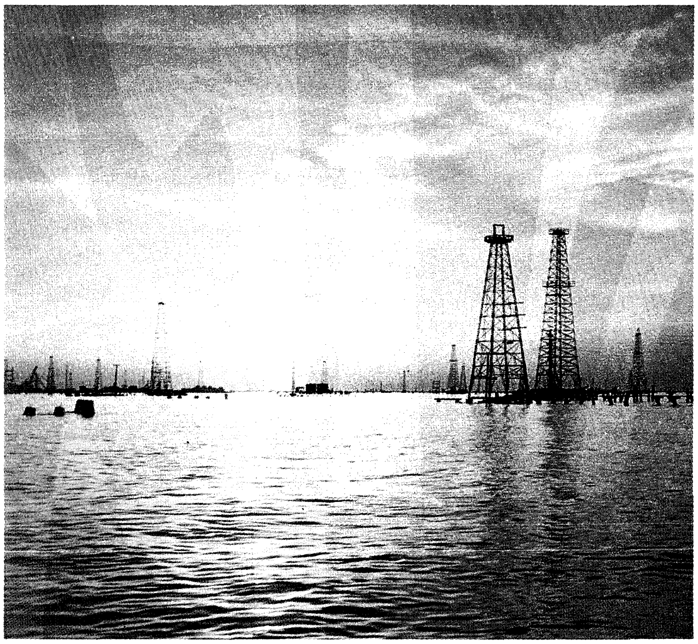
The economy

RESOURCES

Mineral resources. *Mineral fuels.* South America is relatively poor in coal, which is found in Colombia, as well as in Brazil, Argentina, Peru, Venezuela, and Chile (where lower-grade fuels such as lignite and peat are also available). Petroleum is present in great quantities in sedimentary terrains around Lake Maracaibo in Venezuela, and in lesser quantities in the coastal plains of Brazil, Ecuador, and Peru, along the eastern Andes of Bolivia, and in southern Patagonia. The greatest and most important of these mineral fuel reserves are located in Venezuela, one of the largest oil producers in the world. Other reserves are to be found in Argentina, Colombia, Peru, Brazil, Chile, Ecuador, and Bolivia. Natural gas also is found in Venezuela, Argentina, Colombia, and Chile. Uranium can be found in significant quantities in the form of various ores in Argentina, Brazil, and Chile, as well as in Colombia.

Oil
reserves

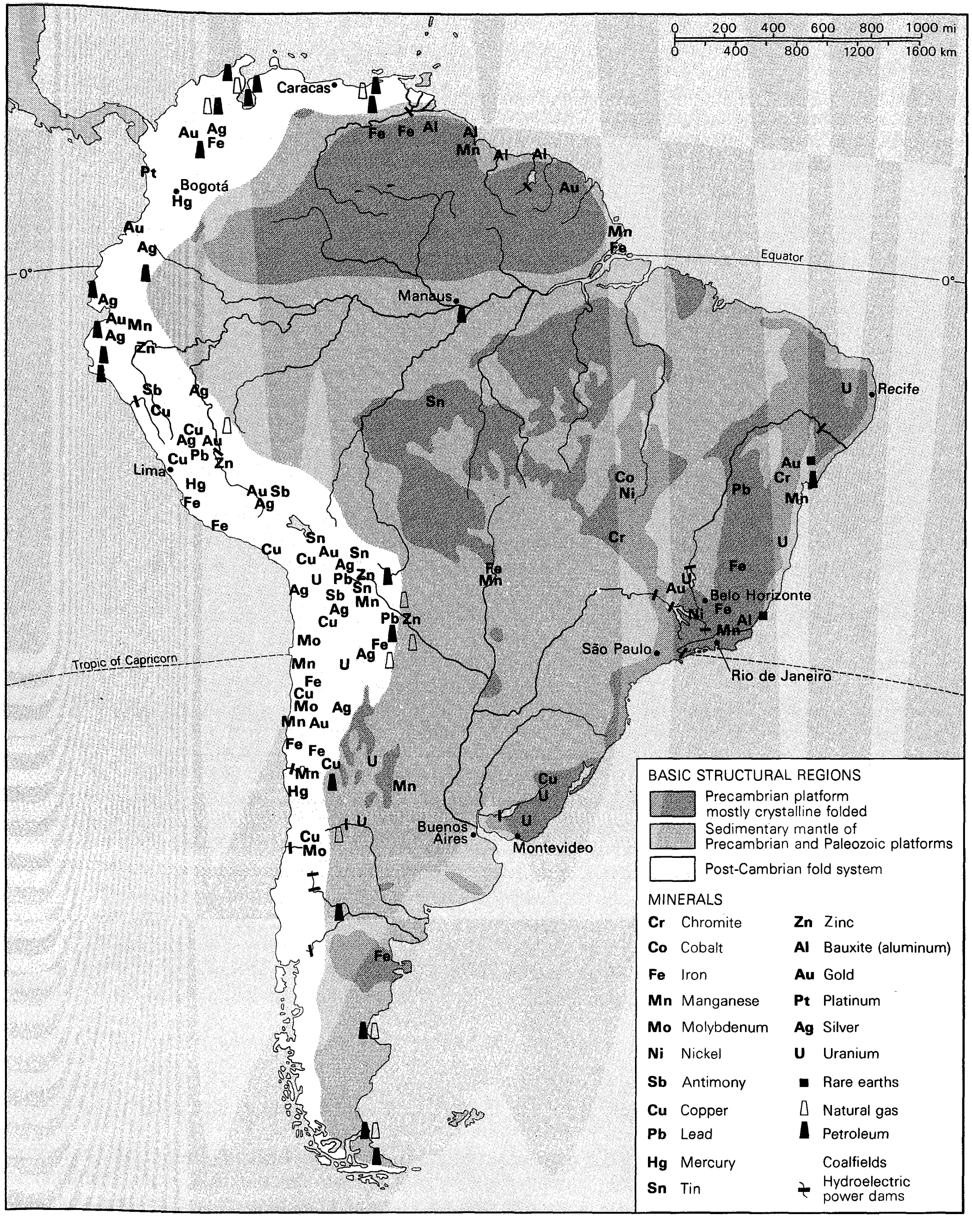
Shostal—EB Inc.



Oil derricks on Lake Maracaibo, Venezuela, centre of the petroleum industry in Latin America.

Metallic deposits. Iron ore is very abundant; South American reserves represent one-fifth of the world total. The most important beds are found in Brazil and Venezuela, representing a fabulous wealth for these countries. In Brazil, the states of Minas Gerais, Pará, and Mato Grosso do Sul contain lodes of magnetite and hematite with 50 to 65 percent iron, which represents the vast majority of the South American reserves. In Venezuela, at the base of the Guiana Highlands, the Sierra de Imataca, particularly Cerro Bolívar and El Pao mountains, have reserves of ore containing a high percentage of iron. Other beds of this type are to be found in Mutún, Bolivia and Chile. Oolitic iron ore (*i.e.,* consisting of small round grains cemented together) is located in Argentina (Sierra Grande) and in Colombia (Paz del Río). Other iron ore deposits are found in Peru (Marcona) and Chile (along a belt from Taltal, Antofagasta, to Ovalle, Coquimbo). Lateritic deposits of ferrous hydroxides are widespread, mainly in Colombia, Brazil, and Argentina.

Among ferroalloys, manganese is found in sedimentary forms in Brazil—mostly in Amapá, Bahia, Minas Gerais,



Basic structural regions and principal mineral and hydroelectric sites of South America.

and Mato Grosso do Sul—in Bolivia, and in much lesser quantities in Chile, Ecuador, and Uruguay. South America is remarkably deficient in nickel, chromite, and cobalt, though small quantities of all are found in Peru, Brazil, and Argentina. Of the non-Communist nations, Chile is third, after the United States and Canada, in the size of its reserves of molybdenum.

Nonferrous metals

Nonferrous metals are particularly abundant in South America, where copper reserves represent more than one-fourth of the world's known reserves; almost all of the South American reserves are found in Chile and Peru. In Chile, the Chuquicamata deposits contain the largest amount of copper known in the world, with ores containing 2.5 percent copper; El Teniente also has reserves. In Peru the most important deposits are found in the Central Andes (at Yauricocha, Morococha, Casapalca, Cerro de Pasco, and Huarón), as well as in the southern Andes, where the Toquepala mine opened in 1960. Copper is also found in Bolivia and in Brazil (at Caraíba, in the state of Bahia).

Tin, in the form of sedimentary deposits and in veins, is found in the eastern Andes of Bolivia in a narrow belt that is approximately 500 miles long by 95 miles wide, mainly running from Oruro to Potosí. Lead and zinc, two metals which are frequently associated in nature, are dispersed among many countries but are mostly found in Peru, as well as in Argentina, Brazil, and Bolivia. Aluminum, in the form of bauxite, is exploited mostly in Suriname. Reserves are found elsewhere, mostly in Guyana, French Guiana, Brazil, and Venezuela. Mercury is found in small quantities in Chile, Colombia, and Peru; antimony is found in Bolivia and in lesser quantities in Peru.

Among the precious metals that are to be found in South America, gold represents only a small percentage of world production, although it is found throughout the continent in varying quantities. In Brazil the states of Minas Gerais, Goiás, and Mato Grosso were well known in colonial times for their gold, but production diminished as a result of the exhaustion of the lodes. There are also gold-mining operations in Colombia, Brazil, Peru, and Chile. Silver is found mainly in Peru, but is also found to a lesser extent in Bolivia, Chile, Argentina, Colombia, and Ecuador. Colombia has the largest reserve of platinum.

Precious stones

Many parts of South America, mainly Brazil, have been known for their gems. The ancient bedrocks are rich in precious stones, which are found in veins of pegmatite (a coarse granite) or are washed out by streams. Diamonds are spread over a good part of the Brazilian Plateau, notably in the region of Diamantina. Some are suitable only for industrial use, but others are of considerable value as gems. Brazil, however, contributes only a small percentage of world production.

Other precious or semiprecious stones abound in the same region, notably topazes, tourmalines, beryls, aquamarines, chrysoberyls, garnets, and sapphires, as well as quartz of sufficiently high grade to be used in electronics (the only source apart from those in Communist countries). Colombia is famous for its emeralds, found in the Muzo mines.

Various mineral elements used in industry—such as beryllium, columbium (niobium), tantalum, thorium, lithium, rare earths, and mica—are found in Brazil and Argentina.

Nonmetallic deposits. South America has neither a significant output nor important reserves of the principal fertilizers—phosphates and potash. In the Atacama Desert, located in northern Chile, there are important deposits of nitrates to be found in the form of caliche, a grey rocklike substance with a high content of sodium chloride, sodium nitrate, and iodine salts. These deposits were formerly of some importance, but synthetic fertilizers have tended to supersede them; they continue, however, to be used as a source of iodine. Many various saline deposits found throughout the continent await investigation as potential sources of salts.

Biological resources. Biological resources are abundant and much diversified, although they are not evenly distributed throughout the continent. Southeastern Brazil, Uruguay, the Argentinian Pampa, and central Chile are areas that are suitable for wide-scale agriculture.

Botanical resources. The plant diversity of the South American continent is enormous; many of the South American plants are useful to humans. In pre-Columbian times, Indian cultures domesticated numerous plants, some of which now play a major role in the world's food supplies.

Though fewer than 200 species constitute the bulk of the neotropical forests, their mixed character is a major obstacle to large-scale exploitation of timber. Many species are used as cabinet woods, including the highly prized mahogany (*Swietenia macrophylla*) from Venezuela, Brazil, Peru, and Bolivia, and several leguminous species such as rosewood (*Dalbergia nigra*); other species are exploited as general utility woods and are mainly used domestically, often as fuel. Balsa (*Ochroma* species) is the lightest and fastest growing wood in the world. Other species produce tanning materials (such as the bark of the quebracho tree), various drugs, or edible products.

Forests are extensive, covering about 2,340,000,000 acres (946,000,000 hectares), an area that represents more than one-half of the entire continent. Brazil is the most densely forested country; its total forested area is greater than that of all the rest of South America put together, and it possesses more than two-fifths of the continent's accessible forests.

Indian corn, or maize (*Zea mays*), probably native to tropical America, is still cultivated to a large extent throughout the continent. Beans (including several species of the genus *Phaseolus*), widely cultivated by small-scale methods, form an important food item in most countries. Cassava, or yuca (*Manihot esculenta*), and sweet potato (*Ipomoea batatas*) are indigenous to the New World, from which they have been introduced to the other warm regions. The potato (*Solanum tuberosum*) originates from the high Andes, where related wild species are still found. Some other plants have been domesticated in this particular environment, such as the quinoa (*Chenopodium quinoa*) and the canahua (*C. canihua*), both giving very small seeds used as cereals, and tuberoses such as ulluco (*Ullucus tuberosus*) and oca (*Oxalis tuberosa*). Squashes and pumpkins (*Cucurbita* species) have been cultivated since pre-Columbian times and have spread throughout the world, as has the tomato (*Lycopersicon esculentum*), indigenous to the west coast. The peanut, or groundnut (*Arachis hypogaea*), originated in the Paraná River Basin, where the wild species has apparently become extinct. Cashews (*Anacardium occidentale*), now cultivated in most tropical countries, and Brazil nuts (*Bertholletia excelsa*), harvested from wild trees in the Amazon region, are widely used as delicacies but are also eaten locally raw or cooked. Cacao (*Theobroma cacao*), native to the Amazon region, was prized by the ancient Indian civilizations and is cultivated in South America, particularly in the State of Bahia, Brazil. Avocado (*Persea americana*) is native to the same region. Pineapple (*Ananas comosus*), probably indigenous to southern Brazil and the Paraná River Basin, was cultivated in pre-Columbian times throughout tropical South America and the West Indies. Papaya (*Carica papaya*) and guava (*Psidium guajava*) are both native to tropical America.

Humans also introduced a great number of plants to the continent. Sugarcane (*Saccharum officinarum*) has been cultivated in all humid tropical countries since early colonial times. Bananas have become an important local food item and are exported to the rest of the world in enormous quantities. Mango, oranges, lemons, and grapefruits are widespread. Coconut is very common, although its origin is much disputed.

Cereals

Among cereals, rice, which was introduced from Asia, is grown in Colombia, Peru, Brazil, and Uruguay but not in sufficient quantities. Wheat, introduced to the southern part of the continent, is, along with other cereals, widespread in Argentina, but it is also raised locally in Colombia.

The two most important native spices are allspice (*Pimenta officinalis*) and red or chili pepper (*Capsicum annuum*).

Grazing is extensively practiced on all grassland areas throughout the continent. Apart from the Llanos of the Orinoco, the main grazing regions extend through eastern and southern Brazil, as well as across Uruguay and Argentina, where various breeds of cattle are raised. Stock raising also flourishes in the temperate zones of the Andes, where cattle are raised, while the upper, drier zone is mainly devoted to raising sheep, alpacas, and llamas. Foraging is also widespread in savanna areas, and even in regions such as the caatinga, where xerophytic plants grow.

Coffee (*Coffea arabica* and related species), imported from the Old World, is extensively cultivated, particularly in Colombia and Brazil. The most celebrated native plant is the yerba maté, or maté (*Ilex paraguariensis*), indigenous to the Paraná Basin and still exploited in its wild state; its leaves are used to prepare a drink that is very popular in some parts of South America. Tobacco (*Nicotiana tabacum*), smoked by Indians in pre-Columbian times, is cultivated in many countries, but mainly in Brazil and Colombia.

A great number of South American plants provide valuable drugs, among which are quinine (obtained from the bark of several trees of the genus *Cinchona,* indigenous on the eastern slopes of the Andes) and cocaine (obtained from the leaves of the coca tree, *Erythroxylon coca,* found in the eastern Andes from Peru to Bolivia). Among a great variety of aboriginal remedies still in use, some may contain medically valuable substances.

Besides peanuts and some introduced plants, South America has a great number of oil-producing plants, such as the babassu palm, a native of Brazil, the nuts of which are rich in oil and are used for soapmaking. The production of essential oils has much development potential.

Vegetable waxes are produced mainly by the carnauba palm (*Copernicia cerifera*) of Brazil, the leaves of which are covered with a waxy secretion. Vegetable ivory is yielded by the hard seeds of the tagua palm (*Phytelephas macrocarpa*) found in northern South America, notably in Ecuador.

Cotton is partly indigenous to South America and has been used since prehistoric times; large quantities are produced in Brazil, Argentina, Peru, and Ecuador. Kapok and plants producing stem or leaf fibres, such as sisal, are extensively grown. The iraca (*Carludovica palmata*), a plant looking like a stemless palm, is cultivated in Colombia and Ecuador for its fibres; extracted from the young leaves, they are woven into "Panama" hats.

Several plants furnish latex, from which rubber is extracted. Para rubber, or seringa (*Hevea brasiliensis*), and related species, a native of the Amazon region, was known by the Indians. Ceará and manihot rubbers, found in the driest part of Brazil, have the potential for use if given suitable agricultural management. Panama rubber, or caucho (*Castilla elastica* and related species), native to the Amazon region, has yielded poor results.

Balata (*Manilkara bidentata*) yields a nonelastic rubber;

chicle is a gum extracted from the latex of sapodilla (*Achras zapota*) and is used in the preparation of chewing gum.

Domesticated animals

Animal resources. Animal resources are less diversified than botanical resources. Llamas and alpacas were domesticated in the high Andes in Inca times and probably earlier; both derive from the guanaco. Llamas are kept as beasts of burden and alpacas for their wool. Guinea pigs were domesticated in pre-Inca times in the same area and raised for meat. The keeping of native domesticated animals did not extend beyond the geographic limits in which their wild ancestors were found, with the exception of the Muscovy duck (*Cairina moschata*). Among animals introduced to the continent were cattle brought by Columbus on his second voyage. Numerous in Brazil, Uruguay, Argentina, Venezuela, and Colombia, cattle have become distributed throughout the continent where there is suitable grazing land. Horses are widespread and play an essential role in the economy of most countries. Sheep are raised successfully in the Argentinian region of Patagonia, in the Andean highlands, and on the Falkland Islands. Pigs and smaller domestic animals are present everywhere.

Game is plentiful in most habitats, though mammals are few and specialized. Deer are represented by several species; red deer have been acclimatized in Argentina. Specialized rodents (such as agoutis, pacas, capybaras, and maras), waterfowl, and a large series of terrestrial birds (such as tinamous, guans, and curassows) provide excellent game. Many Indians, mainly in the rain forest, live upon birds and monkeys. Many animals are collected alive and exported as pets or for zoos, the heavy demand being justified by their strangeness and beauty.

Several neotropical animals provide world-famous fur or wool. Chinchilla (*Chinchilla laniger*) were native to the high Andes of Peru, Bolivia, Chile, and northern Argentina, where thousands lived in flourishing colonies. They were hunted for their delicate gray fur to the point of extinction in their wild state, except possibly in some districts of Bolivia and Argentina. Vicuñas provide the finest wool on Earth and have been hunted since the time of the Incas; they have dwindled alarmingly in the upper Andes and are still poached despite laws and a ban placed upon trade in their fur. The giant otter (*Pteronura brasiliensis*) of the Amazon; several spotted cats, including the jaguar and the ocelot; and rodents, such as the nutria, also provide highly prized furs, but overexploitation of many species has depleted the stocks.

Freshwater fish, abundant in most of the rivers, have been exploited on a large scale since the earliest time, notably in the Amazon region and in the Guianas. Trout have been introduced into Andean lakes and torrents—sometimes to the detriment of the endemic species.

Marine fisheries are very prosperous, since South America is surrounded to a large extent by highly productive fishing areas. Peru is one of the world's major fishing nations.

South America is well known for colonies of seabirds along the Peruvian and Chilean coasts, resulting in the accumulation of dung (guano), a highly prized fertilizer. Pinnipeds (a suborder of aquatic carnivorous animals, including seals and walruses) are exploited for their oil, particularly in Uruguay. Fur seals are distributed along the southern coasts of South America, but their numbers have been considerably reduced by hunting. (J.P.D.)

INDUSTRY

Stages of industrialization

The first stage of industrialization, which might be called the pre-factory stage, has been left behind by most South American countries. The second stage, commonly known as that of the traditional industries (textiles, food, beverages, tobacco, sugar), is still present, although its importance varies from country to country as a result of special conditions or because of historical circumstances. The final stage, the development of basic industries and the production of simple machinery, is in progress in a number of countries in South America, including Argentina, Brazil, and Venezuela.

The process of import substitution that began in some countries even before the Great Depression and that later accelerated during World War II gave birth to many industries producing intermediate and capital goods; in some instances these industries have survived only because they have been protected from foreign competition by subsidies, tariffs, and trade restrictions. Import substitution has shown signs of weakening, however, in both the traditional industries sector, and the production of consumer goods.

Manufactured products are sold at high prices not only because of trade protection but also because of the small scale of production, the use of inadequate technology, and defects in the economic infrastructure (structure of basic services), mainly in the form of insufficient transport and energy.

The slow growth of the industrial sector and the adoption of production techniques requiring a high ratio of capital to labour resulted in a very limited contribution of industrialization to the creation of new sources of employment, especially in view of the rapid growth of the labour force.

The gross domestic product (GDP) originating in the industrial sector is approximately one-third of the gross national product. Of this total, about four-fifths represents manufacturing and the rest civil construction. About one-fourth of the labour force is occupied in the manufacturing sector.

In the two most industrialized countries—Argentina and Brazil—the production of foodstuffs, beverages, and tobacco accounts for only about one-seventh of the total manufacturing output. The production of metallurgy and mechanical industries represents more than one-third of the total manufacturing output, while chemicals and petroleum refining contribute about one-fifth, and textiles, footwear, and apparel contribute about one-tenth.

During the late 20th century, South American industrial production made substantial gains: the production of cement and steel (ingots, rolled, plates, and sheets), pig iron, automobiles, and household appliances has risen greatly.

Unlike some manufacturing industries that have become sophisticated, the construction industry in South America is in an elementary stage. Construction techniques use much labour, quality is low, and costs are quite high. Despite the existence of a huge housing shortage, building has proceeded at a very slow pace.

POWER AND IRRIGATION

Electrical energy output

The total annual generation of electricity in South America has increased considerably, but there is much disparity between countries; Venezuela had more than twice the regional average; Argentina, Chile, and Uruguay about average; and Guyana and Peru only about one-half the average. Industry consumes almost two-fifths of the electric power generated in South America. Household consumption takes another two-fifths, and the rest represents either transmission losses or other uses.

Private installed capacity, which consists mainly of thermoelectric plants operated at high cost, represents a low percentage of total installed capacity. The trend has been toward increases in hydroelectric power—in part because of the increasing importance of the public power services as distinct from private power generation.

Argentina, Brazil, Uruguay, and Venezuela have ambitious electrical installation programs that can take advantage of the region's abundant hydroelectric resources. This will increasingly require extensive use of interconnecting systems that have already been effectively developed in such countries as Brazil, Chile, and Uruguay.

Most of the hydroelectric projects are also used for irrigation, but there are many instances in which the first purpose has been accomplished, but the construction of distribution canals for irrigation has yet to be achieved.

Only a small percentage of arable land and of land under permanent crops is irrigated. Notwithstanding the fact that the largest agricultural countries account for most of South America's irrigated land, Chile, Peru, and Ecuador show the highest proportion of irrigation in relation to cultivable land. In Peru irrigation activities are confined to the narrow strip of coastal plain. In Chile, about one-fourth of arable land uses irrigation water; this land consists mostly of farms of less than 25 acres in size. Because of the relative scarcity of farmland in these countries, it

Agricultural regions of South America.

may be said that large-scale irrigation is practically a condition of national existence.

Argentina accounts for almost one-fourth of the land under irrigation in South America. Irrigated areas in Argentina are devoted mainly to the growing of fruit.

AGRICULTURE

Even though agriculture is a large sector in South America's economy, several countries have to import agricultural commodities, including products that could be supplied by expanding local or regional production. The largest crop in terms of the area harvested and in output is corn, the second largest is wheat, and the third is rice. Cotton, potatoes, barley, sweet potatoes, rye, millet, and sorghum are also important agricultural products. The number of cattle raised in South America represents a good percentage of the world's total, and horses constitute another important livestock. There are also large numbers of pigs and sheep in South America.

Land productivity is, on the whole, far below that prevailing in other regions. The increases in production are chiefly attributable to extensions of the cultivated area.

ral
employ-
nt

In spite of the large shifts of population toward the cities in recent years, a large proportion of the widespread unemployment prevailing in South America is still found in the rural areas. About one-third of the economically active population works in the agricultural sector, as compared with almost one-half of the population for the world as a whole. The lack of educational skills among farm workers, the widespread existence of unemployment, and the limited use of modern methods and management techniques in the countries of South America have resulted in a very low average product per worker for the region.

South America extends over an area of 4,400,000,000 acres, of which only about one-eighth is arable land, land under permanent crops, or land occupied by meadows and pastures. More than one-half of the total land area is covered by forests, and another one-eighth has other uses. It is a general conviction throughout South America that land utilization is inefficient. Inflation control, land taxes based on productive capacity, agrarian reforms that consist of more than changes in the system of land tenure, as well as other policies, are all felt to be helpful in improving the efficiency with which land is used. The great shortage of farm capital (as well as the high cost of obtaining it) is, however, one of the most serious difficulties facing agricultural development in the countries of South America.

In short, the one factor preventing a rapid growth in agricultural output is an unfavourable relation between product prices and input costs. Capital, fertilizer, modern machines, and fuel command high prices, while prices received by farmers tend to be low.

TRADE

Banks and financial institutions are usually large enterprises with branches in many cities and towns; a high proportion of these are government owned. Wholesale and particularly retail business enterprises, on the other hand, are mostly individual concerns and in many cases are family shops. Department stores or chain stores are seldom found in South America.

Characteristics of commerce in South America

In contrast with some highly sophisticated industries in the manufacturing sector, distributive and retail firms use rather elementary methods and are old-fashioned in organization. This is probably due to the scarcity of managerial skills and to the relatively small share of credit that this sector receives in comparison with industry and agriculture. Furthermore, the development of commerce depends heavily on an efficient system of communications and transportation, which is still lacking in much of South America.

Internal trade. The relative importance of intra-regional trade continues to be small, in spite of its rapid growth since World War II. Intra-regional trade accounts for about one-sixth of total exports. In South America there exists a firm conviction that intensification of intra-regional trade is a necessary condition for rapid economic growth because it would help to reduce the region's excessive dependence on a few foreign markets, diversify exports, and help to solve balance-of-payments problems.

South American trade with the rest of Latin America is centred in a few countries. Argentina, Brazil, and Venezuela account for more than one-half of exports; these same three countries also absorb about one-half of the imports from the rest of Latin America.

The Latin American Integration Association

All of the independent South American countries except Guyana belong to the Latin American Integration Association (LAIA; formerly the Latin American Free Trade Association.) Despite formidable obstacles, the LAIA has directed its efforts toward designing a common trade policy for member countries, toward the gradual and automatic reduction of import duties and other restrictions on imports from the rest of the world, and toward arriving at agreements to compensate trade payments between member countries, as well as at making reciprocal credit arrangements between central banks. In addition, Bolivia, Colombia, Ecuador, Peru, and Venezuela have formed the Andean Subregional Group for the purpose of reaching agreement on common trade problems, such as an external tariff, reductions in tariffs applicable to subregional products, and coordinating their policies toward foreign investment.

More than 11,000 products have been granted some concession of one kind or another and have entered the intra-area trade. Trade among LAIA members consists mainly of basic commodities (about three-fourths) and semimanufactured and manufactured goods (about one-fifth). Among basic commodities the most important items are foodstuffs, beverages and tobacco, crude materials, and nonferrous metals. Among manufactured goods the main items of trade are chemicals, machinery, and transport equipment.

All these efforts toward integration are partially responsible for the rapid growth of the area's internal trade and for a large contribution toward a greater balance in trade among these countries. Since the 1960s intra-area trade has stabilized among South American countries, and surpluses and deficits have declined considerably.

External trade. External trade represents a key element in South America's economic growth. Essential imports, particularly capital and basic intermediate goods, are needed to accelerate the industrial process. A major problem has been that exports and net external financing have not been providing sufficient income to pay for those imports.

Despite a satisfactory increase in trade, South America's share of world trade has remained small, primarily because the growth in trade between major world industrialized countries has grown at an even faster rate. The share that South American countries contribute to the world's imports and exports is only a small percentage of the total. South America's share in total U.S. imports, also small, has been declining.

South America's major exports, in value terms, are foodstuffs, fuels, and crude materials. Within the first group the most important are sugar, bananas, cocoa, coffee, tobacco, beef, corn, and wheat; in the second group, petroleum and petroleum products; and in the third group, linseed oil, cotton, cattle hides, quebracho, fish meal, wool, copper, tin, iron ore, lead, and zinc. About one-third of these exports go to the United States, another one-third to western Europe, and one-eighth to Latin America.

Almost three-fourths of South America's imports consist of machinery, vehicles and parts, chemicals and pharmaceuticals, paper and paperboard, textile products, and other manufactures. More than one-third of South America's total imports are from the United States, almost one-third from western Europe, and about one-seventh from Latin America.

In general, South America's foreign trade sector has shown little diversification of exports, a heavy dependence on imports for domestic supplies of industrial goods, and a marked imbalance in trade with the industrialized countries.

TRANSPORTATION

In an area the size of South America, an efficient system of transportation is necessary for the expansion of national markets, as well as for the development of the hinterland. Unlike North America, South America does not have an adequately integrated transportation system. There are many separate road and rail systems, but they vary in extent and type. Since the mid-20th century, however, internal and international air routes have formed a reasonably well-integrated and complete transportation system.

Waterways. Traffic on the inland waterways faces many drawbacks, including dry seasons (and sometimes dry years), the direction of water flow, and difficult rapids. There are two systems of international importance—the Paraná–Uruguay basin (which includes territory in four countries) and the Amazon Basin (six countries), each having several thousand miles of navigable waterways. Furthermore, there are three other minor systems—the Magdalena in Colombia, the Orinoco in Venezuela, and the São Francisco in Brazil. The remaining rivers are unsuitable for navigation. In general, the volume of traffic on the waterways of South America is small, and the prospects for increasing it are limited. The major products transported by waterway are timber, mineral ores, and tropical fruits.

Maritime transport. Sea transport can be divided into three categories. The first of these is represented by the service linking the different ports along a country's coastline, as in Chile, Brazil, and Argentina, which have established regular cargo and passenger services of this type. Second are the services running between the various South American countries. Third are regular services running between countries in South America and other countries of the world.

A determined effort is being made by several countries to develop and enlarge national merchant marines, partly in order to arrest trends that in the past have resulted in their trade being carried by ships from outside the region and partly as an instrument to promote regional integration and to improve the national balance of payments.

Problems of rail transporta tion

Railways. The position of the railways in South America is unsatisfactory. Rail transport is plagued by operational problems and by a persistent loss of importance as a result of competition from road and air transport. Proportionally, railways handle only a small amount of goods because most bulky items moved are for export and are produced close to the coast. Almost all lines are single track, making traffic very slow and discouraging passenger traffic. Many countries have two or more gauges, hindering the possibility of an efficiently integrated rail system. Railways administrations, however, are making continuous efforts to improve services and reduce budget deficits. Except for some minor industrial lines, almost all railroads are government owned.

Roads. The length of roads used in South America is impressive. In many countries, however, only a small percentage is paved, while in other instances they are not wide enough for two vehicles to pass easily. The remainder of the system consisted of improved roads or simply dirt roads.

The improvement of existing roads and the construction of new ones has been proceeding rapidly—perhaps because some countries, such as Argentina and Brazil, manufacture motor vehicles in large quantities, while other countries are interested in expanding their automobile output. Furthermore, the inefficient service of the railroads has opened the way for the development of truck transportation, which has taken an increasingly large share of the volume of goods carried by land.

In developing international highways, particular attention has been paid to road-integration projects in which the Inter-American Development Bank and the World Bank have been heavily engaged. In the construction of the Brasília to Lima route, important progress has been made. Argentina has been investing large amounts to improve the integration of highways between its capital of Buenos Aires and Bolivia, from Mendoza to Santiago (Chile), and in the northeastern region bordering Paraguay and Brazil. Brazil continues to have the longest network of roads belonging to the Pan-American Highway system; the system itself extends throughout Latin America.

Air transport. Air transportation in South America has developed very rapidly since World War II, mainly because it is well suited to the area's requirements and avoids the forbidding geographical obstacles that hamper surface facilities. This is particularly true with respect to passenger traffic, but it applies less to the handling of bulky freight.

Each country has its own system of internal air services, operated generally by government-owned and sometimes by heavily subsidized private companies. This circumstance creates certain gaps in the otherwise reasonably well-integrated air transport system that has developed over the continent.

International air links

All of the South American capitals and most of the large cities are linked by direct air transport services with the major traffic centres of the United States and Europe. Domestic traffic has grown less rapidly than international traffic, but, together these developments resulted in maintenance of South America's share of total world air transport. (H.F.A.)

HISTORY

Only a brief historical survey of South American history is offered here. For full treatments see PRE-COLUMBIAN CIVILIZATIONS and LATIN AMERICA, HISTORY OF.

Pre-Columbian evolution

Before their discovery by the Europeans in the 16th century, the inhabitants of the South American continent lacked any form of script and, unlike the Maya and Aztecs of Mexico and Middle America, also had no type of recorded calendar. Consequently, knowledge of the prehistory of the continent is based on local traditions, accounts written by the first discoverers, and especially on archaeological field excavations. Because traditions of any significance are generally lacking except for the Incas of Peru and because historical accounts are limited to the conquest period, the dependence on archaeology is even greater.

EARLY CULTURES

The earliest inhabitants of South America were nomadic hunters, fishers, and gatherers who pushed southward from North America by way of Middle America and the Isthmus of Panama. There are, to be sure, other possible migration routes, including the transpacific, but the evidence for these is yet to be satisfactorily established. Remains of the early nomads have been found in such widely separated areas as highland Ecuador, eastern Brazil, and southern Chile near the Strait of Magellan. The remains include skulls, none particularly primitive, and stone and bone implements.

The hunting and gathering pattern survived in southern South America until historic times, but elsewhere the development of more advanced cultures and civilizations was based on farming. Various centres of plant domestication have been suggested, such as the marginal areas of the tropical forest, the high Andes, Middle America, and even the Old World for such plants as the bottle gourd, sweet potato, and perhaps cotton. Wherever the origin, the highest civilizations in South America were based on intensive agriculture, and this was best developed in the Andean mountains and along the Pacific coast, particularly in the Central Andes, which includes the mountains and coast of Peru and part of Bolivia.

The gross outline of cultural development in the Central Andes has been reasonably well established. The earliest remains, found on the northern coast of Peru, represent a population that depended heavily on fishing and gathering of shellfish for its subsistence but that also cultivated some domesticated plants, including the bottle gourd, squash, beans, chili pepper, and cotton. These people had no ceramics but did make baskets, mats, crudely flaked implements, and cloth from twined cotton fibres. They lived in small, subterranean houses and cooked their food by placing hot stones in some kind of water containers. Their remains are roughly dated as from 3000 to 1000 BC.

Ceramics were introduced at approximately 1000 BC, together with true weaving and domesticated corn (maize) and cassava (manioc), which initiated a long formative period during which many new techniques were tried and perfected. Systems of irrigation were established, new metallurgical techniques were invented, and many different shapes of sun-baked clay adobes were tried out in buildings. Religion, too, grew in importance, particularly in the Chavin culture. The stylized Chavin feline design, the dominant religious symbol, appears on stone carving, textiles, ceramics, and other media in many parts of the mountains and the coast.

Distinctive regional cultures

The long formative period was the basis for the distinctive regional cultures that flourished in almost every part of the Central Andes from approximately 400 BC to AD 600. This has been called the Early Intermediate, or Classic, Period because of the high artistic and technical achievements in ceramics, metallurgy, weaving, and architecture. Some of the outstanding local cultures are the Moche on the northern coast of Peru, noted for faithfully modelled and realistically painted ceramics; the Nazca on the southern coast, famed for polychrome embroideries and multicoloured clay vessels; Recuay in the northern highlands, with incised statues and small modelled figures on ceramic vessels; and Pucará and Tiahuanaco in the Bolivian highlands, noted for polished and fitted stone masonry and low-relief carving.

Each of the regional cultures started to expand as it grew stronger, and conflict followed. The Tiahuanaco culture became dominant and achieved the greatest extension. It can be traced throughout much of Bolivia, northern Chile, and the coast and highlands of Peru. There are indications that this Tiahuanaco expansionist movement was strongly motivated by religion, but it was nonetheless sufficiently organized to eclipse most of the local styles that it encountered. Although roughly dated from AD 600 to 1000, there is no evidence that any true unity, political or religious, was maintained throughout this time period, and as its influence diminished, regional cultures once again reappeared, each now definitely formulated into local political units. At least one of these, the Chimu on the northern coast, was well enough organized to be called an empire. Its arts and crafts reflected the traditions of the earlier Moche now mixed with Tiahuanaco. Its population was numerous and was settled in large ceremonial cities, such as Chan Chan, near the contemporary town of Trujillo, Peru, or assigned to live in strategically placed garrisons. The political and religious organization shows many parallels to the Inca Empire, which followed.

THE INCAS

The Inca Empire, discovered in full flower by the Spanish conquerors in 1532, was thus the culmination of many years of cultural growth. The Incas contributed their genius for political organization and built up an empire that not only united all the Central Andes but also extended north to Colombia and south to Chile and Argentina. For the Inca period the archaeological evidence is supplemented by traditions and by the written accounts from the early conquest years.

Unfortunately, the accounts preserved are not in agreement on all points, and it is not easy to reconcile discrepancies. For instance, one of the most important documents relating to Inca civilization is the account of Garcilaso de la Vega, son of a woman of the ruling Inca house by one of the conquerors, who had been brought up in his mother's family and had exceptional opportunities for collecting the ancient traditions. But his natural sympathies led him to stress the virtues of the Inca regime to the point of exaggeration. On the other hand, the "official" history of Pedro Sarmiento de Gamboa was written rather with the idea of showing the Incas as oppressors and the Spaniards as liberators.

In general terms, the history of the rise of the Incas to power would seem to be as follows: Their history begins with a frankly mythological account of a migration from the south to Cuzco, under the leadership of Manco Capac (Manqo Qhapaq). For years the Incas, living the same life as other Andean tribes, consolidated their power in the Cuzco valley and then began to make their influence felt among the surrounding tribes. A career of conquest, undertaken partly as a religious crusade, eventually raised the tribe to the position of a ruling caste, whose sovereign was regarded as a god on earth.

The first historical Inca (bearing the royal title of Sapa Inca) was Sinchi Roca (Zinchi Roq'a), by most authorities recorded as the "son" of Manco Capac. His date may be set at about AD 1200. The Inca power began to make itself felt outside the Cuzco valley in a southerly direction (among the Colla peoples) and was consolidated by Sinchi Roca's successor. Mayta Capac (Mayta Qhapaq) continued the policy of expansion toward the south, and the activities of these rulers led to the annexation and settlement of a large region, extending as far as Lake Titicaca, in succeeding reigns.

West and northwest of the Inca domain, the Chanca people, living under similar conditions, had built up a powerful confederation. A clash was inevitable, and the struggle was desperate; but the Inca, supported by their newly acquired tributaries from the Colla, emerged victorious. As a result, a large expanse of territory was added to the Inca sphere, inhabited by cognate peoples, practicing similar customs and religious observances and therefore amenable to the new conditions. The annexation of the Chanca district opened the way to the coast, the conquest of which, for climatic and religious reasons, was a long and laborious process. The reign of Pachacutec Inca Yupanqui (Pachakuti 'Inka Yupanki) seems to have been devoted to a reorganization of the Inca system in view of its new colonial responsibilities. But under Topa Inca Yupanqui (Thupa 'Inka Yupanki) and Huayna Capac (Wayna Qhapaq), the two great "conquerors" of the Inca dynasty, Inca domination was imposed throughout the highland region from Tucumán in Argentina to Quito in Ecuador: The conquest of the Ica (Arhuaco) and Chimu peoples of the coast was a more laborious process. (T.A.J./W.C.Be.)

OTHER PEOPLES

Elsewhere in South America the populations were far less numerous and far less advanced in civilization. In the northern mountains were the Chibchas, and along the northern coasts were the Caribs and Arawaks, the latter extending southward. In Brazil and the upper Plata Basin the Tupi-Guarani tribes predominated, with a semisedentary culture. The extreme south was sparsely populated by the barbarous Patagonians on the east and the warlike but disciplined Araucanians on the west.

European conquest and settlement

THE AGE OF DISCOVERY

Early European explorers

The continent of South America was first visited by Europeans in 1498, when Christopher Columbus, on his third voyage, touched near the mouth of the Orinoco. Others soon came after, and by 1509 the eastern coast had been followed as far as the Río de la Plata. In 1513 Vasco Nuñez de Balboa discovered the Pacific Ocean at the Isthmus of Panama; in 1520 Ferdinand Magellan navigated the strait that bears his name; in 1527 Francisco Pizarro landed on the coast of Peru at Tumbez, and, in the same year, Sebastian Cabot ascended the Río de la Plata and the Paraná River as far as the mouth of the Bermejo; in 1533 Cartagena was founded and the native town of Quito peacefully occupied; in 1535 Pizarro founded Lima, and, in the same year, Diego de Almagro invaded Chile, and Pedro de Mendoza established a settlement at Buenos Aires; in 1537 Gonzalo Jiménez de Quesada made his way from Santa Marta up the Magdalena River to Bogotá, the capital of the Chibchas; and in 1541 Pedro de Valdivia founded Santiago de Chile, and Francisco de Orellana travelled from eastern Ecuador to the Atlantic by the Napo and Amazon rivers. It is claimed that the bay of Rio de Janeiro was discovered by the Portuguese in 1502. Martim Afonso de Sousa visited it in 1531 but went on to found the first Portuguese settlement in Brazil at São Vicente (1532), near Santos.

THE COLONIAL PERIOD

Colonial settlement, western coast. The initial penetration of the Spaniards was into the Inca region. Its primary purpose was to secure precious metals, and, after seizing what the Indians possessed, the conquerors turned promptly to the mining of additional supplies. Agriculture was necessary, however, to provide food and clothing; and, in searching for gold and silver, the Spaniards occupied many places that were suited only for nonmining pursuits. The Spanish monarchs were zealous churchmen, too, and sought from the outset, through priests sent with the expeditions, both to convert and to improve the natives. Thus, many settlements were based on farming, and all kinds of European domestic animals were introduced and propagated with diligence.

Mining of gold and silver

The principal mining regions were in the high Andes inland from Lima and in south central Bolivia. While gold extraction was widely scattered, with Colombia eventually leading, silver was far more plentiful; and the discovery of the huge "silver mountain" at Potosí in 1545 made that place for many years the largest population centre in the hemisphere. The principal farming areas were along the Peruvian coast, where sugar, rice, and corn (maize) were grown on a large scale, and in the "central vale" of Chile, which was for a time the granary of Spanish South America.

Both mining and agriculture were based on the labour of the Indians, who had already been accustomed by their Inca masters to systematic toil. They were adapted without very great difficulty to Spain's *encomienda* system, under the direction of the mine owners and plantation operators who received grants from the Spanish crown. By the end of the 16th century, when the process of subjugation had been in good part accomplished, the Andean countries were organized in a wide system of agricultural and mining settlements. The number of Spaniards needed for troops and administration, as well as for mining, farming, industries, construction, and trade, was large, and these men at once formed unions with the Indian women, since relatively few families came from Spain. The hybrid, or mestizo, populations that resulted from this intermingling soon swelled to large proportions, particularly in the lowlands, and the mestizos played an important auxiliary role as overseers and superior employees in all activities.

As a basis for settlement the mining operations receded somewhat in the 17th century, because the best deposits became partially exhausted and because other occupations increased. In the highlands the Merino sheep gave the Indians a large new industry. In Chile, Peru, and western Argentina, wine grapes and olives were grown. In Ecuador, vegetable ivory, balsa wood, and, after 1700 cinchona were exploited. The numerous edifices and houses of European type were built of brick as well as stone or adobe, with the necessary wood brought from southern Chile. Boatbuilding was active.

Colonial settlement, eastern coast. Unlike the Andean western coastal countries, the eastern regions of the continent had rather few Indians and for two centuries were not known to contain minerals. Settlement from the beginning was based upon agriculture and natural products. The Spanish occupation in the Plata Basin was retarded by the southern Indians, with whom the Spaniards were at first unable to cope. They found in Paraguay, however, a well-watered rolling country peopled by the non-nomadic and nonhostile Guaranis, and Asunción in 1537 became the seat of Spanish operations. From it were founded towns farther down the river and eventually, in 1580, the city of Buenos Aires. By the late 18th century the rich humus of east central Argentina was coming into use for grains, and the plains were used for cattle, while in the north and in Paraguay, tropical crops and maté were produced. The absence of metals and inorganic combustibles handicapped other development, as did the Spanish prohibition of any trade except with Spain via Peru.

The Portuguese settlement of Brazil, almost one-half of the continent, was undertaken through 20 captaincies granted to nobles for tropical plantations. Because the Indians were found to be ineffective workers, blacks were imported in large numbers from Africa. Thus, along the northern littoral, despite uneven management and deficient rainfall, the production of sugar, rice, tobacco, indigo, and cacao soon became extensive; and dyewoods, cabinet woods, and animal skins were also exported. Southward from Rio de Janeiro, and particularly in the cooler tablelands of São Paulo, a more European type of farming came into existence. The hardy pioneer population showed energy in subduing and utilizing the Indians, thus opening the interior of central Brazil. At the beginning of the 18th century came the discovery of gold, diamonds, and a diversity of valuable ores in Minas Gerais, attracting an influx of population and making Brazil the world's main producer of gold for more than 100 years. In the south the settlement was more gradual but came to be based on cattle and sheep. (W.Ft.)

The legacy of Iberian colonialism. This basic sociocultural framework, with all its inherent ambivalences and contradictions, emerged during the colonial era and exercised a deep and lasting impact on the political, economic, and social structure of the new South American nations. Only after many decades was this impact blurred by the action of other external influences, change occurring from within, and a growing sense of national identity.

:ography

The political geography of the region emerged to a great extent as a result of the administrative and judiciary divisions established by Spain and Portugal. The three Spanish viceroyalties of Lima (1542), Nueva Granada (1717), and Río de la Plata (1776), the captaincies general, and the *audiencias* (units that were partly administrative and partly judicial) shaped the political boundaries, while the isolation in which the Spanish metropolis maintained each unit was at least one factor resulting in the fragmentation of Spanish America into 10 (and later into 20) independent states; geography and foreign interests were probably other important causes. Though Brazil maintained its unity, its component states, as well as their pronounced regionalism, were at least in part a heritage of the Portuguese administration and the laxity of its central control. Although the political organization of the independent nations of South America was largely molded after the French and U.S. models, the political culture, values, attitudes, and behaviour—particularly during the 19th century—were to a considerable extent the reflection of Iberian politics.

The cultural heritage. Though intellectual life, and to a lesser extent education, were strongly influenced by France in particular and Europe in general (later also by the United States), much of the Spanish and Portuguese intellectual heritage was transmitted, together with the language, to the new nations. Spanish remained the official language of all the independent states except Brazil (Portuguese), Guyana (English), and Suriname (Dutch).

Both Spanish and Portuguese have been influenced by local conditions. Spoken Spanish presents some differences between the various South American countries and also exhibits differences from the Spanish spoken in Spain. The hypothesis that the Andalusian dialect exercised the greatest influence seems controversial. At least one linguist has distinguished four varieties of Spanish in South America and two main types of pronunciation. Indian influences (and, in Argentina and Uruguay, the influence of European immigration) have had a certain impact. The differences between spoken Portuguese in Brazil and in Portugal itself are perhaps greater than those between Spanish as spoken in South America and as spoken in Spain.

Economic and social factors. In the economy a similar continuity is discernible. Colonial South America was a producer of raw materials—precious metals and tropical crops—and a market for European (mostly Spanish) manufactures. Local manufacturing was discouraged, and the rest of the economy—based mostly on subsistence agriculture and on some artisanal production for local lower class consumption—contributed to the surplus that helped to support the local colonial administration and the higher stratum of colonial society, as well as the Spanish (or, in Brazil, the Portuguese) royal treasury. After independence this economic framework continued to exist in the form of the primary export economy that was predominant in the region until the 1930s and that still remains an essential part of it today.

The same process that may be observed with regard to social organization and stratification was closely related, both during the colonial period and afterward, to the system of land tenure and to the pattern of labour relations. The great landed estate, the hacienda (called fazenda in Brazil), was one of the cornerstones of colonial society. The hacienda became an autonomous, self-sufficient institution not only in economic terms but also politically and socially. It was a self-sufficient productive unit, with the great landowner, or hacendado, generally exercising absolute authority—protective, oppressive, or both—over all the groups living on the hacienda; these included his own family, as well as the numerous servants, serfs, and slaves who provided labour for the agricultural, artisanal, and other activities.

Institution
of the
hacienda

The role of the hacienda was reinforced during the 17th century by the weakening of the colonial administration centred in the cities. Increasingly, the countryside—that is to say the great landowners—acquired importance. For many decades after independence, the role of the hacienda was further reinforced by the breakdown of state organization and authority. The increasing concentration of landed property that emerged during the colonial period typically occurred against the will of the crown; this displeasure was usually expressed in legislative measures, and sometimes there were actual attempts to enforce them. Labour relations established in colonial times also reflected the contradictory attitudes of Iberian rule. The *encomienda* (which meant "to entrust" a number of Indians to a Spaniard) was theoretically established as an institution for the protection of the indigenous population and for its conversion to the Christian faith. In fact, however, it became a means of reducing the Indians to slavery or serfdom. This was an important factor in the abolition of the *encomienda* and similar institutions, but the same semifeudal relationships were reproduced in the hacienda and continued under various partially modernized or transformed forms through the 19th century. In certain areas these relationships did not disappear until the first half of the 20th century, when social change in rural areas began to gain momentum.

In colonial times three main estates (social groups) were legally recognized—the Spaniards, the Indians, and the *castas* (castes), the latter being composed of those of mixed blood (such as the mestizo and mulatto) and of African slaves. In fact, however, the hierarchization was different: the European-born Spaniards, who had a monopoly of

The
colonial
hierarchy
and its
effects

most government offices and of authorized foreign trade, as well as other advantages, formed the highest stratum; below them were the Creoles (white or "whitish") followed by the mestizos; in the lower strata were the mulattoes, zambos, free Africans, slaves, and—at the bottom—the Indians.

This inherited social structure resulted in the failure to create a viable modern political system in the new nations. In addition, the central economic role played by raw-material exports not only reinforced the *latifundium* (landed estate system), maintained economic dependence and vulnerability, and provided an obstacle to industrialization, but it also determined forms of social relationships that in turn tended to perpetuate the archaic social structure. (G.Ge.)

The nations of South America

POSTINDEPENDENCE DEVELOPMENT

With the independence of the Spanish colonies in the early 19th century, the last Spanish restrictions upon trade and local enterprise were swept away. Freedom to export to world markets aided the expansion of agriculture, even though factional strife hampered productivity. Road construction progressed, and after 1850 railways were built from many coastal points into the interior, usually with British and other external assistance. Wheat and hides from Argentina were sold in quantity to Europe. Coffee was introduced into São Paulo and within a few decades gained for Brazil the preeminence in that staple that it thereafter maintained. Cacao became important in Ecuador, Brazil, and Venezuela.

Immigration was actively promoted and reached considerable volume in the Atlantic countries. Agriculture on the western coast showed less expansion, because of remoteness and the exiguity of arable land, while mineral industries for a time flagged. In no part of South America did independence bring the breaking up of the vast landed estates, and agriculture, in consequence, did not have the stimulus of diffused ownership. A compensatory gain in Peru was the exploitation of guano on the Chincha Islands and in Chile the export of natural nitrate from the Atacama Desert. The arrival of manufactures from Europe at lower costs than in colonial days was not favourable to South American industrial development, especially as motive power, industrial training, and local capital were not available. Yet simple industries became widespread: textile mills multiplied greatly; cereals, sugar, and leather were processed; and the output of clothing, furniture, footwear, soap, ceramics, and beverages was everywhere augmented.

The decades just before World War I brought new developments. Natural rubber was exploited in the Amazon, but exports of nuts, waxes, and skins proved more permanent. The Plata region built large packing plants and shipped chilled meat, while quebracho extract was produced in the Paraguay area. Along the Caribbean, bananas were cultivated, and the mountain valleys of Colombia developed mild coffees. Chilean nitrate became a bonanza, and Chile began to utilize its coal and iron. Copper and tin mining were revived in the Andes, and manganese from Brazil and bauxite from the Guianas entered world trade.

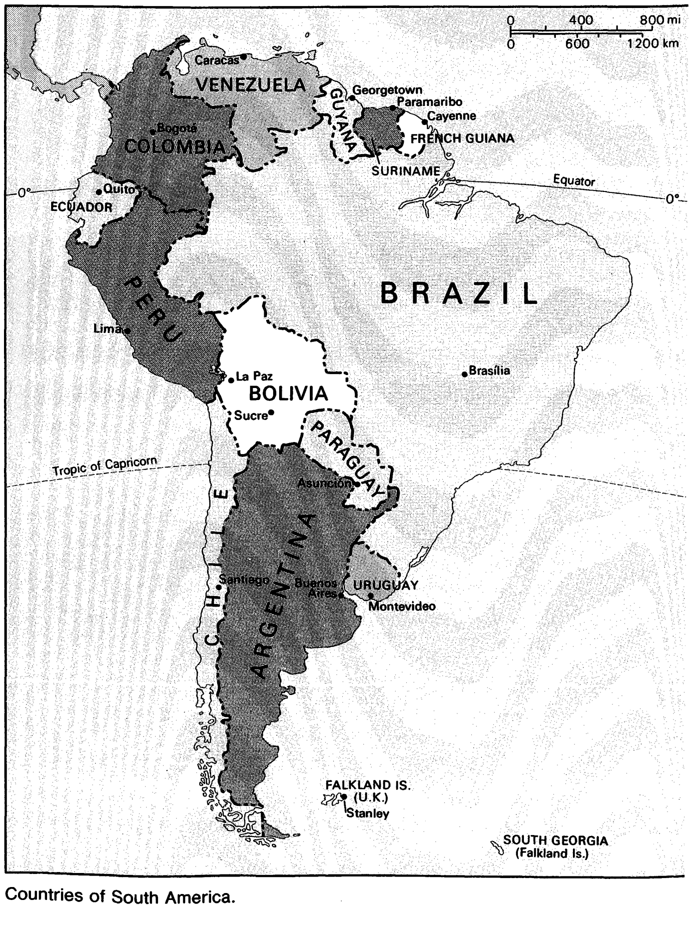
THE 20TH CENTURY

Economic developments. The opening of the Panama Canal benefitted the western coast, and World War I gave added importance to South American metals. Both tended to shift trade away from Europe to the United States. After the war, petroleum extraction was begun in Colombia and Venezuela: and postwar scarcity of manufactures, coupled with mounting nationalistic sentiment, stimulated factory projects for "national" goods. Governments secured large loans from New York City and London and improved roads, harbours, and education. Both immigration and the birth rate rose. The universities and press participated in the modernization movement. The world depression of the 1930s reversed these trends as to metal exports and immigrant imports, although a number of Spanish republican refugees arrived with skills and capital. But popular discontent arising from the Depression caused agrarian reform to be undertaken in several countries, to the ultimate advantage of agriculture.

World War II resuscitated all exports from South America, despite the German submarine campaign, and strengthened the continent's overall financial position. Postwar exports levelled off at better than prewar volume, and the continent could afford large purchases of equipment. Many countries created official development corporations to promote hydroelectric power, new lumbering and metallurgical activities, and general industrialization; and the indexes of industrial production showed gains of 50 percent or more as compared with the interbellum decades. There was a striking increase in the petroleum output of Venezuela, and that nation's vast iron-ore deposits were opened up. Agriculture and sanitation were improved, with technical cooperation from the United States and the UN. Fisheries were expanded, especially in Peru, and the crushing of vegetable oils was increased. (W.Ft.)

Development of resources and industries

Social and political changes. The economic expansion created by a growing demand for primary exports, the new services required as a result of this expansion, and the growing centralizing and coordinating role of the state all helped to transform South American urban society, particularly in the larger cities, and led to the emergence of an urban middle class and to the beginnings of a modern urban working class. These transformations were carried into the political system, leading to an enlargement of participation. The breakdown in international trade created by two world wars and the Great Depression generated conditions favouring industrialization. At the same time urban concentration increased enormously, while the growth of the mass media and of transportation networks broke down the isolation of the countryside and the large marginal areas that usually formed the greater part of the national territory. The timing, speed, and character of these transformations varied widely among the South American nations. In general, Euro-American countries initiated their transformation first, followed by the largest nations in Mestizo-America, and by some of the Indo-American states. Stagnation and involution (*i.e.*,



Countries of South America.

deterioration of already attained levels of modernization and development) have occurred, but mass mobilization and social change are the main characteristics of contemporary South America.

The emergence of new social sectors—first the urban middle classes and then the urban proletariat—deeply modified the cultural, social, and political scene. Nationalism, in different ways and degrees, characterized the outlook of the middle classes and of the populistic regimes that replaced the oligarchic regimes, which had been characterized by "limited" democracy, or (more often) undisguised authoritarianism. Military intervention continued, but its meaning changed. Prior to the 1930s it had represented an expression of factional conflict within the ruling elites, but instead it became a component of the "participation crises" generated by the entry of an increasingly larger proportion of the population into politics. Economic, political, and cultural "dependence" on foreign hegemonic nations—mainly the United States—became a central issue. A growing sense of national identity generated a revaluation of the Indian and mestizo heritage. Even where this element was virtually lacking—as in Euro-America—efforts were nevertheless made to re-create a national-popular tradition. Economic development and the integration of national society became universally accepted, but deep conflicts were created by the contrasting ideologies and interests of the various social sectors that were actively participating in the political arena. New regimes were established, varying from those oriented toward Marxism on the one hand to the modernizing authoritarianism of military rule on the other. The old colonial heritage was clearly disappearing. (G.Ge.)

Foreign relations and national identity

GEOGRAPHICAL FEATURES OF SPECIAL INTEREST

Prominent landforms

ANDES

A vast series of extremely high plateaus surmounted by even higher peaks, the Andes mountain system stretches for 5,500 miles (8,900 kilometres)—from the southern tip of South America to the continent's northernmost coast on the Caribbean. One of the great natural features of the globe, it separates a small western coastal area from the rest of the continent, affecting deeply the conditions of life within itself and in surrounding areas.

The Andes is not a single line of formidable peaks but a succession of parallel and transverse mountain ranges, or cordilleras, and of intervening plateaus and depressions. Distinct eastern and western ranges—respectively named the Cordillera Oriental and the Cordillera Occidental—are characteristic of most of the system. The western cordillera is within the great belt of crustal disturbances bordering the Pacific and is thus the home of both earthquakes and volcanoes.

The directional trend of both the cordilleras is generally south–north, but in several places the Cordillera Oriental bulges eastward to form either isolated peninsula-like ranges or such high intermontane plateau regions as the Altiplano (Spanish: "high plateau"), occupying adjoining parts of Argentina, Chile, Bolivia, and Peru.

Some historians believe the name Andes comes from the Quechua Indian *anti* ("east"); others suggest it is derived from the Quechua *anta* ("copper"). It is perhaps more reasonable to ascribe it to the *anta* of the older Aymara language, which connotes copper colour generally.

Physical features. *Physiography.* There is no universal agreement about the major south-to-north subdivisions of the Andes system. For practicality, the system is dealt with in this article in terms of six south-to-north subdivisions: Patagonian Andes, Central Andes, Peruvian Andes, Ecuadorian Andes, Colombian cordilleras, and Venezuelan Cordillera.

The Patagonian Andes begin on the mountainous Staten Island (3,700 feet [1,125 metres]) of the Tierra del Fuego archipelago, run to the west through Isla Grande, where the important ridges, including Darwin, Valdivieso, and Sorondo—all less than 7,900 feet high—then rise to the north beyond the Strait of Magellan. The physiography of this southernmost subdivision of the system is complicated by the presence of the independent Sierra de la Costa.

Numerous transverse and longitudinal depressions and breaches cut this wild and rugged portion of the Andean range, sometimes completely; many are occupied by ice fields, glaciers, rivers, lakes, or fjords. The crests of the mountains exceed 10,000 feet (Fitzroy reaching 11,070 feet [3,375 metres]) north to latitude 46° S but average only 6,500–8,400 feet from latitude 46° to 41° S, except for Tronador (11,657 feet [3,554 metres]). The line of permanent snow is found at 2,300 feet in Tierra del Fuego, 5,000 feet at Volcán Osorno (41° S), and 12,000 feet in Domuyo (36° 38′ S). A line of active volcanoes—including Yate, Corcovado, and Macá—occurs about 40° S to 45° S. Gigantic ice fields are located between Monte Fitzroy (in Chile, Cerro Chaltel) and Lago Buenos Aires at both sides of Baker Fjord; the Viedma, Upsala, and other glaciers are born there. Other notable features are the more than 50 lakes found south of 39° S. Those depressions free of water form fertile valleys called *vegas.* The passes are low and easy, reaching 6,000 feet at Pino Hachado, 3,800 feet at Lipinza, and 2,000 feet at Mua Mum.

aks in e Patanian ndes

On both sides, but more especially on the western side, the forests are untamed and magnificent, covering the mountains as high as the snow line, although at the higher altitudes toward the north the vegetation is smaller and less dense. Both Argentina and Chile have created national parks to preserve the area's natural beauty.

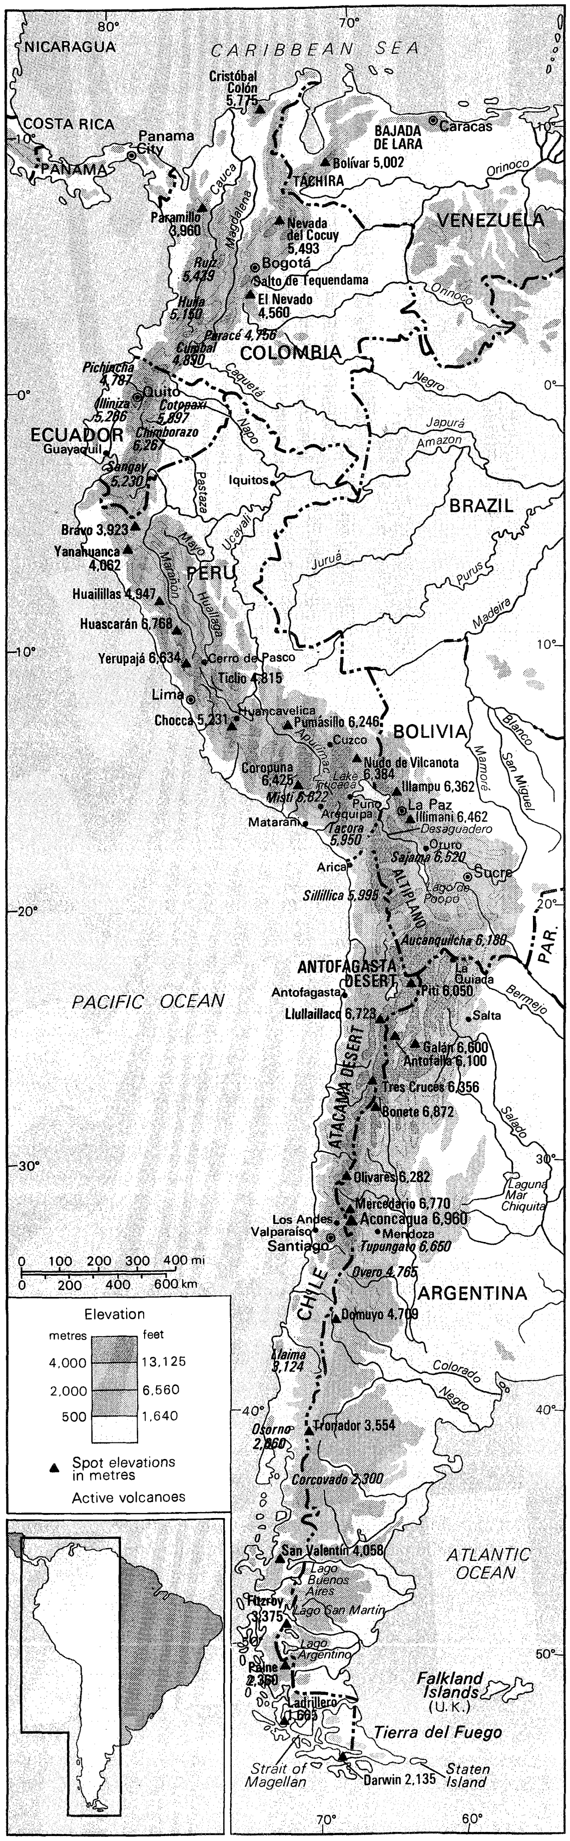
North of Lago Aluminé the axis of the cordillera shifts to the east up to a zone of transition between parallels 37° and 35° S, where the geographic aspect and geologic structure change. This marks the northern end of the Patagonian Andes.

The Central Andes begin at latitude 35° S where the cordillera undergoes a sharp change of character. Its width increases to about 50 miles, and it becomes arid and higher; the passes, too, are higher and more difficult. Glaciers are rare and very high, and there is virtually no vegetation. Lakes disappear north of latitude 39° S, forests, north of 37°. The main range serves as the boundary between Chile and Argentina and also is the divide between rivers flowing to the Pacific and the Atlantic. The last of the southern series of volcanoes, Tupungato (22,309 feet [6,800 metres]) is just east of Santiago, Chile. From there to the peak of Aconcagua, great snowcapped peaks, such as Juncal, rear up. The mighty Aconcagua itself, at 22,834 feet (6,960 metres), is the highest peak in the Western Hemisphere; to its north lies Mercedario (22,206 feet [6,770 metres]), and between them are the passes of Espinacito (16,000 feet) and Patos (12,825 feet). To the south the passes are Pircas (16,961 feet), Bermejo (over 10,000 feet), and Iglesia (13,400 feet). Farther north the passes are more numerous and higher, and the peaks of Bonete, Ojos del Salado, Incahuasi, and Pissis surpass 20,000 feet. The snow line is also much higher.

The peak of Tres Cruces (20,853 feet [6,356 metres]) at latitude 27° S marks the culmination of this part of the cordillera. To the north there is a transverse depression and the beginning of the high plateau called Puna in Argentina, Puna de Atacama in Chile, and Altiplano in Bolivia. The cordillera grows wider as it advances into Bolivia and Peru, where the great plateau is bounded by two ranges: the Occidental and the Oriental.

The beginning of the Altiplano

Northward, to latitude 18° S, the great peaks of El Cóndor, Sierra Nevada, Llullaillaco, Galán, and Antofalla all exceed 19,000 feet. The two main ranges and several volcanic secondary chains enclose depressions called *salares* because of the deposits of salts they contain; Sierra de Calalaste encompasses the big *salares* of Antofalla. Volcanoes of this zone occur mostly on a northerly line along the Cordillera Occidental as far as the Misti (latitude 16° S) in Peru.



Andes mountain system.

At about 18° S the Cordillera Occidental changes to a northwesterly direction to the west side, descending smoothly to the deserts of Atacama and Antofagasta and the southern Peruvian coast.

The eastern range, the Cordillera Oriental, lower and built on a broad bed of lava, is cut and denuded by rivers with steep gradients, fed by heavy rainfall. It has two sections. The southern is 150 miles wide and—with the exception of Chorolque (18,414 feet [5,614 metres])—not very high. The northern, named Cordillera Real, is narrow, with higher peaks and glaciers; and the most important peaks, at over 21,000 feet, are Illimani and Illampu (Nevado de Sorata).

At about latitude 22° S, the Cordillera Oriental penetrates into Bolivia, describing a wide semicircle to the north; the plateau becomes the broadest part of the Andes—the Altiplano de Bolivia.

The Altiplano is one of the largest interior basins of the world—500 miles long, 80 miles wide, and 11,200 to 12,800 feet high; it has no water outlet to the ocean. In about the middle of the plateau there is a great depression, running south to north. Lake Titicaca, the highest navigable lake of the world (110 miles long), is on the northernmost part of the depression; the Río Desaguadero follows the depression, taking the water of Titicaca to the small Lago de Poopó.

Canyons and passes of the Peruvian Andes

The Cordillera Occidental runs parallel to the coast of Peru, while the Cordillera Real from Bolivia ends in the rough mountain mass of Nudo de Vilcanota at latitude 15° S. From there, two lofty and narrow chains emerge northward, the cordilleras of Carabaya and Vilcanota, separated by a deep gorge; to the west of these and northwest from the city of Cuzco a third range appears, the Cordillera de Vilcabamba. The three ranges are products of erosive action of rivers that have cut deep canyons. West of the Vilcabambas, the Río Apurímac runs in one of the deepest canyons of the hemisphere. In the valley west of the Cordillera de Vilcanota stands the city of Cuzco (10,909 feet [3,326 metres]).

Traditionally, the Peruvian Andes have been described as three cordilleras, which join at Nudo de Vilcanota, Pasco, and Loja (Ecuador). Today, the region is considered as a simple plateau. The *nudos* (knots) are erosive products and hydrographic divides; the cordilleras stand on the plateau and were produced by crustal movements and erosion by the large rivers. The plateau in the south is 60 miles wide and 13,000 feet high; in the north it is narrower and lower (less than 12,500 feet).

The Nudo de Pasco is a large, high plateau. To the west it is bounded by the Cordillera de Huarochirí, on the west slope of which the Río Rímac rises in a cluster of lakes fed by glaciers and descends rapidly to the ocean (15,700 feet in 60 miles). The nearly 15,800-foot-high pass of Ticlio is used by a railroad. On the *nudo* there are many small lakes and ponds, the lake of Junín, about 20 miles long, being the largest.

Cordilleras Blanca and Negra

North of the Nudo de Pasco three different ranges run on the plateau: the Cordilleras Occidental, Central, and Oriental. In the Cordillera Occidental at latitude 10° S a deep, narrow valley (Callejón de Huaylas) separates two ranges—Cordillera Blanca (eastern) and Cordillera Negra (western); the Río Santa runs between them and cuts Cordillera Negra to drain into the Pacific. Cordillera Blanca is a complex highland with permanently snow-capped peaks, some among the highest of the Andes (for example, Huascarán, which is just over 22,204 feet [6,768 metres]). The glaciers that rise here are very often broken off by earthquakes and rush down the slopes, demolishing settlements and vegetation alike. Cordillera Negra, so named because it is without snow, is lower. The two ranges join together at latitude 9° S. The Río Marañón, which runs northward between Cordilleras Occidental and Central at about latitude 6° S, changes its direction to the northeast, penetrating into the region of the *pongos* (narrow transverse gorges that cut the cordillera to reach the Amazon Basin). These include Pongo de Rentema (about one and one-fourth miles long, 200 feet wide), Mayo, Mayasito, Huarcaya, and, the most important, Pongo de Manseriche (seven miles long).

Between Cordillera Central and Cordillera Oriental, the Río Huallaga runs in a deep gorge with few small valleys; it cuts the eastern cordillera in Pongo de Aguirre (latitude 6° S). Cordillera Oriental ends in the Amazon Basin at latitude 5° S.

The permanent snow line is 19,000 feet in Nevado Chanchami (about latitude 16° S) and declines to 15,000 feet in Cordillera Blanca and to 13,000 feet in Huascarán. Permanent snow disappears north of latitude 8° S, the puna ends and the so-called humid puna, or *jalca,* begins. Mountains become wider and smoother in appearance; vegetation changes to heathland and trees. The altitude diminishes, and passes are much lower, as at Cuello de Porcullo (7,000 feet).

:hains of olcanoes ı the :cua-orian ındes

A rough and eroded high mass of mountains named Nudo de Loja (latitude 4° S) marks the end of the Peruvian cordillera and the beginning of the Ecuadorian system. This is a large plateau running in a south to north direction and bordered by two chains of high and numerous volcanoes. To the west, in the Cordillera Occidental, geologically recent and relatively low, there is a line of 19 volcanoes, seven of them over 15,000 feet high.

The eastern border is Cordillera Central (formerly Cordillera Oriental), higher and older, with a line of 20 volcanoes. Five are over 16,000 feet.

The plateau in between (sometimes called Avenida de los Volcanes) is 8,000 feet high and 55 miles wide and is covered by volcanic rocks, andesites, and lava. In some places the accumulation of material forms *nudos* and secondary chains that divide the valley into several basins.

On the external slopes of the cordillera the rainfall is heavy, and vegetation flourishes. The high cordillera is cold and desolate, with peaks covered by mist; such regions are known as *páramos.* The central plateau is partially cultivated and supports the majority of the Ecuadorian population. In the transverse ranges there are some important peaks, including El Relado (13,642 feet [4,159 metres]), Imbabura (15,190 feet [4,630 metres]), and Ñaupán (14,852 feet [4,529 metres]).

'he 'ordillera 'riental

A third cordillera has been discovered recently in the eastern jungle of Ecuador; this is the Cordillera Oriental. It seems to be a very old alluvial formation that has been divided by rivers and heavy rainfall into a number of mountain masses, isolated or forming irregular short chains, and covered by luxuriant forest, like the cordilleras of Guacamayo, Galeras, and Lumbaquí. The altitude does not exceed 7,900 feet, except at Cordilleras del Cóndor (13,000 feet) and Cerro Pax (11,000 feet).

North of the international boundary there is a group of high, snowcapped volcanoes (Azufral, Cumbal, Chiles) known as Nudo de Huaca. Farther north begins the great Macizo Central Colombiano, with the volcanic mass of Nudo de Pasto (latitude 1–2° N), which is the most important Colombian physiographic complex and the centre of the country's river system.

Three distinct ranges, the Cordilleras Occidental, Central, and Oriental, run northward. Cordillera Occidental, parallel to the coast and moderately high (12,800 feet near Antioquia), ends in the mountain complex of the Cordillera de Chocó.

Cordillera Central, or Cordillera del Quindío, is the highest (mean altitude almost 10,000 feet) but the shortest (400 miles) range of Colombian Andes; its last spurs disappear south of the confluence of Cauca and Magdalena (latitude 8° N). Most of the volcanoes of the zone are in this range, including Tolima (17,105 feet [5,215 metres]) and Ruiz (17,844 feet [5,439 metres]) among others; Nevado del Huila (16,896 feet [5,150 metres]) is also in the Cordillera Central. At about latitude 5°80′ N, the range widens into the plateau of Antioquia, where Medellín stands.

Between Cordillera Central and Cordillera Occidental is a great depression, the Patía–Cauca Valley, divided into three longitudinal plains. The southernmost is the narrow valley of Patía that drains to the Pacific. The middle plain is the highest (8,200 feet) and constitutes the divide of the other two. The northern plain, the largest (15 miles wide and 125 miles long), is the valley of Cauca, which drains by the Rió Cauca to the Magdalena.

Páramos and *sabanas*

Cordillera Oriental has a slight northeast direction and is the widest and the longest of the system. The average altitude is 7,900 to 8,900 feet. North of parallel 3° N it widens, and after the depression of Uribe (6,130 feet) begins the Macizo de Sumapaz (altitude 10,000 to 13,000 feet), where the large Páramo (high plateau) de Sumapaz is located. The volcanoes Puracé, Picos de la Fragua, and Neiva stand south of this *páramo,* the first in the Cordillera Central, close to Popayán, the other two on the Cordillera Oriental. North of Sumapaz the range divides into two, enclosing a large plain 125 miles wide and 200 miles long, often interrupted by small transverse chains that form several peneplains, called *sabanas* (or savannas), commonly containing shallow lagoons and useless bogs. One-third of the population of Colombia lives there. The largest and most populated is the Sabana de Bogotá; other important *sabanas* are: Ubaté, Chiquinquirá, Tunja, and Sogamoso. East of Honda (latitude 5° N) the cordillera is a series of abrupt parallel chains running to the north-northeast: among them Sierra Nevada del Cocuy (18,000 feet) has snowed peaks. Farther north the central ranges end, but the external chains go on and diverge to the north and northeast; the western is Cordillera de Ocaña (6,500 feet), which on its northeastern side has the sierras of Motilones and Perijá; this is the boundary between Colombia and Venezuela and goes as far as parallel 11° N in the Península de la Guajira. The eastern chain bends to the east and penetrates to Venezuela at the Cordillera de Mérida.

The northern end of the Andes

Rivers on the Cordillera Oriental make their ways on the *páramos* and *sabanas* and cut the borders of the plateau through deep gorges; Salto de Tequendama of the Río Bogotá is an example.

On the border of the Caribbean, between Serranía de Perijá and Isla de la Aguja, stands Sierra Nevada de Santa Marta, an isolated triangular massif that rises abruptly from the coast to snowcapped peaks of 18,947 feet (5,775 metres). Geologically speaking, it does not belong to the Andes.

The Andes of Venezuela are represented by Cordillera de Mérida (280 miles long, 50 to 90 miles wide and about 10,000 feet high); it is separated from Cordillera Oriental of Colombia by the depression of Táchira. It begins in Pico el Cobre, extends first in a northerly direction for 35 miles and then northeast, up to the depression of Barquisimeto, or Bajada de Lara, where it ends. The cordillera is a great uplifted axis (where erosion has uncovered granite and gneiss rocks but where the northwest and southeast sides remain covered by sediments) formed by numerous chains with snow-covered summits separated by longitudinal and transverse depressions—Sierras Tovar, Nevada, Santo Domingo, de la Culata, Trujillo, and others. The Cordillera de Mérida separates the hydrographic regions of the Orinoco and the Caribbean.

To the north, Sierra Falcón and Cordillera del Litoral (called in Venezuela Sistema Andino) do not belong to the Andes but rather to the Guiana system.

Geology. The eastern side of the Andes is in general older than the western. Paleozoic (Cambrian, Silurian, Devonian, and Carboniferous) beds formed from 280,000,000 to over 570,000,000 years ago are found in the eastern Argentinean and Bolivian Andes; Cordilleras Real and Vilcabamba have even more ancient Archean (late Precambrian) as well as Paleozoic rocks, related to the Brazilian Massif. In Peru and Ecuador, the eastern ranges are of ancient gneiss and schists, covered mostly by Mesozoic, or Secondary, sandstones (from about 65,000,000 to 225,000,000 years old). In Colombia, the Cordillera Central shows ancient crystalline rocks (Cambrian to Carboniferous) with intrusion of heat-altered rocks.

The western ranges and the plateaus are mainly of Mesozoic formation, Jurassic and Cretaceous. Rocks of Cretaceous age (up to 136,000,000 years old) are widely distributed in the Patagonian Andes; in Chile there are Jurassic (up to 190,000,000 years old) and Cretaceous sediments. Puna de Atacama and the west ranges of Bolivia show Mesozoic beds with Cenozoic (Tertiary; 7,000,000 to 65,000,000 years old) volcanic material. In Peru, gray limestone covers large parts of the plateau and the Cordillera Occidental. In Ecuador the Mesozoic beds occur with deposits of volcanic material in the valley. In

Colombia the western branch is mostly of Cretaceous beds, as is the Cordillera Oriental.

The entire western coast of South America is included in the great circum-Pacific belt of seismic activity (earthquakes and volcanoes). The great geologic dislocation and the folding of the cordillera started in Cretaceous (Late Mesozoic) time and continued during the Tertiary (early to mid-Cenozoic). During the Mesozoic, the western part of South America was a geosynclinal basin, a vast downwarp in the Earth's surface, covered by the Pacific. Periods of upliftings and subsidences during the Tertiary were accompanied by great volcanic effusions. In the Quaternary (Late Cenozoic), beginning some 2,500,000 years ago, the disturbances continued in a process that is still going on. This involves a continuous raising of the cordilleras and a sinking in the ocean of a great part of the coast, producing an unstable condition caused by the tremendous abrupt difference between the heights of the cordilleras and the great depths of the Pacific. In this geologically recent period, volcanic activity and glaciation produced a period of uniform summit levelling (peneplanation) and denudation by filling depressions with glacial deposits and volcanic material and eroding the overall mountain relief. The modern volcanic system is Quaternary; three main groups were formed: that of the Patagonian and Central Andes (Chile); that between Chile and Peru; and that between Ecuador and Colombia.

Volcanic and earthquake activity in the Quaternary

Soils. The complex interchange between climate, geology, topography, and biology that determines soil types and their condition is deeply affected by altitude. In general, Andean soils are relatively young and suffer great erosion by water and winds because of the unimpeded steep gradients of the land.

In the deep south of the Patagonian Andes the formation of soils is difficult; the action of glaciers and winds has left almost-bare rocks in many places. Northerly peat bogs, podzols, and meadow soils, yellow-brown and red-brown, with thick horizons of humus, are found; drainage is poor. In the region of lakes, dark-brown soils occur. They are rich in organic material and well drained. North of latitude 45° S drainage becomes insufficient in surface as well as in profile. In the upper part of the cordillera, soils are formed directly on weathered rocks; in the lower zones reddish-brown soils with gravel and quartz are found; erosion is heavy.

North of parallel 37° S are found primary soils with water deficiency. In the Atacama Desert, where precipitation and vegetation are scarce, so is the organic material; desertic gray soils bearing mineral salts occur, heavily eroded. This type, with little differences, extends on Cordillera Occidental to north of Peru.

The plateau and the east side of the eastern cordilleras show characteristics of soil closely related to altitude, from Bolivia to Colombia.

In the Andean *páramo* are found rough topography and embryonic soils black with organic material; drainage ranges from very poor to very rapid.

At altitudes between 6,000 and 12,000 feet, red, brown, and chernozem soils occur in soft slopes of valleys and plains. In more poorly drained areas, soils are relatively fertile, being permeable in some places with sandy horizon B (the main layer of the soil profile, extending from the surface down to the bedrock). These soils are economically the most important in Bolivia, Peru, and Ecuador. The *sabana* soils of Colombia are gray-brown, with claypan in certain levels, which makes them impermeable, of very poor drainage.

In the high parts of the mountains are very poor soils, superficial and stony, as represented by Andean rendzina (dark grayish-brown soils) and by brown-black soils. On the east side of the eastern cordilleras, descending to the Amazon Basin, there are thin, dark, humid soils without evolution, suffering great erosion because of heavy rainfall and the steep gradient of the slopes.

The intrazonal soils include humic clay and solonetz (dark alkaline soils) close to the lakes and lagoons. Also included in this group are soils formed from volcanic ash in Cordillera Occidental, south of latitude 14° S (Chile, Peru, and Bolivia).

The azonal soils are alluvials, of incomplete evolution and stratified without definite profile, and lithosols (a group of shallow soils consisting of imperfectly weathered rock fragments) that occupy the major part of the Andean massif. Their superficial layer is directly on rocks. They have incomplete profiles on rough slopes. Erosion is heavy. In Colombia, in slopes and gorges, sandy yellow-brown azonal soils are the base of the large coffee plantations.

Climate. In general, temperature increases from Patagonia to the Equator, but combinations of such factors as altitude, proximity to the sea, the cold Peru (Humboldt) Current, heavy or scarce rainfall, and defenses against wind determine an extensive variety of climates. The hottest rain forests, deserts, or deep gorges are often separated from the polar temperatures of the high puna by a few miles. At identical altitudes, however, there is no parallelism between external (to the Pacific or to the Amazon Basin) and internal slopes of the cordilleras; the external slopes are under the influence of either the ocean or the Amazon Basin.

The isotherm (line of equal average temperatures) 10° C (50° F) extends from the Patagonian Andes to Colombia. As mentioned above, the line of permanent snow varies greatly. It is 2,600 feet at the Strait of Magellan, 7,000 feet at 39° S, 20,000 feet at 27° S, 19,000 feet at 16° S, 16,000 feet at 9° S, and 15,000 feet at the tropical Andes.

Precipitation varies widely. There is heavy rainfall and solid precipitation south of parallel 38° S (180 inches at Lake Quillen). On the Central Andes of Chile and the Atacama Desert, rainfall is scarce, with some precipitation in summer (December, January, February). On the Altiplano de Bolivia and the Peruvian plateau and in the valleys of Ecuador and *sabanas* of Colombia, rainfall is seasonal and not heavy; in some places there is very little. It rains in small amounts on the west side of the Peruvian Cordillera Occidental, somewhat more in Ecuador and Colombia. On the east side of the Cordilleras Orientales (Amazon Basin side), rainfall is usually seasonal and heavy.

Precipitation and temperature

Temperature varies with altitude. Up to 4,900 and 8,200 feet the climate is subtropical and tropical, respectively: dry with hot temperatures during the day and mildly warm at night. At heights of between 8,200 and 11,500 feet it is dry, with mild temperatures; but there are big differences between night and day; this realm constitutes the most populated area of the Andes. At 11,500 to 14,800 feet it is dry and cold, with great differences between day and night and between sunshine and shadow, and it is freezing at night. At 13,500 to 15,700 feet (the puna), occurs the climate of the *páramo,* very cold and dry, with subfreezing temperatures. Above 15,700 feet on the peaks and high ridges, climate is polar with very low temperatures and ice-cold winds.

As in all other areas of the world, microclimates (extremely local developments) are widely varied because of the interplay of latitude, altitude, and other factors.

Plant and animal life. Life on the Andes depends upon altitude; within certain levels, however, the existence of vegetation is determined by climate, watering, and soil and of animal life by the food that is available. The permanent snow line is the upper limit of both. In the Andes, some plants and animals can live at any altitude, and others can only live at certain levels. Cats live only exceptionally above 13,000 feet; white-tailed mice usually do not stay lower than 13,000 feet and live up to 17,000 feet. The Peruvian camelids (llama, guanaco, alpaca, and vicuña) are animals of the Altiplano (11,200 to 12,800 feet), although they can live well at lower altitudes. The condor is believed to fly up to 26,000 feet. Probably the low barometric pressures of high altitudes are less important for vegetation, but altitude imposes a number of climatic factors, such as temperature, wind, radiation, and dryness of atmosphere, that determine the kind of plants growing at the different parts of the Andes.

Dependence of life on altitude

In general, the Andes can be divided into latitudinal bands, each with typical main vegetation and fauna; but latitude imposes differences between south and north; and proximity to the Pacific and to the Amazon Basin creates differences between the external and internal slopes of the Cordilleras Occidental and Oriental.

A zone at about parallel 35° S separates two different regions of the Andes. To the south, in the Patagonian Andes, the flora is austral (of southern aspect) instead of Andean. Magnificent forests of araucaria (a pine), oak, coigue (an evergreen used for thatching), chusquea, cypress, and larch occur.

Northerly characteristics are different. The Cordillera Occidental is very dry in the south, slightly humid (with moisture and scarce rainfall) in central and north Peru, and humid with heavy or moderate rainfall in Ecuador and Colombia. Vegetation follows the climatic scheme: in the south, it is poor and desertic; at higher altitudes, steppe vegetation occurs. Animals include the guemul, puma, vizcacha, cuy (guinea pig), chinchilla, camelids, mice, and lizards; birds include the condor, partridge, parina, huallata, and coot. Agriculture is poor. The east side of the Cordilleras Orientales northward from Bolivia has lush vegetation, most of it natural tropical forest; agriculture is difficult because of the steepness of the slopes, but the rich fauna of the jungle is present.

'lora and
ıuna of
ıe plateau

On the plateau (valleys, plains, ranges, and internal slopes of the cordilleras), life is again closely related to altitude. Tropical palms and eternal snows lie within a few miles of each other; altitude varies from 1,600 feet in deep gorges to more than 20,000 feet in peaks and ridges. Up to 8,000 feet, vegetation is of dry tropical and subtropical climate, and agricultture is important: the great coffee industry of Colombia is mainly located in the warm valleys of this zone. Between 8,200 and 11,500 feet lies the most populated zone of the Andes; some of the major cities of the Andean countries are there, and it supports the main part of Andean agriculture. Temperatures vary from warm in the valleys to moderate low (down to 50° F [10° C]) on the plains, *sabanas,* and slopes; and there is seasonal rainfall and water from rivers. This zone is also suitable for livestock and poultry.

At 11,500 to 13,400 feet relief is usually rough and difficult for agriculture; in Colombia this zone is *páramo* and sub-*páramo,* with seasonal rainfall; in Ecuador rain is abundant; in Peru and Bolivia the *páramo* has from moderate to scarce rainfall.

At 13,400 to 15,700 feet (puna) vegetation is formed by plants that resist the cold temperature and the freezing during the night; above 16,000 feet, vegetation is almost absent.

The people. Man's presence on the Andes is relatively recent; the oldest human bones found have been 10,000 to 12,000 years old, although human habitation may be much older. The lack of oxygen due to the altitude, especially above 12,000 feet, is so physiologically disturbing that it imposes deep adaptative changes even in the cells of the body. The highest altitude in the Andes at which man has been found as a permanent resident is 17,100 feet (shepherds in the south of Peru) and, as a temporary worker, 18,500 to 19,000 feet (Carrasco Mine, in Aucanquilcha, Atacama Desert, Chile).

From Patagonia to the southern limits of the Bolivian Altiplano, the Andes are unpopulated; a few small groups of shepherds and farmers live in the lower slopes and *vegas* of the cordillera.

Northward, the Andes hold the largest part of the population and the majority of the most important cities of Bolivia, Peru, Ecuador, and Colombia. The main populated area is localized between 8,200 and 11,500 feet. In Colombia 11,500 feet is the upper limit of human life, and above 11,500 feet population is sparse; whereas in Peru and Bolivia, most of the inhabitants live above 10,000 feet (4,000,000 Peruvians live between 10,000 and 13,000 feet, and 800,000 live above 13,000 feet).

ıdians
ıd
estizos

Half of the population of Bolivia are Aymara and Quechua Indians; the other half are mestizos (or cholos, mixed); in the Lake Titicaca district live the small and primitive group of the Urus. Population is mainly distributed between the high *páramos,* where, except for a seminomad population of shepherds, the principal occupation is mining, and lower narrow valleys, where the people engage in agriculture.

In Peru, mining is the most important human activity above 11,500 feet, but the great part of the Andean population is dedicated to agriculture and raising sheep, goats, llamas, and alpacas; more and more people are engaged in industry and commerce. In the south, around Lake Titicaca, there is a group of Aymara Indians; but the largest native population is Quechua.

The inhabitants of the Andes of Ecuador are mainly Quechuas and mestizos; in the south there are small groups of Cañaris and, in the north, of Aymara descendants (the Salasacas). Agriculture is the main occupation; some native groups are dedicated to ceramics and weaving.

In Colombia the largest part of the population lives between 5,000 and 10,500 feet. Only 7 percent are native Indians: a nucleus of Chibchas reside on the Altiplano of the Cordillera Oriental; Paeces and Guambianos on the Cordillera Central; Pastos and Quillacingas on the southern mountains. At about 3,000 to 6,500 feet, the zone of coffee plantations is the most densely populated (259 inhabitants per square mile). Agriculture is the main occupation, followed by cattle raising.

Agricultural patterns

The economy. *Agriculture and livestock.* Agricultural operations on the Andes are difficult, and the results are relatively poor. The water supply is inadequate; a large part of the plateau is dry or receives little and irregular seasonal rainfall. Temperatures of the high plains are too cold, and crops are subject to freezing. The terrain is rough, and soils are not well developed; and where fertile valleys do occur, they are narrow and small.

Some agricultural products of the Andes, however, can be grown in sufficient quantity to be exported: the main items are coffee (especially Colombia), cacao, coca, tobacco, cotton, and cinchona (quinine). There are possibilities of increasing the amount of arable land area by irrigation, but not to a great extent. The east side of the eastern cordilleras, facing the Amazon Basin, is in fact being developed, although its steep and rugged nature makes development difficult.

The natural pastures of the plateau are put to good use for cattle raising, and possibilities exist for further development of this activity. Colombia exports cattle, and Peru has a good milk-canning and livestock industry. Sheep, goat, llama, and alpaca raising are widespread in Peru and Bolivia, with both countries exporting sheep and alpaca wool.

Mining. The mining industry of the Andes is one of the most important of the world. Mining is especially extensive in the south. The industry includes mining for copper in Chile and Peru; tin in Bolivia; silver, lead, and zinc in Bolivia and Peru; gold in Peru, Ecuador, and Colombia; platinum and emeralds in Colombia; bismuth in Bolivia; vanadium in Peru; and coal and iron in Chile, Peru, and Colombia. Petroleum is extensively distributed along the whole eastern side of the Andes.

Transportation. The Andes are a formidable barrier for communication, with great effects on the economical and cultural development of the region. Production centres are, in general, far away from seaports, and the mountainous character of the land makes the construction and maintenance of railways and roads difficult and expensive. Most of the railways have been built to transport mining products. Agriculture requires roads because valleys are small and widely separated, making railways too expensive.

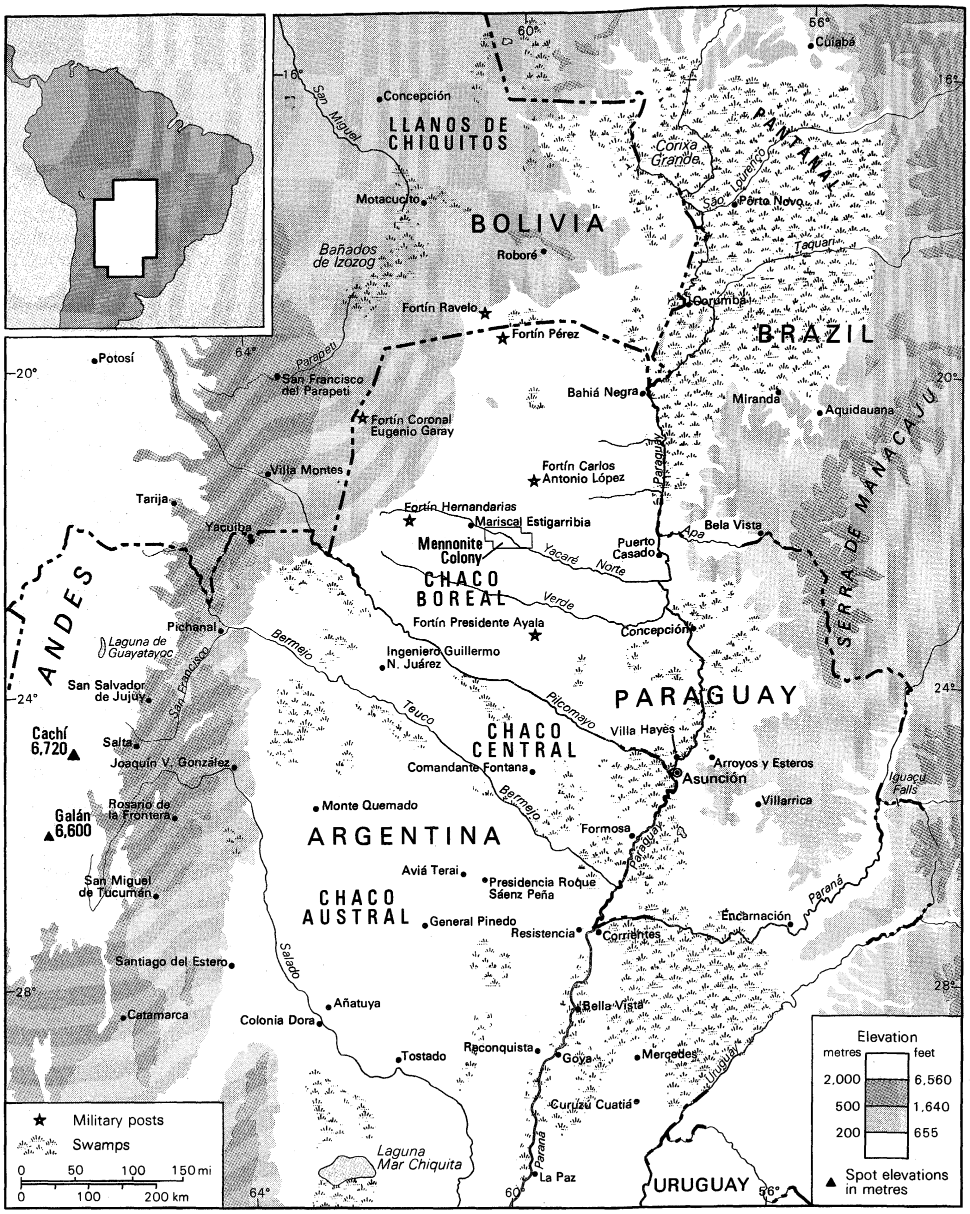
Pack animals

There is still a large use of pack trails between small communities and between farms and markets. Horses, donkeys, and mules are widely used; in Colombia the ox and in Peru and Bolivia the llama are also transport animals.

Railways are few and the internal systems little developed. There are two international railways between Chile and Argentina: the first, Los Andes–Mendoza, through the pass of Juncal, of narrow gauge, was opened in 1910 and connects Valparaíso and Buenos Aires; the second, Antofagasta–Salta (the former in Chile, the latter in Argentina), was opened in 1948.

Bolivia is connected with its neighbours by four railways: La Paz–Buenos Aires, crossing the Puna from Villagra to La Quiaca; La Paz–Oruro–Antofagasta, through Portezuelo de Ascotán; La Paz–Arica, crossing a point 14,000 feet high; and La Paz–Lake Titicaca, which continues on to Arequipa and Matarani (Peru).

In Peru there are two internal but important railways:



The Gran Chaco.

the Puno–Cuzco and the Lima–Cerro de Pasco and Huancavelica, the highest in the world, crossing Ticlio at an altitude of 15,797 feet (4,815 metres).

The main railroad in Ecuador is the Quito–Guayaquil and, in Colombia, the Ferrocarril del Atlántico, from Bogotá to the Caribbean coast, opened in 1961.

The construction of roads on the Andes is very active; thousands of miles are opened every year. The Pan-American Highway is built in the mountains in Colombia and Ecuador; it connects Caracas, Bogotá, and Quito. Various routes in Peru, Bolivia, Argentina, and Chile are included in the system.

Air transport is also important; it is especially developed in Colombia due to the difficulties of overland communication. (M.T.V.)

GRAN CHACO

The Gran Chaco is an immense lowland alluvial plain in interior south central South America. The name is of Quechua origin, meaning "hunting land." Largely uninhabited, the Chaco is an arid subtropical region of low forests and savannas traversed by only two rivers and practically unmarked by roads or rail lines. It is bounded on the west by the Andes mountains and on the east by the Paraguay and Paraná rivers. Its northern and southern boundaries are not as precise: its northern boundary is generally assumed to be the Llanos (high plains) de Chiquitos and Bañados (swamps) de Izozog in Bolivia, and its southern boundary the Río Salado in Argentina. Thus defined, the Gran Chaco covers about 280,000 square miles (730,000 square kilometres), of which slightly more than one-half lies within Argentina, one-third in Paraguay, and the remainder in Bolivia. Two great rivers, the Pilcomayo and the Bermejo, traverse the Chaco from their Andean headwaters to the Paraguay and Paraná rivers in the east. Regional divisions are the Chaco Boreal, north of the Pilcomayo; the Chaco Central, between the Pilcomayo and Bermejo; and the Chaco Austral, south of the Bermejo.

Area and boundaries

Physical features. *Physiography.* The Gran Chaco is the alluvial fill of a vast geosynclinal basin formed by downwarping or submergence of the area between the Andean Cordillera on the west and the Brazilian Shield on the east. Because of its alluvial character, the Gran Chaco is nearly stone free and is composed of extremely deep (up to 10,000 feet [3,048 metres]) unconsolidated sandy and silty sediments. The only rock outcrops of consequence are a few isolated remnants along the Paraguay River (in Paraguay) and some sandstone mesas in northern Paraguay and southern Bolivia.

Drainage. All but the extreme northwestern sector of the Gran Chaco is drained by west-bank tributaries of the Paraguay and Paraná rivers. The Bermejo (Teuco) and the Pilcomayo, even though they manage to traverse the Chaco, are still typical of most Chaco streams. Their courses are marked by countless sloughs, oxbow lakes, braided channels, sandbars, and vast swamplands; and they sustain such high losses from flooding, seepage, and evaporation that only a meagre portion of their full flow ever reaches the parent stream. Most of the Chaco is so poorly drained that the very shallow, irregular channels on the exceptionally level plain lead to rapid and extensive flooding during the rainy summers. At the peak of these floods, as much as 42,000 square miles, or 15 percent, of the area of the Chaco may be inundated, although some of this is as much due to improper drainage of the impermeable subsoils as to overflow of the streams. Potable groundwater supplies are poor. Saline water is common in both deep and shallow wells, and the location and maintenance of freshwater supplies is much a matter of chance. The problem appears to be greatest in the Chaco Boreal, although some hydrologists feel that large-scale studies might reveal a situation more like that of the remainder of the Chaco or like the Argentine Pampa, where groundwater problems are not now considered to be as severe as early settlers and explorers had postulated.

Climate. With a north–south extent of about 700 miles (1,125 kilometres), the Gran Chaco is subject to climates that vary from tropical in the north to warm temperate in the south. Most of the region is, however, subtropical. Average temperatures vary from 65° to 75° F (18° to 24° C), with an average humidity between 60 and 75 percent. Great temperature contrasts, however, exist. Average maximums are near 80° F (27° C), and absolute maximums may exceed 116° F (47° C). The average minimum is about 57° F (14° C), although freezing winter temperatures are known throughout the region.

The highest average annual rainfall is in the east, with 52 inches (1,320 millimetres), which gradually decreases to about 20 inches in the far west. Although the rainfall would normally be adequate for agriculture, from one-third to one-half the total comes in hot summer. Evaporation losses sharply reduce the effective precipitation and give the Chaco an arid nature lost only in the permanent swamps and forests along the Paraguay River.

Although light breezes are common, outbreaks of cool air from the south, called pamperos in Argentina, bring gusty winds of 32–45 miles per hour that occasionally exceed 60 miles per hour. The windiest season, however, is spring, during the transition from warm to hot weather. In the dry season dust storms are not uncommon.

Soils. Chaco soils range from sandy to heavy clay. Soils in the more humid east have more organic material and lateritic subsoils, whereas in the west are soils with less surface organic material and predominately calcareous subsoils. The local determining factor is drainage, whether a function of soil texture or relative relief. Sometimes elevation differences of less than three feet result in different soil types. Grasslands, or savannas, seem to be associated commonly with sandier soils, bushlands with poorly drained clay soils, and the forestland with better drained clay soils. In many cases the high concentration of dissolved salts in the soil water creates physiologically arid conditions in swampy sites, thus extending the arid appearance even into many areas with an abundance of water.

Plant life. The vegetation of the Gran Chaco is intimately associated with the pattern of soils and reflects the same general east–west division. The eastern Chaco is called Parque Chaqueño for its parkish landscape of clustered trees and shrubs interspersed with tall herbaceous savannas. To the west, a wide transition zone grades into the *espinal,* a dry forest of spiny, thorny shrubs and low trees. Chaco vegetation is adapted to grow under arid conditions and is highly varied and exceedingly complex. The climax vegetation is considered to be the *quebrachales,* the vast, low hardwood forests of which various species of quebracho tree are dominant and economically important as sources of tannin and lumber. These forests cover extensive areas away from the rivers; nearer the rivers they occupy the higher, better drained sites, giving rise to a landscape in which the forests appear like islands amid a sea of savanna grasses growing as high as a man on horseback. In the more arid western Chaco, thorn forests, the continuity of which is occasionally broken by palm groves, saline steppes, and savannas induced by fire or deforestation, are dominated by another quebracho tree that has a lower tannin content and is used most often for lumber. There is also a marked increase in the number and density of thorny species, among which the notorious vinal (*Prosopis ruscifolia*) was declared a national plague in Argentina because its thorns, up to a foot in length, created a livestock hazard in the agricultural lands it was invading.

mber

Animal life. True to its native name, the Chaco has an abundance of wildlife. Among the larger animals are the jaguar, ocelot, puma, tapir, giant armadillo, spiny anteater, many foxes, numerous small wildcats, the agouti (a large rodent), the capybara (water hog), the red wolf, palustrian deer, the peccary, and the guanaco. It is one of the last major refuges for the South American member of the ostrich family, the rhea, or nandu, and has long been noted for its abundant and varied bird population. The streams are host to more than 400 fish species, among which are the salmon-like dorado and the aggressive piranha. Countless travellers' tales complain of the pestilent insects. Reptiles are also abundant, with numerous lizards and at least 60 known species of snakes, including many pit vipers and constrictors, while at least six species of poisonous tree toads have been identified.

The people. The indigenous tribes of the Chaco were numerous. Because of their subsistence as hunters, gatherers, and fishermen, tribal units were not much larger than extended families. Nevertheless, from among the diverse dialects, anthropologists have described a few major linguistic associations: the Guaycurú, Lengua, Mataco, Vilela, Zamuco, and Tupí. Most of these people lived under extremely primitive conditions, with settlement dictated by the availability of fresh water, making stream courses the most coveted sites. Implements were fashioned largely from wood and bones because of the absence of stones, while the spiny leaves of the pineapple-like groundcover *carraguatas* served as the universal fibre source. The harsh Chaco forest, quite surprisingly, contains more plant sources of human sustenance in the form of edible pods, fruits, berries, and tubers than surrounding areas, and this factor was well exploited by the native tribes. Game was gathered by trapping, netting, clubbing, and spearing, often in conjunction with large group drives. For those Indian groups still living outside the limits of European settlement, conditions are only slightly modified today, although these people now have domesticated animals and metal tools. Most tribes, however, exist as sort of a peasant pioneer fringe and practice some form of shifting subsistence agriculture.

Aside from the scattered, although successful, *reducciones* (agricultural communes) of the Jesuits, the Chaco defied effective European occupancy until well into the 19th century. Hostile Indian tribes, in concert with the forbidding nature of the Chaco itself, limited European influence in the colonial period to a situation much like a state of siege.

The
Mennonite
colonies

Since World War II, efforts have been made by the respective governments to spur colonization and settlement of the Chaco. Argentine efforts have concentrated along the railways out of Resistencia and Formosa, with pioneer settlements composed mainly of eastern European immigrants and based on cotton production. In the central Paraguayan Chaco, where the Trans-Chaco Road from Villa Hayes to Fortín Coronel Eugenio Garay was completed only in 1965, Mennonite immigrants from Canada had settled in the 1920s and were joined by co-religionists from the Soviet Union in the 1930s. These settlers established self-sufficient colonies and were joined by another large contingent of refugees from the Soviet Union after World War II. These colonies support a population of about 30,000. The primary land use in the Bolivian Chaco is still open cattle range. With nearby supplies of oil and gas in addition to hydroelectric and water storage on the fast-flowing piedmont streams such as the Pilcomayo, future development of the Bolivian Chaco may be more feasible than in some other parts of the Chaco.

The economy. The limited early colonization in the Argentine and Bolivian Chaco was based on exploitation of the longhorn criollo cattle that roamed half wild throughout the region. The western Chaco Austral, near Salta, was also exploited as a source of heavy timbers for the mines in the highlands of Bolivia and Peru. In the late 19th century, the Chaco in Argentina and southern Paraguay became a land of great ranches trading in the criollo cattle; and numerous, small, independent camps of woodcutters (*obrajes*) exploited the abundant hardwoods of the Chaco forests for lumber and firewood. Cattle grazing is still the most extensive land use, with few substantial changes from pioneer days. One of the key problems in improving industry is the apparent endemic nature of many serious cattle diseases and pests against which the criollo cattle have developed some immunity, whereas purebred cattle are fully susceptible.

The tannin processing industry

In the eastern Chaco, vast, highly capitalized industrial ventures established large plants to process the great quantities of tannin found in the various quebracho species. Unlike the *obrajes* of the woodcutters, these operations were large, centralized mills adjacent to rivers or rail lines from which the selective cutting of quebracho has proceeded at a systematic pace. The slow growth habits of the quebracho trees, however, may result in the demise of the tannin industry, as the pace of the harvest has greatly exceeded reforestation. It is uncertain if the relatively untouched Bolivian Chaco holds sufficient quebracho timber to offset diminished production in the exploited sectors or if synthetic products will supplant the present demand for quebracho tannin. Other forest products include lumber and heavy timbers from a variety of other species, firewood, and palo santo oil (holywood oil), from the wood of *Bulnesia sarmientii,* a tree found in the more arid portions of the Chaco.

Although wild cotton had been known in much of the Chaco since pre-Columbian times, it had never been raised as more than an agricultural curiosity until the 20th century. During World War I, with cotton prices at a peak, large areas in Chaco province of Argentina were turned over to cotton culture. Despite bad markets, insect plagues, and often poor weather in many years since that time, the crop area has increased to over 1,000,000 acres. Production methods are antiquated, however, with nearly total reliance on thousands of migrant labourers. The crop is used for both fibre and seed-oil production. Lesser quantities are found in the Paraguayan and Bolivian Chaco.

Discovery of oil in the Bolivian piedmont in the 1920s led within a decade to the disastrous Chaco War between Bolivia and Paraguay, whose leaders held hopes of finding more oil in the neighbouring Chaco Boreal. Paraguayan claims were eventually honoured but did not include any part of the oil-rich piedmont. Subsequent explorations have been disappointing, but hopes still exist for future discovery. (G.E.Ma./M.D.H.M.)

PATAGONIAN DESERT

The Patagonian Desert covers the greater part of the region of Patagonia, that is to say, nearly all of the southern portion of mainland Argentina. With an area of about 260,000 square miles (673,000 square kilometres), it is the largest desert in the Americas, extending from latitudes 37° S to 51° S. It is bounded, approximately, by Andean Patagonia (the southern extension of the Andes mountains) to the west; by the Río Colorado to the north, except where the desert extends beyond the river into the borderlands of Mendoza and La Pampa provinces; by the Atlantic Ocean to the east; and by the Río Coig to the south. The desert thus covers most of the provinces of Neuquén, Río Negro, Chubut, and Santa Cruz; some geographers also include the area north of the island of Tierra del Fuego, which lies at the southern tip of South America and is divided between Argentina and Chile.

Origin of the name

The name Patagonia is derived from the Patagones, as the original inhabitants were called by Spanish explorers in the 16th century. It appears that Ferdinand Magellan, the Portuguese navigator and first European to reconnoitre the coast in that era, coined that name because the natives, with their thick furs, bushy hair, and painted faces, reminded him of Patagon, a dog-headed monster of the Spanish 16th-century romance *Amadís de Gaula.* The phrase *Patagonia, tierra maldita* ("Patagonia, land accursed") is proverbial.

Physical features. *Physiography.* The desert covers the Patagonian tableland that extends from the Andes to the Atlantic Ocean. The general aspect of the tableland is one of vast steppelike (virtually treeless) plains, rising terrace fashion from high coastal cliffs to the foot of the Andes; but the true aspect of the plains is by no means as simple as such a general description would imply. Along the Río Negro, the land rises in a series of fairly level plains from about 300 feet (90 metres) at the coast to about 1,300 feet at the junction of the Limay and Neuquén rivers and 3,000 feet at the base of the Andes. The table land region rises to an altitude of 5,000 feet. South of the Río Negro, the plains are much more irregular; volcanic eruptions have occurred in this area down to fairly recent times. Basaltic sheets, apparently only recently cooled, cover the tableland east of lakes Buenos Aires and Pueyrredón. On the Chico and Santa Cruz rivers, the plains have spread to within about 50 miles (80 kilometres) of the coast and reach almost to the coast south of the Coig and Gallegos rivers. In places, basaltic massifs (mountainous masses) are the salient features of the landscape.

The coast consists largely of high cliffs separated from the sea by a narrow coastal plain. Thus, the plateaus are formed of horizontal strata, some of sedimentary rocks, others of lava flows. Areas of hilly land, composed of resistant crystalline rocks, stand above the plateaus.

Rivers and lakes

Drainage. The deep, wide valleys bordered by high cliffs that cut the tablelands from west to east are all beds of former rivers that flowed from the Andes to the Atlantic, but only a few now carry permanent streams of Andean origin (the Colorado, Negro, Chubut, Senguerr, Chico, and Santa Cruz). The majority either have intermittent streams such as the Shehuen, Coig, and Gallegos, which have their sources east of the Andes, or, like the Deseado, are completely dry, except for salt ponds in the deeper depressions, and so altered by the combined effect of wind and sand as to afford little surface evidence of the rivers that once flowed in them. They serve an important purpose in the collection of the scanty surface water. Alluvial beds of considerable depth but of poor development have been built up in them. The line of contact between the Patagonian tableland and the Patagonian Andes is marked by a chain of lakes found in glacier troughs or cirques, and "closed" in their lower parts by moraines (glacial deposits).

From Lago Nahuel Huapí northward, the lakes—except for Lago Lácar—still drain to the Atlantic. South of Lago Nahuel Huapí, all of the lakes except Viedma and Argentino now drain to the Pacific through deep canyons cut across the Andean cordillera.

Climate. Patagonia is influenced by the South Pacific air current, which brings humid winds from the ocean to the continent. The winds, however, lose their humidity as they blow over the west coast of South America and over the Andes and are thus quite dry when they reach the Patagonian Desert.

The two climatic zones

Climatologically, the Patagonian Desert can be divided into two main zones, the northern and the southern, by a line drawn from the western half of Neuquén province to a point just south of the Península Valdés in northeastern Chubut province.

The northern zone, semiarid, has annual mean temperatures between about 54° and 68° F (12° and 20° C); recorded maximum temperatures vary between about 106° and 113° F (41° and 45° C), and minimum temperatures vary between 12° and 23° F (−5° and −11° C). Sunshine, minimal along the coast, is most plentiful inland to the northwest. The rainfall varies from 3.5 to 17 inches (89 to 432 millimetres) a year. The prevailing winds, from the southwest, are dry, cold, and strong.

The climate of the southern zone of the Patagonian Desert is sharply distinct from the humid one of the Andean cordillera. In the north of this zone, the influence of the Atlantic is practically nonexistent—probably because of the heights of the coastal region (which reach 900 to 1,800 feet around the Golfo San Jorge)—although cold winds coming from the west and the cold Falkland Current both make themselves felt. In the southern part, which is practically peninsular, the Atlantic exerts some influence. The zone has a cold, dry climate, with temperatures that are higher along the coast than they are inland and with strong west winds. Mean annual temperatures range from 43° to 55° F (6° to 13° C), with maximum temperatures at about 108° F (42° C), and minimum temperatures between 16° and −27° F (−9° and −33° C). There are heavy snows in winter and frosts throughout the year; and spring and autumn are so short that summer and winter are the only seasons worth counting. Average annual precipitation (rain and snow) ranges between about 4.5 and eight inches, though as much as 18.5 inches has been recorded. In the central areas of the desert there is less precipitation, and there is more sunshine than on the coast or in the Andean cordillera.

Plant and animal life. Whereas the long, narrow strip of Patagonia's western border has a vegetation like that of the adjacent cordillera, the arid region of the Patagonian Desert comprises two zones, each with its own characteristic vegetation.

The northern zone includes most of Neuquén province, most of Río Negro province, and the northeasternmost part of Chubut. About 84,000,000 acres (34,000,000 hectares) in area, it consists of open bushland, covered with widely spaced thickets between about three and seven feet high. Grasses flourish in the sandy areas, while salt-tolerant grasses and shrubs predominate in the salt flats. In irrigated areas profitable crops can be grown; these include peaches, plums, damsons, almonds, apples, pears, olives, grapes, hops, dates, vegetables, aromatic plants and alfalfa. In the north, the zone merges into one of wooded steppe.

rops
f the
rigated
eas

The second zone, covering the southwesternmost parts of Neuquén and Río Negro provinces, three-quarters of Chubut, and nearly all Santa Cruz province, has an area of 116,000,000 acres. The vegetation is low and very sparse and needs almost no water.

Among the birds of the desert are herons and other waders; predators such as the shielded eagle, the sparrow hawk, and the chimango (beetle-eater); and the almost extinct ñandú, or choique, a flightless bird similar to the African ostrich but not so tall.

The typical marsupial (animal having a pouch for carrying young) of the desert is the comadreja (a member of the weasel family). Species of bats include a long-eared variety. Armadillos, pichis (small armadillos), foxes, ferrets, skunks, mountain cats, and pumas are to be found, as also are maras, or Patagonian hares, and different kinds of burrowing rodents, such as the vizcacha and the tucotuco. Of the larger mammals, the most interesting is the guanaco, a kind of llama, hunted almost to extermination. There are a number of poisonous snakes as well as tortoises and lizards.

Vinchucas (winged bugs), bloodsucker insects (transmitters of American trypanosomiasis, or Chagas' disease), scorpions, and 14 kinds of spiders (including one kind called *Mecysmanchenius,* not found elsewhere) are also to be encountered. The rivers and lakes are naturally poor in fish, but some have been stocked with salmon and trout. Sea fish, however, and crustaceans and mollusks are plentiful off the coast.

he
itagones

The people. The original inhabitants of Patagonia seem to have been Indians from Tierra del Fuego. The most ancient artifacts, such as harpoons, found in the caves along the Strait of Magellan suggest that these people were moving up the mainland coast about 5,100 years ago. Robust and very tall, they constituted the two principal ethnic groups of Patagones—the Puelche-Guennakin in the north, and the Chonik or Tehuelche in the south. The surviving descendants of these Patagones, namely the Yámanes and the Alacalufes, are few in number; a kindred people, the Chono, died out in recent times. The Spanish explorers found the Patagones living as nomadic hunters of guanaco or of ñandú.

Toward the end of the 16th century the Spaniards attempted to colonize the Patagonian coastal region to clear it of English pirates; but a Jesuit settlement on the Golfo San Matías came to nothing. In 1778, however, the English tried to settle on the same bay, and the Spaniards reacted by founding Patagonia's first two towns, San José and Viedma (originally named Nuestra Señora del Carmen). A Spanish settlement at Puerto Deseado lasted from 1780 to 1807; but three years later this region was again devoid of European settlement.

After Argentina became independent, an attempt was made to populate Patagonia to make it part of the national state. Immigration, however, was not massive, though people came for various reasons: some to exploit the economic resources, others (for instance, the Welsh) to enjoy religious or political liberties. By the late 20th century most of the immigrants were Chileans seeking temporary work rather than a fixed domicile. Such transitory immigrants form about 20 percent of the population. Apart from major concentrations at Comodoro Rivadavia and in the towns strung out along the upper valley of the Río Negro, Patagonia's sparse population is mostly rural.

The economy. *Natural resources and their exploitation.* Oilfields around Comodoro Rivadavia, Plaza Huincul, and Catriel are Patagonia's most conspicuous asset, apart from the great deposits of ore at Sierra Grande in Río Negro province, which supply all Argentina with iron. Río Negro province also has deposits of manganese, tungsten (or wolfram), fluorite (calcium fluoride, used as a flux in metallurgy), lead, and heavy spar (barite, the principal ore of barium); Neuquén province has deposits of copper and gold, vanadium (used to toughen steel), and zinc-lead ore; Chubut province has uranium and manganese in moderate quantities. There are also deposits of kaolin and gypsum.

Hydroelectric
development

To exploit the hydroelectric potential of the Neuquén and Limay rivers, a generating station was constructed to produce an estimated 1,650,000 kilowatts—as the centre of the El Chocón–Cerros Colorados complex. The project is also designed to irrigate the Comahue region, thus promoting farming and industry.

Transportation. Argentina's National Route No. 3 runs for more than 1,860 miles from Buenos Aires and Bahía Blanca through the Patagonian coastal region southward to Comodoro Rivadavia. The roads of the desert proper, however, are few and of poor quality. Four railroads run east–west from the coastal region; two, which reach the foothills of the Andean cordillera, are connected with the Bahía Blanca–Buenos Aires line. Air services are based chiefly on the towns of the coastal region.

The chief ports are Rawson, Deseado, Santa Cruz, and Río Gallegos (south of the Río Coig); San Antonio Este, Puerto Madryn, Camarones, and San Julián, all on protected bays; and Comodoro Rivadavia, an outlet for petroleum products. San Antonio Este and Puerto Madryn are being developed for overseas traffic. (E.F.G.D.)

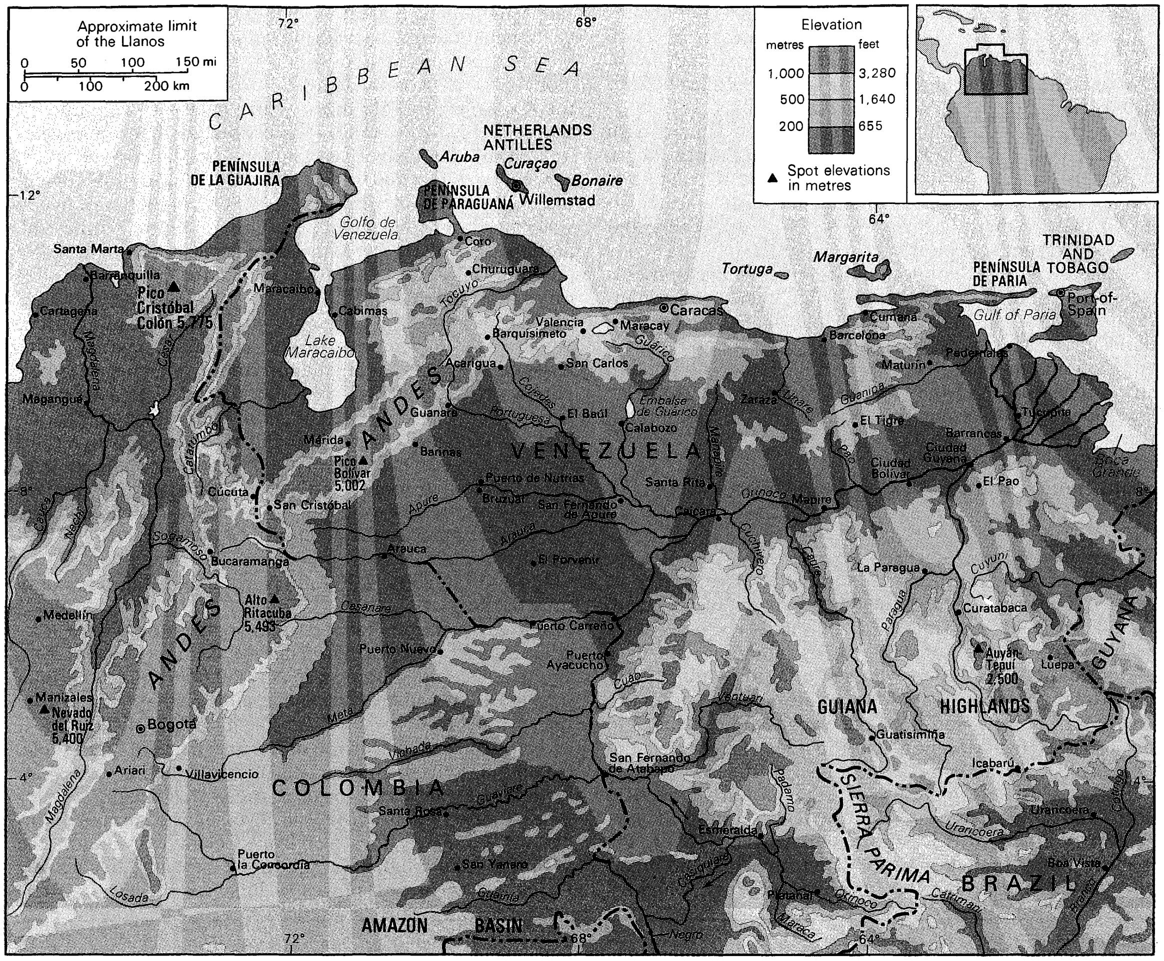
LLANOS

The Llanos (Spanish for "plains") is a grassland, or savanna, that stretches across northern South America, and occupies one-third of Venezuela and about one-fifth of Colombia. The Llanos are delimited by the Andes Mountains in the west and north, the Lower Orinoco River and the Guiana Highlands in the east, and the Río Guaviare and the Amazonian rain forest in the south. The region covers an area of some 220,000 square miles (570,000 square kilometres) and is comparable in size to France or Texas.

The savanna was named by the Spaniards in the 16th century and has been used as a vast cattle range since then. Until the mid-1900s, settlement was limited to widely scattered ranches known as *hatos* ("cow herds"), a few villages, and missionary stations along the lower courses of the region's rivers. Since the 1930s the region has experienced economic growth.

Physical
features

Physical features. *Physiography.* Most of the Llanos lies within 1,000 feet (305 metres) above sea level. The High Plains (Llanos Altos) are most conspicuous near the Andes, where they form extensive platforms between rivers and are some 100 to 200 feet above the valley floors. Away from the mountains they are increasingly fragmented, as in the dissected tableland of the central and eastern Venezuelan Llanos (the Sabana de Mesas)



The Llanos.

and the hill country south of the Río Meta in Colombia (the Serranía).

The Low Plains (Llanos Bajos) are defined by two rivers, the Río Apure in the north and the Río Meta in the south. The lowest portion of the Llanos is an area that lies to the west of the Orinoco Valley. This area is annually converted into an inland lake by the flooding of the region's rivers.

Soils and drainage. The Llanos are drained by the Orinoco River and its left-bank tributaries, including the Guaviare, Meta, Apure, and Cojedes rivers. Seasonal changes between saturation and dehydration have led to advanced laterization of the soil, the process in which the base minerals have been leached away or incorporated into insoluble iron and aluminum silicates. Fine-grained soils form hardpans (cemented layers of soils), and in gravel regions, iron-cemented quartz conglomerates underlie the surface. Excessive acidity and the lack of nutrient bases, organic matter, and nitrogen make virtually all mature soils infertile.

Climate. The wet and dry seasons result from the annual migration of the Intertropical Convergence Zone, a low-pressure trough between the hemispheric easterlies, or trade winds. The zone remains south of the Equator from December to March, bringing the entire Llanos under the influence of the Northeast Trades, which cause the dry and hot summer weather. The zone enters the Llanos from the south in April, reaches its northernmost position along the north coast in July, and moves south again until December. The passage of the zone brings the rainy winter period.

Monthly precipitation is seldom less than 10 inches (254 millimetres) in the Colombian Llanos between April and November. The rains peak about midyear in the Venezuelan north, with monthly totals of around 10 inches. Annual precipitation is highest near the Andes, where Villavicencio receives 180 inches; and there is a pronounced decrease toward the central plains, where Puerto de Nutrias receives 45 inches.

Mean daily temperatures are above 75° F (24° C) throughout the year, and the annual range does not surpass 7° F (4° C). Daily maximum temperatures rise above 95° F (35° C) in the dry period; the dry winds and nocturnal cooling bring relief with normal minimum temperatures between 65° and 75° F (18° and 24° C).

Plant and animal life. Most of the Llanos is treeless savanna. In the low-lying areas, swamp grasses and sedges are to be found, as also is bunchgrass (*Trachypogon*). Long-stemmed grass dominates the dry savanna and is mixed with carpet grass (*Axonopus affinis*), the only natural grass to provide green forage during the dry season.

The most conspicuous trees in the Llanos occur in the gallery forests along the rivers and in the narrower files of trees known as *morichales,* after the dominant moriche palm that follow minor water courses. Broadleaved evergreens originally occupied the high-rainfall zone in the Andean piedmont. There is also a handful of xerophytic trees (*i.e.,* those adapted to arid conditions), including the *chaparro* (scrub oak) and the dwarf palm scattered on the open savanna.

The Llanos have few animals. Most mammals nest in the gallery forests and feed on the grassland. The only true savanna dwellers are a few burrowing rodents and more than 20 species of birds (among them the white and scarlet ibis, the *morichal* oriole, and the burrowing owl). There are several species of deer and rabbit, the anteater and armadillo, the tapir, the jaguar, and the largest living rodent, the capybara. Crocodiles, caimans (a crocodile like amphibian), and snakes, including the boa constrictor, inhabit the rivers, which also teem with little-known varieties of fish. Insects include butterflies, beetles, ants, and mound-building termites.

The people and economy. Cattle raising remains the mainstay of the economy, the base of which was widened

The discovery of oil

by the discovery of petroleum in the 1930s. Oil strikes in the eastern and central Venezuelan Llanos at El Tigre (1937) and Barinas (1948) initiated industrial and urban development. Several of the "boom towns" of that period, such as El Tigre, have grown into sizable cities.

An expansion of intensive agriculture has occurred with the settlement, which began in the 1950s, of pioneer farmers in the Andean piedmont and along the river valleys. Major concentrations of these small farms are located in the Barinas–Guanare–Acarigua district of Venezuela and the Ariari region in Colombia.

Population growth connected with these developments has been impressive. There is a high degree of urbanization; more than half of the people of the Venezuelan Llanos live in cities of more than 10,000 inhabitants. A few thousand Indians (of Carib and Arawak origin) are left on reservations in the Lower Orinoco area.

Population increase has been modest in the Colombian areas. (Di.B.)

Prominent drainage systems and waterways

AMAZON RIVER

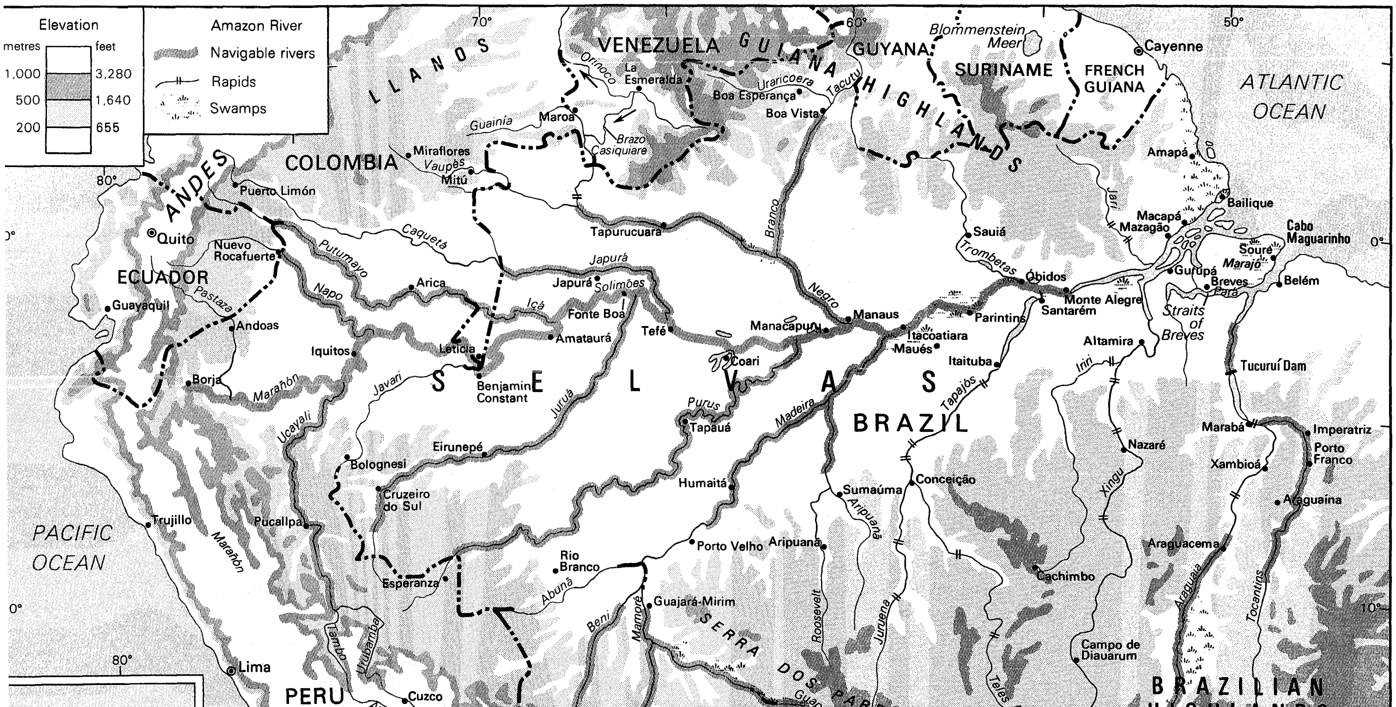
The Amazon (Portuguese and Spanish Amazonas) is the greatest river of South America and the largest river in the world in volume and in area of its drainage basin. Although the name Amazon is popularly employed for the whole of the main stream, in Peruvian and Brazilian nomenclature it is properly applied only to sections of it. In Peru, the upper stream (fed by numerous tributaries flowing down from sources in the high Andes) down to Iquitos, is called Marañón (Portuguese, Maranhão) and from there to the Atlantic, Amazonas. In Brazil the name Solimões is used from Iquitos to the mouth of the Río Negro and Amazonas only from the Río Negro to the sea.

The first European to explore the Amazon River, the Spanish soldier Francisco de Orellana, gave it its name after reporting pitched battles with tribes of female warriors. The length of the great river that he partially explored is about 4,000 miles (6,400 kilometres) slightly less than the Nile but still the equivalent of the distance from New York City to Rome. Its westernmost source is high in the Andes, within 100 miles of the Pacific Ocean; and its mouth is in the Atlantic. It is estimated that about one-fifth of all the water that runs off the Earth's surface is carried by the Amazon. At its mouth, 150 miles wide, there is a mean discharge of 170,000,000,000 gallons of water per hour into the ocean. This is some 10 times the amount carried by the Mississippi River, and it turns the ocean's water from salt to brackish for more than 100 miles from shore.

Physical features. *Physiography.* There are more than 1,000 known tributaries of the Amazon that flow into it from the Guiana Highlands and from the Brazilian Highlands, as well as from the Andes. Seven of these tributaries—the Japurá (Caquetá in Colombia), the Juruá, the Madeira, the Negro, the Purus, the Tocantins, and the Xingu—are more than 1,000 miles long; and one, the Madeira, is more than 2,000 miles from source to mouth. The largest oceangoing steamers can ascend the river 1,000 miles to the great city Manaus. Freighters and small passenger vessels drawing 18–20 feet of water can sail to Iquitos, some 2,300 miles from the Atlantic, at any time of the year.

The Amazon Valley

The vast Amazon Valley (Amazonia) is the largest lowland in Latin America. The drainage basin of the Amazon, about 2,722,000 square miles (7,050,000 square kilometres) in extent and nearly twice as large as that of any other river, stretches over 25 of the Earth's 180° of latitude. It includes the greater part of Brazil and parts of Venezuela, Colombia, Ecuador, Peru, and Bolivia. The Amazon Valley is not an immense swamp; most of Amazon country is terra firma, well above the level of the annual inundations. Going by the river from Belém to Manaus, the tidal forests of the delta are soon left behind; after leaving the Straits of Breves, ranges of hills several hundred feet



The Amazon River Basin and its drainage network.

high begin to appear in the north. At Monte Alegre the hills come down almost to the water's edge; beyond them extends a wide expanse of open *campos,* or grasslands, bounded by ridges along their northern edge. These natural *campos* are characteristic of the Amazonian landscape in many places—the largest of them, the *campos gerais* of the Rio Branco, far to the west, being several thousand square miles in extent.

The Amazon over the millennia has meandered freely over a wide flood plain, on which there appear a series of meander scars, oxbow lakes, and recently abandoned channels. Whenever the deposition of silt or alluvium is great enough to lessen the strength of the main current of the river, it will, during high water, overflow its temporary natural levee and carve out another channel. The new channel will in turn gradually silt up over a period of years or even decades, and the stream will then again shift its course.

The areas that are annually flooded, the *várzeas,* are rejuvenated each year by the deposit of fertile silt left as the waters recede. It is estimated that these valuable soils occupy some 25,000 square miles. (R.E.Cr.)

Geology and hydrography. The Amazon Valley is a great structural depression, a subsidence trough filled with Tertiary sediments, which flares out to its greatest dimension in the upper reaches. It lies between two old and not very high crystalline plateaus, the rugged Guiana Massif on the north and the lower Brazilian Massif, lying somewhat farther from the main river, on the south. The Amazon Valley was occupied by a great freshwater sea during the Pliocene Epoch. Sometime during the Pleistocene an outlet to the Atlantic was established, and the great river and its tributaries became deeply entrenched into the Pliocene surface.

The modern Amazon and its tributaries occupy a great drowned valley. With the rise in sea level that followed the melting of the ice caps, the steep-sided canyons that had been eroded into the Pliocene surface during the lower sea stand were flooded. The old depositional surface is the soil of the terra firma on which much of the Amazon forest has developed. In the upper part of the valley, in the Peruvian and Bolivian Oriente, more recent outwash from the Andes has covered many of the older surfaces.

At the Óbidos narrows, where the river is constricted to a width of a little more than a mile, the average depth of the channel below the mean water level is more than 200 feet (60 metres); in most of the Brazilian part of the river its depth exceeds 150 feet. Depths of more than 300 feet have been recorded at several points ascending the river from Belém. Yet, at the Peruvian border, 2,500 miles (4,000 kilometres) from the Atlantic, the elevation above sea level is less than 300 feet. The maximum free width (without islands) of the river's permanent bed is 8.5 miles, upstream from the mouth of the Xingu. During great floods, however, when it completely fills the floodplain, it spreads out in a band 35 miles wide or more. The average velocity of the Amazon is about 1.5 miles an hour, a speed that increases greatly at flood time.

The great river gradually rises from November to June and then falls until the end of October. The rise of the Negro branch does not occur at the same time, for the steady rains do not commence in its valley until February or March. By June the Negro is full, and then it begins to fall with the Amazon. The flood levels are, in places, from 40 to 50 feet above low river. Taking four roughly equidistant points, the rise at Iquitos is 20 feet, at Tefé 45, near Óbidos 35, and at Belém 12.

The Amazon's course

The Amazon does not meander in the fashion of the Mississippi but for the most part follows a remarkably straight course. It is still in the process of refilling its broad river-cut valley by its own alluvium, depositing silt into settling basins on a massive scale during each flood season. The size of the floodplain is moderate when compared with the volume of the river. The zone of active alluviation is typically 12–30 miles wide and is bordered by steep cliffs (*barrancas*), often capped by a horizon of laterite rock (*canga*). Where these cliffs are being undercut by the river, they produce the *terras caidas,* or "fallen lands," so often referred to by Amazon travellers.

The so-called black-water tributaries of the Amazon—the Xingu, Tapajós, Negro, Tefé, and Trombetas—carry little or no silt, in part because of the bleached sandy character of the country at their headwaters. The Tapajós and Xingu are in reality a bright emerald green, for they lack the strong solution of humic matter that characterizes the Negro. Where such streams enter the main river they are blocked off to form true freshwater lakes and resemble in form, width, and depth marine rias.

The first highland met in ascending the river is on the northern bank, opposite the mouth of the Xingu, and extends for about 150 miles up, as far as Monte Alegre. It is a series of steep, table-topped hills, in part of Devonian and Carboniferous age, interrupted by diabase intrusions. On the southern side, above the Xingu, a line of low bluffs extends in a series of gentle curves with hardly any breaks nearly to Santarém. The line is a considerable distance inland, bordering the floodplain, which is many miles wide. Then the bluffs bend to the southwest and, abutting upon the lower Tapajós, merge into the bluffs that form the terrace margin of that river valley. The next highland on the northern side is Óbidos, a bluff 56 feet above the river, backed by low hills. From Itaquatiara, nearly opposite the Madeira River, to near the mouth of the Negro, the banks are low. Approaching Manaus there are rolling hills; but from the Negro, for 600 miles, only very low land is found, resembling that at the mouth of the river.

On the southern side, from the Tapajós to the Madeira River, the banks are usually low, although two or three hills break the general monotony. From the latter river to the Ucayali, a distance of about 1,500 miles, the forested banks are just out of water and are inundated long before the river attains its maximum flood line. Thence to the Huallaga the elevation of the land is somewhat greater; but not until this river is passed and the Pongo de Manseriche approached does the swelling ground of the Andean foothills raise the country above flood level.

The width of the mouth of the river is usually measured from Cabo Norte to Ponta Tijoca, a distance of 207 statute miles (333 kilometres); but this figure includes the ocean outlet, 40 miles wide, of the Pará River, which should be deducted, because this stream is only the lower reach of the Tocantins. The figure also includes the ocean frontage of Marajó, an island about the size of the kingdom of Denmark, lying in the mouth of the Amazon. Following the coast, a little to the north of Cabo Norte, and for 100 miles along its Guiana margin up the Amazon, is a belt of half-submerged islands and shallow sandbanks. There the tidal phenomenon called the *pororoca,* or bore, occurs, where the soundings are not more than four fathoms (7.3 metres). It commences with a roar, constantly increasing, and advances at the rate of from 10 to 15 miles an hour, with a breaking wall of water from five to 12 feet high. Under such conditions of warfare between the ocean and the river, it is not surprising that the Amazon finds it impossible to build up a delta. Most of the 1,500,000 tons of sediment that the Amazon discharges daily into the sea is carried northward by coastal currents to be deposited along the Guiana coast. (Ed.)

Climate. The climate of Amazonia is warm, rainy, and humid. The length of day and night is equal on the Equator (which runs only slightly north of the Amazon River), and the usually clear nights favour relatively rapid radiation of the heat received from the Sun during the 12-hour day. There is a greater difference between the averages of the noonday and midnight temperatures than between the hottest and coolest months. Hence, night is the winter of the Amazon. To be sure, there are occasional cooler periods, especially during the Southern Hemisphere's winter months when an especially large and powerful air mass from the south polar region pours out over the Amazon Plain and causes a sharp drop in temperature, known locally as a *friagem,* or cold snap. At any time of the year several days of heavy rain will be succeeded by clear sunny days and fresh nights, when the temperature-humidity index is low. In the lower reaches of the river, cooling trade winds blow most of the year.

More important than temperature is the amount of precipitation. Moisture-laden winds blowing from the Atlantic

Ocean across South America are forced to rise when they reach the Andes, where they are cooled and, in cooling, lose their moisture through condensation to feed the great rivers that flow east from the Andes and form part of the Amazon River system. In the lowlands themselves, extensive convectional storms account for much heavy precipitation. There are at least three distinctive climatic types or subregions within Amazonia, based on the rainfall regime: (1) Near the mouth of the Amazon and the western portion of the plain there is an average year-round precipitation of more than 80 inches (2,000 millimetres), fairly well distributed throughout the year. During some years, twice this amount has been recorded, whereas in others there have been prolonged dry seasons. (2) In the rainfall regime that prevails over most of Amazonia there is a season of noticeable slackening of precipitation, although the decrease in rainfall is not severe enough to hinder plant growth. (3) Along the southern edge of the region, the climate of Amazonia grades into that of west central Brazil, with a more distinct dry season during the southern winter.

'hree
limatic
:gions of
.mazonia

The prevailing winds blow between east-northeastward and east-southeastward during the dry season. These winds are moderate in July and August but fresh during the rest of the season, when gusty winds, known locally as *marajós,* sometimes reach great force. This season is the best time for ascending the river. Sailboats descending the river drift with the current.

Normally, the influence of the tide is felt as far as Óbidos, situated about 600 miles above the river mouth. The *pororoca* occurs at times in the Amazon Estuary prior to spring tides; it consists of a wave from five to eight feet high, the crest of which breaks and spreads over the shallow waters of the river and its tributaries.

Soils. The appearance of the vast Amazonian forest vegetation is extremely exotic, leading to the erroneous conclusion that the underlying soil must be very fertile. The luxurious growth, however, stems only from the fragile ecological balance between soil and plants, influenced by light, temperature, and water. Generally, the soil free from flooding is well drained, porous, and of variable structure. Often it is sandy and of low to medium natural fertility because of its lack of phosphate, nitrogen, and potash and relatively high acidity. Small areas are underlain with basaltic and diabasic rocks, which are of high natural fertility. In Brazil these fertile soils are called *terra roxa* (reddish soil) and *terra preta dos Indios* ("black earth of the Indians"). The potentiality of the semiflooded areas is great; their soils do not lack nutrients, but use for agricultural purposes is limited by the periodic inundations.

Plant life. From an airplane, the great treescape of central Amazonia looks like a green carpet with holes or worn spots in the form of oxbow lakes, bright green sloughs, and extensive swamps. There are giants of the forest with white trunks that stand out like clumps of broccoli, flowering trees of many hues, and a great variety of palms. There is in the forests of Amazonia a bewildering diversity of species.

he
›rests of
mazonia

The forest stretches from the swampy mangroves and floating meadows (floating islands composed of intertwined land and water plants) in the east near the Atlantic, to the tree line on the Andes. High in the Andean region, there are large and small meadows (paramos; Spanish *páramos* or *paramillos*) of grass, sometimes with gigantic cacti. The flora in dry areas is distinctly different from that in swampy locations. On lower levels, swamps with arborescent calla-like Araceae (Montrichardia) are common. The Andean forest gradually turns into tropical rain forest, which can be divided into three main types: forest, the ground level of which is not inundated during the rainy season; areas that are regularly inundated; and areas that are occasionally inundated. One can frequently paddle a canoe between the trunks of tree species adapted to such nearly amphibious living. On the Brazilian central plateau, the forest proper is limited by a parklike vegetation of grasses and small to medium trees and bushes, characterized by twisted trunks, thick bark, and leathery leaves. Many of them have big subterranean woody trunks, and roots that reach deep into the groundwater. Where the trees leave sufficient space for a jeep to pass, the vegetation is called *cerrado.* Nearer to the streams, the trees grow taller and denser until they transcend into the forest proper. Pampas (open plain) sometimes suddenly occur.

he three
'pes of
›rest area

The floral province of Amazonia is characterized by the occurrence of rubber-bearing *Hevea* species and *Gnetum* but exhibits many local variations. Four general floral subprovinces may be discerned: (1) the upper Rio Branco, up to the Guianas, with predominantly grasslands and patches of forest; (2) the Jari-Trombetas river area, with varied vegetation of semideciduous, dry forest and *cerrados;* (3) the Río Negro area, which, despite its heavy rainfall, contains much desertlike sclerophilious vegetation (plants with thick leaves, resistant to water loss). This subprovince comprises the Río Negro, the upper part of the Orinoco, the lower and middle Japurá, and the western part of the Trombetas Basin; (4) the rain forest of the Amazon Basin, extending from the base of the Andes to the Atlantic Ocean and up to some parts of the northern boundary of the Amazon Valley.

The variety of trees is enormous; 117 species have been counted in an area of half a square mile. The most frequent varieties are myrtles, laurels, acacias, bignonias, cedrelas, cecropias, rosewoods, Bombacaceae, Brazil nuts, rubber trees, figs, and palms. The only gymnosperms are climbing Gnetums and rare coniferous trees or bushes of the evergreen podocarpus.

Four levels of forest vegetation are distinguishable. The floor level is often covered by a mosaic of small herbs and ferns. The second level is formed by bushes and taller herbs—heliconias, hirtellas, eugenias, calliandras, and others. The third level contains shade-loving trees, such as mauritia, orbygnia, and euterpe. These trees are sometimes covered by orchids, ferns, bromeliads, cacti, and pipers growing on them. It is quite common to find dense groups of palms in the middle of the forest.

The four
growth
levels of
the rain
forest

Higher trees constitute a fourth, or ceiling, level. Generally, these forest giants—such as the silk-cotton, or sumaumeira (*Ceiba*), the para nut, or castanheiro (*Bertholletia*), the sapucaia (*Lecythis*), and the sucupira (*Bowidchia*) with its blue flowers—stand alone and are conspicuous against the skyline.

Beyond the margin of dense forest, the first and second level almost disappear, and one can walk between the trunks of trees and hanging lianas without great difficulty. The diffused lighting prevents the growth of thick underbrush. As the Sun cannot be seen, it is easy to lose one's bearings. Few people have dared to penetrate the forest, and some have been lost on short trips. Even the Indians avoid entering the woods too far from their settlements near the riverbanks. They are afraid of legendary inhabitants of the dense forest and of becoming lost.

Animal life. To give an impression of the complete fauna of the Amazon is as impossible as it is to give one for the flora. More than 8,000 species of insects have been collected and classified. Myriads of mosquitos bother the traveller and may transmit malaria and yellow fever. The leaf-cutting ants (*Atta and Acromyrmex*) in a short time can destroy large parts of a plantation. The extermination, or at least the limitation, of these pests is of great importance to further habitation of the area. The most troublesome insects of all are the ubiquitous, small, black flies, called *piums,* whose bite can itch for days. Fireflies, stinging bees, hornets, wasps, beetles, cockroaches, cicades, centipedes, scorpions, ticks, red bugs, giant spiders, and butterflies are abundant. Sometimes hundreds and thousands of butterflies gather in the afternoon on humid sand near riverbanks or on islets, sipping moisture and often covering several square yards.

The number of fish species is estimated at about 2,000. The Amazon and its tributaries, together with the swamps and oxbow lakes, are in reality a vast sea of freshwater, most of it slowly flowing, in which live millions of fish. One of the best fish, reputed to be the biggest freshwater fish in the world, is the pirarucu, taken with a harpoon, not on rod and reel. It is a welcome source of protein to river dwellers. Thousands of tons of giant catfish, *gamitama, paitsche,* and many others are to be seen in the markets along the river. One of the most dangerous of river fish is

The vast
reserve of
fishes

the small, eight- to 10-inch piranha, ferocious and sharp-toothed, which will often attack any animal that enters the water, or even man; its razor-sharp teeth cut out chunks of flesh, and a school of these fish can do lethal damage in a short time. With the rapid means of transportation afforded by jet airplanes, there also are worldwide markets for tropical fish, such as silver carp, neon tetras, and even piranhas, as well as for aquatic plants.

Electric eels, giant water snakes such as the anaconda, and freshwater stingrays are native to many sectors of the vast river system. The flesh of the stingray is coarse-fibred but very palatable. Crocodiles are hunted for their skins, and turtles and their eggs are considered a delicacy.

Frogs and toads abound. Poisonous snakes are not numerous but are feared. Of the nonpoisonous species, the boa constrictor reaches huge proportions but seldom grows as large as the giant anaconda.

The capybara, largest rodent in the world, looks like a giant guinea pig and may weigh up to 100 pounds; it lives along the Amazon and its tributaries, feeding on the grasses, reeds, and rushes that grow on the banks, and taking refuge in the water when attacked; it is an excellent swimmer and diver; its flesh, though not considered a delicacy, is used for food and is frequently dried for shipment to market; its hide is made into very good leather.

The manatee, often called the sea cow, attains a length of six to eight feet, and a large specimen may weigh up to 2,000 pounds or more. It is hunted for its flesh and its oil, but it is so rare as to be almost extinct. Great efforts are being made at present to capture the animal alive, for shipment to zoos around the world.

The nutria, or tropical otter, is also to be found in less frequented areas and is valuable for its pelt. The tapir, which attains a weight of several hundred pounds, is an expert swimmer and diver and is much sought after for its excellent flesh. The peccary, or wild pig, and many kind of deer are natives of Amazonia.

Water buffalo, brought to the Ilha de Marajó (Island of Marajó) many years ago, have gone wild and now live in the more remote, swampy parts of that ranching area. The Brazilian government has recently introduced domesticated water buffalo and is studying them at an experimental station not too far from Santarém. They seem ideally adapted to such an area and may in time become the basis for a dairying industry, as they are in the brackish inlets and swamps north of Naples, Italy.

One of the most common animals is the small, agile squirrel monkey, in great demand for use in laboratories. There are howler monkeys, woolly monkeys, capuchin monkeys—those that so often accompanied the organ-grinder—and a host of others. The decapitated bodies of monkeys, split and blackened over a charcoal fire, are used extensively for food and are frequently seen for sale in local markets.

In more remote areas is found the sloth, a harmless animal that spends its life hanging from the limbs of trees, the leaves of which are its favourite food. The iguana lizard, often attaining a length of some five feet and looking like a prehistoric monster, climbs trees with the facility of a squirrel and is much sought after because of its delicious flesh.

The people. At the time of the Conquest, the bottom lands of the Amazon and its major tributaries supported relatively dense, sedentary populations who practiced intensive root-crop farming, abetted by fishing and by the hunting of aquatic mammals and reptiles. The *campos,* the higher areas between the rivers and their floodplains, were, and still are in some of the more remote sectors, inhabited by small, widely dispersed nomadic tribes of Indians. These groups rely largely on hunting of animals, large and small, and the gathering of wild fruits, berries, and nuts, and on some small patch agriculture of low yield.

The Amazonian Indians devised means of making the poisonous bitter manioca edible, the end product, *farinha,* being a food staple widely used today over most of tropical America. Amazonian Indians had perfected the use of quinine as a specific against malaria and extracted cocaine from the leaves of the coca tree. They also collected the sap of the Para rubber tree. The Amazonian Indians were skilled rivermen in their dugout canoes and had invented and used the hammock, an ideal bed in which to sleep in the humid tropics. Their ancient arrow poison, curare (*Chondodendron tomentosum*), has been used in the therapy of a host of paralyses and spastic disorders, such as multiple sclerosis, Parkinson's disease, and St. Vitus's Dance.

The early explorers of the Amazon, such as Orellana and Orsua and Aguirre, provisioned themselves from the food supplies of the Indians they met, commandeered their canoes, and took into slavery those that they wanted. The result was a complete breakdown in native life and an appalling decrease in the Indian population. As late as 1906 there were reports of the wholesale capture of wild Indians who were enslaved in order to tap rubber, which was plentiful, with a high price on the world market but which was difficult to get at because rubber trees were sparsely scattered over a huge area, and increasing toil was necessary to locate and work them. Women and children were wantonly butchered, as were any men who became ill or who could not gather their assigned quota. More recently, in the late 20th century, there were further reports of oppressive treatment of Indians by traders and land speculators.

The economy. *Resources.* The resources of the Amazon are many and varied. The first explorers were attracted by gold and diamonds, and industrial diamonds are still mined on the Rio Araguaia. Precious gems are occasionally found there and elsewhere. The most important game animals, used and traded for human nutrition, are: the manatee (or sea cow), which is menaced by extinction; various turtles and their eggs; the tapir; the red deer; the capybara; and, among the Indians, several types of monkeys. Wild forest birds and waterfowl are common game. Fish is also an important food source, especially the huge pirarucu (*Arapaima gigas*). Its flesh is dried in the sun and sold at every marketplace as a durable staple food.

Timber and other forest resources

Excellent timber is furnished by the mahogany (*Swietenia macrophylla*), the Amazonian cedar (*Cedrella odorata*), and many other species. Other trees, such as the cumaru (*Coumoruna odorata*), furnish perfumes and medical ingredients. The louro-inhamuí (*Ocotea barcellensis*) produces a liquid that can be used as a fuel for internal-combustion engines. The big sorva (*Couma macrocarpa*) exudes a drinkable milk sap. The economic kings of trees, however, are the rubber tree (*Hevea brasiliensis*) and the para nut (*Bertholletia excelsa*). The rubber tree has been one of the most important objectives of penetration and exploitation of the forest. It gave rise to a period of great but temporary prosperity, especially to the city of Manaus. Grown in plantations, it continues to make an important contribution to the economy.

Other nutritional sources include the heart of palm (*Euterpe oleracea*), the vanilla orchid, and the guarana (*Paullinia cupana*). Guarana, black pepper, and vanilla have become important agricultural crops. Guarana seeds are used to prepare a stimulating Brazilian soft drink, which may find world markets. Rice is cultivated in some areas. Agriculture and animal husbandry must be conducted carefully and scientifically, however, to preserve the very delicate ecologic balance that sustains the fertility of the soil.

Geological exploration is producing new knowledge of mineral resources. Oil has been found, and tin mining has been carried on for some time. Other valuable minerals are also extracted. (A.R.S.)

Trade and industry. The vast network of rivers is today organized under the control of a hierarchy of traders. Since travel away from the rivers is still extremely difficult, the people scattered in small communities along the riverbanks are dependent for their connections with the outside world on the launch of the trader to whom they are in debt. The largest trading companies are at Belém and Manaus; many smaller traders are controlled by the big companies, each of which occupies a strategic point at a river junction and controls all upstream communications. From many small villages comes a considerable movement of goods downstream, including such products as Brazil nuts, rotenone, cabinet woods, skins, and some

Dominance of trading companie

quantity of rubber. In return, the traders supply foodstuffs, tools, and firearms.

The relative emptiness of the Amazon has intrigued people for many years, and the increasing effectiveness of malaria control, improved diets, and sanitation measures, and the increased ease in transportation are all making the Amazonian region more attractive for human settlement.

The construction of new highways and the immediate development of agriculture along them, the construction of factories, paper mills, and an oil refinery, and the recent development of the tourist industry, all have injected a new dynamism essential to the economic development of the Amazon and its vast hinterland.

he
nportance
' new
ghways

Transportation. The opening of highways between Brasília and Belêm and between Brasília and Pôrto Velho has meant that manufactured goods from southern Brazil arrive with fewer delays and in many cases at freight rates much lower than formerly, when shippers had no competition. New settlements and agricultural developments have appeared along these roads and are themselves generating new passenger and commodity traffic. The road between Manaus and Pôrto Velho is having a profound impact on Amazonia and Manaus. Along the relatively short road (170 miles) from Manaus to Itacoatiara, Japanese colonists have organized agricultural cooperatives and have introduced modern agriculture techniques to produce vegetables, chickens, and eggs for the local markets, and black pepper for export to southern Brazil and the world market. The federal government is allocating millions of cruzeiros to provide lines of communication and supply, mainly by river, for the construction of the Trans-Amazonian and Cuiabá–Santarêm highways. Furthermore, plans are being made and moneys allocated to resettle thousands of families from drought-stricken northeastern Brazil to farms along these new highways.

The highway engineers seek to build the north–south roads as much as possible on the higher, better drained land between the rivers tributary to the Amazon. The Manaus–Pôrto Velho highway follows in general the interfluve area, frequently grass-covered *campos,* between the Purus and Madeira rivers. The Cuiabá–Santarêm highway will follow for the most part the higher interfluve area between the mighty Tapajós and Xingu rivers. The east–west road, however, cuts across the valleys of the north-flowing rivers. The first stretch of the TransAmazonian Highway, from Pôrto Franco in Maranhão to Itaituba in Pará, some 850 miles, was completed in early 1972. The second stretch of some 600 miles, from Itaituba to Humaitá in Amazonas, on the Rio Madeira, was finished almost a year later.

Study and exploration. In early days the river was the only means of access into the forest. Francisco de Orellana was the first to travel on the mainstream from the Peruvian Andes to the Atlantic (1541). Nearly a century later, Pedro Texeira went from Belêm to Quito, Ecuador and the region became more and more known through the explorations of the Portuguese. About 1751 Charles de La Condamine made the first astronomic-geographic survey and brought the deadly Indian arrow poison curare to Europe. At the beginning of the 19th century, the German explorer Alexander von Humboldt, accompanied by the French botanist Aimé Bonpland, mapped the connection between the Amazon and the Orinoco system through the Brazo Casiquiare (Casiquiare River), whose existence was insufficiently known before. The English naturalist Henry Walter Bates spent the years from 1848 to 1859 along the Amazon, collecting thousands of species of animals and writing up his notes of animals, human beings, and natural phenomena in a charmingly objective manner. His book, *The Naturalist on the River Amazons,* originally published in two volumes in 1863, was an immediate success and is one of the great classics on the Amazon River. An official U.S. expedition was sent to Amazonia in the middle of the 19th century; in 1854 in Washington William Lewis Herndon published as a public document the report that he and Lardner Gibbon, lieutenants in the U.S. Navy, had made to Congress under the title of *Exploration of the Valley of the Amazon.* They reported in fascinating detail the possibilities for power navigation in various parts of the river system, the resources available, health problems, social conditions, and possibilities for further settlement and development.

The 20th century has been a period of exploratory and scientific expeditions. In 1913–14, former U.S. president Theodore Roosevelt and Brazilian Col. Cândido Rondon headed an expedition that explored the Rio Roosevelt (originally Río Teodoro), a tributary of the Madeira, and made natural-history collections and observations. An expedition sponsored by Harvard's Institute of Geographical Exploration did important scientific work between the years 1910–24. The American Geographical Society and the American Museum of Natural History have undertaken geographic explorations and sent collecting expeditions into Amazonia over the years. The American Geographical Society compiled data for and published 1-to-1,000,000 scale maps of this vast area. These are only some of the highlights of exploration during the first three decades of the 20th century. Hardly a year passes that enthusiastic scientists and adventure-seeking hunters do not write books on this area.

During World War II the United States government sent dozens of American scientists and technicians into Amazonia to make regional surveys and to study the actual physical and human resources as well as to draw up plans for future development. Since the war, expeditions have been sponsored both by the American Geographical Society and by various United Nations organizations. Brazilian scientists have increasingly concerned themselves with the Amazon region. This is especially true of scientists associated with the Instituto Agronômico do Norte and the Museu Paraense Emílio Goeldi (Goeldi Natural History and Ethnographical Museum), both located in Belêm, the Conselho Nacional de Geografia, and the Instituto Nacional de Pesquisas da Amazônia, established in 1952, in Manaus. (R.E.Cr./A.R.S./Ed.)

ORINOCO RIVER

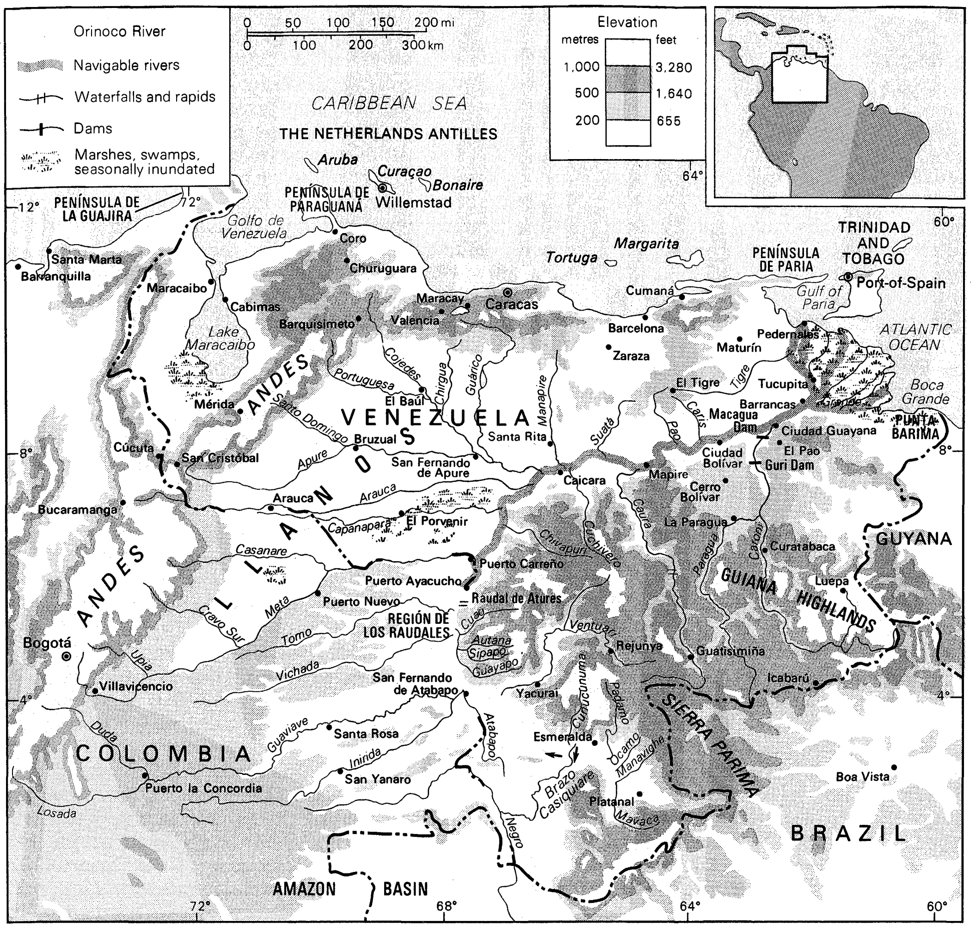
The Orinoco River (Río Orinoco) and its tributaries constitute the northernmost of South America's three major river systems. Bordered by the Andes mountains to the west and the north, the Guiana Highlands to the east, and the Amazon watershed to the south, the river basin covers an area of about 366,000 square miles (948,000 square kilometres). It encompasses approximately four-fifths of Venezuela and one-fourth of Colombia. The Orinoco River itself flows in a giant arc for 1,337 miles (2,151 kilometres) from its source in the Guiana Highlands to its mouth on the Atlantic Ocean. Throughout most of its course it flows through Venezuela, except for a section where it forms part of the frontier between Venezuela and Colombia. The name "Orinoco" is derived from Guarauno words meaning "a place to paddle"—*i.e.,* a navigable place.

For most of its length, the Orinoco flows through impenetrable rain forest or undeveloped grasslands; however, the cities of Ciudad Bolívar and Ciudad Guayana (also known as Santo Tomé de Guayana or Guayana City) are located on its lower course, and this region is fast developing into one of the most industrialized areas of South America. The river forms a waterway used in the exploitation of the vast mineral wealth of the Venezuelan interior.

Physical features. *Physiography.* The western slopes of the Sierra Parima (Parima Mountains), which form part of the boundary between Venezuela and Brazil, are drained by spring-fed streams that give rise to the Orinoco River. The source is placed in Venezuela at 63°21′ W and 2°19′ N, at an elevation of 3,523 feet (1,074 metres). From its headwaters the river flows west-northwest, leaving the mountains to meander through level plains known as the Llanos. The volume of its waters increases as the river receives numerous mountain tributaries, including the Río Mavaca on the left bank and the Manaviche, Ocamo, Padamo, and Cunucunuma rivers on the right.

The Brazo Casiquiare

Below the town of Esmeralda some of the waters of the Orinoco flow south into the Brazo Casiquiare (Casiquiare River, or Channel). This channel, a feature peculiar to the Orinoco River system, is a natural passage that flows for more than 220 miles to the Río Negro linking the Orinoco and Amazon river systems.



The Orinoco River Basin and its drainage network.

After its bifurcation in the Casiquiare, the river bends to the northwest and flows in great meandering curves to its confluence with the Río Ventuari. There the river turns to the west to run between high alluvial banks; its course is marked by numerous extensive sandbars. Near San Fernando de Atabapo, the Atabapo and Guaviare rivers join the Orinoco, marking the end of the Upper Orinoco.

Downstream from San Fernando de Atabapo, the river flows northward and forms part of the border between Venezuela and Colombia. It passes through a transitional zone, the Región de los Raudales (Region of the Rapids), where the Orinoco forces its way through a series of narrow passes among enormous granite boulders. The waters fall in a succession of rapids, ending with the Raudal de Atures (Atures Rapids). In this region, the main tributaries are the Vichada and Tomo rivers from the Colombian plains, and the Guayapo, Sipapo, Autana, and Cuao rivers from the Guiana Highlands.

The Raudal de Atures marks the beginning of the Lower Orinoco Basin, in which the river makes its great bend to the east. In this section, the river flows slowly through the lowest level of the plains and increases to about five miles in width. Along the bend, it receives the largest number of affluents of its entire course, including the Meta, Arauca, and Capanaparo rivers. The Río Apure contributes waters from numerous Andean streams, which form a swampy maze in their lower courses.

From its junction with the Río Apure, the Orinoco meanders eastward over gently sloping plains. Shoals and alluvial islands are abundant; some of the islands are large enough to divide the channel into narrow passages. Tributaries include the Guárico, Manapire, Suatá, Pao, and Caris rivers, which enter on the left bank, and the Río Cuchivero and the Río Caura, which join the main stream on the right. So much sediment is carried by these rivers that they often form islands at their mouths. The Río Caroní, one of the Orinoco's largest tributaries, joins the river on its right bank after passing through the 310-square-mile Guri Reservoir of Guri (Raúl Leoni) Dam, above Ciudad Guayana. Many lagoons, including the Mamo, Amana, and Colorada, are located on the banks of the Orinoco west of its confluence with the Río Caroní and east of Ciudad Bolívar. At the town of Barrancas, the river begins to form its great delta.

The delta region

The delta extends for about 275 miles along the Atlantic coast, from Pedernales on the Gulf of Paria in the north to Punta Barima in the south on the Boca Grande (literally the "Great Mouth"). Scores of islands are connected by innumerable *caños,* or canals, which constitute an intricate network. The main channel of the Orinoco, known in the delta as the Río Grande, flows eastward from Barrancas to discharge into the Boca Grande.

Climate. The climate is tropical, with the seasons marked by differences in rainfall rather than in temperature. The year is divided into two seasons, the rainy and the dry (locally known as winter and summer), the former extending from April to October or November, the latter most marked from November through March or April. Temperature differences, on the other hand, are slight throughout the year; and no month averages more than 69° F (21° C) or less than 64° F (18° C). Whatever the average temperature, there is little difference from month to month. The only marked variation is from day to night, being greater than that from month to month.

Rainfall varies considerably from district to district. The northeast trade winds blow across the coastal districts without losing much precipitation, in some places leaving less than 20 inches (508 millimetres) per year. Areas lying behind topographic barriers also get little rain, while windward slopes are generally well watered. In some areas enough rain falls to support a lush jungle growth and, in others, enough for a true selva (rain forest). The Llanos suffer severely from drought from about January to April, and then suffer equally from flooding of the whole countryside from June to October.

Hydrography. The river basin, as a geomorphological feature, dates from the Quaternary Period (from 2,500,000 years ago to the present). The enormous quantities of material produced by highlands are carried down by torrential rains to the rivers. The rivers, unable to hold the excessive material, overflow or break their banks, producing periodic floods that submerge the lowlands. Under these conditions, drainage presents an unstable and indefinite pattern, marked by the shifting of rivers, lagoons, and swamps over the lower lands. The Orinoco Delta is rapidly extending into the ocean, but the tremendous amounts of sediment that accumulate are accelerating the subsidence occurring in the entire delta region.

he
ainage
attern

Wide fluctuations in the river's flow reflect the seasonal rainfall regime. During the dry season or "low-water" period from October to March, the average river depth is about 49 feet in the lower basin near Ciudad Bolívar. The rise of the Orinoco begins with manifest regularity in April at the beginning of the rainy season. The "high water" period from April to October reaches its maximum in July. The depth of the river at this period is about 165 feet at Ciudad Bolívar. From June to August the lowlands of the basin are flooded and in some places are 65 feet under water. At the end of August the waters gradually recede and reach their lowest point in October.

Plant and animal life. The Llanos are grass-covered plains with isolated stands of palms and chaparro (scrub oak). The tributary streams that cross the plains have deposited alluvial soils, and strips of forests line their banks. Some of this natural tree cover, however, has been reduced by deforestation. The Guiana Highlands are covered with high, dense forest that is interrupted by small patches of savanna. The tropical rain forest of the Upper Orinoco Valley contains hundreds of species of trees. Rain forest also covers the delta region.

More than a thousand species of birds frequent the Orinoco region; among the more spectacular are the scarlet ibis, the bell bird, the umbrella bird, and numerous parrots. The numerous fish include the voracious caribe (piranha) and the *laulao,* a catfish that often weighs more than 200 pounds. The Orinoco crocodile is the longest of its kind in the world, reaching a length of more than 20 feet. The array, or side-necked turtle, which grows to a shell-length of about 30 inches, nests on the sandy islands of the river.

ıdigenous
ɔoples of
ıe basin

The people. Except for the Guajiros of Lake Maracaibo, all of the Venezuelan aboriginal population lives within the Orinoco Basin. The most important indigenous groups include the Guaicas (Waicas), also known as the Guaharibos, and the Maquiritares (Makiritares) of the southern uplands, the Warao of the delta region, and the Guahibos and the Yaruros of the western Llanos. These peoples live in intimate relationship with the rivers of the basin, using them as a source of food as well as for purposes of communication.

The important towns, with the exception of Ciudad Bolívar, are built on high ground to avoid recurrent flooding. Town plans reflect Spanish influence: streets are arranged in a chequered pattern with a central plaza. Most of the original colonial buildings have vanished, although some old homes still remain. In the small villages, thatched huts are the usual dwellings.

The economy. *Navigation and river crossings.* The Orinoco and its tributaries have long served as vast waterways for the indigenous inhabitants of the Venezuelan interior. Especially during the floods of the rainy season, with outboard motors are the only means of communication throughout large areas of the river basin. Large river steamers travel upriver for about 700 miles from the delta to the Raudal de Atures. Dredging has allowed large oceangoing vessels to navigate the Orinoco from its mouth to its confluence with the Río Caroní—a distance of 226 miles—in order to tap the iron-ore deposits of the Guiana Highlands. The Llanos and the Guiana region were connected in 1967 with the completion of the 5,507-foot bridge across the Orinoco at Ciudad Bolívar. In 1961, the Venezuelan government bridged the mouth of the Río Caroní to connect the new industrial town of Puerto Ordaz with the old Orinoco port of San Félix, thereby creating the urban unit of Ciudad Guayana.

Resources. The Guiana Highlands are rich in mineral deposits. Iron ore, which is more than 60 percent pure, is mined at Cerro Bolívar and El Pao.

Other minerals include deposits of manganese, nickel, vanadium (a metallic element used to form alloys), and chrome. There are also deposits of gold and diamonds. Petroleum and natural gas are exploited in the northern and northwestern parts of the basin.

The site of the Saltos del Caroní (Caroní Falls) had one of the largest hydroelectric potentials in South America, amounting to 10,000,000 kilowatts. A vast project to tap this power source includes the Macagua and Guri dams, development of which began in 1959 and 1968, respectively. The falls consequently were submerged.

The Llanos, along the great bend of the Orinoco, have long formed one of Venezuela's major cattle-raising areas. Seasonal subsistence farming is carried out along the river from the confluence with the Apure to Ciudad Bolívar. West of the Apure junction, cotton is grown on a commercial scale. Land reclamation and flood control projects in the delta region are planned in order to open vast agricultural lands.

The
Ciudad
Guayana
complex

Industrial development of the river basin is concentrated at Ciudad Guayana. The semiautonomous government body Corporación Venezolana de Guayana (Venezuelan Guiana Corporation) is conducting a careful development plan based on the resources of the nearby Guiana Highlands and the Río Caroní. The dams at Saltos del Caroní supply power for industry, including a steel mill, an aluminum plant, and a paper factory. Power is also supplied by natural gas, which is piped from the oil fields north of the Orinoco River.

Study and exploration. European exploration of the Orinoco River Basin began in the 16th century. A series of expeditions sponsored by the banking house of Welser of Augsburg penetrated the Llanos southward across the Apure and Meta rivers. From the east, several Spanish expeditions ascended the river from its mouth without much success. In 1531 the Spanish explorer Diego de Ordaz voyaged up the river, and that same year another Spanish explorer, Antonio de Berrio, descended the Casanare and Meta rivers and then descended the Orinoco to its mouth.

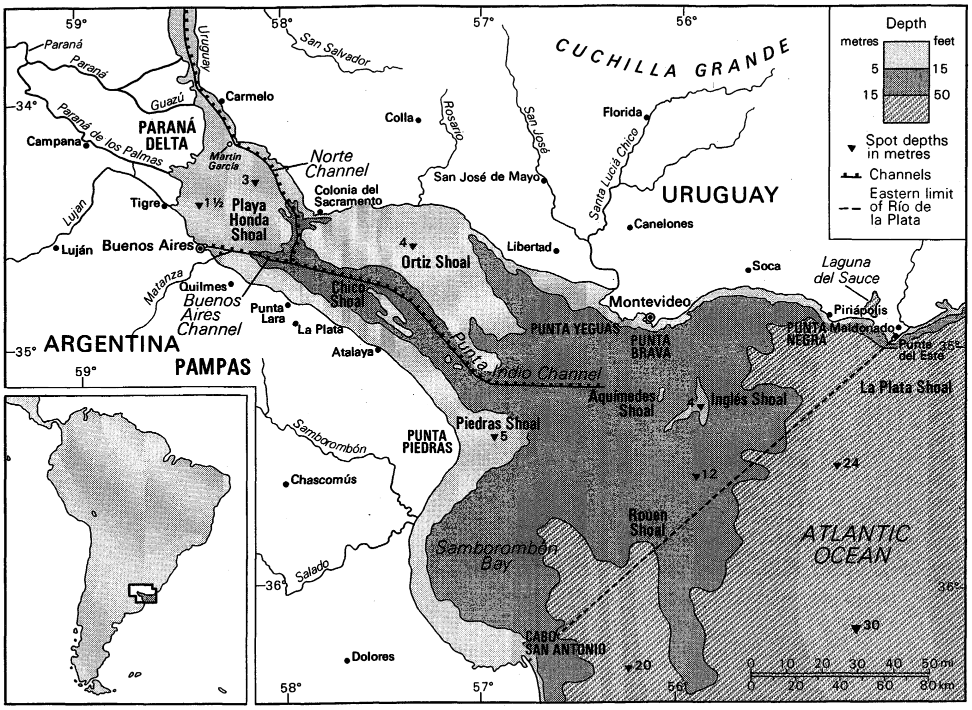
In 1744 Jesuit missionaries discovered the Brazo Casiquiare. Alexander von Humboldt, the German naturalist, travelled over 1,700 miles of the river basin in 1800. By 1860 steamships were navigating the Orinoco. The source of the river remained in dispute, however, until a Venezuelan expedition finally identified it in 1951.

(Me.F.G.)

RÍO DE LA PLATA SYSTEM

The Río de la Plata (literally River of Silver; in English often called the River Plate) is a tapering intrusion of the Atlantic Ocean occurring on the east coast of South America between Uruguay to the north and Argentina to the south. While some geographers regard it as a gulf, others even as a sea, and still others as a river, the majority regard it as the estuary of the Paraná and Uruguay rivers (as well as of the Paraguay River, which drains into the Paraná). As such, the Río de la Plata receives waters draining from the basin of these rivers, which covers northern Argentina, the greater part of Uruguay, Paraguay, eastern Bolivia, and much of southern Brazil and represents an area of 1,600,000 square miles (4,144,000 square kilometres). Montevideo, the capital of Uruguay, is located on the northern shore, and Buenos Aires, the capital of Argentina, is on the southwestern shore.

The head of the Río de la Plata is where the delta of the Paraná and the mouth of the Uruguay meet; the eastern, or Atlantic, extremity lies about 180 miles (290 kilometres) seaward and would be represented by a line on a map drawn from Cabo San Antonio, Argentina, to Punta del Este, Uruguay. The breadth of the estuary increases from the head seaward: it is 31 miles from Punta Lara on the southern (Argentine) shore to the port of Colonia del Sacramento on the northern (Uruguayan) shore, and 136 miles from shore to shore at the Atlantic extremity of the estuary. To those who regard the Río de la Plata as a river, it is the widest in the world,



Río de la Plata.

with a total area of 13,500 square miles (35,000 square kilometres).

Physical features. *Physiography.* The two contributory rivers bring down about 2,000,000,000 cubic feet of silt every year. The muddiness of the water in the Río de la Plata itself is increased by the tides and winds that prevent the settling of the deposit on the bed. The deposit thus forms great shoals, banks, or bars of clay, sand, and organic matter: the Playa Honda Shoal is just off the Paraná Delta; the Ortiz and Chico shoals are further downstream; and the Rouen, the Inglês, the Alemán, and the Arquímedes shoals are still farther out. The depth of the water—varying from six feet (two metres) above the shoals to 65 feet in the intervening channels—is reduced along the south coast by an offshore shoal.

Silt and shoals

The Argentine coast of the estuary is low-lying; its banks are of marine debris and coarse sand, and the coast is subject to flooding in places. The Uruguayan coast stands quite high and consists largely of rocks and dunes. Off the Uruguayan coast there are several small islands, such as Hornos, San Gabriel, López, Lobos, Farallón, and—opposite the mouths of the Uruguay and Paraná Guazú rivers—Martín García.

The volume of water discharged by the Río de la Plata into the Atlantic is estimated at 776,925 cubic feet per second. Although the water of the tributary rivers is so widely distributed over the length and breadth of the estuary that variations in their volume do not affect the level of the water, the level is considerably affected by variations of the tides and, especially, of the winds reaching it. The ocean tides, weak though they may be, flow 120 miles up the Paraná and the Uruguay rivers from their mouths on the estuary. The average tidal range is six inches at Montevideo and two and a half feet at Buenos Aires. The pampero (the southwest wind) and the southeast wind both exert a great influence on the Río de la Plata: the pampero, when it is most powerful, drives the water on to the Uruguayan coast, so that the water level drops on the Argentine side; the southeast wind has the contrary effect, flooding parts of the Argentine shore, and causing the level to drop on the Uruguayan coast.

The Paraná River (Spanish Río Paraná; Portuguese Rio Paraná), together with its tributaries, forms the larger of the two river systems that drain into the Río de la Plata Estuary on the east coast of South America. The Paraná is 2,485 miles (3,998 kilometres) long and extends from the confluence of the Grande and Paranaíba rivers in southern Brazil, running generally southwestward for most of its course, before turning southeastward to drain into the Río de la Plata. Paraná means "father of the waters" in the Guarani language.

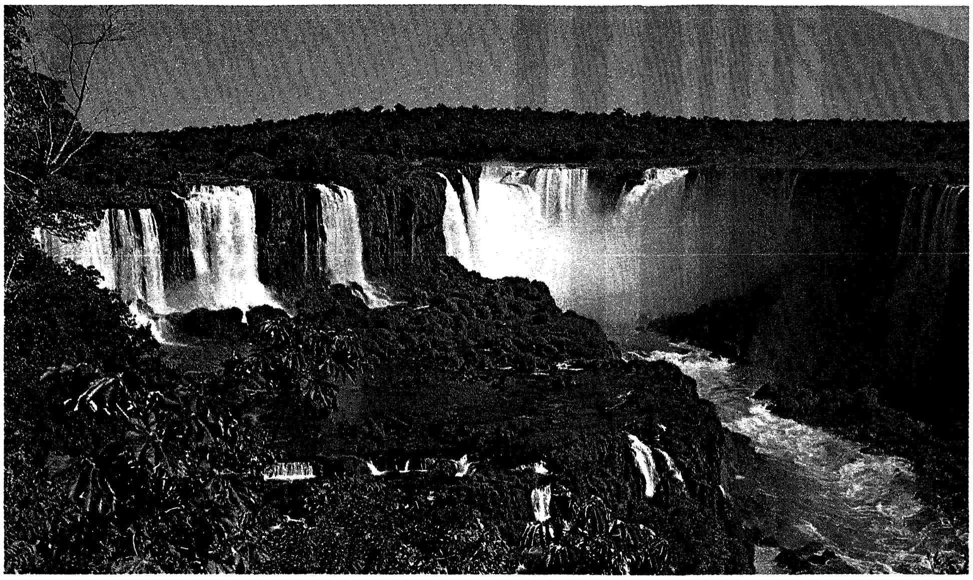
The Grande rises in the Serra da Mantiqueira, part of the mountainous hinterland of Rio de Janeiro, and flows westward for approximately 800 miles; but its numerous waterfalls (such as the Cachoeira do Marimbondo [Marimbondo Falls], with a height of 72 feet [22 metres]) makes it of little use for navigation. The Paranaíba, which also has numerous waterfalls, is formed by many affluents, the northernmost headstream being the São Bartolomeu, which rises in the Serra dos Pirineus near Brasília.

From its origin in the Grande–Paranaíba confluence to its junction, 1,740 miles downstream, with the Paraguay, the river is known as the Alto (Upper) Paraná. This upper course of the river receives many tributaries, some from the right, some from the left. The three most important of these tributaries, namely the Tietê, the Paranapanema, and the Iguaçu, all belong to the left bank, having their sources near the Atlantic coast of Brazil (the first two in São Paulo state, the last-named in Paraná state).

The Alto Paraná and its tributaries

The Alto Paraná flows at first in a southwesterly direction down a deep cleavage in the ancient Brazilian massif, the configuration of which determines its course. Just before it begins to run along the frontier between Brazil to the east and Paraguay to the west, the river has to cut through the Serra de Maracaju (or Cordillera de Mbaracayú), which has the effect of a dam; as the river approaches this natural barrier, it expands its bed into a lake two and a half miles wide and four and a half miles long. Pôrto Guaíra in Brazil stands on the southern shore of this lake. The river's passage through the mountains was, until 1982, marked by the Salto das Sete Quedas (Guaíra Falls), which had eight times the water volume of the Niagara River of North America. The completion of the Itaipu hydroelectric project's first stage in that year submerged the falls in the waters of the reservoir.

From the Iguaçu confluence to its junction with the Paraguay River, the Alto Paraná continues as the frontier between Paraguay and Argentina. So long as it is flanked on the left (Argentinian) bank by the steep edge of the Sierra de Misiones, the river proceeds in a generally southwesterly direction, but twists repeatedly to and fro over a rocky bed studded with outcrops of melaphyre (a dark-coloured rock of porphyritic texture). At Posadas in Argentina, however, where it is about one and a half miles



Iguaçu Falls, where the Río Iguaçu drops about 270 feet over a series of approximately 275 separate waterfalls.

Manley—Shostal/EB Inc.

wide, it turns abruptly westward and begins a more amply meandering course, embracing islands of quite considerable size and punctuated so frequently by rapids and by outcrops of basalt that navigation is difficult. At the Apipé Rapids the river is only about four to six feet deep.

The Río Iguaçu ("Great Water" in the Guaraní language) joins the Alto Paraná at the point where Brazil, Paraguay, and Argentina converge, 82 miles downstream from Pôrto Mendes. Rising in the Serra do Mar near the Brazilian city of Curitiba (for which reason it is sometimes called the Rio Grande de Curitiba), the Iguaçu has a course of 820 miles from east to west, during which some 70 waterfalls reduce its bed's altitude above sea level by a total of about 2,650 feet. While the Ñacunday Falls are 131 feet high, the spectacular Iguaçu Falls, on the frontier between Brazil and Argentina, 14 miles upstream from the Iguaçu–Alto Paraná confluence, have a height of about 270 feet. One of the currents into which the river is divided descends from this height at a single drop, but most of the others make two successive drops of 98 feet each. The cataracts have a mean water volume of 59,400 cubic feet per second. The crescent-shaped edge over which the water pours is more than one and a half miles wide; thereafter, the river passes for several miles through the Garganta del Diablo, or Devil's Gorge—a canyon only 164 feet wide between heights varying from 65 to 328 feet. At its junction with the Alto Paraná, however, the Iguaçu is 820 feet wide and 40 feet deep.

At Paso de Patria, on the right (Paraguayan) bank, at a place appropriately named Confluencia, the Paraná receives its greatest tributary, the Paraguay River, that joins it on the right bank.

ıe
iver of
ckades"

The fifth largest river in South America, the Paraguay River (Spanish Río Paraguay; Portuguese Rio Paraguai) is 1,584 miles (2,550 kilometres) long. The name Paraguay is taken from the Guaraní language and could be translated "river of *paraguas* (coloured, plumed birds)" or "river of cockades," an allusion to the plumed headdresses once worn by the riverine peoples.

The Paraguay rises in Brazil, in the central plateaus of Mato Grosso, at an altitude of 980 feet (300 metres) above sea level. Where it becomes navigable, about 150 miles downstream, near Cáceres in Brazil, after its confluence with the Sepotuba, it is 275 feet wide and 20 feet deep. Another 20 miles downstream, where the Jauru joins it at an altitude of 400 feet above sea level, the Paraguay enters the alluvial Mato Grosso *pantanal* (floodplain); it crosses the plain's western edge over a sandy bed, flowing around the many islands in its course. During its passage through the *pantanal,* it receives such important tributaries as the Cuiabá, the Taquari, and the Miranda.

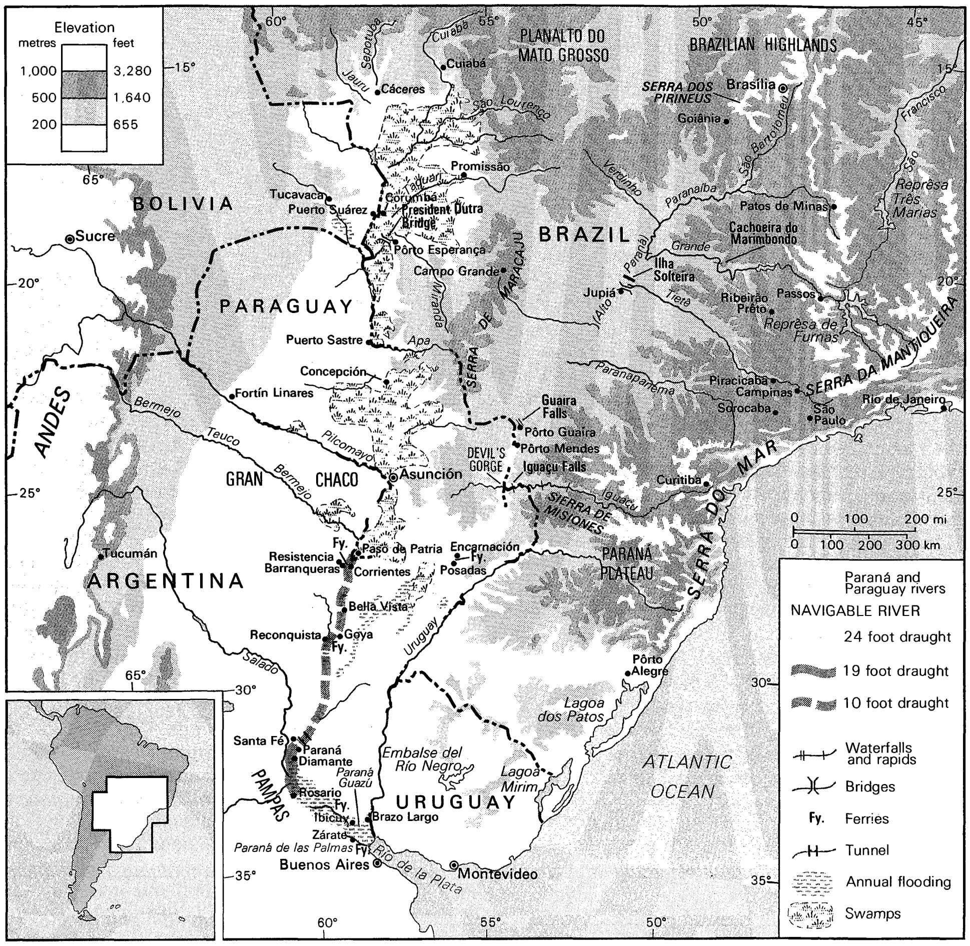
About 470 miles downstream, it flows north to south to form the boundary between Brazil and Paraguay before being joined by a tributary, the Río Apa, which flows in from the east and demarcates part of the Brazilian–Paraguayan frontier. The river then enters Paraguay, having travelled about 950 miles from its source. After flowing for more than 200 miles across Paraguay, it is joined by the Río Pilcomayo at the Argentinian border, near Asunción. It then flows south-southwest along the Argentinian–Paraguayan frontier for about 140 miles, until it is joined on its west bank by the Bermejo. Continuing along the border for another 40 miles, it then empties into the Paraná River at a short distance from the Argentinian city of Corrientes.

Throughout its hydrographic basin, which covers more than 380,000 square miles (985,000 square kilometres), altitudes rarely exceed 650 feet above sea level. Rainfall varies from 40 to 80 inches annually. Over a long distance, the gradient of the river varies from about three-quarters of an inch to an inch per mile. The various streams of the basin have low banks or natural levees, built up when silt is deposited along the slower flowing portions of the river channel during flood stage. When the river recedes, its banks thus remain elevated above the level of the neighbouring plains. During floods a continuous water table, often as much as 15 miles wide, underies the inundated plains, and about 38,600 square miles of surface area are flooded.

The Paraguay River has varying rates of flow between its source and its mouth. Above Corumbá, in Brazil, it has a typically tropical regime—at its highest in February and at its lowest from July to August. Below Corumbá, the high point occurs in July and the low point from December to January.

From its confluence with the Apa for the 630 miles to its mouth, the Paraguay, while still navigable, runs on a shallow, broad bed, with an average width of about 2,000 feet. Its right (Argentinian) bank gradually lowers, whereas its left (Paraguayan) bank becomes elevated, forming cliffs. Along this stretch, floods develop principally on the western bank, spreading over the Argentinian plain for distances of from three to six miles. These lands form part of the Gran Chaco. Downstream from the complex of low hills south of Assunção known as Lomas Valentinas, the floods spill out over both banks, inundating areas between six and nine miles wide. At this point, the riverbed has an average width of about 2,300 feet.

After its juncture with the Paraguay, the combined stream of the Paraná turns southward as it passes Corrientes. It now becomes a typical "plainstype" river, banked by its own alluvial deposits and having an extensive floodplain



The Paraná and Paraguay river basins.

on its righthand side for the next stretch of its course, with tracts up to 24 miles wide liable to inundation. Its permanent bed, about two and a half miles wide at Corrientes, narrows to about 8,000 feet at Bella Vista, to about 7,000 feet at Santa Fé, and to about 6,000 feet at Rosario and is strewn throughout with chains of islands. Santa Fé, on the right bank opposite the port of Paraná, stands where the Paraná River receives its last considerable tributary, the Salado. Between Santa Fé and Rosario, however, the right bank begins to rise as the river skirts the edge of the undulating plain, which flanks it down to the delta, and reaches altitudes ranging from about 30 to 65 feet. The left bank, meanwhile, is always higher than the right but has to sustain the erosive action of the water, which becomes more and more turbid as great masses of earth are constantly falling into it; in the delta the main branch of the river runs along a break in the terrain, with its left bank consisting of a cliff about 75 feet high.

The delta

The delta of the Paraná has its apex as far north as Diamante, upstream from Rosario, where branches of the river begin to turn southeastward. About 11 miles wide at its upper end, the delta is 40 miles wide at its lower, where the separated branches flow into the Río de la Plata, about 200 miles from Diamante. With an area of 5,500 square miles in 1970, the delta—from calculations based on the maps made in 1818, 1912, and 1945—appears to be advancing at the rate of 230 feet per annum, the yearly volume of alluvial deposit being estimated at 165,000,000 tons. Within the delta the river divides again and again into distributary branches, the most important being the two last great channels, the Paraná Guazú and the Paraná de las Palmas. The islands of the delta, alluvial in origin, are low-lying and of varying size. Their shores and the outer fringes of the river have protective embankments covered with trees, but may nevertheless be submerged in times of flooding, when they present the appearance of flooded forests.

The velocity of the current of the Paraná changes frequently during the river's long course. For the Alto Paraná, the rate becomes slower wherever the bed widens (especially when a real lake is formed, as at Itaipu Dam) and very much faster wherever the bed narrows (as in the canyon downstream from Itaipu). Farther downstream it slackens on its way to Posadas, but accelerates thereafter over a series of rapids and races. Downstream from Corrientes it becomes slower again, stabilizing its flow at a mean rate of two and a half miles per hour on the way to the Río de la Plata.

The volume of flow

The volume of the Paraná is, for practical purposes, correlated to the amount it receives from the Paraguay, which supplies about 25 percent of the total. High periods occur normally in the summer (November–February); low periods in August and September. An important factor is that the Alto Paraná and the Paraguay reach their maximum flow at different times. Whereas the mountainous basin of the Alto Paraná is drained so rapidly that water begins to rise at Corrientes in November, reaching its maximum height there in February, the swamps of the upper basin of the Paraguay retain precipitation so much longer that the Paraguay's high water does not reach Corrientes till May, reaching its maximum in June. Thus, levels on the lower Paraná begin to sink in March, then rise again from May, and sink again from July to September. Whenever both the Alto Paraná and the Paraguay reach their highest levels at the same time, the lower Paraná has to carry an exceptionally heavy volume of water—as it did in 1905, when the delta experienced heavy flooding.

The Uruguay River (Spanish Río Uruguay; Portuguese Rio Uruguai) is the second major system, 932 miles (1,500 kilometres) in length, that flows into the Río de la Plata. Like the Upper Paraná and the Paraguay, the Uruguay originates in Brazil, formed by several small streams that rise on the western slopes of the Serra do Mar, at 27°09′ S. From the south it is joined by the Pelotas, the two rivers serving to divide the states of Rio Grande do Sul and Santa Catarina. After flowing west, the Uruguay turns southwest at its juncture with the Peperi Guaçu, the first sizable affluent to join it from the north. For most of its course, the fast-flowing Peperi Guaçu marks the boundary between the Argentine province of Misiones and Brazil. Now the Uruguay serves to divide Brazil and Argentina. A few miles beyond the juncture with the Peperi Guaçu, the river is constricted between rocky walls in the Salto Grande de Misiones, a two-mile stretch of rapids with a total descent of 26 feet (eight metres) in eight miles. At the cataracts, the river narrows suddenly from 1,500 feet to an extreme of 70 feet.

Several small rivers join the Uruguay from the west and are navigable in their lower reaches by canoes and small boats. The principal of these, from north to south, are the Aguaypey, Mirinay, Mocoretá (which divides Entre Ríos and Corrientes), and Gualeguaychú. The important affluents of the Uruguay, however, come from the east. The Ijuí, Ibicuí, and the Quaraí (Guareim) are short rivers but of considerable volume; the last forms part of the boundary between Brazil and Uruguay. At the mouth of the Quaraí, the Uruguay becomes the boundary line between Argentina and Uruguay, and the river flows almost directly south. The Negro River, 434 miles long and the Uruguay's largest tributary, joins the latter only 60 miles from the estuary of the Río de la Plata. The Negro rises on the Brazilian border in Rio Grande do Sul and flows westward through central Uruguay. Sizable river craft can reach Mercedes, 32 miles from its mouth. Like the Upper Paraná, the Uruguay is generally clear and carries little silt except in the seasonal floods. After its juncture with the Negro, the Uruguay broadens sharply to a width of four to six miles and becomes a virtual extension of the Río de la Plata estuary.

Climate. The Río de la Plata has a temperate climate and copious rainfall at all seasons, amounting to 39 inches (990 millimetres) a year. The mean annual temperature is 55° F (13° C), and monthly averages are always over 50° F (10° C). Humidity, at 70 percent, is notably high. The prevailing winds are the north, the pampero, and the southeast. Frosts are frequent in the winter months.

The basin of the Upper Paraná has a hot and humid climate all the year round. The winters are dry, and the summers (lasting from November to April) are rainy, with precipitation averaging 60 inches a year but decreasing toward the west. Rainfall takes the form of drenching downpours often accompanied by hailstorms; the rainwater is drained away rapidly into the mainstream. The middle and lower basins have a subtropical climate of temperate humidity, with less plentiful rainfall (except in the Misiones Region) but without seasonal differences, the mean annual precipitation being 39 inches in the delta as opposed to 66 in Misiones. The climate along the Lower Paraná is very humid indeed and sometimes quite stifling in summer; the moist vapours become still thicker in the delta when the river brings down the torrential waters of the tropical basin.

The predominant climate of the Paraguay Basin is of the hot and humid savanna type, characterized by dry winters from April to September and heavy rains in summer from October to March. More than 80 percent of the annual precipitation occurs in the summer months, with little or no rainfall in June and July. Annual mean temperatures are above 64° F (18° C), the absolute maximum temperature being from 104° to 107° F (40° to 42° C) and the abslute minimum temperature being about 34° F (1° C). October is frequently the warmest month, except in the south, where the warmest month is January and where the contrast between rainy summers and dry winters is more pronounced. The extreme southern portion of the basin has a humid, moderately warm climate in which the heaviest rains occur during the summer and the winters are not completely dry.

Plant and animal life. The Brazilian section of the Alto Paraná forms the boundary between two natural zones: that of the forest to the east, that of the savanna to the west. Wood and maté tea leaves from the forest are shipped on the river, and the treeless savannah, with grasses and bushes, is good for cattle raising. On Argentina's section of the river, forest extends from the Misiones region to the vicinity of Corrientes; some forest trees, outside the zone of the forest proper, still occur in areas of woodland all the way downstream to the delta.

Species of fish

The Paraná has a rich and varied animal life. Among its many edible fish, the pejerrey (a marine fish, silver in colour, with two darker bands on each side), the dorado (a brilliantly coloured river fish with a golden appearance), the surubi (a fish with a long rounded body, flattened at the nose), the pati (a large scaleless fish, which frequents deep and muddy waters), and the pacu (a large river fish with a flat body, almost as high as it is long) are worth mentioning; every year sportsmen visit the stretch of the river upstream from Corrientes to angle for dorado. Reptiles include the iguana lizard, two species of caiman (a crocodilian), the water boa, the rattlesnake, the cross viper, and the yarará (the most prevalent South American representative of the viper family). Frogs and toads are plentiful, as also are freshwater crabs. There are innumerable species of insects and spiders, and the islands are plagued by mosquitos. Herons, cormorants, storks, and game birds are also seen.

The *pantanal* complex

In the Paraguay River system, some of the *pantanal*'s vegetation, called the "*pantanal* complex," is typical of the Mato Grosso plateau regions, while some other is typical of lowlands. Plants that thrive in water and in moist soils as well as those that flourish at moderate temperatures or are adapted to dry regions are found within the complex. As on the banks of the Niger in West Africa, both forest and grassland types occur. The water plants, found on the permanently flooded lands, are typified by the water hyacinth and by the "Victoria regia" water lily. Moisture-loving species, such as the trumpetwood and the guama, flourish over most of the floodplain. On the savanna, after the floods, various grasses such as paspalum and knotroot bristle grass reappear. Vegetation of a more evolved type, which thrives at moderate temperatures, occupies the unflooded highland. It is represented by nut-bearing palms and by various types of laurels. In the forests of the region, the carandá, or copernicia palm (a tropical palm that yields wax), the paratudo, the muriti palm (a large fan palm), and various types of quebracho trees (South American hardwoods that are a source of tannin) predominate. In the Gran Chaco region along the west bank of the river, and in other sections where drought is more pronounced, plants adapted to dry conditions occur. In the lowlands of eastern Paraguay, forest cover and savanna grasslands alternate.

Among the fish of the Paraguay River, some of which supplement the diet of the riverine population, are the dorado (a fish resembling salmon), the piranha (a fish resembling the bluegill that travels in large schools and devours any meat that falls in the water), and the pacu (which resembles bass).

The estuary of the Río de la Plata is very rich in fish; pejerrey (kingfish), corbina (white sea bass), patí (large scaleless river fish), surubí (the largest Argentinian river fish), dorado (a large golden fish resembling a salmon), and pacú (a large river fish almost as high as it is long) are among the edible species.

The people. *The Paraná.* The peoples who live up and down the Paraná, be they fishermen, farmers, herdsmen, boatmen, pilots, shipwrights, or raftmakers, all share certain customs and interests in common arising from their environment, from their racial identity, and from the cultural underdevelopment of the region. Originally, almost the whole length of the river region was populated by Guaraní Indians. The Spaniards, for whom the river was the only practicable way of penetrating the interior of the country, mingled freely with the Guaraní. The cultural, physical, and linguistic characteristics of the present population reflect this mingling.

On the Alto Paraná most of the people are poor fishermen living in huts on the fringe of the forest, and depending on the river both for their food and for their transport: apart from their fishing, they profit from services rendered to passing river traffic.

On the lower Paraná the economy is more diversified, but still primitive. Apart from fishing and providing services, the islanders raise livestock; some crops, such as maize, manioc, tobacco, and fruit, are grown. Settlement of the adjacent country was begun from the banks of the river and the economy remains dependent on the river in the absence of a system of roads.

The most distinctive features of human life and activity on the Paraná can best be observed in the delta, where water transport is the sole means of movement for people and for goods alike. Such local fruit growing as there is contributes little to ecological development, as the fruit trees are not suited to the climate and are frequently damaged by floods; it would seem more rational to proceed with the afforestation of the islands liable to flooding with pine and other softwood species.

The original inhabitants

The Paraguay. Before the arrival of the Spaniards in the 16th century, the region was inhabited primarily by the Paiaguá (a part of the Guaycure tribe) and by the Guaraní. A subgroup of the Guaraní, the Xaraiés, lent their name to the original designation of the *pantanal*—the Lagoon of the Xaraiés. The Paiaguá and the Guató of the *pantanal* engaged in foraging, hunting, and fishing. Others, such as the Tereno and the Guiana (Arawak), practiced a rudimentary type of agriculture, building hillocks above flood level. The southern Guaraní cultivated corn (maize) and cassava (manioc). The inhabitants of the Gran Chaco—the Paiaguá, Mataco, Mascoy, and Zamuco—were nomadic fishers and hunters.

In what is now Paraguay, the Spaniards and Portuguese interbred freely with the indigenous Amerindians. Consequently, the present riverine population of the country is largely mestizo, or mixed, and Guaraní as well as Spanish is the common language. In Brazil, however, miscegenation was less general, so that some groups of indigenous peoples remain, forming isolated nuclei. Others, like the Bororo, the Tereno, the Cadiueu, and the Bacairi, constitute minorities who have adopted Christianity and Brazilian culture and who live on the fringe of the region.

Among the first Europeans to enter the region were the Spanish Jesuits who mapped the river in the 17th century. In the 19th century, the first hydrographic survey of the river was made, followed in the 20th century by a more detailed hydrographic survey.

The Río de la Plata. The shores of the Río de la Plata are the most densely populated areas of Argentina and of Uruguay alike. The great ports, Buenos Aires and Montevideo, where the density is highest, are primarily concerned with exporting meat from the hinterland; the refrigerators and shipyards required for this trade are located in the coastal zone, as are flour mills, factories for vegetable oils, textile industries, metallurgical plants, and petroleum refineries.

For the people living along its shores, the Río de la Plata has always been useful as a waterway. For their essential livelihood they have looked inland to the pampas. Nevertheless, the estuary, as a thoroughfare for trade, is important not only to the people of the coasts but also to the remotest inhabitants of the whole drainage basin.

The economy. The economic usefulness of these river systems is not commensurate with the area that they drain. A principal problem is that of navigation. A large portion of the rivers cannot be used at all or only by very shallow draught vessels. Elsewhere navigation can only be maintained by constant dredging and renovation of port facilities. The other economic uses to which these rivers might lend themselves, such as irrigation or hydroelectric power, are equally difficult to achieve. The swamps of Xarayes and the Chaco long made agriculture a virtual impossibility in these areas. The gradual use of the potential electric power represented by sites such as Itaipu or Foz do Areia, however, has supported the development of the cities and industrial sites and of agriculture as well.

Buenos Aires is one of the principal seaports of the world and the main port of Argentina. Vessels approach it from the main estuary channel by one of two side channels that are clearly marked and dredged. Ocean vessels can travel up the Paraná River as far as Santa Fe or Paraná. Ocean trade can also reach Concepción del Uruguay directly by the Uruguay River.

Commerce farther upstream on these river systems operates under conditions that fluctuate considerably. Passage of vessels depends to a large extent on seasonal variations in depth. Long fleets of barges carry the bulk of the river freight. The current, narrowness, and curves above Corrientes on the Upper Paraná, however, rule out such barge transport. Several rapids on the Upper Paraná can only be passed with the use of winches to pull the vessels. Narrowness of the river, whirlpools, and the increased speed of the current make navigation more dangerous as the mouth of the Iguaçu is approached. A railroad, 38 miles long, to the town of Guairá circumvents the Itaipu site and opens up another 400 miles of navigable river farther up the Paraná. Beyond, stretches of the Paraná and of tributaries are navigable only by launches or canoes.

On the Paraguay River, vessels drawing seven feet are able to reach Corumbá in Brazil at all seasons; smaller ships can reach Cáceres, Brazil. Navigation of the Pilcomayo, Bermejo, and Salado is negligible, because of shifting channels, sandbars, and shallowness.

The value of these river systems as a commercial artery is, therefore, concentrated on the lower reaches. A large volume of ocean shipping reaches Rosario and Concepción del Uruguay, although the major seaports are Buenos Aires and Montevideo. The great bulk of river transport is concentrated within the limits of Asunción on the Paraguay, Corrientes on the Paraná, and Salto on the Uruguay. Local ship lines provide regular passenger and freight service to all navigable parts of these river systems. Rafts, canoes, and motorboats provide irregular although important service on the tributaries and upper reaches of these rivers.

Study and exploration. The Río de la Plata was discovered by Juan Díaz de Solís, chief navigator of Spain, in 1516, as a result of efforts to find a route to the Pacific. The estuary was temporarily named in his memory after his death on its shores at the hands of unfriendly Charrua Indians. Ferdinand Magellan touched at the estuary in 1520 during his circumnavigation of the globe. In 1526, Sebastian Cabot ascended the rivers as far as the present city of Asunción and obtained silver trinkets in barter with the Guaraní Indians. Spanish dreams gave the estuary its permanent name, Río de la Plata, in the hope that it might indeed become a river of silver. The major Spanish expedition that settled near the present location of Buenos Aires in 1536 under Pedro de Mendoza proved a fiasco. After much misfortune the survivors moved upstream to the surroundings of the more docile Guaraní Indians at Asunción. Buenos Aires was not refounded until 1580, and throughout the Spanish colonial era the Río de la Plata remained a backwash of the empire. The estuary was virtually closed to legal commerce until the end of the 18th century. Spain renewed its interest in the area only when Portuguese and English ambitions threatened to expand into the Río de la Plata in the 1760s.

Navigation of the river systems became a problem when the national states of Argentina, Uruguay, Brazil, and Bolivia emerged on its courses. Territorial conflicts and restrictions on navigation caused several wars, culminating in the titanic struggle by Francisco Solano López' Paraguay against Brazil, Uruguay, and Argentina from 1864 to 1870. In the 20th century, similar conflicts sharpened by rumoured oil wealth resulted in the Chaco War between Paraguay and Bolivia.

The development of agricultural wealth, particularly in Argentina, resulted in greater appreciation of the commercial value of these river systems after the mid-19th century. Wheat, beef, wool, and hides entered the river and world trade in increasing quantities from Argentina and Uruguay, while from Brazil and Paraguay came forest and tropical products and maté, or Paraguayan tea. Port construction and dredging made Buenos Aires more valuable as a seaport, and by 1902 similar improvements had been completed at Rosario. Marking of channels, soundings, dredging, and other aids to navigation became a responsibility of all the riparian states. (Ed.)

SÃO FRANCISCO RIVER

One of the greatest rivers in South America, the São Francisco, 1,800 miles (2,900 kilometres) long, is the third largest river system of Brazil and the largest river wholly within the country. It is regarded as "the river of national unity" because it has long served as a line of communication between Brazil's maritime and western regions and between the north and the south. The river is named for the 16th-century Jesuit leader, St. Francis Borgia (São Francisco de Borja y Aragon). It is an important source of hydroelectric power and irrigation for northeastern Brazil. The São Francisco Valley includes a total area of 243,682 square miles (631,133 square kilometres).

ıe upper
urse

Physical features. *Physiography.* The São Francisco rises at about 2,400 feet (730 metres) above sea level on the eastern slope of the Serra da Canastra (Canastra Mountains) in southwestern Minas Gerais state (*estado*), some distance south of the national capital of Brasília. It flows for more than 1,000 miles northward across the State of Bahia to the twin cities of Juazeiro and Petrolina. In this stretch the river receives its main left-bank tributaries—the Paracatu, Urucuia, Corrente, and Grande rivers—and its main right-bank tributaries—the Verde Grande, Paramirim, and Jacaré.

About 100 miles above Petrolina, the river begins a great curve to the northeast and enters a 300-mile-long stretch of rapids and falls. In this section the São Francisco forms the border between the states of Bahia to the south and Pernambuco to the north. The upper rapids are navigable during periods of high water, but below Petrolina the river is impassable. The broken course—during which the São Francisco receives the San Pedro, Ipueira, and Pajeú rivers—culminates in the great Paulo Afonso (Paulo Afonso Falls). At the top of the falls, the river divides suddenly and violently and cuts three successive falls through the granite rocks for a total drop of about 275 feet. Below the falls the river flows about 190 miles to its one mile-wide mouth on the Atlantic Ocean, about 60 miles north of Aracaju. In its lower section it is joined by the Rio Moxotó and forms the border between the states of Sergipe to the south and Alagoas to the north.

Climate. The climate of most of the river basin is hot and dry. The average maximum temperature for the region is 97° F (36° C) and the average minimum 66° F (19° C). The highest temperature recorded is 107° F (42° C). The prevailing winds are from the southeast, east, and northeast. Rainfall is deficient over most of the area and drought is frequent. Average annual precipitation measures 20 to 40 inches (508 to 1,016 millimetres) in the middle basin and 40 to 80 inches at the river mouth; about 8 percent of the basin receives only 10 inches of rain annually. Precipitation occurs during the summer months, from December to March, while the rest of the year—the winter season—is dry.

Plant and animal life. The upper river valley is an area of *caatinga,* or thorn forest. Important plants include the caroa, used for its fibres, and the mamona, which yields castor oil. There are trees, such as the oil, carnauba, and date palms; the *cajú* (cashew), which yields edible fruits; the palma, a spineless cactus with a high water content; and rubber trees. The upper middle valley, extending to the falls zone, is less dry and is covered with grassland (*campos cerrados*) and forests of semideciduous trees. Hardwoods include the jacaranda, Brazilian cedar (*cedro*), and vinhatico; and cochineal cactus, aloes, and vanilla plants also grow there.

The falls zone passes through the dry Brazilian interior, known as the *sertão.* The small amount of rainfall in the area permits the growth of only drought-resistant brush and grasses. The dry forests of the hilly uplands support carnauba and babassu palms and such plants as the cactus, the rock rose, and the rhododendron. Underground water in the region is too saline for irrigation or drinking.

The lower São Francisco flows through a floodplain of fine silt soils. Most of the original tropical semideciduous forest that grew along the river has been cleared for agriculture.

The river's fish are an important source of food. They include robalo, sardines, pocomó, and sarapó. The river mouth supports meru (squalas), manatees (sea cows), and sharks.

The people and economy. Except for the blacks who live along the coast, the people of the São Francisco Basin are of mixed Portuguese and Indian descent. The upper middle valley is an agricultural region in which cotton, rice, and corn (maize) are grown. The region also produces pineapples, barley, potatoes, rye, maté (tea), melons, sugarcane, beans, coffee, castor and cottonseed oils, and rum. Its major urban centre is Pirapora.

Pastoralism and *vazante* agriculture

The dry *sertão* is used largely for the grazing of cattle, goats, sheep, and donkeys. Along the river banks *vazante* agriculture is practiced: during the rainy season, shallow waterbeds (*vassantes*) are enclosed by bars of river sediment, and support the cultivation of cassava (manioc), water beans, and melons. Truck crops are grown on the river banks, and carnauba, caroá, and rubber are collected. The major town is the market centre of Salvador. Most of the lower river valley is dry and suitable to pastoral activities. Along the coast, wetland rice is grown.

Because the river flows through the driest region of Brazil, it is subject to seasonal changes in water level of up to 30 feet (10 metres). All of its tributaries run dry during the winter; above Juàzeiro, the riverbed varies from a narrow channel during drought periods to several miles in width during the rainy season.

The river is navigable for small steamers for more than 1,000 miles from Pirapora, Minas Gerais, to Várzea Redonda, Bahia, upstream of Petrolina. Sandbars at the river's mouth prevent the entry of deep-draft ocean vessels. There is a railway bridge across the river at Pirapora, and another bridge connects the cities of Petrolina and Juázeiro. Although river transport is slow and difficult, the São Francisco is an important link between the mining district of Minas Gerais and roads that radiate north and east from Juàzeiro.

The river's hydroelectric potential

The river's hydroelectric potential is its most important resource. The main centre of power for northeastern Brazil is the Paulo Afonso Cachoeira, site of the Trés Marias Dam. There are also hydroelectric plants providing electricity to the coastal cities of Salvador, Aracaju, and Recife at dams on the upper and lower stretches of the river.

The river basin is also important as a source of irrigation water. The largest storage dam is at Quixadá, Ceará state. There are large reservoirs at Cachoeira and Pedra d'água, and there are plans for a reservoir on the Jaguaribe and a 300-mile-long irrigation canal to join the São Francisco at Petrolina to branches in eastern Pernambuco, Paraiba, and eastern Ceará states.

The river basin contains deposits of agate, gold, iron, diamonds, opals, antimony, galena (the principal ore of lead), mercury, copper, arsenic, manganese, cobalt, and pyrites. There are also deposits of salt, sulfur, alum, marble, limestone, and clay. (C.E.Ca.)

BIBLIOGRAPHY

General works: PIERRE BIROT, *Les Régions naturelles du globe* (1970), contains two chapters on the Andes and on the old shields that constitute a modern approach to the structure of South America; JEAN DORST, *South America and Central America* (1967), a natural history of the continent, region by region; E.J. FITTKAU *et al.* (eds.), *Biogeography and Ecology in South America,* 2 vol. (1968–69), a series of valuable contributions on various aspects of natural history and relations between man and environment in South America; ARTHUR S. MORRIS, *South America* (1979), a general regional geography of the continent, showing interrelationships between landscape and economy.

Geological history: HEINRICH GERTH, *Der Geologische Bau der Südamerikanische Kordillere* (1955), a controversial book from which our modern views on the geology of the Andes originated; and *Geologie Südamerikas,* 2 vol. (1932–35), a comprehensive book on the geology of the continent, now somewhat outdated; WILLIAM F. JENKS (ed.), *Handbook of South American Geology* (1956), a country-by-country survey of the geological history of the continent and an analysis of the main formations; HANS STILLE, *Einführung in den Bau Amerikas* (1940), a classic book on the geology and structure of the Western Hemisphere; GEORGE W. STOSE (ed.), *Geologic Map of South America* (1950); E.F. SUSZCZYNSKI, "La Géologie et la tectonique de la Plateforme amazonienne," *Geol. Rdsch.,* 59:1232–53 (1970), a modern view on the structure of the oldest parts of South America; L.G. WEEKS, "Paleogeography of South America," *Bull. Am. Assoc. Petrol. Geol.,* 31:1194–1241 (1947).

Physical geography: "The Soil Resources of Latin America," *World Soil Resources Rept. 23* (1965), a survey of soils and

land use; HENRY W. BATES, *A Naturalist on the River Amazon,* 2 vol. (1863), a classic book on the discovery of Amazonia by one of its first modern explorers; ISAIAH BOWMAN, *The Andes of Southern Peru* (1916, reprinted 1968), a comprehensive view of geological structure and natural history; D.L. BRAMAO and LEMOS PETEZVAL, "Soil Map of South America," *Proc. Int. Congr. Soil. Sci.* (1960); GILBERT J. BUTLAND, *Latin America: A Regional Geography* (1960), a valuable contribution; FRED A. CARLSON, *Geography of Latin America,* 3rd ed. (1952), describes the structure of the continent and the natural regions; PRESTON E. JAMES, *Latin America,* 4th ed. (1969), a broad survey; CARL TROLL (ed.), *Geo-ecology of the Mountainous Regions of the Tropical Americas* (1968), a series of contributions to ecological problems in relation to relief and climate in the Andes.

Vegetation and animal life: MARSTON BATES, *The Land and Wildlife of South America* (1964), a book of interest to the general reader by a leading naturalist; ANGEL CABRERA and JOSÉ YEPES, *Historia natural Ediar. Namíferos sudamericanos* (1940), the only comprehensive book on South American neotropical mammals and their life; ANGEL L. CABRERA and ABRAHAM WILLINK, *Biogeografía de América Latina* (1973), a detailed analysis by biological zones of the animal and vegetable life of the continent; CARL H. EIGENMANN and WILLIAM R. ALLEN, *Fishes of Western South America,* 2 vol. (1942), a key to neotropical fishes and their characteristics; THOMAS H. GOODSPEED, *Plant Hunters in the Andes,* 2nd ed. rev. (1961), a work that contains firsthand data on high mountain vegetation; STEPHEN HADEN-GUEST, JOHN K. WRIGHT, and EILEEN M. TELLAFF, *A World Geography of Forest Resources* (1956), an inventory of world forestry containing a chapter on South America; ROBERT C. MURPHY, *Oceanic Birds of South America,* 2 vol. (1936), oceanography of the South American seas and life histories of all of the marine species; PAUL W. RICHARDS, *The Tropical Rain Forest* (1952), a classic book on the rain forest and its characteristics throughout the world; RODOLPHE MEYER DE SCHAUENSEE, *A Guide to the Birds of South America* (1970), a key to the bird life of the continent, with the description and distribution of every species; G.G. SIMPSON, "History of the Fauna of Latin America," *Am. Scient.,* 38:361–389 (1950), a geological history of neotropical mammals and their distribution in South America; FRANZ VERDOORN (ed.), *Plants and Plant Science in Latin America* (1945), a work that contains contributions on vegetation, agriculture, and land use.

Natural resources: AMÍLCAR O. HERRERA, *Los recursos minerales de América latina,* rev. ed. (1965), a survey of the resources of the continent; CARL A. LAMEY, *Metallic and Industrial Mineral Deposits* (1966), a world survey of mineral resources, with much data on South America; ULRICH PETERSEN, "Metallogenic Provinces in South America," *Geol. Rdsch.,* 59:834–897 (1970), information on the geological origin and localizations of the main sites where ores have been found; the COMMISSION FOR INLAND FISHERIES OF LATIN AMERICA, *The Inland Waters of Latin America* (1979), a detailed scientific inventory.

Human resources: An excellent general survey of ethnic origins, geographic distribution of the various groups, and racial relations, may be found in MAGNUS MORNER, *Race Mixture in the History of Latin America* (1967); and in MARVIN HARRIS, *Patterns of Race in the Americas* (1964, reprinted 1974); and a similar summary and historical analysis in NICOLÁS SÁNCHEZ-ALBORNOZ, *La Población de América latina* (1973; Eng. trans., *The Population of Latin America: a History,* 1974). Two major contributions on the South American Indians are JULIAN H. STEWARD and LOUIS C. FARON, *Native Peoples of South America* (1959); and CLARK WISSLER, *The American Indian,* 3rd ed. (1950). Steward's work is a general summary of the monumental *Handbook of South American Indians,* 7 vol. (1946–59). A typology of the ethnic origins and their distribution in the various South American subcultures is provided by CHARLES WAGLEY and MARVIN HARRIS, "A Typology of Latin American Subcultures," *Am. Anthrop.,* 57:428–451 (1955). On indigenous languages, in addition to chapters in the previously mentioned books, one of the classics is CESTMIR LOUKOTKA, *Classification of South American Indian Languages* (1968). RAMIRO CARDONA G. (ed.), *América Latina: Distribución espacial de la población* (1975), provides detailed papers on aspects of location of human populations in the region. ROBERT M. LEVINE, *Race and Ethnic Relations in Latin America and the Caribbean: An Historical Dictionary and Bibliography* (1980), includes approximately 1,200 entries in the dictionary and more than 1,340 books and articles in the bibliography. The most complete statistics and interpretations on mass European immigration before 1930 is found in WALTER F. WILLCOX (ed.), *International Migrations,* 2 vol. (1929–31, reprinted 1969). A more recent contribution is WILFRID D. BORRIE *et al., The Cultural Integration of Immigrants* (UNESCO, 1959). In addition, the International Labour Office's publication, *Indigenous Peoples: Living and Working Conditions of Aboriginal Populations in Independent Countries* (1953), gives data and documents on the situation of the Indians in South America.

Political geography: J.P. COLE, *Latin America: An Economic and Social Geography* (1965), is a comprehensive treatise. For a perceptive interpretation of the Spanish in South America, see SALVADOR DE MADARIAGA, *El auge del Imperio Español en América* (1945; Eng. trans., *The Rise of The Spanish American Empire,* 1965, reprinted 1977). An important anthology, including sources and interpretation, covering the period from conquest to modern times, is LEWIS HANKE (ed.), *History of Latin American Civilization* (1967). An excellent history covering the same period is HUBERT HERRING, *A History of Latin America from the Beginnings to the Present,* 3rd ed. rev. (1968). A general textbook, covering various aspects of culture and society in the region, from colonial times to our days, is HELEN M. BAILEY and ABRAHAM P. NASATIR, *Latin America: The Development of Its Civilization,* 3rd ed. (1973). An integrated overview of the social, economic, and political modernization of the region is given in GINO GERMANI, "Stages of Modernization in Latin America," in *Studies in Comparative International Development* (1969–70). On the varieties of Spanish, see PEDRO HENRIQUEZ URENA, *Sobre el Problema del Andalucismo Dialectal de América* (1932). See also J.H. PARRY, *The Discovery of South America* (1979), an account relying heavily on contemporary chronicles; and JORGE I. DOMINGUEZ, *Insurrection or Loyalty: The Breakdown of the Spanish American Empire* (1980).

Resource development and commerce: J.P. COLE (*op. cit.*), is a comprehensive study of the population, physical background, major historical events, institutions and main aspects of economic development, together with more detailed analyses for individual countries. See also the UNITED NATIONS, ECONOMIC COMMISSION FOR LATIN AMERICA (UN-ECLA), *Economic Survey of Latin America* (annual), a report covering major developments in the economic field and economic trends for each country—some issues also deal with specific aspects such as energy, transportation, or small industry; and the *Economic Bulletin for Latin America* (published twice yearly), which includes special articles as well as informative and methodological notes and updates the statistical data in the annual surveys. ALCIRA LEISERSON, *Notes on the Process of Industrialization in Argentina, Chile, and Peru* (1966), focuses primarily on the main political characteristics of these countries as they undergo industrialization, and analyzes the relationship between populism and the rise of the new technocratic elites. The report of the INTER-AMERICAN DEVELOPMENT BANK, *The Process for Industrialization in Latin America* (1969), refers particularly to regional integration, technological innovation, external markets for regional manufactures, external financing, and the role of government and private enterprise in industrial development. BÉLA KÁDÁR, *Problems of Economic Growth in Latin America* (1980), is an overview of the development experience with case studies drawn from five countries. The *Report of the Latin American Symposium on Industrial Development* (UN, 1966), contains an evaluation of the process of industrialization, its past evolution, present characteristics, and future prospects. The PAN AMERICAN UNION, *Industrialization in Latin America: Priority Problems* (1967), analyzes the relationship between industrialization, import substitution, and employment. LEHMAN B. FLETCHER and WILLIAM C. MERRILL, *Latin American Agricultural Development and Policies* (1968), contains papers dealing with policies for economic growth in the agricultural sectors of eight countries. JOHN A. HOPKINS, *The Latin American Farmer* (USDA, 1969), is a thorough study of farm conditions in Latin America. ROBERT T. BROWN, *Transport and the Economic Integration of South America* (1966), is a very complete study of the various modes of transportation and their relation to economic integration; see also CHARLES J. STOKES, *Transportation and Economic Development in Latin America* (1968); PAN AMERICAN UNION, *General Problems of Transportation in Latin America* (1962); and the UN-ECLA, *Transport in Latin America,* 3 vol. (1965). DONALD W. BAERRESEN, MARTIN CARNOY, and JOSEPH GRUNWALD, *Latin America Trade Patterns* (1965), is a general historical survey of trade between the Latin American countries and a detailed analysis of more recent developments in trade among LAFTA members. Also of interest are UN-ECLA, *Regional Integration and the Trade of Latin America* (1968), a study of various possible forms of economic integration and of obstacles to achieving their objective; and its *Statistical Bulletin for Latin America,* a monthly publication giving statistical information on selected economic indicators; PAN AMERICAN UNION, *Latin America's Foreign Trade: Problems and Policies* (1966); the UNITED NATIONS, FOOD AND AGRICULTURAL ORGANIZATION, *Production Yearbook* and *Trade Yearbook* (both annual); and the INTERNATIONAL MONETARY FUND and INTERNATIONAL BANK FOR RECONSTRUCTION AND DEVELOPMENT, *Direction of Trade* (monthly).

Demography: An important series of studies of demographic trends may be found in the special issue of the *Milbank Memorial Fund Quarterly,* vol. 43, no. 4, pt. 2 (1965), on *Components of Population Change in Latin America.* A short

general presentation by a major Latin American demographer is the article by CARMEN A. MIRO, "The Population of Latin America," in CLAUDIO VELIZ (ed.), *Latin America and the Caribbean* (1968). Another general article is KINGSLEY DAVIS, "The Place of Latin America in World Demographic History," *Milbank* (*op. cit.*), 42:19–47 (1964). Many demographic studies appear in the *Economic Bulletin for Latin America,* a journal published in English (twice yearly) by the United Nations Economic Commission for Latin America, Santiago de Chile. On fertility, see the special issue of the *Milbank* (*op. cit.*), vol. 46, no. 3 (1968), on *Current Research on Fertility and Family Planning in Latin America;* and O. ANDREW COLLVER, *Birth Rates in Latin America* (1965). On urbanization, internal migration, and living conditions in the cities, see PHILIP M. HAUSER (ed.), *Urbanization in Latin America* (1961); and GLENN H. BEYER (ed.), *The Urban Explosion in Latin America* (1967). Current demographic statistics appear in the *Statistical Abstract of Latin America* (annual). DOUGLAS BUTTERWORTH and JOHN K. CHANCE, *Latin American Urbanization* (1981), a review of rural–urban migration of the lower classes.

South Asian Arts

South Asia, consisting of the huge subcontinent of India, includes Pakistan, Bangladesh, Sri Lanka (formerly Ceylon), as well as the nation of India itself. In spite of differences in physical appearance, complexion, stature, and other ethnological features, the people of the entire region of South Asia are unified by a common cultural and ethical outlook; a wealth of ancient textual literature in Sanskrit, Prākrit, and regional languages is a major unifying factor. Music and dance, ritual customs, modes of worship, and literary ideals are similar throughout the subcontinent, even though the region has been divided into kaleidoscopic political patterns through the centuries.

The close interrelationship of the various peoples of South Asia may be traced in their epics, as in the *Rāmāyaṇa* and the *Mahābhārata.* Kinship between the gods and heroes of regions far distant from each other is evident, and the place-names themselves often evoke common sources. Moreover, there have been continual attempts to impose a political unity over the region. In the 3rd century BC, for example, the emperor Aśoka had almost all of this region under his sway; in the 11th century AD, Rājendra I Cōḻa conquered almost the whole of India and a good portion of Southeast Asia; and the great Mughal Akbar again achieved this in the 16th century. Though the expansion and attenuation of boundary lines, the bringing together or pulling apart politically of whole regions, have characterized all of South Asian history, the culture has remained essentially one.

The geography of the region encouraged a common adoration of mountains and rivers. The great Himalayas, which form the northern boundary, are the loftiest of mountains and are conceived to be the embodiment of nobility, the abode of immaculate snow, and the symbol of a cultural ideal. Similarly, the great rivers such as the Brahmaputra and the Indus are regarded as the mothers of their respective regions, assuring prosperity through their perennial supply of water.

The association of lakes and springs with water sprites and sylvan fairies, called *nāga*s and *yakṣa*s, is common throughout the region. Karkoṭa, the name of an early dynasty, itself signifies *nāga* worship in Kashmir. Sculptures of *nāga*s and *yakṣa*s found in widespread sites suggest a common spirit of adoration, as do sculptures, paintings, temples, and religious texts that for centuries were preserved within an oral tradition without losing their immaculate intonation. The same classical dance is seen in sculpture in Gandhāra in Pakistan, in Bhārhut in the north, and in Amarāvatī in the south.

The relation of the various arts to each other is very close in South Asia, where proficiency in several arts is necessary for specialization in any one. Thus, it is believed that without a good knowledge of dance there can be no proficiency in sculpture, for dance, like painting or sculpture, is a depiction of all the world. For its rhythmic movements and exposition of emotion, dance also requires musical accompaniments; hence, knowledge of musical rhythm is essential. For the stirring of emotion either in music or in dance, knowledge of literature and rhetoric is believed to be necessary; the flavour (*rasa*) to be expressed in music, dance, sculpture, or painting requires a literary background. Thus all the arts are closely linked together.

The arts were cultivated in South Asia not only as a noble pastime but also in a spirit of dedication, as an offering to the Almighty. Passages in literature refer to princes studying works of art for possible defects. One inscription that mentions the name of the *sūtra-dhāra* ("architect") of the 8th-century Mallikārjuna temple at Pattadakal epitomizes the accomplishments and ideals, in both theory and practice, of the artist.

Artists traditionally have enjoyed a high position in South Asian societies. Poets, musicians, and dancers held honoured seats in the royal court. An inscription mentions the appreciation bestowed by Rājendra Cōḻa on a talented dancer, and the architect of the temple at Tiruvoṟṟiyūr, who was also patronized by Rājendra, was eulogized for his encyclopaedic knowledge of architecture and art. Nonetheless, the folk arts were closely linked with the elite arts. Tribal group dances, for example, shared common elements with classical art, dance, and music. Among the artistic traditions of the Indian subcontinent, sculpture in the round (*citra*) is considered the highest artistic expression of form, and sculpture in relief (*ardhacitra*) is next in importance. Painting (*citrābhāsa,* literally "the semblance of sculpture") ranks third. Feeling for volume was so great that the effect of chiaroscuro (*i.e.,* use of light and shade to indicate modelling) was considered very important in painting; a passage from a drama of the 5th-century poet Kālidāsa describes how the eye tumbles over the heights and depths suggested in the modelling of a painting. A classical text on art, *Citrasūtra* enumerates noteworthy factors in paintings: the line sketch, firmly and gracefully drawn, is considered the highest element by the masters; shading and depiction of modelling are valued by others; the decorative element appeals to feminine taste; and the splendour of colour appeals to common taste. The use of a minimum of drawing to produce the maximum effect in suggesting form is considered most admirable.

Portraits play an important role in the visual arts of South Asia, and there are many literary references to the effective depiction of portraits both in painting and in sculpture. A 6th-century text, the *Viṣṇudharmottara,* classifies portraiture into natural, lyrical, sophisticated, and mixed, and men and women are classified into types by varieties of hair—long and fine, curling to right, wavy, straight and flowing, curled and abundant; similarly, eyes may be bow-shaped, of the hue of the blue lotus, fishlike, lotus-petal-like, or globular. Artistic stances are enumerated, and principles of foreshortening are explained. Paintings or sculptures were believed to take after their creators, even as a poem reflects the poet.

Although South Asia has continually been subjected to strong outside influences, it has always incorporated them into native forms, resulting not in imitation but in a new synthesis. This may be seen even in the art of the Gandhāra region of Pakistan, which in the 4th century BC was immersed in Greco-Roman tradition. In the sculpture of this period Indian themes and modes have softened the Western style. Foreign influence is evident after the invasion of the Kushāns in the 1st century AD, but the native element predominated and overwhelmed the foreign influence. During the Mughal period, from the 16th century, when Muslims from Central Asia reigned in South Asia, the blend of Iranian and Indian elements produced a predominantly Indian school that spread throughout the region, making it a unified cultural area under imperial rule. The influence of Islāmic art was enhanced by the second Mughal emperor, Humāyūn, who imported painters from the court of the Shāh of Persia and began a tradition that blended Indian and Persian elements to produce an efflorescence of painting and architecture.

Art in all these regions has reflected a system of government, a set of moral and ethical attitudes, and social patterns. The king's desire to serve the people and to take care of them almost as his offspring is evident as early as the 3rd century BC. The ideal of the king as the unrivalled bowman, as the unifier, as the tall and stately noble spirit, as the sacrificer for the welfare of the subjects, and as the hero of his people (who conceive of him as on a stately elephant) is comprehensively illustrated in a magnificent series of coins from the Gupta Empire of North India of the 4th–6th centuries. The concepts of righteous conquest and righteous warfare are illustrated in sculpture. The long series of sculptures illustrating the history of the South Indian Pallava dynasty of the 4th–9th centuries gives an excellent picture of the various activities of government—war and conquests, symbolic horse sacrifices, the king's council, diplomatic receptions, peace negotiations, the building of temples, appreciation of the fine arts (including dance and music), the coronation of kings, and so on, all clearly demonstrating what an orderly government meant to the people. Similarly, moral and ethical attitudes are illustrated in sculptures that lay stress on *dharma*—customs or laws governing duty. The doctrine of *ahiṃsā,* or noninjury to others, often is conceived in the symbol of a deer, and the ideal of a holy place has been conceived as a place where the deer roams freely. The joy in giving and of renunciation is clearly indicated in art. Sculptures illustrate simple and effective stories, as from the *Pañcatantra,* one of the oldest books of fables in the world. The spirit of devotion, faith, and respect for moral and ethical standards pervading the social structure in South Asia through the centuries is continuously represented in South Asian painting and sculpture. (C.S.)

The article is divided into the following major sections:

Literature

The peoples of South Asia have had a continuous literature from the first appearance in the Punjab of a branch of the Indo-European-speaking peoples who also settled all of Europe and Iran. In India this branch of Indo-Aryans, as they are usually called, met earlier inhabitants with different languages and no doubt a different culture—possibly a culture akin to that of the Indus Valley civilization, which had a script, and perhaps a literature of its own, of which nothing is known. Certain to have been settled in India were peoples who spoke languages of Dravidian origin, as well as other languages, called Munda, now preserved only by aboriginal tribes, which show affinities with the languages of Southeast Asia.

The earliest literature is of a sacred character and dates from *c.* 1400 BC in the form of the Rigveda. This work stands at the beginning of the literature of the Veda, or canonical Hindu sacred writings, which as a whole is roughly contemporary with the settlement of the Indo-Aryan peoples in the Punjab and farther east, in the mesopotamia of the Ganges and Yamunā rivers. The language of the Rigveda, which is a compilation of hymns to the high gods of the Aryan religion, is complex and archaic. It was simplified and codified in the course of the centuries from 1000 to 500 BC, which saw the development of prose commentaries called the *Brāhmaṇas, Āraṇyakas,* and *Upaniṣads.* While there must have been a long tradition of grammarians, the final codification of the language is ascribed to Pāṇini (5th or 6th century BC), whose grammar has remained normative for the correct language ever since. This language is called Sanskrit (Tongue Perfected). Sanskrit has had a scarcely interrupted literature from *c.* 600 BC until today, but its greatest efflorescence was in the classical period, from the 1st to 7th centuries AD. Because it was identified with the Brahminical religion of the Vedas, reform movements such as Buddhism and Jainism disdained the use of Sanskrit and adopted literary languages—amalgams of different dialects of the parent language—of their own, Pāli in Buddhism and Ardhamāgadhī in Jainism. These languages, usually called Prākrits—that is, derivative as well as more "natural" languages—produced a vast and, again, mostly sacred literature. In a further development of these dialects, the early beginnings can be seen of modern Indo-Aryan languages of northern India: Bengali (also the language of Bangladesh), Hindi (the official language of the Republic of India since 1947), Rajasthani, Punjabi, Gujarati, Marathi, Kashmiri, Oriya, Assamese, and Sindhi, each of which produced a literature of its own. Their names are derived from the regions in which they are spoken, regions with uncertain boundaries, where the different dialects fused at the borders. They all retained a close family resemblance that made bilingualism easy and a fact of Indian literary life.

Far more marked was the difference between Indo-Aryan speech and the languages of the Dravidian family, which are structurally wholly different, though in time a measure of convergence took place. Among them, the oldest recorded is Tamil, now the language of Tamil Nadu (Madras) state and of northern Ceylon (now called Sri Lanka), whose literature goes back to the early centuries of the Christian Era. Later to be put to literary uses were the cognate Telugu (Andhra Pradesh), Kannada (or Kanarese, Mysore state), and Malayalam (Kerala state) languages.

Influence
of Sanskri

In spite of this linguistic differentiation, the literatures composed in all of these languages reflect, in different degrees, the monumental influence of Sanskrit literature, Sanskrit being the universal Indian language of culture. This influence was one of both substance and form: in substance it provided the basic themes of literary enterprise, notably through the epics, the *Mahābhārata* and *Rāmāyaṇa,* the Hindu popular texts of the *Purāṇas,* especially the *Bhāgavata,* and the mythological repertory that came with Sanskritic Hinduism; in form, Sanskrit belles lettres bequeathed models of literary composition, and Sanskrit poetics provided the aesthetic theory underlying the models. The impact of Islām created a new language, Urdu (from Persian: Camp), based on Hindi; Urdu was the lingua franca of the army. Urdu was used later for literature and at present is the mother tongue of most Indian Muslims and their brethren in Pakistan. Its influence, however, does not compare with that of Sanskrit.

Comparable to the impact of Sanskrit, but far more alien, is that of English, which began to assert itself in the 18th century. The language brought with it new literary forms that were gradually adapted to the old ones, producing new genres—without necessarily giving up the older ones—in the local languages and giving rise to an interesting literature in the English language. Once more, a universal cultural language to a large extent unified aims in the scattered languages; English still plays this role, though it appears to be slowly declining.

SANSKRIT, PĀLI, AND PRĀKRIT LITERATURES: 1400 BC–AD 1200

Sanskrit: formative period (1400–400 BC). The oldest document in the literature of South Asia is the Rigveda, or Veda of the Stanzas (*c.* 1400 BC), the fundamental text of Brahminical Hinduism. Not literary but religious-magical in its purposes, it is mostly a compilation of hymns, dedicated to a number of gods of the Vedic religion. They have the regular structure of an invocation: the attention of the god is evoked; a brief account of some of his feats is given, to hold his attention; and an exhortation for his help concludes the hymn. The poets, of whom little is known, appear to have come at the close of a priestly poetical tradition, rivalling one another in allusions to obscure exploits, in language often opaque and at times intended to mystify. Nevertheless, the Rigvedic hymns include lines of great beauty. They may occur in a riddling verse, such as "When the ancient Dawns first dawned, the great Syllable was born in the footsteps of the Cow," alluding to the birth of speech at the beginning of creation. Or they may occur in poetry addressed to a deity whose beauty inspires the poet to well-turned lines. To the Dawns, for example: "They approach equally in the east, spreading themselves equally from the same place./ The Goddesses waking from the seat of order, like herds of kine set loose, the Dawns are active"; or to the goddess of the night: "Night coming on, the goddess shines/ In many places with her eyes:/ All-glorious she has decked herself./ Immortal goddess, far and wide/ She fills the valleys and the heights:/ Darkness with light she overcomes."

Nonsacred verses are very rare in the Rigveda, but, when they occur, they can be quite powerful, as in a hymn of a gambler, who is speaking:

It pains the gambler when he sees a woman,
Another's wife, and their well-ordered household:
He yokes these brown steeds early in the morning,
And, when the fire is low, sinks down an outcast.

"Play not with dice, but cultivate thy cornfield;
Rejoice in thy goods, deeming them abundant:
There are thy cows, there is thy wife, O gambler."
This counsel Savitri the kindly gives me.

etry

Although not literary in purpose, the Rigveda had a decisive influence on the form of Sanskrit poetry: except for narrative verse, the basic unit of all subsequent poems (no matter how many verses they consist of) is the single stanza that contains one complete thought.

The second Veda (*c.* 1200 BC), the Yajurveda (Veda of the Yajus [Formulas]), contains sacred formulas recited by a group of priests at the great Vedic sacrifices; and the third (*c.* 1100 BC), the Sāmaveda (Veda of the Chants), is in essence an anthology of the Rigveda. More literary interest attaches to the fourth Veda (1200 BC), the Atharvaveda (an *atharvan* was a special priest), which contains hymns, incantations, and many magic charms.

The succeeding literature (*c.* 1000–700 BC), the *Brāhmaṇas* ("Disquisitions About the Ritual"), continues not the poetry but the liturgical concerns of the Rigveda. They were written in a dry, expository prose, so that only their narrative portions have any literary interest. Much the same is true of the next layer of Vedic texts (800–600 BC), the *Āraṇyakas* ("Books Studied in the Forest").

ie
panisads

But the picture changes in the *Upaniṣads* (*c.* 1000–500 BC; "Collections of Esoteric Equations"). These prose texts at times convey the actual mode of teaching of a revered sage, in a style that can be strikingly intimate:

"Bring me a fruit of that *nyagrodha* (banyan) tree."
"Here it is, venerable Sir."
"Break it."
"It is broken, venerable Sir."
"What do you see there?"
"These seeds, exceedingly small, venerable Sir."
"Break one of these, my son."
"It is broken, venerable Sir."
"What do you see there?"
"Nothing at all, venerable Sir."
The father said: "That subtle essence, my dear, which you do not perceive there—from that very essence this great *nyagrodha* arises. Believe me, my dear."

While the older *Upaniṣads* are in prose, the later ones, dating from around 500 BC, mark a shift back to verse. They are the oldest examples of didactic verse, a genre that later gained enormous popularity.

The contribution of late-Vedic texts to later literature is preeminently that of the development of an expository prose style and the evolution of a sacred language, which, in order to be effective, must be completely correct. Thus, the Vedic religion evolved a science of phonetics and, later, of grammar, which was summed up in the 5th or 6th century BC by the grammarian Pāṇini in *Aṣṭādhyāyī* ("Eight Chapters"), a book that was to become basic to Sanskrit education. This language, Sanskrit, remained the language *par excellence* for later literature and was used for literary purposes until the 13th century and, epigonically, until today.

Sanskrit: epic and didactic literature (400 BC–AD 1000). After the formative period of the Vedic age, literature moved in several different directions. The close of the Vedic period was one of great cultural renewal, with the founding of the new monastic religions of Buddhism and Jainism (6th century BC) and the more slowly emerging rearticulation of Brahminism into Hinduism. Neither the earliest Buddhists nor the Jains availed themselves of Sanskrit in their preachings, apparently viewing the language as the preserve of a Brahmin elite. Sanskrit continued in derivative works of Vedic inspiration and above all in the *Mahābhārata* and the *Rāmāyaṇa.*

Mahābhārata. From references in Vedic literature it appears that side by side with the ritual texts there flourished a more secular literature carried on by bards. Originally charioteers to noblemen and thus witnesses of their feats, they chronicled the martial history of the families to which they were attached. From these beginnings, part chronicle, part panegyric, developed the epic style.

Like most Sanskrit poetry, the *Mahābhārata* consists of couplets, two successive lines with the same metre. Generally, one metre is used throughout the poem, though for stylistic effects other metres may be interspersed. The epic metre, or *śloka,* is a very fluid one that lends itself excellently to improvisation. The *Mahābhārata* is the longest poem in history, with about 100,000 couplets, more than seven times the size of Homer's *Iliad* and *Odyssey* combined. Its characters go back to around 1000 BC, but in its present form the epic could not have been composed before 400 BC. From that time until AD 400, it underwent continuous elaboration, by insertions of episodes (one of which is related in the religious poem called the *Bhagavadgītā*), accounts of separate adventures of the heroes, tales generated by their ancestors, and so on; and in the end it became a storehouse of general Hindu lore, with lengthy didactic books inserted.

The main narrative of the *Mahābhārata* recounts the growing up of two sets of cousins, both of whom aspire to a throne, the title to which is clouded. The protagonists, the Pāṇḍavas, stake their possessions in a dice game with the antagonists, the Kauravas, who are in effective control of the realm; they lose, and must live for 13 years in exile. This the five brothers do, along with the wife they hold in common. Upon their return from exile, they are refused their promised share of the kingdom, and, though parleys are held, war is inevitable. All of the Indian dynasties and tribes take sides in a war that lasts for 18 days, which only seven warriors, among them the Pāṇḍavas, survive. Noteworthy is the picture of gloom and doom that the *Mahābhārata* draws: there is little extolling of the heroic virtues of prowess and gallantry; rather, the wastefulness and bloodshed of war are pointed up, prefiguring a later concern with *ahiṃsā,* or nonviolence.

This summary does no justice to an extremely complex story with hundreds of participants, but it sketches the general outline of epic events. The main story has an unmistakable epic and heroic tone, and some of the events and encounters are completely comparable to those in epics of other peoples. But narrative and stylistic unity are disrupted by the inserted quasi-related and unrelated secondary episodes, each of which has a style of its own, ranging from light badinage to sonorous morality tales. It was in these episodes that the *Mahābhārata* lived on and greatly influenced succeeding literature; the story of Śakuntalā, for example, which the great 5th-century classical poet Kālidāsa embroidered, the slaying of Śiśupāla, the battle of the hero Arjuna with the mountain man, the story of Nala, and so on. But the most celebrated episode surely is the *Bhagavadgītā*.

The *Bhagavadgītā*

The influence of the *Bhagavadgītā* ("Song of the Lord") has mainly been on the development of Hindu religion and philosophy. Still, it is open to doubt whether it would have exerted this influence were it not for its poetry. Like most of the *Mahābhārata,* the style is simple and direct, not given to embellishment; nevertheless, the poem often reaches the height of expressiveness, as in its evocation of the theophany of Krishna as Vishnu, in the 11th of its 18 chapters. It led to imitations such as the *Īśvaragītā,* ("Song of the Lord [Śiva]"), also in the *Mahābhārata,* in which the god Śiva (Shiva) is celebrated.

Rāmāyaṇa. While the unity of the *Mahābhārata* has been disrupted by interpolations, the unity of the second epic, the *Rāmāyaṇa,* has been remarkably preserved. It is less an epic than a romance, recounting the story of prince Rāma and his wife Sītā. The first book, a later addition, tells of the youth of the prince, who later, by the trickery of one of his father's wives, is excluded from the throne to which he is heir. He goes into voluntary exile in the forests with his wife and his brother Lakṣmaṇa. There a demon, Rāvaṇa, abducts Sītā to his island kingdom of Laṅkā. In the course of his quest for her, Rāma allies himself with a monkey nation, whose general, Hanumān, later revered as a god, discovers Sītā on Laṅkā. A monumental battle ensues. "As the sky can only be likened to the ocean and the ocean to the sky, so the battle of Rāma and Rāvaṇa can only be likened to the battle of Rāvaṇa and Rāma." After his victory, Rāma is restored to the throne, but (in what appears to be a later addition) the populace accuses Sītā of misbehaviour, probable adultery, while in Laṅkā. Rāma thus abandons her to a hermitage (the sage of the hermitage, Vālmīki, is credited with the authorship of the *Rāmāyaṇa*), where she gives birth to their twin sons. Ultimately, Rāma takes Sītā and his sons back. In the later additions, the first and probably the last books, King Rāma is accepted as an incarnation of the god Vishnu, rather than merely a perfect man and hero.

It is the main story of the romance that has made an indelible impression on Indian culture, morally as well as literarily. Rāma is the perfect, just king; Sītā, the model of an Indian wife; Lakṣmaṇa (the brother), the paragon of fraternal love; and the monkey Hanumān, the epitome of a servitor's loyalty. It was translated into and adapted in many modern Indian languages, and (like parts of the *Mahābhārata*) it found its way into Java. Vālmīki himself was hailed by later classical poets as the first true poet (*kavi*), and indeed much of his work has a poetic freshness and literary intention that is largely absent from the *Mahābhārata.* Vālmīki's great tools are metaphor and simile, as is also true of later literature. He delights in description of pastoral scenes, in lamentations and grand martial spectacles, and in the idyll of the hermitage, which depicts a serene sage leading a life of quiet meditation and living on simple forest fare in a tranquil woodland close to a sacred river. And the entire work is suffused with a confident, unwavering morality, for which the heroes of the *Mahābhārata* are still searching.

Harivaṃśa and Purāṇas. The role of the *Mahābhārata* as the storehouse of Hindu lore was supplemented by the *Harivaṃśa* ("Genealogy of Hari"—that is, the god Vishnu), which deals with the ancestry and exploits of Krishna, the Pāṇḍavas' friend and adviser in the epic but now wholly deified and identified with the great god Vishnu. Then, from perhaps the 4th century, the literature of the *Purāṇas* took over. Encyclopaedic works, often of considerable length, the *Purāṇas* deal with the mythology of time and space and of deities, with sagas of great heroic dynasties, and with legends of saints and ascetics; their interest is largely religious. Aesthetically, the most important of them is the *Bhāgavata-Purāṇa* (9th or 10th century), which celebrates the blessed lord (*bhagavat*) Vishnu in his many theophanies but is particularly evocative in its celebration of Vishnu's incarnation as Krishna and the playful story of his youth. The influence of the *Bhāgavata-Purāṇa,* particularly the 10th book, on Indian religion, art, and literature has been monumental. In the opinion of one scholar, this book constitutes the greatest poem ever written; and so it is in the popular estimation of the Hindus. It was adapted in many Indian languages and provided themes and scenes for the flourishing miniature styles of the Middle Ages.

Pāli and Prākrit literature (c. 200 BC–AD 200). No more than the Vedic literature do the literatures of early Buddhism and Jainism have a literary intention. Their texts, written in dialects other than Sanskrit, articulate the teachings of the religious founders and their successors. Because they were transmitted orally for a considerable time before they were written down in the form they would retain, they underwent the inevitable censorship of the centuries, both negative in the form of documents dropped out of use and positive in the form of newer documents added. The dates given here are only approximations of the time of the documentary fixation of the dates.

Buddhist texts. The earliest records of Buddhism are not textual but inscriptional, in the famous edicts of the Mauryan emperor Aśoka, who reigned *c.* 269–232 BC. Among these inscriptions on stone, the so-called 13th rock edict—in which Aśoka, after the massacre of the Kaliṅgas (modern Orissa), abjures war—is the most moving document of any dynastic history. The inscriptions were written in a variety of Prākrits; that is, Indo-Aryan languages closely cognate to, but considerably later than, the earliest stabilized Sanskrit.

Pāli, the language of textual literature

The vehicle of the extant textual literature is the Pāli language, which is held to be a western Indian dialect on a substratum of several central and eastern ones. It was the language in use by the Theravāda school of Buddhism; but, since that school became the dominant one among many in early Buddhism, the Pāli language is often identified with the Buddha's own speech. Most of the canonical literature is exclusively of religious interest, but interspersed in it are works of considerable literary interest.

Foremost perhaps are discourses put into the Buddha's mouth—for example, his sermon "In the Deer Park"—and no doubt deriving from fairly accurate memories. With their straightforward, lively, and incisive style, homely similes, and simple humour, they are excellent examples of the homiletics of early Buddhist preaching. Incorporated in the canon, too, are more general works of literature. The *Dhammapada* ("Verses on the Buddhist Doctrine") is a fine example of the moralistic, aphoristic strain in Indian literature, in which virtue is extolled and vice condemned. It has remained a work of considerable diffusion in all Buddhist countries, and, as in the case of the *Bhagavadgītā* in Hinduism, much of its popularity is due to its literary style. The *Suttanipāta* collection of the Buddhist canon, composed in a more formal style, contains 55 narrative and didactic poems, in the form of dialogues and ballads; they are composed in a metre akin to the Sanskrit *śloka.* Of great interest are the *Theragāthā* and the *Therīgāthā* ("Hymns of the Senior Monks" and "Hymns of the Senior Nuns"), which give at times a vivid insight into the ambience in which a conversion to Buddhism took place: a monk celebrates his newfound freedom in an idyll of the hermit's life; and a nun reminisces over the pains of deserting her home and child, yet without regrets, since she has won the freedom of Buddhism. The prosodic variety of Buddhist lyrics is great; about 30 different metres can be distinguished. Pāli poems, with their new metres (often based on a musical phrase), stylistic features, figures of speech, and choice diction, foreshadow classical *kāvya* literature in Sanskrit, whose extant specimens date from a later period.

The *Jātakas*

Of great importance is a huge volume called *Jātakas* ("Birth Stories"), recounting some 500 episodes supposedly having occurred in the Buddha's earlier lives. Only those parts in archaic verse are canonical; the prose portion was written later (*c.* 3rd century AD), probably in

Ceylon. The *Jātakas* consist of fairy tales, animal stories and fables (the future Buddha may be incarnate in an animal), ballads, and anecdotes. Though their setting is often imaginary, they provide significant material for the historian of society and culture. These mostly short tales abound in moving, delicate, often rustic touches that have made them the delight of the Buddhist world. Their themes are illustrated in bas-reliefs of Buddhist shrines (or *stūpas*) at Bhārhut and Sānchi and monumentally on the great *stūpa* of Java, the Borobuḍur.

Of considerable literary as well as historical interest is the Pāli text *Milinda-pañha* ("The Questions of Milinda"). Milinda is identical to the Greek Menander, the name of a Bactrian Indo-Greek king (*c.* 140–110 BC) who was skeptical of the verities of Buddhism and was enlightened by the teaching of an elder, Nāgasena. The extensive Buddhist erudition that the sage displays is artfully presented in the form of simile and parable, and the work has contributed importantly to the edification of audiences in the countries where Buddhism came to be established. The style, in spite of the repetitions so typical of Buddhist doctrinal texts, is lively and presents the reader with an invaluable picture of contemporary Indian life.

Jaina texts. Less interest attaches to Jaina canonical works, which were written in an adapted and stabilized literary dialect called Ardhamāgadhī (Semi-Māgadhī, Māgadhī being the dialect of the ancient kingdom of Magadha, in present day Bihār). The belletristic contribution of Jaina literature is discussed below.

harac-
ristics of
e *kāvya*
yle

Classical Sanskrit kāvya (200–1200). Prepared for by the systematization of the Sanskrit language by Pāṇini, the development of the great epics, notably the *Rāmāyaṇa,* and the refinements of prosody represented by the Pāli lyrics, there arose, in the first centuries AD, a Sanskrit literary style that governed canons of taste for a millennium and remained influential far later through modern Indian languages and their literatures. The style, called *kāvya,* is characterized by an extremely self-conscious effort on the part of the writer to compose poetry pleasing to both the ear and the mind. It evolved an elaborate poetics of figures of speech, among which the metaphor and simile, in their many manifestations, predominate; a careful use of language, governed by the stated norms of grammar; an ever-increasing tendency to use compound nouns instead of drawing on the quite plentiful possibilities of Sanskrit inflection; a sometimes ostentatious display of erudition in the arts and sciences; an adroitness in the use of varied and complicated, if appropriate, metres—all applied to traditional themes such as the epic had provided and to the rendering of emotions, most often the love between men and women.

The style finds its classical expression in the so-called *mahākāvya* ("great poem"), most akin to the epyllion ("miniature epic") art form of the Alexandrian poets (a school of Greek poets, *c.* 3rd–1st centuries BC); the strophic lyric (a lyric based on a rhythmic system of two or more lines repeated as a unit); and the Sanskrit theatre. It can also be extended to narrative literature, especially the prose novel. The great masters in the *Kāvya* form (which was also exported to Java) were Aśvaghoṣa, Kālidāsa, Bāṇa, Daṇḍin, Māgha, Bhavabhūti, and Bhāravi.

The earliest surviving *kāvya* literature was written by a Buddhist, Aśvaghoṣa, said to have been a contemporary of the Kuṣāṇa (Kushān) king Kaniṣka (1st century AD). Aśvaghoṣa's work also marks a shift away from the Pāli of the Theravāda branch of Buddhism back to the more and more accepted Sanskrit of the Mahāyāna branch. Two works are extant, both in the style of *mahākāvya:* the *Buddhacarita* ("Life of the Buddha") and the *Saundarānanda* ("Of Sundarī and Nanda"). Compared with later examples, they are fairly simple in style but reveal typical propensities of writers in this genre: a great predilection for descriptions of nature scenes, for grand spectacles, amorous episodes, and aphoristic observations. The resources of the Sanskrit language are fully exploited; stylistic embellishments (*alaṅkāra*) of simile and metaphor, alliteration, assonance, and the like are employed, often quite felicitously. The original *Buddhacarita,* rediscovered in 1892, had been known from Tibetan and Chinese translations. The Sanskrit text is fragmentary, breaking off in the 14th canto (major division of the poem) with the enlightenment of the Buddha, while the other versions take the story through the Buddha's Nirvāṇa. Though intended to instruct the reader to turn away from the sensuous life and follow the Buddha's path, the work is at its best in descriptions of that very life. This is even more apparent in the *Saundarānanda,* which recounts a well-known story of how the Buddha converted his half-brother Nanda, who was deeply in love with his wife, Sundarī, and with the good life, to the monastic life of austerity. In his mastery of the intricacies of prosody and the subtleties of grammar and vocabulary, Aśvaghoṣa shows himself the complete forerunner of the Hindu *mahākāvya* authors.

The mahākāvya. In its classical form, a *mahākāvya* consists of a variable number of comparatively short cantos, each composed in a metre appropriate to its particular subject matter. The subject matter of the *mahākāvya* itself is taken from the epic, which is not, however, followed slavishly. Most *mahākāvya*s display such set pieces as descriptions of cities, oceans, mountains, the seasons, the rising of the sun and moon, games, festivals, weddings, embassies, councils, war, and triumph. It is typical of the genre that, while each strophe, or stanza, is intended to be part of a narrative sequence, it more often stands by itself, a discrete unit conveying one idea or developing one image. In this, the tendency of the Rigvedic stanza (see above *Sanskrit: formative period [1200–400 BC]*) continues in the classical literature. Although the lines of the classical stanza are long enough to convey their meaning quite explicitly, it is the pride of the poet to suggest rather than to express. Sometimes this is done by simple collocation of words: for example, in the first line of Kālidāsa's *Meghadūta* a *yakṣa* (a mischievous elf-like creature) is afflicted by a curse, "the more painful because it spelt separation from his beloved"; the next word notes that he had been negligent in his duties; taken together, the two words, though syntactically unrelated, suggest that it was his amour that made him neglect his duties. Another common suggestive device is the double meaning, or play on words. These double meanings often add a certain graceful playfulness to the poetry, reminding one that the poem was written first of all to give pleasure to the man of taste.

Traditionally there are six model *mahākāvya*s, three by Kālidāsa and one each by Bhāravi, Māgha, and Śriharṣa, to which sometimes the *Bhaṭṭikāvya* is added.

The works
of Kālidāsa

Nothing is known with certainty of the life of Kālidāsa, the greatest of Sanskrit poets, but there is substantial agreement that at one time he lived in Ujjayinī (Ujjain, in the present state of Madhya Pradesh), the capital of Avanti and an important centre of Sanskrit culture in a commercially busy area. His name, which means Servitor of Kālī, indicates that he was a follower of that goddess, whom he was to celebrate as Pārvatī, the daughter of the mountain, in the *Kumārasaṃbhava.* Probably he lived during the reign of Candra Gupta II Vikramāditya (*c.* 380–*c.* 415), and there are reports that he died, by the hand of an envious courtesan, while a guest of King Kumāradāsa of Ceylon.

Compared with those of others, Kālidāsa's style might be called simple, but it is a very studied, very felicitous simplicity, hiding the actual complexity of his constructions. In two of his *mahākāvya*s, Kālidāsa draws on epic lore. The first, and probably earlier one, is the *Kumārasaṃbhava* ("Birth of the War God"), which describes the courting of the ascetic Śiva, who is meditating in the mountains, by Pārvatī, the daughter of the Himalayas; the destruction of the god of love (after his arrow has struck Śiva) by the fire from Śiva's third eye; and the wedding and lovemaking of Śiva and Pārvatī, which results in the conception of the war god. The original is in eight cantos, but a sequel was added by an imitator. The second *mahākāvya,* the *Raghuvaṃśa* ("Dynasty of Raghu"), deals with themes from the *Rāmāyaṇa:* it describes the vicissitudes of the Solar dynasty of the ancient Indian barons, culminating in the *Rāmāyaṇa* story of Rāma and Sītā. The *Raghuvaṃśa* is famous for its beautiful descriptions and incidental narratives, which give the poem a somewhat episodic character; among them are a description of the six seasons (spring, summer, rainy, autumn, winter, and dewy) and the story of a young hermit who went to the river to fill a water jar for his parents and was killed by a stray arrow.

Unique in Sanskrit love poetry is Kālidāsa's *Meghadūta,* in which the poet tries to go beyond the strophic unity of the short lyric (see below), which normally characterizes love poems, by stringing the stanzas into a narrative. This innovation did not take hold, though the poem inspired imitations along precisely the same story line. The *Meghadūta* is the lament of an exiled *yakṣa* who is pining for his beloved on a lonely mountain peak. When, at the beginning of the monsoon, a cloud perches on the peak, he asks it to deliver a message to his love in the Himalayan city of Alakā. Most of the poem, composed in an extremely graceful metre, consists of a description of the landmarks, cities, and the like on the cloud's route to Alakā. It must be considered among the finest poems, if not the finest poem, written in Sanskrit. Kālidāsa also wrote for the theatre (see below) and was no doubt the most versatile author of Sanskrit literature; his works became well-nigh canonical models.

Bhāravi (6th century) probably hailed from the south during the reign of the Pallava dynasty. He took up a *Mahābhārata* theme in his *Kirātārjunīya* ("Arjuna and the Mountain Man"), recounting the Pāṇḍava prince Arjuna's encounter and ensuing combat with a wild mountaineer who in the end proves to be the god Śiva. Bhāravi's language and style are more difficult than Kālidāsa's, but the poem is highly regarded in Indian literary tradition.

Māgha, who wrote in the 8th century, was a conscious rival of Bhāravi, whom he attempted to surpass in every respect. His *Śiśupālavadha* ("The Slaying of King Śiśupāla") is based on an episode of the *Mahābhārata* in which the rival King Śiśupāla insults the hero-god Krishna, who beheads him in the ensuing duel. Māgha is a master of technique in the strict Sanskrit sense of luscious descriptions; intricate syntax; compounds that, depending on how they are split, deliver quite different meanings; and the full register of stylistic embellishments.

To some critics, the preoccupation with technique, the triumph of form over substance, appears to have spelled the doom of the *mahākāvya.* A curious but entirely Sanskritic phenomenon, for example, is the *Bhaṭṭikāvya,* a poem by Bhaṭṭi (probably 6th or 7th century). It again deals with the story of Rāma and Sītā, but at the same time it illustrates in stanza after stanza, in exactly the proper sequence, the principal rules of Sanskrit grammar and poetics. Less artificial is the *Naiṣadhacarita* ("The Life of Nala, King of Niṣadha"), written by the 12th-century poet Śrīharṣa and based on the story of Nala and Damayantī in the *Mahābhārata.* An example of another kind of excess indulged in by *mahākāvya* writers is the *Rāmacarita* ("Deeds of Rāma"), by the 12th-century poet Sandhyākāra, which celebrates simultaneously the hero-god Rāma and the poet's own king, Rāmapāla of Bengal. Many other works were written in this style, and, even today, one may encounter a *mahākāvya* treatment of a great man such as Mahatma Gandhi or Jawaharlal Nehru.

Jayadeva's *Gītagovinda*

Difficult to classify is the work of the 12th-century Bengal poet Jayadeva, who wrote the *Gītagovinda* ("Cowherd Song"). The basic structure of this long poem, in which the poet recounts the youthful loves of the cowherd hero and god Krishna, largely based on the story of the *Bhāgavata-Purāṇa,* is that of the *mahākāvya.* Generously interspersed between cantos, however, are erotic-religious lyrics of extremely musical assonances, which were, and still are, sung. Jayadeva's work, rather lacking in the grammatical rigidity of the other *mahākāvya* writers, has been extremely popular and affords a fine example of the devotional lyric (see below).

The short lyric. It is in the short, one-stanza lyric that Sanskrit poetry is revealed most intimately in its real aims. As noted, almost all of high Sanskrit poetry is strophic in fact; in the lyric it is so in intention. It is eminently a genre of the poetic moment, making an aesthetic observation and placing it within the Sanskritic universe of discourse. It may be an observation of anything: a fish glintingly jumping from a pond, aboriginal tribesmen engaged in a bloody rite, love in all its manifestations, a glimpse of God perceived or remembered. But in the monumental lyric collections that have been preserved, and in the many stray verses still circulating among educated Hindus in India as so-called *subhāṣita*s ("well-turned" couplets), the more common topics are praise of the god of one's devotion and the vagaries of love.

In the short lyric it is hard to make a distinction that depends on the language in which it is composed; for, although the language may be different, the subject matter and forms are the same. Many love lyrics, especially when they describe feelings experienced by women, are composed not in Sanskrit but, instead, in one of the Prākrits, or Middle Indo-Aryan languages, among which the dialect called Māhārāṣṭrī is particularly popular. The collection of 700 poems in this language, compiled by Hāla under the name of *Sattasaī* ("The Seven Hundred"), tends to be simpler in imagery and in the emotion portrayed than their Sanskrit counterparts, but essential differences are difficult to pinpoint.

The devotional lyric, a short verse expressing the author's devotion to a god, is linked with both the hymnal poetry of the Rigveda—though far less determined by a desire for compelling magic—and the temple worship of Hinduism. Though by no means always, there is often a particularism about them: the deity is invoked as it appears in a specific iconic stance or in a local temple or in a manifestation especially pleasing to the poet. The number of such verses is countless; every major religious and philosophic leader is held to have added to their stock. Some are especially famous: the *Sūryāṣṭaka* ("Eight Strophes for the Sun"), by Mayūra; the collections attributed to the philosopher Śaṅkara, the *Saundaryalaharī* ("The Wavy River of the Beautiful Sky"); and the *Kṛṣṇakarṇāmṛta* ("The Elixir of Hearing of Krishna"), by Bilvamaṅgala, among others. These *stotra* ("lyrics of praise") quite often were set to music, and people continue to sing them today—without necessarily comprehending the full intention of the Sanskrit, much as hymns in Latin were traditionally sung by Roman Catholic believers.

The love lyric

The entire erotic experience, from budding love to the aftermath of consummation, is represented brilliantly in lyric poetry. But among the many themes inspired by love, poets have been most attracted to the lament of separated lovers. It is mostly the sufferings of the woman that are portrayed, but the grief of the man is also depicted—in Kālidāsa's *Meghadūta,* for example. The love lyrics consist of single verses, many of which seek to suggest the mood of *śṛṅgāra* (physical love). While often extremely erotic, they are very rarely obscene. Sanskrit norm banned all coarse expressions for sexual play; and, although much probably escapes the modern reader, blunt allusions to genital organs are rare and, where allusions occur, extremely veiled. Bodily parts with less overt sexual connotations, such as breasts and buttocks, are frankly mentioned and described—in fact, celebrated. In allusions to sexual intercourse the terminology of the *Kāmasūtra* of Vātsyāyana is frequently invoked, as though this ancient textbook of Indian erudition was a protection against possible opprobrium—not unlike Latin terms resorted to in the West for actions that most know by shorter, more colloquial names.

The erotic and the devotional lyric merge freely, and at times it is impossible to make out whether the free sexual imagery employed is to be taken literally or as an allegory of the human soul courting the love of its god. The task—not a very pressing one—is made more difficult by the fact that some *bhakti* (devotion) religions have developed the poetics of love poetry into a kind of theology, a phenomenon quite characteristic of Bengal Krishnaism (see below *Indo-Aryan literatures: 12th–18th century*).

Authors of *subhāṣita*s often collected them themselves, the favourite form being that of the *śataka* ("century" of verses), in which 100 short lyrics on a common theme were strung together. Mention has been made of Hāla's *Sattasaī* ("The Seven Hundred," consisting of lyrics in the Māhārāṣṭrī dialect). Four well-known Sanskrit collections, of the 7th century, are the famous "century" of Amaru, king of Kashmir, and the three "centuries" by the poet

Bhartṛhari; one of the latter's collections is devoted to love, another to worldly wisdom—a very popular theme in epigrammatic verse—and the third to dispassion. Of the same type but in a different vein is *Caurapañcāśikā* ("Fifty Poems on Secret Love"), in which the 12th-century poet Bilhaṇa fondly recalls the pleasure of his clandestine amours with a local princess.

The theatre. Of all the literary arts, the Indians esteemed the play most highly, and it is in this form that most of the other arts were wedded together. Its origins are obscure, but there is reason to assume that the play developed out of recitations of well-known epic stories by professional reciters. It is an extremely rich genre with a number of outstanding playwrights.

The style is extremely varied. Although it might be called a Sanskrit play, Sanskrit is by no means the only language used, for the less educated characters, including all women, speak Prākrits of different degrees of niceness. The action is carried by prose, but at the least provocation—indeed, at any of the poetic moments characteristic of the strophic lyric—the author reverts to verse, sometimes in mid-sentence. Two principal types of play are distinguished: the *nāṭaka,* which is based on epic material, and the *prakaraṇa,* which is of the author's invention, though often borrowed from narrative literature.

pes of
·ama

Characteristic of the Sanskrit theatre are elements of sacrality. The play begins and ends with a benediction, many of which consist of subject matter taken from sacred texts. It is also expressed in numerous taboos: the play must have a happy outcome in which harmony, interrupted by the drama of the play, is restored; improper scenes, such as eating, dressing and undressing, and sexual intercourse, are not to be portrayed; no violence among the higher characters is permitted; war, which often occurs, should simply be reported on, often by lower characters, not in any way staged.

Fragments of Buddhist plays prior to the flowering of Hindu theatre have survived, but no complete plays earlier than 13 ascribed to the playwright Bhāsa. There is considerable controversy over the authenticity of the Bhāsa plays, but at least some of them must be authentic, perhaps dating back to the 3rd century. The plays are based on the epic and on the *Bṛhat-kathā* narrative cycle (see below); among the latter, the *Svapnavāsavadattā* ("The Dream of Vāsavadattā") is the most famous. Of considerable interest also is the *Daridra-Cārudatta* ("The Poverty of Cārudatta"), which became the basis for the play *Mṛcchakaṭika* ("Little Clay Cart") of Śūdraka (see below).

It must be assumed that there was an efflorescence of poetry and theatre in the city of Ujjayinī, one of the capitals of the Gupta Empire, in the 5th century, for a number of authors can be placed there during this reign; among these were Viśākhadatta, Śūdraka, Śyāmilaka, the writer of one of the best farces, and Kālidāsa, who at the beginning of the development of the genre produced some of the greatest plays in the tradition.

ılidāsa's
ıys

Three plays by Kālidāsa remain, one of which is the *Mālavikāgnimitra* ("Agnimitra and Mālavikā"), a harem play of amorous intrigue at a royal court. The other two are based on old themes. *Vikramorvaśī* ("Urvaśī Won by Valour") is based on a story as old as the Rigveda, that of the nymph Urvaśī, who is loved by King Purūravas, whom she marries on the condition that she shall never see him nude. The accident happens, and the nymph returns to heaven, leaving her husband crazed with longing, until a final reunion. But the Indian tradition holds the *Abhijñānaśakuntalā* ("Śakuntalā and the Token of Recognition") to be the greatest of all Sanskrit plays. It recounts a *Mahābhārata* story—rather freely to be sure—of a hermit girl secretly married to a visiting king, who leaves with her a keepsake that will serve her as a token of recognition. She gives birth to a son, Bharata, and goes to the King's court; on the way she loses the ring in a river, where a fish swallows it. The King fails to recognize her and rejects her, and her mother, a nymph, carries her to heaven. When the ring is recovered by a fisherman and the King's memory is restored, he searches for Śakuntalā but does not find her. In the end he meets a boy who proves to be his son and is restored to him.

Kālidāsa's great forte is the portrayal of emotions—ordinary enough in themselves (budding love, love consummated, rejection, despair, a father's love for his son)—but Kālidāsa applies to them a mastery of expression and image that makes the play a work of perennial beauty.

Next to nothing is known of Śūdraka except that he must have hailed from Ujjayinī. His is the most charming of all *prakaraṇa* plays (those that are not based on epic material): the *Mṛcchakaṭikā* ("Little Clay Cart"), the story of an impoverished merchant and a courtesan who love each other but are thwarted by a powerful rival who tries to kill the woman and place the blame on the hero, Cārudatta. The play offers a fascinating view of the different layers of urban society. Viśākhadatta, the author of a rare semihistorical play called *Mudrārākṣasa* ("Minister Rākṣasa and his Signet Ring"), apparently was a courtier at the Gupta court. His play is a dramatization of the Machiavellian political principles expounded in the book *Arthaśāstra,* by Kauṭilya, who appears as the hero of the play.

To the 7th-century king Harṣa of Kanauj are attributed three charming plays: *Ratnāvalī* and *Priyadarśikā,* both of which are of the harem type; and *Nāgānanda* ("The Joy of the Serpents"), inspired by Buddhism and illustrating the generosity of the snake deity Jīmūtavāhana.

The
plays of
Bhavabhūti

Ranked by Indian tradition close to Kālidāsa himself, Bhavabhūti (early 8th century) was the author of three plays, two of which are based on the *Rāmāyaṇa* story. The *Mahāvīracarita* ("The Exploits of the Great Hero") treats of Rāma's battle with Rāvaṇa and the *Uttararāmacarita* ("The Later Deeds of Rāma") treats of the life of Rāma after he has abandoned Sītā. Bhavabhūti lacks the elegance and grace of Kālidāsa but is more pensive—even brooding—than his predecessor. His style is also very forceful. His *prakaraṇa Mālatī-Mādhava* ("Mālatī and Mādhava") is a complex love intrigue intermingled with sorcery and Tantric practices, including a human sacrifice and much violence.

This list by no means concludes that of the playwrights in the Sanskrit tradition. The writing of plays, mostly derivative from the great models, has continued until the present day.

Apart from the more seriously intended plays described above, the Sanskrit theatre also has a rich repertory of farces, which are usually in one act. Most interesting of these are the *bhāṇa*s, which may be monologues in which an actor addresses imaginary persons and is answered by them, as he paints a picture of town life full of personal and social satire. Among the best in this little-studied genre is Śyāmilaka's 5th-century *Pādataḍitaka* ("The Courtesan's Kick").

Narrative literature. Sanskrit narrative literature is extremely rich, so rich in fact that at one time it was believed that all folktales originally came from India. Many indeed have, and they have found a place in *The Arabian Nights' Entertainment,* Boccaccio's *Decameron,* and other such works down to the fairy tales of Hans Christian Andersen and the fables of Jean de La Fontaine. Certain collections of animal tales, some of which go back to the Buddhist *Jātaka* stories, had incredible histories. The most famous is the *Pañca-tantra* ("The Five Chapters"), which, within a framework of a lesson in the art of politics addressed to young princes, presents a number of animal characters who in their actions both admonish and exhort the reader to a life certain to lead to worldly success. A shorter version, partly drawn from the *Pañca-tantra,* is the *Hitopadeśa* ("Good Advice"). The *Pañca-tantra* found its way to the West through translations into Persian, Arabic, Syrian, Hebrew, and Latin, until most of the medieval literatures possessed their own versions of it. No less extensive were its migrations to Southeast and East Asia.

The *Pañca-*
tantra

The principal work of the novelistic and picaresque tale is the *Bṛhat-kathā* ("Great Story") of Guṇāḍhya, written in Prākrit and now lost, save for Sanskrit retellings. The most important among these Sanskrit versions is the *Kathāsaritsāgara* ("Ocean of Rivers of Stories") of Somadeva (11th century), which includes so many subsidiary tales that the main story line is frequently lost. Perhaps more faithful to the original—in any case far less distracting—is the *Bṛhatkathāślokasaṃgraha* ("Summary in Verse of the

Great Story"), by Budhasvāmin (probably 7th century), one of the most charming of Sanskrit texts. Other collections of tales include the *Vetāla-pañcaviṃśatikā* ("Twenty-five Tales of a Ghost"), *Śūkasaptati* ("The Seventy Stories of a Parrot"), and the *Siṃhāsana-dvātrim-sātikā* ("Thirty-two Stories of a Royal Throne").

Related to the *Bṛhat-kathā* cycle, though the exact relationship is unclear, is the Jain Prākrit text of the *Vāsudevahiṇḍī,* "The Roamings of Vāsudeva" (before 6th century), describing the acquisition of numerous wives by Krishna Vāsudeva.

Though the tales are often artless, sometimes they are elaborately embroidered in the Sanskrit *kāvya* style. A fine example is the *Daśakumāracarita* ("Tales of Ten Princes"), by Daṇḍin (6th/7th century), in which, within the framework of a boxing story, the picaresque adventures of 10 disinherited princes are described in prose. While tending overly to description, the work remains eminently readable for the modern reader, a quality that cannot be attributed to the prose novels of the 7th-century writer Bāṇa: the *Harṣacarita,* "The Life of Harṣa" (king of Kanauj and the author of three plays, discussed above), which is important for its information on culture and society; and the *Kādambarī* (the name of the heroine), which describes the affairs of two sets of lovers through a series of incarnations, in which they are constantly harassed by a cruel fate. (J.A.B.v.B.)

DRAVIDIAN LITERATURE: 1ST–19TH CENTURY

Of the four literary Dravidian languages, Tamil has been recorded earliest, followed by Kannada, Telugu, and Malayalam. Tamil literature has a classical tradition of its own, while the literatures of the other languages have been influenced by Sanskrit models.

Early Tamil literature (1st–10th century). *Caṅkam literature.* Early classical Tamil literature is represented by eight anthologies of lyrics, 10 long poems, and a grammar called the *Tolkāppiyam* ("Old Composition"). According to a fanciful Tamil tradition, this literature was produced by poets of three "academies," or *caṅkams,* that in the hoary past were centred in the southern Indian city of Madurai and supposedly lasted 4,400, 3,700, and 1,850 years, respectively. The *Tolkāppiyam* was ascribed to the second *caṅkam,* the eight anthologies and 10 long poems to the third; according to tradition, nothing is extant from the first *caṅkam.* The early literature, itself known as *caṅkam,* comprises 2,381 poems, ranging from four to nearly 800 lines each and assigned to 473 poets who are known by name or epithet; about 100 poems are anonymous. Though the literature does not go back as far as native tradition would have it, it is generally ascribed to the first three centuries of the Christian Era and represents the oldest non-Sanskrit literature to be found on the South Asian subcontinent.

The eight anthologies and their contents, excluding opening invocations that were added later, are as follows: *akam* anthologies consisting of (1) *Kuṟuntokai,* 400 love poems, (2) *Naṟṟiṇai,* 400 love poems, (3) *Akanāṉūṟu,* 400 love poems, (4) *Aiṅkuṟunūṟu,* 500 love poems, each 100 (assigned to a different poet) dealing with one of five phases of love, (5) *Kalittokai,* 150 love poems in a metre called *kali;* and *puṟam* anthologies consisting of (6) *Puṟanāṉūṟu,* 400 poems, (7) *Patiṟṟuppattu* ("The Ten Tens"), 100 poems on kings (the first and last decades are missing), and (8) *Paripāṭal,* a collection of 70 religious poems. *Paripāṭal* and *Kalittokai* appear to be the latest of the anthologies; *Kuṟuntokai* and *Puṟanāṉūṟu* probably contain the earliest compositions. The remarkable work of grammar and rhetoric, *Tolkāppiyam,* is the crucial text for an understanding of early Tamil language and literature. Divided into three sections (each consisting of *cūttirams*, or aphorisms)—sounds, words, and meaning—the *Tolkāppiyam* details, in the third, the canons of *caṅkam* poetic traditions.

Characteristics of *caṅkam* poetry

In the *Tolkāppiyam* and the anthologies, poems are classified by theme into *akam* ("interior") and *puṟam* ("exterior"), the former highly structured love poems, the latter heroic poems on war, death, personal virtues, the ferocity and glory of kings, and the poverty of poets. Both the *akam* and the *puṟam* had well-defined *tiṇai*s (genres) that paralleled one another: *e.g.,* the *kuṟiñci* genre, in love poetry, which dealt with the lovers' clandestine union on a hillside by night; and the *veṭci* genre, in heroic poetry, which dealt with the first onset of war, by nocturnal cattle stealing. Both *kuṟiñci* and *veṭci* are names of flowers that grow on the hillside, here symbolic of the poetic genre, the mood, and the theme. By such pairings across *akam* and *puṟam,* love and war become part of the same universe and metaphors for one another; the same poets—for example, Paraṇar and Kapilar—wrote great poems in both genres. The basic technique depended on a taxonomy of Tamil nature and culture, of culturally defined time, space, nature, and human nature. For example, matched in metaphor with five phases of *akam* love (union; infidelity; anxious waiting; patient waiting; and the lover or lovers eloping or journeying for wealth, knowledge, and so on) are six seasons, six parts (dawn, forenoon, noon, afternoon, evening, and night) of the day, and five landscapes (hill, seashore, forest, pasture, and wasteland, named after characteristic flowers—*kuṟiñci, neytal, mullai,* and *marutam*—and the evergreen tree, *pālai*) and their contents (including gods, foods, birds, beasts, drums, occupations, lutes, musical styles, flowers, and kinds of running or standing water). Each landscape becomes a repertoire of images—anything in it, bird or drum, tribal name or dance, may evoke a specific feeling. A favourite poetic device is *uḷḷuṟai* (*i.e.,* metonymy, a figure of speech consisting of the description of one thing used to evoke that of another with which it is associated). Thus, the natural scene implicitly evokes the human scene; for example, bees making honey out of *kuṟiñci* flowers evokes the lovers' union. Not only is the poet's language Tamil, but the landscapes, the personae, and the appropriate moods and situations formulate the realities of the Tamil world into a code of symbols. For some five or six generations, the *caṅkam* poets spoke this common language of symbols, creating a body of lyrical poetry probably unequalled in passion, maturity, and delicacy by anything in any Indian literature.

Eighteen Ethical Works. The *Patiṟeṇ-kīṟkkaṇakku* ("Eighteen Ethical Works"), usually dated as post-*caṅkam* (4th–7th centuries), are all affected by Jainism and Buddhism. Of these the *Tirukkuṟaḷ* ("Sacred Couplets"), ascribed to Tiruvaḷḷuvar, is the most celebrated. Its 1,330 hemistichs (half lines of verse) are probably the final distillation of different periods. There are many parallels in the work to the Sanskrit *Kāma-sūtra,* the treatise on erotic love, to *Manu-smṛti,* an ancient treatise on special obligation and religious law, and to *Artha-śāstra,* Kauṭilya's treatise on politics. The *Kuṟaḷ* has three sections: *aṟam,* or virtue (Sanskrit *dharma*); *poruḷ,* government and society (Sanskrit *artha*); and *kāmam,* love (Sanskrit *kāma*). There is no special treatment of *mokṣa,* or salvation, though *aṟam* seems to include it. In the *aṟam* (virtue) section, the *Kuṟaḷ* sums up a world-affirming wisdom, the wisdom of human sympathy, expanding from wife, children, and friends to clan, village, and country. In the *poruḷ* (government and society) section, the aphorisms project a vision of an ideal state, based on educated human nature, and relate the good citizen to the good man. Prostitution, disease, drink, and gambling are listed, with foreign enemies, as dangers to the state. In the *kāmam* (love) section, the *Kuṟaḷ* follows the *caṅkam's* love—eros, or sexual love—yet anticipates agape, the perfecting of love through many lives, which appears in religious poetry of the next age.

Epics. The age of the Pallavas (300?–900), a warrior dynasty of Hindu kings, is known for its epics, beginning with *Cilappatikāram* ("The Jewelled Anklet") and *Maṇimēkalai* ("The Girdle of Gems") and including an incomplete narrative, *Peruṅkatai* ("The Great Story"), the *Cīvakacintāmaṇi* ("The Amulet of Cīvakaṉ") by Tiruttakkatēvar, and *Cūḷāmaṇi* ("The Crest Jewel") by Tōlāmoḻittēvar. The last three works depict Jaina kings and their ideals of the good life, nonviolence, and the attainment of salvation through self-sacrifice. They are also characterized by excellent descriptions of city and country and by a mixture of supernatural and natural elements. In their episodic methods of narration and set descriptions of erotic, heroic, and religious themes, these Jaina epics became both models and sources for later epic works.

'he
'ilappati-
āram

The *Cilappatikāram,* by Iḷaṅkō Aṭikaḷ, is in three books, set in the capitals of the three Tamil kingdoms: Pukār (the Cōḻa capital), Maturai (*i.e.,* Madurai, the Pāṇṭiya [Pāṇḍya] capital), and Vañci (the Cēra capital). The story is not about kings but about Kōvalaṉ, a young Pukār merchant, telling of his marriage to the virtuous Kaṇṇaki, his love for the courtesan Mātavi, and his consequent ruin and exile in Maturai, where he dies, unjustly executed when he tries to sell his wife's anklet to a wicked goldsmith who had stolen the Queen's similar anklet and charged Kōvalaṉ with the theft. Kaṇṇaki, the widow, comes running to the city and shows the King her other anklet, breaks it to prove it is not the Queen's—Kaṇṇaki's contains rubies, and the Queen's contains pearls—and thus proves Kōvalaṉ's innocence. Kaṇṇaki tears off one breast and throws it at the kingdom of Maturai, which goes up in flames. Such is the power of a faithful wife. The third book deals with the Cēra king's victorious expedition to the north to bring Himalayan stone for an image of Kaṇṇaki, now become a goddess of chastity (*pattiṉi*).

The *Cilappatikāram* is a fine synthesis of mood poetry in the ancient Tamil *caṅkam* tradition and the rhetoric of Sanskrit poetry—even the title is a blend of Tamil and Sanskrit—including in the epic frame *akam* lyrics, the dialogues of *Kalittokai* (poems of unrequited or mismatched love), chorus folk song, descriptions of city and village, lovingly technical accounts of dance and music, and strikingly dramatic scenes of love and tragic death. One of the great achievements of Tamil genius, the *Cilappatikāram* is a detailed poetic witness to Tamil culture, its varied religions, town plans and city types, the commingling of Greek, Arab, and Tamil peoples, and the arts of dance and music.

Maṇimēkalai (the heroine's name, "Girdle of Gems"), the second, "twin," epic (the last part of which is missing), by Cātaṉār, continues the story of the *Cilappatikāram;* the heroine is Mātavi's daughter, Maṇimēkalai, a dancer and courtesan like her mother. Maṇimēkalai is torn between her passion for a princely lover and her spiritual yearnings, the first encouraged by her grandmother, the second by her mother. She flees the attentions of the prince, and, while he pursues her, she attains magical powers: she changes forms; survives prison, lecherous villains, and other dangers; converts the Queen; and finally goes to Pukār, which is being destroyed by oceanic erosion, worships Kaṇṇaki, and arrives in Vañcī to work in famine relief and to perform "penance." Unlike the *Cilappatikāram,* the *Maṇimēkalai* is partisan to Buddhism. It is known for its poetry and its lively discussions of religion and philosophy.

Bhakti poetry. From the 6th century onward, a movement with religious origins made itself heard in literature. The movement was that of *bhakti,* or intense personal devotion to the two principal gods of Hinduism, Śiva and Vishnu. The earliest *bhakti* poets were the followers of Śiva, the Nāyaṉārs (Śiva Devotees), whose first representative was the poetess Kāraikkāl Ammaiyār, who called herself a *pēy,* or ghostly minion of Śiva, and sang ecstatically of his dances. Tirumūlar was a mystic and reformer in the so-called Siddhānta (Perfected Man) school of Śaivism, which rejected caste and asceticism, and believed that the body is the true temple of Śiva. There were 12 early Nāyaṉār saints. Similar poets, in the tradition of devotion to the god Vishnu, also belonged to this early period. Called Āḻvārs (Immersed Ones), they had as their first representatives Poykai, Pūtaṉ, and Pēyār, who composed "centuries" (groups of 100) of linked verses (*antāti*), in which the final line of a verse is the beginning line of the next and the final line of the last verse is the beginning of the first, so that a "garland" is formed. To these Āḻvārs, God is the light of lights, lit in the heart.

ıe
āyaṉārs

The most important Nāyaṉārs were Appar and Campantar, in the 7th century, and Cuntarar, in the 8th. Appar, a self-mortifying Jain ascetic before he became a Śaiva saint, sings of his conversion to a religion of love, surprised by the Lord stealing into his heart. After him, the term *tēvāram* ("private worship") came to mean "hymn." Campantar, too, wrote these personal, "bone-melting" songs for the common man. Cuntarar, however, who sees a vision of 63 Tamil saints—rich, poor, male, female, of every caste and trade, unified even with bird and beast in the love of God—epitomizes *bhakti.* To him and other Bhaktas, every act is worship, every word God's name. Unlike the ascetics, they return man to the world of men, bringing hope, joy, and beauty into religion and making worship an act of music. Their songs have become part of temple ritual. Further, in *bhakti,* erotic love (as seen in *akam*) in all its phases became a metaphor for man's love for God, the lover.

In the 9th century, Māṇikkavācakar, in his great, moving collection of hymns in *Tiruvācakam,* sees Śiva as lover, lord, master, and guru; the poet sings richly and intimately of all sensory joys merging in God. Minister and scholar, he had a child's love for God.

Āṇṭāḷ (8th century), a Vaiṣṇava poetess, is literally lovesick for Krishna. Periyāḻvār, her father, sings of Krishna in the aspect of a divine child, originating a new genre of celebrant poetry. Kulacēkarar, a Cēra prince, sings of both Rāma and Krishna, identifying himself with several roles in the holy legends: a *gopī* in love with Krishna or his mother, Devakī, who misses nursing him, or the exiled Rāma's father, Daśaratha. Tiruppāṇāḻvār, an untouchable poet (*pāṇaṉ*), sang 10 songs about the god in Śrīraṅgam, his eyes, mouth, chest, navel, his clothes, and feet. To these Bhaktas, God is not only love but beauty. His creation is his jewel; in separation he longs for union, as man longs for him. Tirumaṅkaiyāḻvār, religious philosopher, probably guru (personal religious teacher and spiritual guide in Hinduism) to the Pallava kings, and poet of more than 1,000 verses, was apparently responsible for the building of many Vaiṣṇava temples. The last of the Āḻvārs, Nammāḻvār (Our Āḻvār), writing in the 9th century, expresses poignantly both the pain and ecstasy of being in love with God, revivifying mythology into revelation.

Period of the Tamil Cōḻa Empire (10th–13th century). The next period, the time of the Tamil Cōḻa Empire (10th–13th centuries), saw an awakening of neighbouring literatures: Kannada, Telugu, and Malayalam. The first extant Kannada work is the 9th-century *Kavirājamārga* ("The Royal Road of Poets"), a work of rhetoric rather indebted to Sanskrit rhetoricians, containing the first descriptions of the Kannada country, people, and dialects, with references to earlier works. From the 10th century on, *campū* narratives (part prose, part verse) became popular both in Kannada and in Telugu, as did renderings of the Sanskrit epics *Rāmāyaṇa* and *Mahābhārata* and Jaina legends and biography.

In Kannada, this period was dominated by the "three gems" of Jaina literature, Pampa, Ponna, and Ranna, as well as by Nāgavarma I, a 10th-century Kannada grammarian. Pampa was the *ādikavi* ("first of poets"), having attained that stature with two great epics: *Vikramārjuna Vijaya* and *Ādipurāṇa.* The former is a rendering of the *Mahābhārata,* with the hero, Arjuna, identified with the poet's royal patron, Arikēsarī. This felicitous epic is known for its succinct, powerful characterizations, its rich descriptions of Kannada country and court, its moving sentiments, and its harmonious blend of Sanskrit and Kannada. While the *Vikramārjuna* is a secular work, Pampa's *Ādipurāṇa* tells the story of the Jaina hero-saint Purudēva, his previous lives, his life from birth to marriage to holy death, as well as the lives of his sons, Bharata and Bāhubali.

Telugu had its *ādikavi* ("first of poets"), in the Brahmin Nannaya Bhaṭṭa (1100–60), who, in *campū* style, wrote three books of a version of the *Mahābhārata,* later finished by Tikkana (13th century) and by Errāpraggaḍa. Like other regional versions of the *Mahābhārata,* the Telugu version is not a literal translation but an interpretation, with many local elements and differences of emphasis; for example, Nannaya emphasizes the importance of Vedic religion. Such works have made the Sanskrit epics and *Purāṇas* part of a live and growing tradition, both oral and literary, in the regional language.

The work
of Kampaṉ

This period also saw the eminence of Kampaṉ's Tamil version of the *Rāmāyaṇa* (12th century). In him there is a climactic blend of earlier *caṅkam* poetry, Tamil epics, the Āḻvārs' fervour of personal *bhakti* (devotion) toward Rāma, folk motifs, and Sanskrit stories, metres, and poetic devices. Instead of a just king and a perfect man, Rāma is an incarnation of Vishnu and an intense object of devotion, dwarfing the Vedic gods; Kampaṉ called his work *Irāmāvatāram* ("Rāma's Incarnation"); yet the emphasis is not on Vishnu but on *dharma* ("the law"), localized and Tamilized. More like Sanskrit than *caṅkam* poets, Kampaṉ revels in elaborate metaphor, hyperbole, and fanciful descriptions of virtue and nature. The work is long, consisting of about 40,000 lines; the *Yuttakāṇṭam* ("War Canto") alone, with 14 battles, equals the *Iliad* in length. The poem is also justly known for its variety of style, its exploitation of the resources of Tamil and Sanskrit both in form and content, its humour, and its handling of the narrative, dramatic, and lyric modes.

Kampaṉ's popularity extended not only into all of Tamil country but apparently into the north, influencing some episodes of Tulsī's Hindi version of the *Rāmāyaṇa,* and into northern Kerala, where 32 plays based on Kampaṉ are enacted ritually with marionettes in Śiva temples.

Pre-15th-century Tamil influence on early Malayalam, the language of Kerala, was strong and led to the literature of *pāṭṭu* ("song"), in which only Dravidian, or Tamil, phonemes may occur and Tamil-like second-syllable rhymes are kept. The best known *pāṭṭu* is *Rāmacaritam* (*c.* 12th–13th century; "Deeds of Rāma"), probably the earliest Malayalam work written in a mixture of Tamil and Malayalam. Other *pāṭṭu*s in Tamilized Malayalam, written by a family of poets (14th–15th centuries) from Niraṇam in central Travancore, appear in *Kaṇṇassan Pāṭṭukaḷ,* in which Tamil conventions of metre and phonology are loosened and more Sanskrit is allowed. Similar in style is a version of the *Rāmāyaṇa* by Rāma Paṇikkar, an abridged *Bhagavadgītā* by his uncle Mādhava Paṇikkar, and a condensed *Mahābhārata* and the 10th book of the *Bhāgavata-Purāṇa* by another uncle, Śaṅkara Paṇikkar.

As strong as Tamil influence was, the predominant influence on Malayalam was Sanskrit, in language as well as literary form. The influence on language led early to a mixture of Sanskrit and Malayalam in a literary dialect called *maṇipravāḷa* (meaning "necklace of diamonds and coral"). The author of the *Līlātilakam,* a 14th-century treatise on grammar and poetics, describes both the Tamilizing and Sanskritizing trends and genres and insists on harmonious blendings. Many kinds of poems were composed in *maṇipravāḷa* styles: *kūḍyāṭṭam*s (dramatic presentations using Sanskrit *śloka*s, or epic metres, for hero and heroine, *maṇipravāḷa* for the clown, and Malayalam for explanations intended for the laity); didactic works such as the 11th-century *Vaiśikatantram* ("Advice to a Courtesan by Her Mother"); 13th- and 14th-century *campūs* (narratives combining prose and verse) on dancers, such as *Unniyati Caritam* by Dāmōdara Cākkiyār; and several short poems in praise of women and kings. *Maṇipravāḷa* poems like these are essentially artifical expressions of courtly high-caste poets, preoccupied with eroticism and harlots. The *Candrōtsavam* (*c.* 1500; "Moon Festival") is a satire on the voluptuary *maṇipravāḷa* tradition, jostling together all the famed courtesans of the period.

Coexisting with the Tamilized and Sanskritized Malayalam poems produced by scholars was a live *pacca* ("pure, fresh") Malayalam tradition represented mostly by folk songs and ballads—for example, *Vaḍukkan Pāṭṭukaḷ* (hero ballads of the northern Malabar Coast); songs sung during weddings, deaths, or festivals; and work songs. All three styles—the indigenous folk style, the Tamil, and the Sanskrit—began to converge and influence each other by the 15th century in works such as *Kṛṣṇa Pāṭṭu* ("Song of Krishna") and *Gāthā* ("Song"). Such grafting reached its full flowering in the 16th-century poet Eḻuttaccan (Father [or Leader] of Letters), who popularized the *kiḷippāṭṭu* ("parrot song"), a genre in which the narrator is a parrot, a bee, a swan, and so on. His outstanding works are *Adhyātma Rāmāyaṇam, Bhāratam,* and *Bhāgavatam,* all based on Sanskrit originals yet powerfully re-created with masterly language craft.

While Vaiṣṇava works were proliferating in Malayalam, Śaiva movements swept the other three languages, Tamil, Kannada, and Telugu. In Tamil, the hymns of the Nāyaṉārs were arranged and anthologized for scriptural and recitative use by the 11th century. Another such consolidation of sacred materials was Cēkkiḻār's 12th-century *Toṇṭar Purāṇam,* or *Periyapurāṇam,* narrating in epic style the lives of the 63 great Śaiva saints and creating a tradition for all Śaivas, even in the Kannada and Telugu areas. The theology of the Siddhānta (Perfected Man) school of Śaivism was elaborated in Meykaṇṭār's *Civañāṉapōtam* (13th century).

The new Kannada genre of the 13th century

By the 12th century, a new Kannada genre, the *vacana* ("saying" or "prose poem"), had come into being with the Vīraśaiva saints. In the language of the people, the saints expressed their radical views on religion and society, rejected both Brahminical ritualism and Jaina ascetic world negation, called all men to the *anubhāva* ("experience") of God, and broke the bonds of caste, creed, and sexual difference. Five important poet-saints were Dāsimayya; Basava, a self-searching social reformer and a minister of the Jaina king Bijjaḷa; Allama Prabhu, the elder and metaphysical master of them all; Mahādēviyakka, a woman saint singing love poems to Śiva; and Cannabasava, a brilliant theologian of the movement, who elaborated the theory of "six stages" of mystic ascent for the devotee. The many-facetted lyrics written by the poet-saints were in the spoken dialects of Middle Kannada, yet they drew on archetypal human images as well as ancient pan-Indian symbology for their intense and searing expressions of *bhakti.* Inspired by these lyrics, Harihara, in the late 12th century, wrote some 120 *ragaḷe* (blank verse) biographies of the Śaiva saints, including the Vīraśaiva (or Liṅgāyat) and the earlier Tamil Nāyaṉārs. In the early 13th century, his disciple and nephew, Rāghavāṅka, wrote, in *ṣaṭpadi*s (six-line stanzas), of the lives of saints, in well-structured works such as *Sōmanātha Carite* and *Siddharāma Caritra;* his most mature work is *Hariścandrakāvya,* an unequalled reworking of an ancient Job-like story of Hariścandra, who suffered every ordeal for his love of truth. The Vīraśaiva saints' lives and the *vacana* ("saying" or "prose poem") literature were codified in a masterpiece called *Śūnya Sampādane* ("The Achievement of Nothing"), consisting of dialogues interweaving the saints' *vacana*s, with the poet Allama Prabhu as the central figure.

Contemporary with the 13th-century Vīraśaiva saints were Telugu Śaiva poets such as Pālkuriki Sōmanātha, who composed the *Basavapurāṇam* employing popular metres and idiomatic Telugu. His *Paṇḍitārādhya Caritra* is a life of the Śaiva devotee Paṇḍitārādhya as well as a book of general knowledge including social customs, arts, crafts, and particularly music. His *Vṛṣādhipa Śatakam* consists of verses in Tamil, Kannada, Marathi, Sanskrit, and Telugu. This work was probably the first of the genre of *śataka*s ("centuries" of verses) literature, particularly popular in Telugu but also written in the other three languages as well as in Sanskrit (see above *Sanskrit: formative period* [*1200–400 BC*]).

Also of the 13th century is Āṇḍayya's *Kabbigara Kāva* ("The Poet's Defender"), in Kannada, a linguistic tour de force, eschewing unmodified Sanskrit forms; and Mallikārjuna's *Sūktisudhārṇava,* an excellent Kannada anthology of lyrics and passages. From 1240 to 1326, poets of Telugu produced over 100 verse renderings of the Sanskrit epic *Rāmāyaṇa* and many more in prose, the earliest being *Raṅganātha Rāmāyaṇa,* assigned to Gōna Buddhā Reḍḍi.

14th–19th century. The next age, from the 14th to the 16th century, is the great age of the Vijayanagar Empire. In this period, Kannada and Telugu were under the aegis of one dynasty and were also hospitable to the influence of neighbouring Muslim Bahmanī kingdoms. Śrīnātha was a 15th-century poet honoured in many courts for his scholarship, poetry, and polemics. He rendered Sanskrit poems and wrote *Haravilāsam* (Four Śaiva Tales); *Krīḍābhirāmam,* a charming, often vulgar account of social life in Warangal; and *Palanāṭi Vīra Caritra,* a popular ballad on a fratricidal war. Many erotic *cāṭu*s, or stray epigrams, are also attributed to him. Bammera Pōtana, a great Śaiva devotee in life and poetry, unschooled yet a scholar, is widely known for his *Bhāgavatam,* a masterpiece that is said to excel the original Sanskrit *Bhāgavata-Purāṇa.* Tāḷḷapāka Annāmācārya, son of a great family of scholars, fathered an exciting new genre of devotional song, all addressed to the god Śrī Veṅkaṭeśvara of Tirupati (a form of Vishnu). His *Saṅkīrtana Lakṣaṇam* is a collection of 32,000 songs in Sanskrit and Telugu, which made a significant contribution to Karnatic (southern Indian) musical technique.

The 16th century was an age of patronage by Vijayanagar kings, beginning with Kṛṣṇa Dēva Rāya, himself a poet versed in Sanskrit, Kannada, and Telugu. The *rāyala yugam* ("age of kings") was known for its courtly *prabandhas*, virtuoso poetic narratives by and for pandits (learned men). Among the most famous court poets were Piṅgaḷi Sūranna, whose verse novel, *Kalāpurṇōdayam* (1550)—a story full of surprises, magic, and changes of identity—is justly celebrated for its artistry; and Tenāli Rāmakṛṣṇa, known for his clownish pranks and humour, whose writings are the centre of a very popular cycle of tales in all four Dravidian languages.

During the 16th century and for the next few centuries, Telugu poets also flourished outside the Telugu country, especially in Tanjore (Thanjavūr) and Madurai, in Tamil country, and Pudukkoṭṭa and Mysore, in Kannada country. Their most important contribution was to native Kannada and Telugu dance drama on mythological themes, called *yakṣagāna.* The form is comparable to *kathākali* in the Malayalam area and to *terukkūttu* ("street drama") and *kuṟavañci* ("gypsy drama") in the Tamil area. The earliest Telugu *yakṣagāna* text is *Sugrīva Vijayam* (*c.* 1570), by Kandukuru Rudra Kavi; the earliest in Kannada is probably Śāntavīra Dēśika's *Saundarēśvara* (1678). The most celebrated of Kannada *yakṣagāna* dramatists is the versatile Pārti Subba, who flourished around 1800 and is known for his moving *Rāmāyaṇa* episodes and songs.

The 15th and 16th centuries produced some of the most popular classics in Kannada. Of these the greatest is Gadugu's *Kumāra Vyāsa,* or *Nāraṇappa*'s, 10 cantos of the *Mahābhārata;* recited in assemblies as well as in households, these are a continual delight, abounding in humour, passion, and memorable poetry. In *Prabhuliṅgalīle,* Cāmarasa made poetry out of the life of the poet-saint Allama. The *Jaimini Bhārata* and the many versions of *Rāmāyaṇa* episodes (especially Sītā's abandonment in the forest) written by the distinguished Śaiva epic poet Lakṣmīśa are known for their melodious verses and moving scenes. Ratnākaravarṇi's *Bharateśa Vaibhava* is a great Jaina story, tersely told in a Kannada song metre and celebrated for its depiction of many *rasas* ("moods"), especially the erotic.

Kannada Vaiṣṇava *dāsa*s ("servants [of God]") wrote in a song genre called *pada,* parallel and often indebted to the Vīraśaiva *vacana*s ("sayings" or "prose poems"). Purandaradāsa, a rich 16th-century merchant turned mendicant, saint, and poet, composed *bhakti* (devotional) songs on Viṭṭhala (a manifestation of the god Vishnu), criticizing divisions of caste and class and calling on the mercy of God. His *pada*s and *kīrtanas* ("lauds") are also landmarks in Karnatic music. Karnatic music. Kanakadāsa, his contemporary and a shepherd by birth, wrote *pada*s and longer popular works. *Dāsa* songs are part of the repertory of all South Indian musicians.

The folk *tripadi* ("three-line verse") of Sarvajña (1700?) is a household word for wit and wisdom, like the *Kuṟaḷ* in Tamil (see above *Eighteen Ethical Works*) and the "century" of four-line verses in Telugu by Vēmana (15th century). The moral, social, satiric, and wise proverb-like aphorisms of Vēmana and Sarvajña are widely quoted by pundit and layman alike. Equally popular in the Malayalam region is the 18th-century folk poet of *tuḷḷal*s (a song-dance form), Kuñcan Nampiyār, unparalleled for his wit and exuberance, his satiric sketches of caste types, his versions of Sanskrit *Purāṇa* narratives projected on the backdrop of Kerala, and his humorous renderings even of mythic characters.

The 17th and 18th centuries also saw Tamil court poetry—*Purāṇas,* translations from the Sanskrit, and praise poems, known more for their learning and imitative character than for their genius. This was also a period of many schisms and the founding of monasteries in Śaivism and Vaiṣṇavism, which led to many sectarian and polemic works. Muslims and Christians also wrote epics in the Hindu *Purāṇa* style; for example, Umaṟu-p-pulavar's 17th-century *Cīṟā-p-purāṇam,* on the life of the prophet Muḥammad, and Father Beschi's *Tēmpāvaṇi,* on the life of St. Joseph, with echoes from both Kampaṉ and the 16th-century Italian poet Torquato Tasso.

Probably the most impressive Tamil poetry of this period is that of Arunakiriv's learned and melodious *Tiruppukaḻ* (praise of Munikaṉ) and of the Cittars, eclectic mystics known for their radical, fierce folk songs and common-speech style. Tāyumāṉavar (18th century) and Paṭṭiṉattār (and later, in the 19th century, Rāmaliṅkar) are poets of unconditioned love, self-search, and rejection of corrupt society.

The 17th and 18th centuries are also periods of datable folk expression, which include many *tiruviḷaiyāṭal* ("stories of God's sport") *purāṇas;* temple tales (about miracles that took place in the temple); *kuṟavañci* (*i.e.,* "gypsy," a kind of musical dance drama); *paḷḷu*s (plays about village agricultural life); realistic *noṇṭi-nāṭakam*s ("dramas of the lame"), in which a Hindu temple god cures lameness; *kummi* songs sung by young girls, clapping as they dance round and round; and *ammāṉai* ballads. Noteworthy historical ballads are *Kaṭṭa Pommaṉ,* about a chieftain who revolted against the British, and *Tēciṅku-rācaṉ Katai,* about the prince of Gingi and his Muslim friend. Malayalam *āṭṭakkatha,* the literature associated with *kathākali,* the complex traditional dance drama, was also written during this period. Royal poets such as Kōṭṭayattu Tampurān, in the 17th century, and Kārttika Tiruṇal, in the 18th, wrote *āṭṭakkathās.* (A.K.R.)

INDO-ARYAN LITERATURES: 12TH–18TH CENTURY

It is difficult to pinpoint the time when the Indo-Aryan dialects first became identifiable as languages. Around the 10th century AD, Sanskrit was still the language of high culture and serious literature, as well as the language of ritual. The spoken language, however, had continued to develop, and at the turn of the millennium there began to appear, at different times during the subsequent two or three centuries, the languages now known as the regional languages of the subcontinent: Hindi, Bengali, Kashmiri, Punjabi, Rajasthani, Marathi, Gujarati, Oriya, Sindhi (which did not develop an appreciable literature), and Assamese; Urdu did not develop until much later (see below *Islāmic literatures: 11th–19th century*).

Regional
languages

The literatures in their early stages show three characteristics: first, a debt to Sanskrit that can be seen in their use of Sanskrit lexicon and imagery, in their use of myth and story preserved in that refined language, and frequently in their conformity to ideals and values put forward in Sanskrit texts of poetics and philosophy; second, a less obvious debt to their immediate Apabhraṃśa past (dialects that are immediate predecessors of the modern Indo-Aryan vernaculars); third, regional peculiarities.

The narratives in the early stages of the development of the languages are most often mythological tales drawn from the epics and *Purāṇas* of classical Hindu tradition (see above *Sanskrit, Pāli, and Prākrit literatures: 1400 BC–AD 1200*), though in later times, in the 17th and 18th centuries, secular romances and heroic tales were also treated in narrative poems. Although the themes of the narratives are based on *Purāṇa* tales, often they include materials peculiar to the area in which the narrative was written.

In addition to themes, regional literatures frequently borrowed forms from the Sanskrit; for example, the *Rāmāyaṇa* appears in a 16th-century Hindi version by Tulsīdās, called the *Rāmcaritmānas* ("Lake of Rāma's Deeds"), which has the same form, though a different emphasis, as the Sanskrit poem. The stylized conventions and imagery of Sanskrit court poetry also appear, though here, too, with different emphasis; for example, in the work of the 15th-century Maithili (Eastern Hindi) lyric poet Vidyāpati. Even the somewhat abstruse rhetorical speculations of the Sanskritic poetic schools of analysis were used as formulas for the production of 17th-century Hindi court poetry; the

Rasikapriyā ("Beloved of the Connoisseur") of Keśavadāsa is a good example of this kind of tour de force.

There are other characteristics common to the regional literatures, some of which come not from Sanskrit but most likely from the Apabhraṃśa. There are two poetic forms, for example, that are found in many northern Indian languages: the *bārah-māsā* ("twelve months"), in which 12 beauties of a girl or 12 attributes of a deity might be extolled by relating them to the characteristics of each month of the year; and the *caütīs* ("thirty-four"), in which the 34 consonants of the northern Indian Devanāgarī alphabet are used as the initial letters of a poem of 34 lines or stanzas, describing 34 joys of love, 34 attributes, and so on.

Finally, there are common characteristics that may have come either through Apabhraṃśa or through the transmission of stories and texts from one language to another. The stories of Gopi-candra, the cult hero of the Nātha Yogī sect, a school of mendicant *sannyāsin*s, were known from Bengal to the Punjab even in the early period. And the story of the Rājput heroine Padmāvatī, originally a romance, was beautifully recorded, with a Ṣūfī (mystic) twist, by the 16th-century Muslim Hindi poet Malik Muḥammad Jāyasī and later by the 17th-century Bengali Muslim poet Ālāol. From the late 13th through the 17th century, bhakti (devotional) poetry took hold in one region after another in northern and eastern India. Beginning with the *Jñāneśvarī*, a Marathi verse commentary on the *Bhagavadgītā* written by Jñāneśvara (Jñānadeva) in the late 13th century, the devotional movement spread through Mahārāshtra, in the works of the poet-saints Nāmdev and Tukārām; through Rājasthān, where it is represented by the works of Mīrā Bāī; through northern India, in the poetry of Tulsīdās, Sūrdās, Kabīr, and others; through Mithilā, in the work of the great poet Vidyāpati; and into Bengal, where Caṇḍīdās and others sang of their love of God. Because of the *bhakti* movement, beautiful lyric poetry and passionate devotional song were created; and in some cases, as in Bengal, serious philosophical works and biographies were written for the first time in a regional language rather than in Sanskrit. The languages and their literatures gained strength as mediums of self-expression as well as exposition. And, although there is much Sanskrit imagery and expression in the poetry and song, as well as similarities to Sanskrit textual models, its basic character is not Sanskritic: true to the nature of any spoken, everyday language, it is more vital than polished, more vivid than refined.

Spread of *bhakti* poetry

One more historical generality can be stated regarding regional Indian literature before considering the characteristics peculiar to the several "Indian literatures." In all of the early literatures, writing was lyrical, narrative, or didactic, entirely in verse, and all in some way related to religion or love or both. In the 16th century, prose texts, such as the Assamese histories known as the *buranji* texts, began to appear.

Hindi. What is commonly spoken of as Hindu is actually a range of languages, from Maithili in the east to Rajasthani in the west. The first major work in Hindi is the 12th-century epic poem *Pṛthvīrāj Rāsau,* by Chand Bardaī of Lahore, which recounts the feats of Pṛthvīrāj, the last Hindu king of Delhi before the Islāmic invasions. The work evolved from the bardic tradition maintained at the courts of the Rājputs. Noteworthy also is the poetry of the Persian poet Amīr Khosrow, who wrote in the Awadhi dialect. Most of the literature in Hindi is religious in inspiration; in the late 15th and early 16th centuries, the reform-minded Kabīr, for example, wrote sturdy short poems in which he sought to reconcile Islām and Hinduism.

The most celebrated author in Hindi is Tulsīdās of Rājāpur (died 1623), a Brahmin who renounced the world early in life and spent his days in Benares (Vārānasi) as a religious devotee. He wrote much, mostly in Awadhi, and focussed Hinduism on the worship of Rāma. His most important work is the *Rāmcaritmānas* ("Sacred Lake of the Acts of Rāma"), which is based on the Sanskrit *Rāmāyaṇa.* More than any other work it has become a Hindu sacred text for the Hindi-speaking area and annually has been staged in the popular Rām Līlā festival.

Outstanding among the followers of Vallabha, philosopher and *bhakti* ("devotion") advocate of the Middle Ages, is the blind poet Sūrdās (died 1563), who composed countless *bhajan*s (chants) in praise of Krishna and Rādhā, which are collected in the *Sūrsāgar* ("Ocean of Sūrdās"). While many of the *bhakti* poets were of modest origin, an exception was Mīrā Bāī, a princess of Jodhpur, who wrote her famous lyrics both in Hindi and Gujarati; the quality of her poetry, still very popular, is not as high, however, as that of Sūrdās. Significant also is the religious epic *Padmāvatī* by Jāyasī, a Muslim from former Oudh state. Written in Awadhi (*c.* 1540), the epic is composed according to the conventions of Sanskrit poetics.

The 18th century saw the beginning of a gradual transformation from the older forms of religious lyric and epic to new literary forms influenced by Western models that began to be known. The new trends reached their pinnacle in the work of Prem Chand (died 1936), whose novels (especially *Godān*) and short stories depict common rural life; and in the work of Harishchandra of Benares (died 1885), honoured as Bhāratendu (Moon of India), who wrote in the Braj Bhasa dialect.

Bengali. While developments in Bengali literature began somewhat earlier, they followed the same general course as those in Hindi. The oldest documents are Buddhist didactic texts, called *caryā-pada*s ("lines on proper practice"), which have been dated to the 10th and 11th centuries and are the oldest testimony to literature in any Indo-Aryan language.

Bengali poetry, including poetry by Bengalis in other dialects, is largely written in three distinct genres. It is certain that well before the 15th century there existed texts in a typically Bengali genre called *maṅgal-kāvya* ("poetry of an auspicious happening"), which consists of eulogies of gods and goddesses; such poetry is likely to have had a considerable history in oral transmission before it was committed to writing. A good example of an orally transmitted *maṅgal* poem is the *Caṇḍī-māngal* ("Poem of the Goddess Caṇḍī"), by Mukundarāma, which was put into written form in the latter part of the 15th century. *Maṅgal* poetry remained a favourite genre well into the 18th century, when Bhārat-candra wrote the *Annadā-maṅgal* ("Maṅgal of the Goddess Annadā [the Giver of Food]"), a witty and sophisticated poem that bears little resemblance to its more rustic forebears. Despite this popularity, it is the devotional lyrics to the divine pair Krishna and Rādhā that are still known and sung today in Bengal, and these lyrics are the gems of medieval Bengali literature.

The three genres of Bengali poetry

Poems of the second genre, the *mahākāvya* ("great poem," but not to be confused with the Sanskrit *mahākāvya* genre), are based mainly on the Sanskrit models of the *Mahābhārata, Rāmāyaṇa,* and *Purāṇas.* Kṛttibās Ojhā (late 14th century) stands at the beginning of this literature; he wrote a version of the *Rāmāyaṇa* that often differs from the Sanskrit original, for he includes many local legends and places the setting in Bengal. Kavīndrā (died 1525) wrote on the *Mahābhārata* theme, as did Kāsiram Dās in the 17th century.

The third genre, *padāvalī* ("string of verse") songs, is also found elsewhere; inspired by the religious *bhakti* movement, the songs resemble the devotional poetry of the Nāyaṉārs and Āḻvārs in Tamil. It was such poetry that established Bengali as a significant literary language. The earliest work in what may be considered a distinctively Bengali style is the *Śrīkṛṣṇa-kīrtana* ("Praise of the Lord Krishna"), a long *padāvalī* poem by Caṇḍīdās, which is dated to the early 15th century. In it the poet praises the virtues and celebrates the loves of Krishna, a theme that had remained popular in Bengal ever since its first glorification by the Bengali Sanskrit poet Jayadeva, who composed his *Gītagovinda* ("The Cowherd Song") in the 12th century. *Padāvalī* songs describe and glorify all phases of Krishna's love for the cowherds' wives (especially Rādhā, who later became a goddess), and it is love poetry before it is religious poetry. After the great Bengali mystic and saint Caitanya (died 1533), love *is* religion, and the erotic is inspirited with religious fervour. The great flowering of this poetry occurred in the 16th and 17th centuries.

Religious edification took the forms not only of *maṅgal*s and *padāvalī*s but also of biography (more like hagiography) and philosophy. Important in that style is the long hagiography *Caitanya-caritāmṛta* ("Elixir of the Life of Caitanya"), by the 16th-century author Kṛṣṇadās.

While most of the literature is Hindu in theme and inspiration, there arose a secular Bengali literature among Bengali Muslims. One of the outstanding Muslim poets is Ālāol, author of the *Padmāvatī* (*c.* 1648), which was written after the poem of the same name by the Hindi poet Jāyasī.

Assamese. The earliest text in a language that is incontestably Assamese is the *Prahlāda-caritra* of Mena Sarasvati (13th century); in a heavily Sanskritized style it tells the story, from the *Viṣṇu-Purāṇa,* of how the mythical king Prahlāda's faith and devotion to Vishnu saved him from destruction and restored the moral order. The first great Assamese poet was Kavirāja Mādhava Kandalī (14th century), who translated the Sanskrit *Rāmāyaṇa* and wrote *Devajit,* a narrative on the god Krishna. In Assamese, too, the *bhakti* movement brought with it a great literary upsurge; the most famous Assamese poet of the period was Śaṅkaradeva (died 1568), whose 27 works of poetry and devotion are alive today and who inspired such poets as Mādhava-devi to write lyrics of great beauty. Peculiar to Assamese literature are the *buranji*s, chronicles written in a prose tradition brought to Assam by the Ahoms of Burma. These date in Assamese from the 16th century, while in the Ahom language they are much earlier.

Oriya. *Mādaḷā-pāñji* ("The Drum Chronicle") texts in Oriya, the chronicles of the great temple of Jagannātha in Puri, date from the 12th century. They are in prose, and as such they represent the earliest prose in a regional Indo-Aryan language, although they cannot be said to be literary texts. The 14th century was productive for Oriya literature. Dating from this period are the anonymous *Kalasa-cautīśa,* which tells in 34 verses the story of the marriage of the god Śiva and the mountain goddess Pārvatī, and the famous *Caṇḍī-purāṇa* of Saraladāsa. But the *bhakti* period was once again the most stimulating one; the best known medieval Oriya poet is Jagannātha Dās (whose name means Servant of Jagannātha), a 16th-century disciple of the Bengali Vaiṣṇava saint Caitanya, who spent the better part of his life in Puri. Among the many works of Jagannātha Dās is a version of the Sanskrit *Bhāgavata-Purāṇa* that is still popular in Orissa today.

Marathi. With Bengali, Marathi is the oldest of the regional literatures in Indo-Aryan, dating from about AD 1000. In the 13th century, two Brahminical sects arose, the Mahānubhāva and the Varakari Panth, both of which put forth vast quantities of literature. The latter sect was perhaps the more productive, for it became associated with *bhakti,* when that movement stirred Mahārāshtra in the early 14th century, and particularly with the popular cult of Viṭṭhoba at Pandharpur. It was out of this tradition that the great names of early Marathi literature came: Jñāneśvara, in the 13th century; Nāmdev, his younger contemporary, some of whose devotional songs are included in the holy book of the Sikhs, the *Ādi Granth;* and the 16th-century writer Eknāth, whose most famous work is a Marathi version of the 11th book of the *Bhāgavata-Purāṇa.* Among the *bhakti* poets of Mahārāshtra the most famous is Tukārām, who wrote in the 16th century. A unique contribution of Marathi is the tradition of *povāḍā*s, heroic stories popular among a martial people. There is no way of dating the earliest of these; but the literary tradition is particularly vital at the time of Śivajī, the great military leader of Mahārāshtra (born 1630), who led his armies against the might of the Mughal emperor Aurangzeb.

*povāḍā*s

Gujarati. The oldest examples of Gujarati date from the writings of the 12th-century Jaina scholar and saint Hemacandra. The language had fully developed by the late 12th century. There are works extant from the middle of the 14th century, didactic texts written in prose by Jaina monks; one such is the *Bālāvabodha* ("Instructions to the Young"), by Taruṇa-prabha. A non-Jaina text from the same period is the *Vasanta-vilāsa* ("The Joys of Spring"). The two Gujarati *bhakti* poets, both of the 15th century, are Narasiṃha Mahatā (or Mehtā) and Bhālaṇa (or Puruṣottama Mahārāja); the latter cast the 10th book of the *Bhāgavata-Purāṇa* into short lyrics. By far the most famous of the *bhakti* poets is the woman saint Mīrā Bāī, who lived in the first half of the 16th century. Mīrā, though married, thought of Krishna as her true husband, and the lyrics telling of her relationship with her god and lover are among the warmest and most movingly personal in any Indian literature. One of the best known of the non-*bhakti* Gujarati poets is Premānanda Bhaṭṭa (16th century), who wrote narrative poems based on *Purāṇa*-like tales; although his themes were conventional, his characters were real and vital, and he infused new life into the literature of his language.

Punjabi. Punjabi developed a literature later than most of the other regional languages of the subcontinent; and some of the early writings, such as those of the first Sikh Gurū, Nānak (late 15th and early 16th centuries), are in Old Hindi rather than true Punjabi. The first work identifiable as Punjabi is the *Janam-sākhī,* a 16th-century biography of Gurū Nānak by Bala. In 1604, Arjun, the fifth Gurū of the Sikhs, collected the poems of Nānak and others into what is certainly the most famous book to originate in the Punjab (though its language is not entirely Punjabi), the *Adi Granth* ("First Book"). Writing that is not merely incidentally Punjabi began in the 17th century and is almost entirely by Muslims. Between 1616 and 1666, a writer named ʿAbdullāh, for example, composed a major work called *Bāra Anva* ("Twelve Topics"), which is a treatise on Islām in 9,000 couplets. Muslim Ṣūfīs, such as Bullhē Shāh (died 1758), also contributed many devotional lyrics, and Ṣūfī Islām can be said to have been the main stimulus to Punjabi literature in the medieval period. There are also many romances in the language (as in Rajasthani) which, being oral literature, are undatable.

Kashmiri. The hitherto commonly accepted period of Old Kashmiri is 1200–1500; but in fact the earliest example of the language is found in 94 four-line stanzas embedded in the Sanskrit philosophical work *Mahānaya-prakāśa* ("Illumination of the Highest Attainment"), which some scholars now date as late as the 15th century. As is true for Gujarati, the most famous poets of Kashmiri in this period are women. Lallā (14th century) wrote poems about the god Śiva; and Hubb Khātun (16th century) and especially Arani-mal (18th century) are famous for their hauntingly beautiful love lyrics. Despite these outstanding poets in Kashmiri, the great literary language of Kashmir in the medieval period was Persian, which was encouraged by many rulers of the country, such as Zayn-ul-ʿĀbidīn, in whose 15th-century court were many scholars and poets writing in both the Kashmiri and Persian languages.

(E.C.D.)

ISLĀMIC LITERATURES: 11TH–19TH CENTURY

The adventure of Islām in India began in the 8th century with the conquest of Sind (the extreme western province), but it was only in the 11th and 12th centuries that Muslim literary and cultural traditions reached the Indian heartland. Then, in the 13th century, refugee noblemen, soldiers, and men of letters from Iran and Central Asia came pouring into India. Although the causes changed, the attraction of India as a place of refuge and gracious patronage did not decline for several subsequent centuries. At the same time Muslim soldier-adventurers continued with their conquests, joining hands with their non-Muslim Indian counterparts in many instances, establishing minor or major kingdoms all over the subcontinent. The political map of India remained very much in flux—except for a brief period during the reign of Akbar—until Queen Victoria declared herself empress of India in 1858. The period of Muslim influence thus extends over 800 years.

At the time of the spread of Muslim power and culture in India, Sanskrit was the chief language of Hindu cultural, learned, and religious expression, while Buddhism and Jainism had lent their prestige and patronage to various Prākrits. The progress of and developments in these literatures remained unaffected by the advent of Islām in India. The emergence of the new Indo-Aryan languages out of the Prākrit and Apabhraṃśa stages of Sanskrit, however, was furthered by the newcomers, who preferred these regional languages over Sanskrit and encouraged the development

literatures

of popular regional literatures. The conversion to Islām of a large number of indigenous people enhanced these developments. Thus, the vehicles of literary expression used by those professing Islām in India were regional dialects and languages, both Indo-Aryan and Indo-Iranian, such as Braj, Awadhi, Sindhi, Baluchi, Urdu, Dakhini, and Bengali, as well as the foreign Arabic, Turkish, and Persian spoken by the Muslim immigrants and conquerors. Of these, only Persian and Urdu require detailed consideration; the others will be discussed only briefly.

Arabic. Arabic was the language of the conquerors of Sind. But it enjoyed more permanent prestige as the language of the Qurʾān, the sacred book of Islām; as such it was extensively used for religious scholarship during the medieval period. Even as late as the 18th century, Shāh Walī Allāh, the greatest theologian to have lived in India, wrote his most important treatises in Arabic. Arabic was also used early for historiography and for making Indian scientific books available to the Middle East in translation. One does not find, however, much in the way of significant Arabic belles lettres in India.

Turkish. Although the earliest Muslim conquerors in northern India were Turks, their language was Persian. It was only during the reigns of Bābur and his son Humāyūn (1526–56) that Turkish flourished for a while as a medium of learned expression. Bābur himself was the foremost contributor. Although his memoirs are better known, he also left a volume of verses of considerable merit.

Regional languages. The literatures of the Indo-Iranian languages of Baluchi and Pashto are exclusively creations of Muslim writers. In the Indo-Aryan languages of Kashmiri, Sindhi, and Punjabi, Muslims were the most influential contributors; the names of Lallā (14th century) for Kashmiri, Shāh ʿAbd-ul-Laṭīf (17th–18th century) for Sindhi, and Wāris̄ Shāh (18th century) for Punjabi exemplify that fact. Muslim chieftains gave impetus to the growth of Bengali literature through their patronage of writers and through their efforts to have Sanskrit classics translated into Bengali. There are also many famous Muslim names during the medieval period of Bengali literature, such as Dawlat Qāz̄ī and Ālāol in the 17th century. In the heartland of northern India, notable contributions were made by Muslims to Hindi literatures in the Braj and Awadhi dialects. Malik Muḥammad Jāyasī, Raḥīm, and Manjhan (all 16th century) and ʿUs̄man (17th century) are some of the important names. In the 16th, 17th, and 18th centuries in India there was a tremendous production of mystic (Ṣūfī and *bhakti*) poetry in all of the important dialects and languages. It was a period of great mystic, syncretic movements, and the Muslim contribution in the form of love narratives and lyrics was considerable. Quite often metres, motifs, and assorted rhetorical features of Persian *mas̄navīs* and *ghazals* (see below *Urdu*) were used in a new medium. Moreover, interaction and assimilation took place between the Muslim Ṣūfī traditions, thought, and practices and the Indian *bhakti* schools. Muslim *bhakti* poets either expressed Ṣūfī ideas, which were close to monotheistic orthodoxy as well as to the doctrines of Indian saints Kabīr and Nānak, in the Indian dialects through narrative poems modelled on Persian *mas̄navīs* or chose the path of ecstasy and became devotees of Krishna (which was still close to the more orthodox forms of Ṣūfism). None of them followed the devotional style of Tulsīdās, their contemporary and a devotee of Rāma.

It was, however, in Persian and Urdu that Muslim men of letters made the greatest contributions—contributions that led in the former case to the establishment of an "Indian" school of Persian poetry and influenced profoundly the development of poetry in Afghanistan and Tadzhikistan and, in the latter case, led to the emergence of a unique pan-Indian language and literature in Urdu.

Persian. Maḥmūd of Ghazna, with whom the chain of Muslim conquests in northern India began, was also the patron of Ferdowsī, one of the greatest of Persian poets. The later conquerors admired literature no less. Since the language of all of them was Persian, the growth of Persian literature in India kept pace with its conquest by the Muslims.

Masʿūd Saʿd Salmān (born 1046 in Lahore), who later became the governor of Jullundhur, was the first noteworthy person of Indian origin to have written poetry in Persian. The first truly great poet was Amīr Khosrow, who wrote in the 13th and 14th centuries. Of Turkish descent, born in the district of Etah in northern India, Khosrow was connected with royal courts all his life, even after 1272, when he became a disciple of the great mystic Niẓām-ud-Dīn Awliyā. He wrote five books of poems, or *dīvāns*, composed of *ghazals* (see below *Urdu*), panegyrics and several *mas̄navīs*—altogether some 200,000 couplets. In poetry, his innovative spirit displayed itself in *waṣf-nigārī*—that is, descriptions of natural objects in short poems, which Khosrow incorporated within longer ones. His keenness of observation is also evident in his use of local fauna and flora as poetic images. Khosrow's distinction lies not so much in the fact that he is an innovator, however, as in the fact that he is equally superb in narrative poetry, panegyrics, and lyrics. The range of his popularity and influence can best be gauged by the fact that, in northern Indian folk literature, one comes across numerous songs and riddles consistently attributed to Amīr Khosrow.

The poems of Amīr Khosrow

In the centuries that followed Khosrow, until the end of the Islāmic period, India contributed to Persian literature in two ways: first, through the production of dictionaries that helped to standardize the language and consolidate its vocabulary; second, through the development of the so-called Indian style of Persian poetry.

It is generally agreed that this Indian style, *sabk-e hindī,* did not originate within the geographic confines of India, though it reached its most sublime form there at the hands of poets who either were born in India or spent their most productive years at various Indian courts. Some of the characteristics of the style are (in the words of one modern critic) the emphasis on

> parallel statement . . . ; on complex conceit like that of the seventeenth century English "metaphysical" poets, arising out of economy of expression and telescoping into a single image a variety of emotional states; on "cerebral" artifice in pushing familiar images to unfamiliar and unexpected lengths; and on the creation of a synthetic poetic diction in which a whole phrase constitutes a single image.

The keen observation of daily life that is also characteristic of Indian Persian poetry could have been inspired by the traditions of classical Sanskrit poetry, with which these poets must have been familiar through the extensive translations done during the reign of the Mughals.

The century (1556–1657) of the reigns of Akbar, Jahāngīr, and Shāh Jahān was the most glorious period for Persian poetry in India, though, except for Fayẕī, all of the important poets were immigrants from Persia who found relief from religious and political persecution as well as generous patronage at the hands of the great Mughals and the lesser kings of southern India. The great men of letters of that period were ʿUrfī, Ṭālib Āmulī, Naẓīrī, Ẓuhūrī, Kalīm, and Ṣāʾib.

The greatest poet of the Indian style, however, was ʿAbdul Qādir Bēdil, born in 1644 in Patna, of Uzbek descent. He came early under the influence of the Ṣūfīs, refused to be attached to any court, and travelled widely throughout India during his long life. Bēdil's 16 books of poetry contain nearly 147,000 verses and include several *mas̄navīs*. Though ignored by the Iranians, Bēdil's poetry had an impact on Tadzhik and Uzbek literatures, and its influence is still evident in Afghanistan. A poet of great virtuosity and philosophic bent, he was well acquainted with Indian religions and philosophy. His anti-feudal views and his critical and skeptical attitude toward all kinds of dogma make his poetry relevant even today. His style is difficult, his metaphors and syntax quite complex (though the language itself is quite simple); and yet, as a modern critic puts it, "the intensity of his subjective assessment is so acute and factual, and his metaphysical experience so intense, that genuine poetry emerges in all its splendour."

The works of ʿAbdul Qādir Bēdil

Urdu. Earlier varieties of Urdu, variously known as Gujari, Hindawi, and Dakhani, show more affinity with eastern Punjabi and Haryani than with Khari Boli, which provides the grammatical structure of standard modern Urdu. The reasons for putting together the literary products of these dialects, forming a continuous tradition with those in Urdu, are as follows: first, they share a common milieu, consisting of Ṣūfī and Muslim court culture, increasingly dominated by the life and values of the urban elite; second, they display wholesale acceptance of Perso-Arabic literary traditions, including genres, metres, and rhetoric; third, they show an increasing acceptance of Perso-Arabic grammatical devices and vocabulary; and fourth, they tend to prefer Perso-Arabic forms over indigenous forms for learned usage.

Apart from themes and metaphysics, the influence of Ṣūfī hospices and royal courts can be seen in two practices that were essential to the development of Urdu poetry (and also unique to the Urdu milieu in the medieval period) and that still exist in modified forms. First, Urdu poets generally chose an *ustād,* or master, just as a Ṣūfī novice chose a *murshid,* or preceptor, and one's poetic genealogy was always a matter of much pride. Second, poets read poetry in private or semiprivate gatherings, called *mushāʿirah,* which displayed hierarchies, status consciousness, and rivalries reminiscent of royal courts.

Urdu literature began to develop in the 16th century, in and around the courts of the Quṭb Shāhī and ʿĀdil Shāhī, kings of Golconda and Bījāpur in the Deccan (central India). In the later part of the 17th century, Aurangābād became the centre of Urdu literary activities. There was much movement of the literati and the elite between Delhi and Aurangābād, and it needed only the genius of Walī Aurangābādī, in the early 18th century, to bridge the linguistic gap between Delhi and the Deccan and to persuade the poets of Delhi to take writing in Urdu seriously. In the 18th century, with the migration of poets from Delhi, Lucknow became another important centre of Urdu poetry, though Delhi never lost its prominence.

The first three centuries are dominated by poetry. Urdu prose truly began only in the 19th century, with translations of Persian *dāstāns,* books prepared at the Delhi College and the Fort William College at Calcutta, and later with the writers of the Aligarh movement.

'he 'orks of ḷazīr .kbarā-ādī

To focus on essential matters, the discussion that follows forgoes a chronological account of the poetry, concentrating instead on characteristics of particular genres and the achievements of the most significant of their practitioners up to 1857. There is one poet, however, who cannot be described as a practitioner of the classical Perso-Arabic traditions adopted by his fellow poets. Naẓīr Akbarābādī, who wrote in the late 18th and early 19th centuries, was a poet of consummate skill who chose to display it in short poems (in various forms) written in the language of popular speech as well as of literature. His themes show similar eclecticism. In his voluminous body of work, there are poems on such diverse topics as popular festivals, the seasons, the vanities of life, erotic pleasures and pursuits, dancing bears, and niggardly merchants. He is a master of the telling detail that immediately brings any event to life. Generally ignored by elitist poets and literary chroniclers of his time, Naẓīr has gained increasing respect and recognition as the first and best poet of the people.

Qasīdahs. *Qasīdah*s are poems written with a "purpose"—the purpose being worldly gain, in the case of poems praising kings and noblemen, or benefit in the afterworld, in the case of poems praising God, the prophet Muḥammad, and other holy personages. These panegyrics are generally overly long and are written in a highly ornate and hyperbolic style, the poets vying to display their prowess by using as many rhymes and discovering as many associative themes as possible. Because of their style and language they are of special interest to lexicographers. Not much scholarly work has been done on the *qasīdah*s written in the Deccan, but in northern India a number of poets are regarded highly for their achievements in this genre: in the 18th century, Sawdā and Inshāʾ, and in the 19th, Ẕawq and Ghālib.

Ḥaju and shahr-āshūb. Less ornate, if not less elaborate, and more edifying are the *ḥaju* (derogatory verses, personal and otherwise) and the *shahr-āshūb* (poems lamenting the decline or destruction of a city). They provide useful information about the mores and morals of the period from the 18th to mid-19th century and truly depict the problems facing the society at large. The poems are not formally restricted to any particular metre or stanza pattern. Sawdā again is one of the more famous names.

Urdu lamentatory elegies

Marsiyeh. *Marsiyeh* means "elegy," but in Urdu literature it generally means an elegy on the travails of the family and kinsmen of Ḥusayn (grandson of Muḥammad) and their martyrdom in the field of Karbalā, Iraq. These elegies and other lamentatory verses were read at public gatherings, especially during the month of Muḥarram. Although a large number of *marsiyeh*s were written in the Deccan and at Delhi, it was in Lucknow, with the patronage of Shīʿite elite and royalty, that *marsiyeh*s gained the tenor and magnitude of epic poetry. The two great masters of that 19th-century period were Mīr Anīs and Mīrzā Dabīr, who together established *musaddas* (a six-line stanza with an *aaaa bb* rhyme scheme) as the preferred form for *marsiyeh*s and added several new topics and details to the ranks of associated themes, thus carrying the form beyond a simple lament. An interesting aspect of these elegies is that, although the scene and personae are Arab, there is no attempt at verisimilitude: Arab gallants and maidens speak and gesture like the elites of Lucknow. Perhaps this added to the pathos and effectiveness of the poems at public readings.

Masnavī. *Masnavī* was the preferred genre for all descriptive and narrative purposes, for it allows the most freedom (only the lines of each couplet must rhyme). In the Deccan, all major poets wrote at least one long *masnavī,* but lack of knowledge of the dialect has prevented their full appreciation. Thus, the more famous *masnavī*s are by later poets of Delhi and Lucknow, such as Mīr, Mīr Ḥasan, Dayā Shankar Nasīm, and Mīrzā Shawq. The topics of descriptive *masnavī*s range from mundane events of life, hunting trips of kings, and the vagaries of nature's seasons to autobiographical discourses. Narrative *masnavī*s are considerably longer, running into hundreds of couplets. In the Deccan several poets wrote abridged versions of Persian *masnavī*s, but many others wrote original compositions utilizing Indian romances as well as the better known Persian and Arabic ones. Apart from the names of the protagonists in the *masnavī*s inspired by Persian and Arabic poems, all else is always local; the landscape, cityscape, processions, customs and rituals, social values and taboos, even the physical characteristics of the people are totally Indian, though dominantly Muslim and feudal. Despite their length, these narratives gained much popularity and, at least in northern India, were often read in public places, in much the same way as storytellers told stories. The *masnavī* form was also used by some of the Hindi Ṣūfī poets.

Characteristics of the *ghazal*

Ghazal. For the most part, the history of Urdu poetry in India is the story of Urdu *ghazal,* which has been the favourite of both poets and their audiences in every period. A short lyric, with prosodic requirements of both metre and rhyme, *ghazal* demands great skill and thought from the poet, for its couplet must be a complete semantic entity and fully express a whole, well-integrated poetic experience. Favourite themes are erotic love, Ṣūfī love, and metaphysics. Naturally, Urdu poets began by closely imitating, often even plagiarizing, Persian masters, but later on they spoke in a more authentic voice. They continued, however, to employ a vocabulary of love that owed almost everything to Persian and shared very little with the traditions of lyrical poetry in other Indian languages. For example, with few exceptions, the lover is always masculine; expression of love is never made by a woman. Unique, too, is the use of masculine grammatical forms and imagery for the beloved, even when, in every other way, the poem is clearly celebrating heterosexual love. This peculiarity, as well as other traditions borrowed from Persian masters, gives a *ghazal* couplet a tremendously wide range of interpretations. It is amazing indeed what a master poet can condense into one terse couplet.

The two greatest *ghazal* writers in Urdu are Mīr Taqī Mīr, in the 18th century, and Mīrzā Asadullāh Khān Ghālib, in the 19th. They are in some ways diametrical opposites. The first prefers either very long metres or very short, employs a simple, non-Persianized language, and restricts himself to affairs of the heart. The other writes in metres of moderate length, uses a highly Persianized vocabulary, and ranges wide in ideas. Mīr speaks of passion and pathos; Ghālib betrays a skeptic's mind and leaves nothing unquestioned, not even his feelings. But both have left indelible marks on the ideas and emotions of succeeding generations. Ghālib wrote poetry in Persian as well as Urdu and also published a couple of volumes of letters in Urdu that helped usher in modern prose. In many ways he bridges the gap separating the medieval sensibility from the modern. The contemporary mind, however, is also moved by the authentic passion of Mīr, idolizing him for the sublimity of his concept of love and for his personal integrity. The poems of Ghālib and Mīr represent the best of the Urdu *ghazal;* and the Urdu *ghazal,* as an anonymous wit has remarked, is the Muslims' greatest gift to India, after the Tāj Mahal. (C.M.N.)

SINHALESE LITERATURE: 10TH CENTURY AD TO 19TH CENTURY

The island nation of Ceylon (now called Sri Lanka), formally a part of South Asia, has been little noticed by the subcontinent, apart from the fact that according to an uncertain tradition it is celebrated in the *Rāmāyaṇa* as the island called Laṅkā. Buddhist sway was introduced there early, during the reign of Aśoka Maurya (*c.* 269–232 BC); and, while on the subcontinent Buddhism prospered, declined, and finally disappeared, in Ceylon it has continued until today. Although there are obvious borrowings in Ceylon from subcontinental literature, notably Sanskrit, and there was rather precarious communication with India through the island's Hindu community of Tamils, Ceylon never became culturally continuous with the mainland. The language itself, although of Indo-Aryan stock, is strongly mixed with a substratum of Dravidian. Also, it was Ceylon's fate early to fall victim to European colonialism, first to the Portuguese, then to the Dutch, and finally to the British, before it regained nationhood in 1948.

While there are inscriptions that antedate the Christian Era, no texts appear to survive from before the 10th century AD. The first texts that emerged were aids in Sinhalese—glossaries, paraphrases, and the like—to the study of the Pāli texts of Buddhism. More interesting are Sinhalese renderings of the life and virtues of the Buddha. Important in this genre, hagiographical rather than literary, is the *Amāvatura* ("Flood of the Ambrosia"), by Guruḷugōmī, which in 18 chapters purports to narrate the life of the Buddha, with specific emphasis on one of his nine virtues—his capacity to tame recalcitrant people or forces. In a similar vein is the literature of devotion and counsel, in which Buddhist virtues are celebrated.

Historical records

Exceptional in the context of the South Asian subcontinent is the early and persistent interest in historical records. Such interest had begun in Pāli with the *Dīpavaṃsa* ("Chronicle of the Island") and had continued with the *Mahāvaṃsa* ("Great Chronicle") and *Cūlavaṃsa* ("Lesser Chronicle"), but it had a life of its own in Sinhalese. The most important, and possibly the oldest, of such chronicles is the *Thūpavaṃsaya* ("Chronicle of the Great Stupa"), by Pārakrama Paṇḍita. Subsequent chronicles, or genealogies of places, comprise the history of all of the major Buddhist monuments. Several chronicles were also inspired by the Tooth Relic, received from Kaliṅga in the 4th century by King Kīrtiśrīmēghavarṇa. Such chronicling included that of the kings who protected the relic.

All of this literature was mostly in prose, but poetry as a literary form no doubt antedated it, as evidenced by early inscriptions. Much poetry was occasioned by Pāli *Jātakas* (stories of the Buddha's previous births) and other Buddhist stories, though Hindu stories were not lacking; for example, a version of the Sanskrit *Mahābhārata* (received through a Tamil source) was cast in the style of a *Jātaka* in the *Mahāpadaraṅga-Jatakaya.*

Likewise of Hindu Indian origin was a genre that took off from the Sanskrit poet Kālidāsa's "Meghadūta" (see above *Classical Sanskrit kāvya* [*200–1200*]), in which an exiled lover sends a message to his beloved by way of a monsoon cloud, thus giving the poet the opportunity to dwell on the description of landmarks in a poetic travelogue. This genre, so-called *saṃdeśa* literature, by no means unknown on the mainland, proliferated widely on Ceylon.

Of a different style are panegyrics and war poems, the earliest of which is the *Parakumbasirita* ("History of Parakramabahu VI," king in Jayavardhanapura from 1410 to 1468). Again reminiscent of the mainland and the religious tradition are the plentiful eulogies of the Buddha. Popular, too, was didactic verse, among the most notable of which is the *Kusajātaka,* 687 stanzas of epigrams and exempla by the 17th-century poet Alagiyavanna Mohoṭṭāla.

MODERN PERIOD: 19TH AND 20TH CENTURIES

The modern period was ushered in by the arrival of the British, the influence of Western models becoming discernible in the early 19th century. Reform-minded Hindus, led by Rammohan Ray, took a positive attitude to Western literature and urged on their countrymen a Western type of education. Newly formed literary clubs spread the influence of predominantly British works, thereby opening the Indian educated elite to Western culture and literature in general. After a period of translation, authors sought to imitate Western models and eventually to be independently creative in the new styles.

Effects of Westernization

The most striking result of Westernization was the introduction of prose on a major scale. Vernacular prose, rarely looked upon previously as a medium for art, was now used as a literary vehicle, and such hitherto unknown forms as the novel, novella, and short story began to emerge. In poetry the thrall of tradition was stronger, and verse in the older forms continued to be written. With modernity, realism appeared, as well as symbolism in some quarters, and there was new psychological and social interest.

From Bengal spread a new sense of national purpose, which became the principal motivation for much English as well as vernacular literature. Three trends can be distinguished in the products of this increasing literary activity. The old traditionalism was transformed into romanticism, which looked to the past, to Indian history, for inspiration and sought to preserve what was considered valuable in the past; a tendency to mysticism went hand in hand with the romantic mood (a mood that was also widespread in 19th-century Europe). Greater social awareness in European literature was reflected in the literature of Indian progressives, in whose works a somewhat romantic Marxism prevailed. Finally, there was a humanistic trend. The teachings of Mahatma Gandhi, combining social concerns with traditional ethics, later exerted a very great influence on literature.

In the years preceding and following India's independence (1947) and control of the princely states, the fervour of writers sometimes turned to an increasingly articulate progressivism of various Marxist schools; sometimes to disappointment and bitterness; and most recently, it appears, to a mood of introspection. These developments, which occurred with a different pace in different regions, are described briefly below. A complete coverage of the most modern literature has not been attempted, but an endeavour has been made to mention persons who are considered to be representative.

Bengali. Except for the iconoclastic poet Michael Madhusudan Datta, poetic activity in the mid-19th century was giving ground to experimentation with the new prose style learned from English. During this period, Bengali literature produced a spate of novels—satiric, social, and picaresque. While Michael's work *Mēghanādavadh* (1861; a long poem on the Rāma theme in which Rāma and Lakṣmaṇa become the villains and Rāvaṇa the hero) caused a stir, the literary event of the period was the appearance on the scene of Bankim Chandra Chatterjee, whose first novel, *Durgeśanandinī* ("Daughter of the Lord of the Fort"), appeared in 1865. While not at first overtly nationalist, Bankim Chandra became more and more an apologist for the Hindu position. In *Kṛṣṇacaritra,* Christ suffers in comparison with Krishna, and in his best known work, *Ānanda-maṭh* (1892; "The Abbey of Bliss"), the motherland in the person of the goddess Durgā is extolled.

Chatterjee and Tagore

Perhaps first among novelists of the late 19th and early 20th centuries is Saratchandra Chatterjee, whose social concerns with the family and other homely issues made his work popular. But the early 20th century is certainly best known for the poet who towers head and shoulders above the rest, Rabindranath Tagore. Poet, playwright, novelist, painter, essayist, musician, social reformer, Rabindranath produced works, still not completely collected, that fill 26 substantial volumes. The winner of the Nobel Prize for Literature in 1913, primarily for his little book of songs called *Gītāñjali,* which was much praised by Ezra Pound and William Butler Yeats, Tagore is more known for these devotional poems than for the wit and clear thought with which his later work is filled. He was the last of an era, looking back as he did to the religious and political history of Bengal for his inspiration. Those who followed him were more concerned with introspection and dramatic imagery.

If Tagore was the last poet in the Bengali tradition, Jibanananda Das was the first of a new breed. Musing and melancholy, yet known for vivid and unusual imagery Jibananada is a poet who has much influence on younger writers in Bengal. There have been many other poets in the 20th century who are equally powerful but stand somewhat apart from the mainstream. One of these was Sudhindranath Datta, a poet much like Pound in careful and etymological use of language; another is the poet and prose writer Buddhadeva Bose.

Bose has been termed a progressive, and indeed he consciously turned away from the tradition orientation of Tagore and sought inspiration in schools foreign to Bengal—for example, the French Symbolists. He is the leader of an artistic faction, the Kallol school, and editor of an influential literary magazine, *Kavitā.* Unjustifiably called obscene, his writing has been experimental, probing into social and psychological realities of Bengali life.

While there have been, and still are, literary factions associated with political positions, they have been less definitive than some in other parts of India. Bengali writers in the 20th century have tended to be personal and individual rather than propagandist for political positions.

Assamese. Assamese literature began with Hemchandra Baruwa, a satirist and playwright, author of the play *Bahiri-Rang-Chang Bhitare Kowabhaturi* (1861; "All That Glitters Is Not Gold"). The most outstanding among the early modern writers was Lakshminath Bezbaruwa, who founded a literary monthly, *Jōnāki* ("Moonlight"), in 1889, and was responsible for infusing Assamese letters with 19th-century Romanticism. Later 20th-century writers have tried to remain faithful to the ideals of *Jōnāki.* The short story in particular has flourished in the language; notable practitioners are Mahichandra Bora and Holiram Deka.

The year 1940 marked a shift toward psychology, but World War II effectively put an end to literary development. When writers resumed after the war, there was a clear break with the past, in experimental verse and the growth of the novel form.

Hindi. Modern Hindi literature began with Harishchandra in poetry and drama, Mahavir Prasad Dvivedi in criticism and other prose writings, and Prem Chand in fiction. This period, the second half of the 19th century, saw mainly translations from Sanskrit, Bengali, and English. The growth of nationalism and social reform movements of the Arya Samaj led to the composition of long narrative poems, exemplified by those of Maithili Sharan Gupta; dramas, by those of Jayashankar Prasad; and historical novels, by those of Prasad, Chatureen Shastri, and Vrindavan Lal Varma. The novels drew mainly on the periods of the Maurya, Gupta, and Mughal empires.

ı
ɔetry

This period was followed by the Non-cooperation and *satyāgraha* movements of Mahatma Gandhi, which inspired poets such as Makhan Lal Chaturvedi, Gupta, and Subhadra Chauhan and novelists such as Prem Chand and Jainendra Kumar. Eventual disillusionment with Gandhian experiments and the increasing influence of Marxism on European literature influenced writers such as Yashpal, Rangeya Raghava, and Nagarjuna.

S.N. Pant, Prasad, Nirala, and Mahadevi Varma, the most creative poets of the 1930s, drew inspiration from the Romantic tradition in English and Bengali poetry and the mystic tradition of medieval Hindi poetry. Reacting against them were the Marxist poets Ram Vilas Sharma and Nagarjuna and experimentalists such as H.S. Vatsyayan "Agyeya" and Bharat Bhuti Agarwal. Nirala, who developed from a mystic-romantic into a realist and experimentalist, was the most outstanding poet of the 1950s; and Sarweshwar Dayal Saxena, Kailash Vajpeyi, and Raghubir Sahay were the most creative poets of the 1960s.

Two trends, represented by the work of Prem Chand and Jainendra Kumar, led Hindi fiction in two different directions: while social realists like Yashpal, Upendranath Ashk, Amritlal Nagar, Mohan Rakesh, Rajendra Yadav, Kamleshwar, Nagarjuna, and Renu faithfully analyzed the changing patterns of Indian society, writers such as Ila Chandra Joshi, "Agyeya," Dharm Vir Bharati, and Shrikant Varma explored the psychology of the individual, not necessarily within the Indian context.

Among the dramatists of the 1930s and 1940s were Govind Ballabh Pant and Seth Govind Das; because of their highly Sanskritized language, their plays have had a limited audience. Plays by minor writers such as Ramesh Mehta, however, are repeatedly staged by professional theatres. In between these extremes there are some notable playwrights.

Gujarati. In Gujarāt, too, the advent of British rule deeply influenced the literary scene. The year 1886 saw the *Kusumamālā* ("Garland of Flowers"), a collection of lyrics by Narsingh Rao. Other poets include Kalapi, Kant, and especially Nanalal, who experimented in free verse and was the first poet to eulogize Gandhi. Gandhi, himself a Gujarati, admonished poets to write for the masses and thus inaugurated a period of poetic concern with changes in the social order. Many incidents in Gandhi's life inspired the songs of poets. The Gandhi period in Gujarāt as elsewhere gave way to a period of progressivism in the class-conflict poetry of R.L. Meghani and Bhogilal Gandhi. In post-independence India, poetry has tended to become subjectivist and alienated without, however, fully superseding the traditional verse of devotion to God and love of nature.

Among novelists, Govardhanram stands out; his *Sarasvatīchandra* is a classic, the first social novel. In the novel form, too, the influence of Gandhiism is clearly felt, though not in the person of Kanaiyalal Munshi, who was critical of Gandhian ideology but still, in several *Purāṇa*-inspired works, tended to preach much the same message. In the period after independence the modernists embraced existentialistic, surrealistic, and symbolistic trends and gave voice to the same kind of alienation as the poets.

Marathi. The modern period in Marathi poetry began with Kesavasut and was influenced by 19th-century British Romanticism and liberalism, European nationalism, and the greatness of the history of Mahārāshtra. Kesavasut declared a revolt against traditional Marathi poetry and started a school, lasting until 1920, that emphasized home and nature, the glorious past, and pure lyricism. After that, the period was dominated by a group of poets called the Ravikiraṇ Maṇḍal, who proclaimed that poetry was not for the erudite and sensitive but was instead a part of everyday life. Contemporary poetry, after 1945, seeks to explore man and his life in all its variety; it is subjective and personal and tries to speak colloquially.

Among modern dramatists, S.K. Kolhatkar and R.G. Gadkari are notable. Realism was first brought to the stage in the 20th century, by Mama Varerkar, who tried to interpret many social problems.

Novelists
of the
20th
century

The *Madhalī Sthiti* (1885; "Middle State"), of Hari Narayan Apte, began the novel tradition in Marathi; the work's message was one of social reform. A high place is held by V.M. Joshi, who explored the education and evolution of a woman (*Suśīlā-cha Diva,* 1930) and the relation between art and morals (*Indu Kāḷe va Saralā Bhoḷe,* 1935). Important after 1925 were N.S. Phadke, who advocated art for art's sake, and V.S. Khandehar, who countered the former with an idealistic art for life's sake. Noteworthy contemporary novelists are S.N. Pendse, V.V. Shirwadkar, G.N. Dandekar, and Ranjit Desai.

Punjabi. Modern Punjabi literature began around 1860. A number of trends in modern poetry can be discerned. To the more traditional genres of narrative poetry, mystic verse, and love poems was added nationalist poetry in a humorous or satiric mood and experimental verse. Among the more important Punjabi poets are Bhai Vir Singh, in the 19th century, and Purana Singh, Amrita Pritam, and Baba Balwanta, in the 20th century.

Modern prose is represented by Bhai Vira Singha, Charana Singha, and Nanaka Singha, all of whom wrote novels; the same writers, as well as Gurbhaksh Singh and Devendra Satyarathi, also wrote short stories. Among playwrights mention may be made of I.C. Nanda, Harcharan Singh, and Santa Singh Sekhon.

Rajasthani. It is generally agreed that modern Rajasthani literature began with the works of Suryamal Misrama. His most important works are the *Vamsa Bhaskara* and the *Vira satsaī*. The *Vamsa Bhaskara* contains accounts of the Rājput princes who ruled in what was then Rājputāna (at present the state of Rājasthān), during the lifetime of the poet (1872–1952). The *Vira satsaī* is a collection of couplets dealing with historical heroes. Two other important poets in this traditional style are Bakhtavara Ji and Kaviraja Muraridana.

The period of nationalist strife against the British inspired a number of poets to verse that was both nationalist and in the traditional heroic vein; among them are Hiralala Sastri, Manikyalala Varma, and Jayanarayana Vyasa. This period was followed by one in which progressive social ideals inspired such poets as Ganeshilala Vyasa, Murlidhara Vyasa, and Satyaprakasha Jodhi.

Primarily known for their lyrics are Kanhaya Lal Sethiya and Megharaja Mukula, among others, and known for their narrative poems are Manohara Sharma, Shrimanta Kumara, and Naraina Singha Bhati.

Modern prose is represented in the novel, short story, and play. Among the novelists are Shiva Candra Bharatiya, Shri Lal Jodhi, Vijaya Dana Detha, and Yadavendra Sharma Chandra; the short-story writers are Rani Lakshmi Kumari Chandavata, Narasingh Rajapurohita, Dinadayala Ojha, and Purushottama Lala Menariya. Vijaya Dana Detha and Rani Lakshmi Kumari Chandavata are also known for their retelling of Rajasthani folktales. Among the playwrights is Shivachandra Bharatiya.

Tamil. In the second half of the 19th century two tendencies were present in Tamil literature. One was the old traditional prose style of the *Patiṉeṇ-kīḻkkaṇakku*, or "Eighteen Ethical Works" (see above *Dravidian literature: 1st–19th century*), learned and severely scholastic; among others, V.V. Svaminatha Iyer and Arumuga Navalar wrote in this style. Another tendency, begun by Aruṇācala Kavirāyar in the 18th century, sought to bring the spoken and written languages together. This tendency developed on one side into such works as the operatic play *Nantaṉār Carittarak Kīrttaṉai* by Gopalakrishna, and on the other into ballads, often based on the lore of the Sanskrit *Purāṇas*. Despite attempts to effect a synthesis between the two languages, however, the scholastic style has continued to have a profound influence on modern Tamil literature; the normal spoken language, in fact, never became a literary medium.

First Tamil novel

The first novel in Tamil appeared in 1879, the *Piratāpamutaliyār Carittiram*, by Vetanayakam Pillai, who was inspired by English and French novels. In important respects Pillai's work is typical of all early modern Tamil fiction: his subject matter is Tamil life as he observed it, the language is scholastic, and the inspiration comes from foreign sources. Not strictly a novel, his work, which has a predominantly moral tone, is a loosely gathered string of narratives centred around an innocent hero.

Quite different is the *Kamalāmpāḷ Carittiram* ("The Fatal Rumor"), by Rajam Aiyar, whom many judge to be the most important prose writer of 19th-century Tamil literature. In this work, the author created a series of characters that appear to have become classics; the story is a romance, yet life in rural Tamil country is treated very realistically, with humour, irony, and social satire. In language Aiyar follows the classical style, which he intermixes with informal conversation, a style that has been imitated by modern authors.

The turn of the century saw the development of the *centamiḻ* style, which in many respects is a continuation of the medieval commentatorial style. The best representative is V.V. Swaminathan, who also is responsible for the rediscovery of the Tamil classical legacy, usually called "Tamil Renaissance," which tended to direct the mood of writers back to the glorious past. The pride in Tamil subsequently gave rise to a purist tradition and a second style, called *tuyattamiḻ*, or "pure Tamil." With exaggerated Tamilian self-consciousness, the language was purged of all non-Tamil loanwords, particularly Sanskrit, which removed the literary language even further from the spoken one. This style was not ineffective in verse but led easily to rhetoric.

The purist trend brought forth a reaction in *putumaṇipravāla naṭai*, "the new *maṇipravāla*" (see above *Dravidian literature: 1st–19th century*), which was Sanskritized with a vengeance and is of little literary interest.

The scholastic and formalist character of Tamil prose was predominant in the literature until the advent, in the early 20th century, of the poet and prose writer Subrahmanya Bharati. Bharati sought to synthesize the popular and the scholastic traditions of Tamil literature, and he created thereby a Tamil that was amenable to all literary expression. This synthesis, however, did not extend to the literary language itself, which in grammar continued the formal language, though for syntax, vocabulary, etc., he drew upon colloquial speech. In doing so he saved the language from the Sanskrit tradition of *Purāṇa* writing. His style is the *maṟumaḷarcci naṭai*, the "renaissance style."

In the first half of the 20th century, R. Krishnamurthy was an immensely popular writer. Under the pseudonym Kalki, he was an influential journalist who wrote voluminous historical romances.

In the 1930s there was a literary movement inspired by a journal called *Manikkoti*. Writers in this movement contributed extremely important new works, both in verse and prose, to Tamil letters. Among them was Putumaippittan, who wrote realistically, critically, and even bitterly about the failings of society.

Contemporary literature is represented by T. Janakiraman, who writes novels, short stories, and plays with themes from urban Tamil middle-class family life; Jayakanthan, a sharp and passionate writer, with a tendency to shock his readers; and L.S. Ramatirthan, probably the finest stylist at work in Tamil today, who started by writing in English.

Malayalam. In Malayalam the modern movement began in the late 19th century with Asan, who was temperamentally a pessimist—a disposition reinforced by his metaphysics—yet all his life was active in promoting his downtrodden Ezhava community. Ullor wrote in the classical tradition, on the basis of which he appealed for universal love, while Vallathol (died 1958) responded to the human significance of social progress.

Contemporary poetry records the encounter with problems of social, political, and economic life. The tendency is toward political radicalism.

Drama, native in Malayalam tradition, emerged in the modern period as farce, comedy, and satire but turned in the 1920s to a more sombre appraisal of outdated social conventions. The novel dates back to the late 1880s and was early concerned with social realism. At present the general tendency is introspective.

Emergence of modern Kannada poetry

Kannada. Modern Kannada poetry emerged about the beginning of the 20th century and showed a spirit of national purpose that pervaded other literature as well. By 1920, after major translations from Western models had been published, new literary forms such as the lyric and the short story came to the fore in the works of Panje Mangesh Rao and B.M. Srikantiah. Other prominent Kannada writers were D.V.G. Masti, Govinda Pai, and K.V. Puttappa ("Kuvempu"). In recent years a modernist movement has influenced the literature.

Urdu. The modern period in Urdu literature coincides with the mid-19th-century emergence of a middle class that saw in Western thought and science a means to needed social reform. Naẓīr Aḥmad wrote novels about the conflicts of Muslim middle class people. Shiblī, a poet and critic, wrote on the lives of great Muslims. The more famous novelists of the later period are Ratan-Nāth Sharshār, ʿAbd-ul-Ḥalīm Sharar, and Mīrzā Ruswā. The fathers of modern Urdu poetry were Ḥālī and Muḥammad

Ḥusayn Āzād, the latter particularly characterized by a fine sensitivity for the past.

The greatest modern poet is Iqbāl. Writing in the early 20th century, he was influenced by the general sense of national purpose and the freedom movement. His poetic imagery, the power of his expression, and his philosophical outlook won the admiration of his fellow Muslims. In prose the most important writer of short stories was Prem Chand, who late in his career took to writing in Hindi. The 1930s saw the influence of progressivism, which attempted to make literature an arm of social revolution. Among the representative writers of this period are Sajjad Zahir, Upendranath Ashk, and Ismat Chughtai, the last a woman who is considered among the best.

English. There has been Indian literary activity in English for the last 200 years. It began with the insistence of the reformist Rammohan Ray and other like-minded Hindus that, for India to take its rightful place among nations, a knowledge of and education in English were essential. English literary activity took on a new aspect with the independence movement, whose leaders and followers found in English the one language that united them.

Among the first poets were Henry Derozio, Kashiprasad Ghose, and Michael Madhusudan Datta, all of whom wrote narrative verse. In the following generation there was Toru Dutt, important among women poets in this genre. Carrying on her work was Sarojini Naidu, judged by many the greatest of women poets; among her writings are *The Golden Threshold* (1905), *The Bird of Time* (1912), and *The Broken Wing* (1917). Best known of the Indian poets in English was the Bengali Rabindranath Tagore (see above *Bengali*), who, however, wrote most of his verse first in Bengali, and then translated it. A very different figure from Tagore is Sri Aurobindo, who started out as an ardent nationalist and was jailed by the British. After his conversion from activism to introspection, which took place in jail, he established a hermitage in Pondicherry. He left behind a rich *oeuvre* of verse that has inspired a contemporary school of mystic poets. Other modern poets show the influence of T.S. Eliot and Ezra Pound.

The independence movement gave strong impetus to expository prose. Important contributors to this genre were Bal Gangadhar Tilak, who edited the English journal *Mahratta,* Lala Lajpat Rai, Kasturi Ranga Iyengar, and T. Prakasam. Mahatma Gandhi, too, wrote widely in English and edited *Young India* and the *Harijan.* He also wrote the autobiography *My Experiments with Truth* (originally published in Gujarati, 1927–29), now an Indian classic. In this he was followed by Jawaharlal Nehru, whose *Discovery of India* is justly popular.

ose
tion

Prose fiction in English began in 1902 with the novel *The Lake of Palms,* by Romesh Chunder Dutt. The next important novelist is Mulk Raj Anand, who fulminated against class and caste distinction in a series of novels, *The Coolie* (1936), *Untouchable* (1935), *Two Leaves and a Bud* (1937), and *The Big Heart* (1945). Less fierce, though a better craftsman, is R.K. Narayan, who has published nine novels (as well as many short stories), among them *The Guide* (1958), *The Man-Eater of Malgudi* (1961), and *The Vendor of Sweets* (1967); his work has a wider circle of readers outside India than within. Other Indian novelists in the English medium are Santha Rama Rau, Manohar Malgonkar, Kamala Markandeya, and Khushwant Singh. The most popular is Raja Rao, whose novels *Kanthapura* (1938), *The Cow of the Barricades* (1947), and *The Serpent and the Rope* have attracted a wide following.

Sinhalese. Traditional contemporary poetry continues to be Buddhist in subject matter and sentiment. A more modern literature arose under the influence of Western models; notable among the contemporary representatives of Sinhalese literature are Kumaranatunga, a critic, Matin Wickremasinghe, a novelist, and Tennakoon, a poet.

(J.A.B.v.B.)

Music

FOLK, CLASSICAL, AND POPULAR MUSIC

Rural areas. The wide field of musical phenomena in South Asia ranges from the relatively simple two- or three-tone melodies of some of the hill tribes in central India to the highly refined art music heard in concert halls in the large cities. This variety reflects the heterogeneous population of the subcontinent in terms of race, religion, language, and social status. In the villages, music is not just a form of entertainment but is an essential element in many of the activities of daily life and plays a prominent part in most of the rituals. These include life-cycle events, such as birth, initiation, marriage, and death; events of the agricultural cycle, such as planting, transplanting, harvesting, and threshing; and a variety of work songs. Much of this music could be described as functional, for it serves a utilitarian purpose; for instance, a harvest song might well give thanks to God for a bountiful harvest, but underlying this is the idea that singing this song in its traditional manner will help to ensure that the next harvest will be equally fruitful. These songs are usually sung by all of the members participating in the activity and are not sung for a human audience. They are often sung in the form of leader and chorus, and the musical accompaniment, if any, is generally provided by drone instruments (those sustaining or reiterating a given note or notes), usually of the lute family, or percussion instruments, such as drums, clappers, and pairs of cymbals. Occasionally, a fiddle or flute might also accompany the singers, who often dance while they sing.

In each area and even within a single area, different social groups have their own individual songs whose origins are lost in antiquity. The songs are passed on from one generation to another, and in most cases the composers are unknown. Apart from folk songs, one also hears outdoor instrumental music in villages. The music is provided by an ensemble of varying size, which consists basically of an oboe type of instrument (usually a *sheh'nai* in North India and *nagaswaram* in the south) and a variety of drums. Sometimes straight, curved, or S-shaped horns may be added. These groups play at weddings, funerals, and religious processions. The musicians are professional or semiprofessional and usually belong to a very low caste. Such ensembles are found in tribal as well as folk societies and in villages as well as in cities.

Itinerant
musicians

Other professional music is also found in the rural regions. Most areas are visited by religious mendicants, many of whom travel around the countryside singing devotional songs, accompanying themselves either with a one-, two-, or three-stringed lute that generally provides only a drone or with a frame (tamborine-like) drum. They carry with them a small begging bowl and maintain themselves entirely on what they receive in alms. There are also itinerant magicians, snake charmers, acrobats, and storytellers who travel in the rural areas, often providing the only entertainment available in the villages. Music is often involved in their acts, and the storyteller generally sings his tales, which may be taken from the two epics, the *Mahābhārata* and the *Rāmāyaṇa,* or from the *Purāṇas,* the legends that describe the adventures of the incarnations of God as they rid the world of evil. Sometimes the narrative songs are concerned with historical characters and describe the wars and the heroic deeds of the regional rulers. Some storytellers specialize in generally tragic stories of romance and of lovers.

During certain religious festivals, the villages might be visited by a travelling band of players who enact some of the mythological episodes connected with the festival. Such performances are accompanied by music and may also include dances. During the festivals villagers may visit neighbourhood shrines or temples, there encountering religious mendicants singing devotional songs and perhaps watching elaborate enactments of the episodes connected with the festival. Thus, the villagers become familiar with the mythological and philosophical aspects of their religion, in spite of the low level of literacy in the rural areas and the difficulties of communication, often limited to a narrow dirt road traversed by bullock carts.

In modern times, rural areas are being influenced to a greater extent by urban culture. The principal impact has come through the introduction of relatively inexpensive transistorized radios, which have found their way into fairly remote villages. In addition, travelling cinemas, set up quickly and easily in tents, have visited the rural areas for some years. As a result, the traditional rural forms of music and dance are in the process of change.

Classical music. In the cities many different forms of music can be heard. Of these the best known in the West are the classical music of North India, including Pakistan, sometimes called Hindustani music, and that of South India, or Karnatic music. Both classical systems are supported by an extensive body of literature and elaborate musical theory. Until modern times, classical music was patronized by the princely courts and to some extent also by the wealthy noblemen. Since India gained independence in 1947, and with the abolition of the princely kingdoms, the emphasis has shifted to the milieu of large concert halls. The concertgoer, radio, and the cinema are now the main patrons of the classical musicians. In recent times the growth of university music programs, particularly involving classical music, has placed greater emphasis on music history and theory and has provided a further source of income for musicologists and musicians. The traditional system of private instruction, however, still continues to this day.

Raga and *tāla*

Classical music is based on two main elements, raga and *tāla*. The word raga is derived from a Sanskrit root meaning "to colour," the underlying idea being that certain melodic shapes, involving specific intervals of the scale, produce a continuity of emotional experience and "colour" the mind. Since neither the melodic shapes nor their sequence are fixed precisely, a raga serves as a basis for composition and improvisation. Indian music has neither modulation (change of key) nor changing harmonies; instead, the music is invariably accompanied by a drone that establishes the tonic, or ground note, of the raga and usually its fifth (*i.e.,* five notes above). These are chosen to suit the convenience of the main performer, as there is no concept of fixed pitch. While a raga is primarily a musical concept, specific ragas have acquired, particularly in North Indian music, a number of extramusical elements and are associated with particular periods of the day, seasons of the year, colours, deities, and specific moods.

The second element of Indian music, *tāla,* is best described as time measure and has two main constituents; the duration of the time measure in terms of time units that vary according to the tempo chosen; and the distribution of stress within the time measure. *Tāla,* like raga, serves as a basis for composition and improvisation.

Indian classical music is generally performed by small ensembles of not more than five or six musicians. Improvisation plays a major part in a performance, and great emphasis is placed on the creativity and sensitivity of the soloist. A performance of a raga usually goes through well-defined stages, beginning with an improvised melodic prelude that is followed by a composed piece set in a particular time measure. The composition is generally quite short and serves as a frame of reference to which the soloist returns at the conclusion of his improvisation. There is no set duration for the performance of a raga. A characteristic feature of North Indian classical music is the gradual acceleration of tempo, which leads to a final climax.

Film music

Nonclassical music of the cities. Classical music interests only a small proportion of the peoples of South Asia, even in the cities. Since about the 1930s a new genre, associated with the cinema, has achieved extraordinary popularity. Most Indian films are very much like Western musicals and generally include six or more songs. Film music derives its inspiration from a number of sources, both Indian and Western; classical, folk, and devotional music are the main Indian sources, while Western influence is seen most obviously in the use of large orchestras that employ both Western and Indian instruments. The influence of Western popular music, too, is very evident. In spite of the eclectic nature of Indian film music, most of the songs maintain an Indian feeling that arises largely from the vocal technique of the singers and the ornamentation of the melody line. This music is an experimental and developing form, and there have been attempts to add harmony and counterpoint, some of which may seem rather naïve to the Western ear. But the film music differs from typical Western music in that the melody line is generally not dictated by harmonic progressions and in that the harmonies used are incidental additions.

Aside from classical and film music, there are several other forms of urban music, some of which closely resemble the music of the rural areas. In city streets one is likely to encounter an outdoor band of oboes and drums announcing a wedding or a funeral. Street musicians, religious mendicants, snake charmers, storytellers, and magicians perform at every available opportunity, and work songs are sung by construction workers and other labourers. In private homes still other forms of music are performed, ranging from religious chanting to traditional folk and devotional songs. In public places of entertainment, the listener may encounter, apart from classical and film music, theatrical music from one of the relatively modern forms of regional theatre; and in the lowbrow places of entertainment courtesans still sing and dance in traditional fashion. In the larger cities there are performances of Western chamber music and occasionally symphony concerts, as well as popular dance music, rock, and jazz in the night clubs.

ANTIQUITY

In a musical tradition in which improvisation predominates, and written notation, when used, is skeletal and more a tool of the theorist than of the practicing musician, the music of past generations is irrevocably lost. References to music in ancient texts, aesthetic formulations, and depictions and written discussions of musical instruments can offer clues. In rare instances an ancient musical style may be preserved in unbroken oral tradition. For most historical eras and styles, surviving treatises explaining musical scales and modes—the framework of melody—provide a particularly important means of recapturing at least a suggestion of the music of former times, and tracing the musical theory of the past makes clear the position of the present musical system.

Little is known of the musical culture of the Indus Valley civilization of the 3rd and 2nd millennia BC. Some musical instruments, such as the arched, or bow-shaped, harp and more than one variety of drum, have been identified from the small terra-cotta figures and among the pictographs on the seals that were probably used by merchants. Further, it has been suggested that a bronze statuette of a dancing girl represents a class of temple dancers similar to those found much later in Hindu culture. It is known that the Indus civilization had established trade connections with the Mesopotamian civilizations, so that it is possible that the bow harp found in Sumeria would also have been known in the Indus Valley.

Vedic chant. *Compilation of hymns.* It is generally thought among scholars that the Indus Valley civilization was terminated by the arrival of bands of semi-nomadic tribesmen, the Aryans, who descended into India from the northwest, probably in the first half of the 2nd millennium BC. An important aspect of Aryan religious life was the bard-priest who composed hymns in praise of gods, to be sung or chanted at sacrifices. This tradition was continued in the invaders' new home in northern India until a sizable body of oral religious poetry had been composed. By about 1000 BC this body of chanted poetry had apparently grown to unmanageable proportions, and the best of the poems were formed into an anthology called Rigveda, which was then canonized. It was not committed to writing, but text and chanting formula were carefully handed down by word of mouth from one generation to the next, up to the present period. The poems in the Rigveda are arranged according to the priestly families who used and, presumably, had composed the hymns. Shortly after this a new Veda, called the Yajurveda, basically a methodical rearrangement of the verses of the Rigveda with certain additions in prose, was created to serve as a kind of manual for the priest officiating at the sacrifices. At approximately the same time, a third Veda, the Sāmaveda, was created for liturgical purposes. The Sāmaveda was also derived from the hymns of the Rigveda, but the words were distorted by the repetition of syllables, pauses, prolongations, and phonetic changes, as well as the insertion of certain meaningless syllables believed to have magical significance. A fourth Veda, the Atharvaveda, was accepted as a Veda considerably later and is quite unrelated to the other three. It represents the more popular aspects of the Aryan religion and consists mostly of magic spells and incantations.

Each of these Vedas has several ancillary texts, called the *Brāhmaṇas, Āraṇyakas,* and *Upaniṣads,* which are also regarded as part of the Vedas. These ancillary texts are concerned primarily with mystical speculations, symbolism, and the cosmological significance of the sacrifice. The Vedic literature was oral and not written down until very much later, the first reference to a written Vedic text being in the 10th century AD. In order to ensure the purity of the Vedas, the slightest change was forbidden, and the priests devised systems of checks and counterchecks, so that there has been virtually no change in these texts for about 3,000 years. Underlying this was the belief that the correct recitation of the Vedas was "the pivot of the universe" and that the slightest mistake would have disastrous cosmic consequence unless expiated by sacrifice and prayer. The Vedas are still chanted by the Brahmin priests at weddings, initiations, funerals, and the like, in the daily devotions of the priests, and at the now rarely held so-called public sacrifices.

From the Vedic literature it is apparent that music played an important part in the lives of the Aryan peoples, and there are references to stringed instruments, wind instruments, and several types of drums and cymbals. Songs, instrumental music, and dance are mentioned as being an integral part of some of the sacrificial ceremonies. The bow harp (*vīṇā*), a stringed instrument (probably a board zither) with 100 strings, and the bamboo flute were the most prominent melody instruments. Little is known of the music, however, apart from the Vedic chanting, which can still be heard today.

Chant intonation. The chanting of the Rigveda and Yajurveda shows, with some exceptions, a direct correlation with the grammar of the Vedic language. As in ancient Greek, the original Vedic language was accented, with the location of the accent often having a bearing on the meaning of the word. In the development of the Vedic language to Classical Sanskrit, the original accent was replaced by an automatic stress accent, whose location was determined by the length of the word and had no bearing on its meaning. It was thus imperative that the location of the original accent be inviolate if the Vedic texts were to be preserved accurately. The original Vedic accent occurs as a three-syllable pattern: the central syllable, called *udātta,* receives the main accent; the preceding syllable, *anudātta,* is a kind of preparation for the accent; and the following syllable, *svarita,* is a kind of return from accentuation to accentlessness. There is some difference of opinion among scholars as to the nature of the original Vedic accent; some have suggested that it was based on pitch, others on stress; and one theory proposes that it referred to the relative height of the tongue.

In the most common style of Rigvedic and Yajurvedic chanting found today, that of the Tamil Aiyar Brahmins, it is clear that the accent is differentiated in terms of pitch. This chanting is based on three tones; the *udātta* and the nonaccented syllables (called *pracaya*) are recited at a middle tone, the preceding *anudātta* syllable at a low tone, and the following *svarita* syllable either at the high tone (when the syllable is short) or as a combination of middle tone and high tone. The intonation of these tones is not precise, but the lower interval is very often about a whole tone, while the upper interval tends to be slightly smaller than a whole tone but slightly larger than a semitone. In this style of chanting the duration of the tones is also relative to the length of the syllables, the short syllables generally being half the duration of the long.

The more musical chanting of the Sāmaveda employs five, six, or seven tones and is said to be the source of the later secular and classical music. From some of the phonetic texts that follow the Vedic literature, it is apparent that certain elements of musical theory were known in Vedic circles, and there are references to three octave registers (*sthāna*), each containing seven notes (*yama*). An auxiliary text of the Sāmaveda, the *Nāradīśikṣā,* correlates the Vedic tones with the accents described above, suggesting that the Samavedic tones possibly derived from the accents. The Samavedic hymns as chanted by the Tamil Aiyar Brahmins are based on a mode similar to the D mode (D-d on the white notes of the piano; *i.e.,* the ecclesiastical Dorian mode). But the hymns seem to use three different-sized intervals, in contrast to the two sizes found in the Western church modes. They are approximately a whole tone, a semitone, and an intermediate tone. Once again, the intervals are not consistent and vary both from one chanter to another and within the framework of a single chant. The chants are entirely unaccompanied by instruments, and this may account for some of the extreme variation of intonation.

The changes brought by the 20th century have weakened the traditional prominent position of the Vedic chant. The Atharvaveda is seldom heard in India now. Samavedic chant, associated primarily with the large public sacrifices, also appears to be dying out. Even the Rigveda and Yajurveda are virtually extinct in some places, and South India is now the main stronghold of Vedic chant.

Music and
drama

The classical period. The ritual of the Vedas involves only the three upper classes, or castes, of Aryan society: the Brahmin, or priestly class; the Kṣatriya, or prince-warriors; and the Vaiśya, or merchants. The fourth caste, the Śūdras, or labourers, were excluded from Vedic rites. The primary sources of religious education and inspiration for the Śūdra were derived from what is sometimes called the fifth Veda: the epic poems *Rāmāyaṇa* and *Mahābhārata,* as well as the collections of legends, called the *Purāṇas,* depicting the lives of the various incarnations of the Hindu deities. The *Rāmāyaṇa* and the *Mahābhārata* were originally secular in character, describing the heroic deeds of kings and noblemen, many of whom are not recorded in history. Subsequently, religious matter was added, including the very famous sermon *Bhagavadgītā* ("Song of the Lord"), which has been referred to as the most important document of Hinduism; and many of the heroes of the epics were identified as incarnations of the Hindu deities. The legends were probably sung and recited by wandering minstrels and bards even before the advent of the Christian Era, in much the same way as they still are. The stories were also enacted on the stage, particularly at the time of the religious festivals. The earliest extant account of drama is to be found in the *Nāṭya-śāstra* ("Treatise on the Dramatic Arts"), a text that has been dated variously from the 2nd century BC to the 5th century AD and even later. It is virtually a handbook for the producer of stage plays and deals with all aspects of drama, including dance and music.

Theatrical music of the period apparently included songs sung on stage by the actors, as well as background music provided by an orchestra (which included singers) located offstage, in what was very like an orchestra pit. Melodies were composed on a system of modes, or *jāti*s, each of which was thought to evoke one or more particular sentiments (*rasa*) by its emphasis on specific notes. The modes were derived in turn from the 14 *mūrchanā*s—seven pairs of ascending seven-note series beginning on each of the notes of two closely related heptatonic (seven-note) parent scales, called *ṣaḍjagrāma* and *madhyamagrāma.* The *mūrchanā*s were thus more or less analogous to the European modal scales that begin progressively on D, E, F, G, etc. A third parent scale, *gāndhāragrāma,* was mentioned in several texts of the period and some even earlier but is not included in the system laid out in the *Nāṭya-śāstra.*

Qualities of the scales. The two parent scales differed in the positioning of just one note, which was microtonally flatter in one of the scales. The microtonal difference, referred to as *pramāṇa* ("measuring") *śruti,* presumably served as a standard of measurement. In terms of this standard it was determined that the intervals of the *mūrchanā*s were of three different sizes, consisting of two, three, or four *śruti*s, and that the octave comprised 22 *śrutis*. An interval of one *śruti* was not used. Several modern scholars have suggested that the *śruti*s were of unequal size; from the evidence in the *Nāṭya-śāstra,* it would appear, however, that they were thought to be equal. There has been no attempt to determine the exact size of the *śruti*s in any of the traditional Indian musical treatises until relatively modern times (18th century). The term *śruti* was also used to define consonance and dissonance, as these terms were understood in the period. In this connection, four terms are mentioned: *vādī,* comparable to the Western term sonant, meaning "having sound"; *saṃvādī,* to the Western consonant (concordant; reposeful); *vivādī,* to dissonant (discordant; lacking repose); and *anuvādī,* to assonant (neither consonant nor dissonant). As in the ancient Greek Pythagorean system, which influenced Western music, only fourths and fifths (intervals of four or five tones in a Western scale) were considered consonant. In the Indian system of measurement, tones separated by either nine or 13 *śruti*s correspond in size to Western fourths and fifths and are described as being consonant to each other. "Dissonant" in this system referred only to the minor second, an interval of two *śruti*s, and to its inversion (complementary interval), the major seventh (20 *śruti*s). All other tones, including the major third, were thought to be assonant.

Melodically important microtonal differences

The musical difference between the two parent scales is best seen not in terms of the microtonal deviation mentioned earlier but rather in terms of a musically influential consonance found in one but lacking in the other and vice versa. In each of the parent scales there are two nonconsonances, one of which is the tritone (interval of three Western whole tones, such as F-B) of 11 *śruti*s inevitable in all diatonic scales (seven-note scales of the major scale and *mūrchanā* type) and which in Europe during the Middle Ages was described as *diabolus in musica* ("the devil in music").

The second is a microtonal nonconsonance unique to this ancient Indian system. It can be illustrated by referring in the subsequent explanation to Table 1, in which the seven Indian notes *ṣaḍja, ṛṣabha, gāndhāra, madhyama, pañcama, dhaivata,* and *niṣāda* are given in their commonly abbreviated forms, *ṣa, ṛi, ga, ma, pa, dha,* and *ni.*

The nonconsonance arises from variances of one *śruti* from the fundamental consonances of the fourth and the fifth—a variance of about a quarter tone. In the *ṣaḍjagrāma* scale the interval *ṛi-pa* (E^- to A) contains 10 *śrutis; i.e.,* one more than the nine of the consonant fourth. Comparably, in the *madhyamagrāma* scale the interval *ṣa-pa* (D to A^-) contains 12 *śruti*s, or one fewer than the consonant fifth. These variances involve the consonant relationships of two melodically prominent notes, the first and the fifth. In the *madhyamagrāma* the first note, *ṣa,* has no consonant fifth, and perhaps for this reason this scale is said to begin not on the *ṣa* (D) but on its fourth, the note *ma* (G); hence, it resembles the G mode—*i.e.,* the ecclesiastical Mixolydian mode—whereas the *ṣaḍjagrāma* resembles the D mode, the ecclesiastical Dorian.

There is a striking resemblance of the *ṣaḍjagrāma* scale to the intervals used by the Tamil Aiyar Brahmins in their chanting of the Sāmaveda. Not only are their hymns set in a mode similar to the D mode, but they seem to use three different-sized intervals, the intermediate one corresponding to the three-*śruti* interval. The *Nāṭya-śāstra* claims to have derived song (*gīta*) from the chanting of the Sāmaveda, and the resemblances between the two may not be entirely fortuitous.

The two parent scales are complementary and between them supply all the consonances found in the ancient Greek Pythagorean scale. Thus, if in a mode the consonance *ṛi-pa* (E–A) were needed, one would tune to the *madhyamagrāma* scale. But, if the consonance *ṣa-pa* (D–A) were important, it could be obtained with the *ṣaḍjagrāma* tuning.

Introduction of new notes

There was a further development in this system caused by the introduction of two additional notes, called *antara ga* (F♯) and *kākalī ni* (C♯), which could be substituted for the usual *ga* (F) and *ni* (C). The *antara ga* eliminates the 11-*śruti* tritone between *ga* and *dha* (F–B), but its use creates a further tritone between F♯ and C. The second additional note, *kākalī ni* (C♯), eliminates this tritone but once again creates a new one, this time between C♯ and G. This process of adding notes, if carried further, would eventually lead to the circle, or, rather, the spiral, of fourths or fifths found in Western music (whereby a sequence of fifths, such as C–G, G–D, D–A, etc., leads eventually back to a microtonally out-of-tune C); there is no evidence that such a circle or spiral was known in ancient India.

Mode, or jāti. From each of the two parent scales were derived seven modal sequences (the *mūrchanās* described above), based on each of the seven notes. The two *mūrchanās* of a corresponding pair differed from each other only in the tuning of the note *pa* (A), the crucial distinction in the tunings of the two parent scales. One of each pair was selected as the basis for a "pure" mode, or *śuddha-jāti;* in the groups of seven pure modes, four used the tuning of the *ṣaḍjagrāma* and three that of the *madhyamagrāma.* In addition to these seven pure modes, a further 11 "mixed" modes, or *vikṛta-jāti*s, are also mentioned in the *Nāṭya-śāstra.* These were derived by a combination of two or more pure modes, but the text does not explain just in what way these derivations were accomplished.

The *jāti*s were similar to the modern concept of raga in that they provided the melodic basis for composition and, presumably, improvisation. They were not merely scales, but were also assigned 10 melodic characteristics: *graha,* the initial note; *aṃśa,* the predominant note; *tāra,* the note that forms the upper limit; *mandra,* the note that forms the lower limit; *nyāsa,* the final note; *apanyāsa,* the secondary final note; *alpatva,* the notes to be used infrequently; *bahutva,* the notes to be used frequently; *ṣāḍavita,* the note that must be omitted in order to create the hexatonic (six-note) version of the mode; and *auḍavita,* the two notes that must be omitted to create the pentatonic (five-note) version of the mode.

No written music survives from this early period. It is not clear from the description whether or not the music was like that of the present period. There is no mention of a drone, nor do the instruments of the orchestra—consisting of the *vipañcī* and *vīṇā* (bow harps?), bamboo flute, a variety of drums, and singers—appear to include any specifically drone instrument, such as the modern tamboura. The evidence tends rather to suggest, from the emphasis on consonance and some of the playing techniques, that some form of organum (two or more parts paralleling the same melody at distinct pitch levels) and even some type of rudimentary harmony may have been characteristic.

MEDIEVAL PERIOD

Precursors of the medieval system. It is not clear just when the *jāti* system fell into disuse, for later writers refer to *jāti*s merely out of reverence for Bharata, the author of the *Nāṭya-śāstra.* Later developments are based on musical entities called *grāma-rāga*s, of which seven are mentioned in the 7th-century Kuṭimiyāmalai rock inscription in Tamil Nadu state. Although the word *grāma-rāga* does not occur in the *Nāṭya-śāstra,* the names applied to the individual *grāma-rāga*s are all mentioned. Two of them, *ṣadjagrāma-rāga* and *madhyamagrāma-rāga,* are obviously related to the parent scales of the *jāti* system. The other five seem to be variants of these two *grāma-rāga*s in which either or both the altered forms of the notes *ga* and *ni* (F♯ and C♯) are used. In the *Nāṭya-śāstra,* the reference to the various *grāma-rāga*s is far removed from the main section in which the *jāti* system is discussed, and there is no obvious connection between the two. Each of the *grāma-rāga*s is said to be used in one of the seven formal stages of Sanskrit drama. They have been reconstructed as shown in Table 2.

Further development of the grāma-rāgas. In the next significant text on Indian music, the *Bṛhaddeśī,* written by the theorist Mātaṅga about the 10th century AD, the *grāma-rāga*s are said to derive from the *jāti*s. In some respects, at least, the *grāma-rāga*s resemble not the *jāti*s but their parent scales. The author of the *Bṛhaddeśī* claims to be the first to discuss the term raga in any detail. It is clear that raga was only one of several kinds of musical entities in this period and is described as having "varied and graceful ornaments, with emphasis on clear, even, and deep tones and having a charming elegance." The ragas of this period seem to have been named after the different peoples living in the various parts of the country, suggesting that their origin might lie in folk music. Mātaṅga appears to contrast the two terms *mārga* and *deśī. Mārga* (literally "the path") apparently refers to the ancient traditional musical material, whereas *deśī* (literally "the vulgar dialect spoken in the provinces") designates the musical practice that was evolving in the provinces, which may have had a more secular basis. Although the title *Bṛhaddeśī* ("The Great Deśī") suggests that the latter music might have been the focus of the treatise and that the *grāma-rāga*s were possibly out of date by the time it was written, the surviving portion of the text does not support such a theory.

The mammoth 13th-century text *Saṅgītaratnākara* ("Ocean of Music and Dance"), composed by the theorist Śārṅgadeva, is often said to be one of the most important landmarks in Indian music history. It was composed in the Deccan (south central India) shortly before the conquest of this region by the Muslim invaders and thus gives an account of Indian music before the full impact of Muslim influence. A large part of this work is devoted to *mārga*—that is, the ancient music that includes the system of *jāti*s and *grāma-rāgas*—but Śārṅgadeva mentions a total of 264 ragas. Despite the use in both the *Bṛhaddeśī* and the *Saṅgītaratnākara* of a notation equivalent to the Western tonic sol–fa (*i.e.,* with syllables, as do–re–mi . . .) to illustrate the ragas, modern scholars have not yet been able to reconstruct them with assurance.

The basic difficulty scholars face lies in determining the intervals used in each of the ragas. In the ancient system, the *jāti*s were something like the ancient Greek and medieval church modes in that each was derived from a parent scale by altering the ground note and the tessitura (range). In modern Indian music, however, the ragas are all transposed to a common ground note. This change may well be connected with the introduction of the drone and the evolution of the long-necked-lute family on which the drone is usually played. In the old system, with the changing ground note, it would have been necessary to retune drone instruments from one raga to another, which would have been a cumbersome and impractical operation to carry out during a recital. It may have been this factor that provided the impetus for the change to the standard-ground-note system. There is no conclusive evidence to show just when this change might have taken place, and it is not clear whether the *Bṛhaddeśī* and the *Saṅgītaratnākara* are using the old ground-note system or one similar to that used in modern times.

THE ISLĀMIC PERIOD

Impact on musical genres and aesthetics. The Muslim conquest of India can be said to begin in the 12th century, although Sind (now in Pakistan) had been conquered by the Arabs as early as the 8th century. Muslim writers such as al-Jāḥiẓ and al-Masʿūdī had already commented favourably on Indian music in the 9th and 10th centuries, and the Muslims in India seem to have been very much attracted by it.

In the beginning of the 14th century the great poet Amīr Khosrow, who was considered to be extremely proficient in both Persian and Indian music, wrote that Indian music was superior to the music of any other country. Further, it is stated that, after the Muslim conquest of the Deccan under Malik Kāfūr (*c.* 1310), a large number of Hindu musicians were taken with the royal armies and settled

in the North. Although orthodox Islām considered music illegal, the acceptance of the Ṣūfī doctrines, in which music was an accepted means to the realization of God, enabled Muslim rulers and noblemen to extend their patronage to this art. At the courts of the Mughal emperors Akbar, Jahāngīr, and Shāh Jahān, music flourished on a grand scale. Apart from Indian musicians, there were also musicians from Persia, Afghanistan, and Kashmir in the employ of these rulers; nevertheless, it appears that it was Indian music that was most favoured. Famous Indian musicians, such as Svāmī Haridās and Tānsēn, are legendary performers and innovators of this period. After the example set by Amīr Khosrow, Muslim musicians took an active interest in the performance of Indian music and added to the repertoire by inventing new ragas, *tāla*s, and musical forms, as well as new instruments.

Influence of religious movements

The Muslim patronage of music was largely effective in the north of India and has had a profound influence on North Indian music. Perhaps the main result of this influence was to de-emphasize the importance of the words of the songs, which were mostly based on Hindu devotional themes. In addition, the songs had been generally composed in Sanskrit, a language that had ceased to be a medium of communication except among scholars and priests. Sanskrit songs were gradually replaced by compositions in the various dialects of Hindi, Braj Bhasa, Bhojpuri, and Dakhani, as well as in Urdu and Persian; nevertheless, the problems of communication, in terms of both language and subject matter, were not easily reconciled. A new approach to religion was, in any case, sweeping through India at about this time. This emphasized devotion (*bhakti*) as a primary means to achieving union with God, bypassing the traditional Hindu beliefs of the transmigration of the soul from body to body in the lengthy process of purification before it could achieve the Godhead. The Islāmic Ṣūfī movement was based on an approach similar to that of the *bhakti* movements and also gained many converts in India. A manifestation of these devotional cults was the growth of a new form of mystic-devotional poetry composed by wandering mendicants who had dedicated their lives to the realization of God. Many of these mendicants have been sanctified and are referred to as poet-saints or singer-saints, since their poems were invariably set to music. A number of devotional sects sprang up all over the country, some Muslim, some Hindu, and others merging elements from both. These sects emphasized the individual's personal relationship with God. In their poetry, man's love for God was often represented as a woman's love for man and, specifically, the love of the milkmaid Rādhā for Krishna, a popular incarnation of the Hindu god Vishnu. In the environment of the royal courts, there was a less idealistic interpretation of the word love, and much of the poetry, as well as the miniature painting, of the period depicts the states of experience of the lover and the beloved.

This attitude is also reflected in the musical literature of the period. From early times, both *jāti*s and ragas in their connection with dramatic performance were described as evoking specific sentiments (*rasa*) and being suitable for accompanying particular dramatic events. It was this connotational aspect, rather than the technical one, that gained precedence in this period. The most popular method of classification was in terms of ragas (masculine) and their wives, called *rāgiṇī*s, which was extended to include *putra*s, their sons, and *bhāryā*s, the wives of the sons. The ragas were personified and associated with particular scenes, some of which were taken from Hindu mythology, while others represented aspects of the relationship between two lovers. The climax of this personification is found in the *rāgamāla* paintings, usually in a series of 36, which depict the ragas and *rāgiṇī*s in their emotive settings.

Theoretical developments. From the middle of the 16th century, a new method of describing ragas is found in musical literature. It was also at about this time that the distinction between North and South Indian music became clearly evident. In the literature, ragas are described in terms of scales having a common ground note. These scales were called *mela* in the South and *mela* or *thāṭa* in the North.

Emergenc of moder theoretica concepts

It was in the South that a complete theoretical system of *mela*s was introduced, in the *Caturdaṇḍiprakāśika* ("The Illuminator of the Four Pillars of Music"), a text written in the middle of the 17th century. This system was based on the permutations of the tones and semitones, which had by this time been reduced to a basic 12 in the octave. The octave was divided into two tetrachords, or four-note sequences, C–F and G–c, and six possible tetrachord species were arranged in an order showing their relationship with each other. It will be noted in the sequence of tetrachords shown below that each lower tetrachord has an analogous upper tetrachord and that the outer notes of each are constant, whereas the inner notes change their pitch.

1.	C	D♭	E♭♭	F	and	G	A♭	B♭♭	c
2.	C	D♭	E♭	F		G	A♭	B♭	c
3.	C	D♭	E	F		G	A♭	B	c
4.	C	D	E♭	F		G	A	B♭	c
5.	C	D	E	F		G	A	B	c
6.	C	D♯	E	F		G	A♯	B	c

The list could have extended further, except that apparently no pitch distinction was made between the enharmonic pairs D–E♭♭, D♯–E♭, A–B♭♭, and A♯–B♭. (Enharmonic notes have different pitch names but sound either the same pitch or, in some tuning systems, have very slight differences in pitch.)

By utilizing all possible combinations of a lower with an upper tetrachord, 36 *mela*s, or raga scales, were derived; a further 36 were formed by using F♯ in place of the F in the lower tetrachord. The *mela*s were named in such a way that the first two syllables of the name, when applied in a code, gave the number of that *mela* in the sequence. The musician, given the number, could easily reconstruct the scale of the *mela*. The names of the *mela*s were often derived from prominent ragas in those *mela*s, with a two-syllable prefix that supplied the code numbers; for instance, the name of the *mela Dhīra-śaṅkarābharaṇa* is derived from the raga *Śaṅkarābharaṇa,* the two syllables *dhīra* giving the code number 29, which indicates a scale similar to the Western major scale, or C mode. The *Caturdaṇḍiprakāśika* acknowledges the theoretical nature of its analytical system and mentions clearly that only 19 of the possible 72 *mela*s were in use at the time that the text was written.

Although North Indian texts also describe ragas in terms of *mela*s or *thāṭa*s, there is no attempt to arrange them systematically. In the *Rāgataraṅgiṇi* ("The River of Rāga"), probably of the 16th century, 12 *mela*s are mentioned:

bhairavī	C	D	E♭	F	G	A	B♭	c
toṛī	C	D♭	E♭	F	G	A♭	B♭	c
gaurī	C	D♭	E	F	G	A♭	B	c
karṇāta	C	D	E	F	G	A	B♭	c
kedāra	C	D	E	F	G	A	B	c
imana	C	D	E	F♯	G	A	B	c
sāraṅga	C	D	E♯	F♯	G	A♯	B	c
megha	C	D	E	F	G	A♯	B	c
dhanāśrī	C	D♭	E	F♯	G	A♭	B	c
pūravā	C	D	E	F♯	G	A$^+$	B	c
mukhārī	C	D	E♭	F	G	A♭	B♭	c
dīpaka	no description							

Although it appears from the description of *sāraṅga* and *megha mela*s that enharmonic intervals were used, there is good reason to believe that the E♯ and A♯ in the two *mela*s really represent their chromatic counterparts, F and B♭, and that F and F♯ (and B and B♭) do not appear in sequence. The A$^+$ in the *mela pūravā* is said to be raised by one *śruti.* The description of the ragas in these *mela*s shows that the North Indian system was by this time also based on 12 semitones.

THE MODERN PERIOD

With the collapse of the Mughal Empire in the 18th century and the emergence of the British as a dominant power in India, the subcontinent was divided into many princely states. Music continued to be patronized by the rulers, although the courts were never again to achieve their former opulence.

Musically, there has been a continuous evolution from the Islāmic period to the present, and both North and

South Indian classical music have continued to expand. South Indian music has clearly been influenced more by theory than has the North. The 72-*mela* system continues to be the basis of classifying the ragas in South India, but it has had more than a classificatory significance. Many new ragas have been composed in the past few centuries, some of them inspired by the theoretical scales of the *mela* system. As a result, there are now ragas in all of the 72 *mela*s.

luence
theory
compo-
on

In North Indian music, theory has had little influence on performance practice. This can be ascribed to the language problem, an especially significant influence on the many Muslim musicians in North India, who were not able to cope with the Sanskrit musical literature. Thus, there had been no attempt to systematize the music, and there was a considerable gap between performance and theory until the present century. Vishnu Narayana Bhatkande, one of the leading Indian musicologists of this century, contributed a great deal toward diminishing the gap. Being both a scholar and a performer, he devoted much effort to collecting and notating representative versions of a number of ragas from musicians belonging to different family traditions, or *gharānā*s. Based on this collection, he concluded that most of the ragas of North Indian music can be grouped into the following scales, called *thāṭa*s (compare the South Indian *mela*s shown above):

kalyāṇa	C	D	E	F♯	G	A	B	c
bilāvala	C	D	E	F	G	A	B	c
khamāja	C	D	E	F	G	A	B♭	c
bhairava	C	D♭	E	F	G	A♭	B	c
pūrvī	C	D♭	E	F♯	G	A♭	B	c
mārvā	C	D♭	E	F♯	G	A	B	c
kāfī	C	D	E♭	F	G	A	B♭	c
āsāvarī	C	D	E♭	F	G	A♭	B♭	c
bhairavī	C	D♭	E♭	F	G	A♭	B♭	c
toṛī	C	D♭	E♭	F♯	G	A♭	B	c

The *thāṭa*s do not cover all the ragas used in North Indian music, but there is reason to believe that most of the ragas having scales other than the above are relatively modern innovations. New ragas are constantly being created, and some North Indian musicians are using the vast potential of the South Indian *mela* system as their source of inspiration.

Mela and *thāṭa* are theoretical devices for the classification of ragas. Ragas have scalar elements, such as specified ascending and descending movements, that might or might not employ adjacent steps. They may also employ oblique or zigzag movements. Ragas can be heptatonic, hexatonic, or pentatonic and may also have accidentals (sharpened or flattened notes) that occur only in specific melodic contexts. A further distinction between scale and raga is found in the varying emphasis placed on different notes in a raga. Ragas, furthermore, also have melodic elements, such as certain recurrent nuclear motives (brief melodic fragments) that enable the raga to be identified more easily. One scale type can be the basis for perhaps 20 or 30 ragas, in which case it is the nonscalar elements that provide the distinguishing features of each raga in the group.

Rhythmic organization. *South India.* Just as the system of classifying raga is better organized in South Indian music, so too is the system of classifying *tāla,* or time measure. The main group is composed of 35 *tāla*s, called the *sūlādi-tāla*s. Each *tāla* is composed of one, two, or three different units: short, medium, and long. The medium unit is twice the duration of the short; the long unit is, however, a variable and may be three, four, five, seven, or nine times the duration of the short. There are seven basic *tāla* patterns, and, because the long unit of these *tāla*s can be of five different durations, the total number of *tāla*s in this system is 35. The basic *tāla* patterns are:

dhruva-tāla—long, medium, long, long
maṭhya-tāla—long, medium, long
rūpaka-tāla—medium, long
jhampā-tāla—long, short, medium
tripuṭa-tāla—long, medium, medium
āṭa-tāla—long, long, medium, medium
eka-tāla—only a single long.

The total duration of each pattern is controlled by the duration of the variable long; thus, if the long unit is five times the short, a *tāla* pattern such as *dhruva-tāla* will be 5 + 2 + 5 + 5, or 17 units. Several of these *tāla*s have the same total duration but are distinguished from each other by their internal subdivisions. In the course of a performance, the vocalist, as well as the audience, may mark the time by clapping, hand waving, and finger counting.

In addition to the *sūlādi-tāla*s, there are four *cāpu-tāla*s that are used in South Indian classical music. Said to derive from folk music, they consist of two sections of unequal length, 1 + 2, 2 + 3, 3 + 4, and 4 + 5. Of these, the 3 + 4 combination is the most prominent. On rare occasions a performer may use one of the "classical" *tāla*s referred to in Sanskrit texts. These generally involve long time cycles composed of as many as 100 short units. The most frequently heard time measures, however, are *ādi-tāla,* a modified eight-beat version of *tripuṭa-tāla* (4 + 2 + 2); *miśra-cāpu-tāla* (3 + 4); and *rūpaka-tāla* (4 + 2). The difficult and long *tāla*s are used primarily as a tour de force. Each *tāla* may be performed in either slow, medium, or quick tempo; there is no gradual acceleration as in North Indian music.

North India. In North Indian music the *tāla*s are fewer and not organized in any systematic manner. As in South Indian music, the two main factors are the duration of the time cycle and the subdivisions within the cycle. Each of these subdivisions is marked by a clap or a wave, with the greatest emphasis falling on beat 1 of the cycle, which is called *sam.* North Indian *tāla*s have a further feature, the *khālī* ("empty"), a conscious negation of stress occurring at one or more points in each *tāla* where one would expect a beat. It often falls at the halfway point in the time cycle and is marked by a wave of the hand. There is nothing comparable to the *khālī* in the South Indian system. A further distinguishing feature found only in North Indian *tāla*s is the emphasis placed on the characteristic drum pattern of each *tāla,* called *ṭhekā.* Two *tāla*s might have the same duration and subdivisions but might, nevertheless, be differentiated from each other by different characteristic drum patterns. In addition, the *tāla*s are also associated with different forms of song and even particular tempi. The usual North Indian *tāla*s range from six to 16 time units in duration. The most popular are *tīn-tāla* (4 + 4 + 4 + 4), *eka-tāla* (2 + 2 + 2 + 2 + 2 + 2), *jhap-tāla* (2 + 3 + 2 + 3), *kaharavā* (4 + 4), *rūpaka-tāla* (3 + 2 + 2), and *dādrā* (3 + 3). *Tīn-tāla* should not be confused with Western $\frac{4}{4}$, or common time, for the time cycle repeats only after 16 units and is more like four bars of common time.

Characteristic North Indian rhythmic features

Musical forms and instruments. *South India.* Both raga and *tāla* provide bases for composition and improvisation in Indian classical music. A performance usually begins with an improvised section, called *ālāpa,* played in free time without accompaniment of drums. It may have various sections and might on occasion last half an hour or longer. It is followed by a composed piece in the same raga, set in a particular *tāla.* In South Indian music all composed pieces are primarily for the voice and have lyrics. In North India, however, there are also some purely instrumental compositions, called *gat* and *dhun.* The emphasis on the composition varies in the different forms of song and, to some extent, in the interpretation of the performer. In South Indian music the composed piece is generally emphasized more than in the North. Much of the South Indian repertoire of compositions stems from three composers, Tyagaraja, Muthuswami Dikshitar, and Syama Sastri, contemporaries who lived in the second half of the 18th and the beginning of the 19th centuries. The devotional songs that they composed, called *kṛti,* are a delicate blend of text, melody, and rhythm and are the most popular items of a South Indian concert. The composed elements in these songs sometimes include sections such as *niraval,* melodic variations with the same text, and *svara-kalpana,* passages using the Indian equivalent of the sol–fa syllables, which are otherwise improvised.

The longest item in the South Indian concert, called *rāgam-tānam-pallavi,* is, on the other hand, mostly improvised. It begins with a long *ālāpa,* called *rāgam* in

Interaction of composition and improvisation

this context, presumably because this elaborate, gradually developing *ālāpa* is intended to display the raga being performed in as complete a manner as possible, without the limitations imposed by a fixed time measure. This is followed by another improvised section, *tānam,* in which the singer uses meaningless words to produce more or less regular rhythms, but still without reference to time measure. This section, too, is without drum accompaniment. The final section, *pallavi,* is a composition of words and melody set in a particular *tāla,* usually a long or complex one. The *pallavi* may have been composed by the performer himself and be unfamiliar to his accompanists, usually a violinist who echoes the singer's phrases and a drummer who plays the mridanga, a double-ended drum. The statement of the composition is followed by elaborate rhythmic and melodic variations that the accompanists are expected to follow. It is customary to have a drum solo at the end of the *pallavi,* and the performance concludes with a brief restatement of the *pallavi.*

Other forms used in South Indian classical music derive largely from the musical repertoire of *bhārata-nāṭyam,* the classical South Indian dance. The *varṇam,* a completely composed piece, serves mainly as a warming up and is performed at the beginning of a concert. *Pada* and *jāvali* are two kinds of love songs using the poetic imagery characteristic of the romantic-devotional movement mentioned earlier. *Tillānā* has a text composed mostly of meaningless syllables, which may include the onomatopoeic syllables used to represent the different drum sounds. This is a very rhythmic piece and is usually sung in fast tempo.

Melodic, drone, and rhythmic instruments

The ensemble used in present-day South Indian classical music consists of a singer or a main melody instrument, a secondary melody instrument, one or more rhythmic percussion instruments, and one or more drone instruments. The most commonly heard main melody instruments are the *vīṇā,* a long-necked, fretted, plucked lute with seven strings; the *veṇu,* a side-blown bamboo flute; the *nagaswaram,* a long, oboe-like, double-reed instrument with finger holes; the violin, imported from the West about 200 years ago, played while seated on the floor with the scroll resting on the player's left foot; and the *goṭṭuvādyam,* a long-necked lute without frets, played like the Hawaiian guitar, with a sliding stop in the left hand.

The violin is by far the most common secondary melody instrument in South India. It plays in unison where the passage is composed but imitates the voice or main melody instrument in the improvised passages. Of the rhythm instruments, the mridanga, a double-conical, two-headed drum, is the most common. Others include the *kañjīrā,* a tambourine; the *ghaṭam,* an earthenware pot without skin covering; the *morsiṅg,* a metallic jew's harp; and the *tavil,* a slightly barrel-shaped, double-ended drum, which accompanies the *nagaswaram.* The most prominent drone instrument is the four-stringed tamboura, a long-necked lute without frets. It accompanies the voice and all melody instruments, except the *nagaswaram,* which is usually accompanied by the *oṭṭu,* a longer version of the *nagaswaram* but without finger holes. A hand-pumped harmonium drone, called *śruti* or *śruti* box, sometimes replaces the *oṭṭu* or the tamboura.

North India. The most common vocal form in North Indian classical music at the present time is the *khyāl,* a Muslim word meaning "imagination." The *khyāl* is contrasted with the *dhruvapada* (now known as *dhrupad*), which means "fixed words." The two forms existed side by side in the Islāmic period, and it is only in the last century or two that *khyāl* has achieved ascendancy. There are two types of *khyāl.* The first is sung in extremely slow tempo, with each syllable of the text having extensive melisma (prolongation of a syllable over many notes), so that the words are virtually unrecognizable. It is not usually preceded by a lengthy *ālāpa;* instead, *ālāpa*-like phrases are generally sung against the very slow time measure to the accompaniment of the drums. Also characteristic of the *khyāl* are the *sargam tānas,* passages using the Indian equivalent of the sol-fa syllables, and the *ā-kār tānas,* which are rapid runs sung to the syllable *aah.* The second type of *khyāl,* which may be as much as eight times faster than the slow and is generally set in a different *tāla,* follows the slow. Its composed portion is usually quite short, and the main features of the improvisation are the *ā-kār tānas.* Occasionally, a composition called *tarānā,* made up of meaningless syllables, may replace the fast-tempo *khyāl.*

The *ṭhumrī* is another North Indian vocal form and is based on the romantic-devotional literature inspired by the *bhakti* movement. The text is usually derived from the Rādha-Krishna theme and is of primary importance. The words are strictly adhered to, and the singer attempts to interpret them with his melodic improvisations. It is quite usual for a singer to deviate momentarily from the raga in which the composition is set, by using accidentals and evoking other ragas that might be suggested by the words, but he always returns to the original raga.

Some of the North Indian musical forms are very like the South Indian. The vocal forms *dhrupad* and *dhamār* resemble the *rāgam-tānam-pallavi.* They begin with an elaborate *ālāpa* followed by the more rhythmic but unmeasured *non-tom* using meaningless syllables such as *te, re, na, nom,* and *tom.* Then follow the four composed sections of the *dhrupad* or *dhamār,* the latter being named after *dhamār-tāla* of 14 units (5 + 5 + 4) in which it is composed, the former name derived from *dhruvapada.* The song, usually in slow or medium tempo, is first sung as composed; then the performer introduces variations, the words often being distorted and serving merely as a vehicle for the melodic and rhythmic improvisations. Although the *dhrupad-dhamār* form has been out of favour for over a century, it is now apparently being revived.

Instrumental forms

Instrumental music has gained considerable prominence in North India in recent times. The most common instrumental form is the *gat,* which seems to have derived its elements from both *dhrupad* and *khyāl.* It is usually preceded by *ālāpa* and *joṛ,* which resemble the *ālāpa* and *non-tom* sections of the *dhrupad.* On plucked stringed instruments these two movements are often followed by *jhālā,* a fast section in which the rhythmic plucking of the drone strings is used to achieve a climax. The performer usually pauses before the composed *gat* is introduced. Like the *khyāl,* the *gat* can be in slow or fast tempo. The composition is generally short, and the emphasis is on the improvisations of the melody instrumentalist and the drummer, who for the most part alternate in their extemporizing. The final climax may once again be achieved by a *jhālā* section, in which the tempo is accelerated quite considerably. Other forms played on instruments are the *ṭhumrī,* basically an instrumental rendering of a vocal *ṭhumrī,* and *dhun,* which is derived from a folk tune and does not usually follow a conventional raga. One may also hear a piece called *rāga-māla* (literally, "a garland of ragas"), in which the musician modulates from one raga to another, finally concluding with a return to the original raga.

Musical instruments of North India

The most prominent melody instruments used in North Indian classical music are the sitar, a long-necked fretted lute; *surbahār,* a larger version of the sitar; the sarod, a plucked lute without frets and a shorter neck than that of the sitar; the *sāraṅgī,* a short-necked bowed lute; the bansuri, a side-blown bamboo flute with six or seven finger holes; the *sheh'nai,* a double-reed wind instrument similar to the oboe, but without keys; and the violin, played in the same manner as in South India. Secondary melody instruments are used only in vocal music, the two most common being the *sāraṅgī* and the keyboard harmonium, an import from the West. The violin and the *surmaṇḍal,* a plucked board zither, are also used in this context. In recent times, instrumental duets, in which the musicians improvise alternately, have grown in popularity. In these duets the musicians may imitate each other's phrases, temporarily creating something of the effect of a secondary melody instrument.

As with South Indian music, the drone is usually provided by a tamboura (Bengali *tanpura*) or a hand-pumped reed drone similar to the harmonium but without a keyboard, called *sur-peṭī* in North India. The *sheh'nai* is usually accompanied by one or more drone *shehnais,* called *sur.*

The rhythmic accompaniment is usually provided on the tabla, a pair of small drums played with the fingers. As accompaniment to the somewhat archaic *dhrupad,* however, the pakhavāj, a double-conical drum, similar to the South Indian mridanga, is generally used. The *sheh'nai* in classical music is usually accompanied by a small pair of kettledrums, called *ḍukaṛ-ṭikaṛ.*

Interaction with Western music. It is in the sphere of musical instruments that the influence of Western music is most obvious. In addition to the violin and the harmonium, many other Western instruments are occasionally used. These include the clarinet, saxophone, trumpet, guitar, mandolin, and organ. Scholars have criticized the use of some of these instruments on the ground that their tuning, being based on the Western tempered scale (having 12 equal semitones), is not suitable for the performance of Indian music, and All-India Radio has forbidden the use of the harmonium in its programs. Most of the leading North Indian singers, however, have been using the harmonium as a secondary melody instrument for many years and have continued to do so in concerts and on recordings.

Apart from the area of musical instruments, Indian music appears to have absorbed very little of Western music. It is possible that some modern developments in classical music might have been inspired by Western music. These include the slightly increased use of chromaticism (using a succession of semitones) and some of the new drone tunings in which the major third is added (making for example, the drone on the first, third, and fifth notes of the scale, rather than on the first and fifth only). But the evidence is not conclusive, and it could equally be argued that these are natural developments within the system. Western technology has, of course, had a profound influence on Indian music. Sound-amplification devices have made concerts available to large audiences, and the intimate atmosphere in which the music was traditionally performed is now seldom encountered. The Indian musician has been obliged to adapt his music, once played before a select and musically educated group of listeners, to new circumstances involving a mass of people, many of whom are unable to appreciate the finer points of the music. The use of microphones during concerts has had a marked effect on voice production, and, since the voice no longer needs to project over distances, many modern singers now sing with a relaxed throat and produce a more mellow tone.

ıpact
ıtside
India

Since the mid-1950s, Indian classical music has been performed fairly regularly in the West. Initially, the audiences were composed mainly of South Asians, but gradually an increasing number of Westerners have been attending the concerts. Perhaps the music would not have reached beyond a very limited audience were it not for the interest shown by the American violinist Yehudi Menuhin, who sponsored a number of programs in the West, and the British popular-music group the Beatles, who attempted to incorporate the sound of the sitar and other elements of Indian culture into the world of Western popular music. At the same time, several North Indian instrumentalists, such as Ravi Shankar, Ali Akbar Khan, Vilayat Khan, Imrat Khan, and Nikhil Banerjee, were received with overwhelming enthusiasm by Western audiences. By the end of the 1960s the sitar and tabla were heard frequently in Western pop music, jazz, cinema, and television programs, as well as in radio and television advertisements.

Within three or four years, the mass Western involvement with Indian music was over. It is perhaps too early to assess the full impact of this period. It would seem that Indian music has not as yet had any significant influence on Western music. A few modern composers have attempted to incorporate elements of Indian music into their compositions, but their works remain as experiments. The fusing of Indian music and jazz would seem to have more possibilities, since improvisation is an important factor in both, but present attempts have not fulfilled this expectation. Most of these attempts seem to be premature and based on an inadequate understanding of one or the other musical system. (N.A.J.)

Dance and theatre

Theatre and dance in South Asia stem principally from Indian tradition. The principles of aesthetics and gesture language in the *Nāṭya-śāstra,* a 2,000-year-old Sanskrit treatise on dramaturgy, have been the mainstay of all the traditional dancers and actors in India. Even folk performers follow some of its conventions; *e.g.,* the *Kandyan* dancers of Ceylon (now Sri Lanka), who preserve some of the whirls and spins described in this ancient Indian text. Despite the influence of the different religious waves that swept the subcontinent through the centuries, the forms of South Asian dance and theatre were always able to preserve their ancient core.

Traditionally, dance and acting are inseparable. The classical South Asian dancer, equipped with a repertoire of gesture language, alternates between *nṛtta,* pure dance; *nṛtya,* interpretive dance; and *nāṭya,* dance with a dramatic element. (The Sanskrit word *naṭa* means a dancer-actor.) Traditional theatre throughout both South and Southeast Asia is a combination of music, dance, mime, stylized speech, and spectacle. The classical and folk actor must be a dancer, a singer, and a mime in one.

Influence
on South-
east Asia

Between the 2nd century BC and the 8th century AD, South Indian kings sent overseas trade missions, priests, court dancers, and sometimes armies to Southeast Asia. During these years of cultural expansion, Indian dance forms, mythological lore, and the language of gesture flourished in Burma, Cambodia, Java, Sumatra, and Bali. Later, when India's economic and political power shrank, its cultural empire remained intact. Even when these Southeast Asian countries embraced Buddhism or Islām, they continued performing dance dramas with Hindu gods and goddesses, adding to these their own local myths, costumes, and masks. The two Hindu epics, the *Rāmāyaṇa* and the *Mahābhārata,* storehouses of dramatic personae of traditional dramas, have been absorbed by these countries as part of their own cultural heritage. Some dance forms and gesture vocabulary that died out in their land of birth have been preserved in Bali. For a discussion of the dance and theatre of Southeast Asia see the article SOUTHEAST ASIAN ARTS.

THE PERFORMING ARTS IN INDIA

The royal courts and temples of India traditionally have been the chief centres of the performing arts. In ancient times, Sanskrit dramas were staged at seasonal festivals or to celebrate special events. Some kings were themselves playwrights; the most notable of the playwright-kings was Śūdraka, the supposed 4th-century author of *Mṛcchakaṭika* (The Little Clay Cart). Other well-known royal dramatists include Harṣa, who wrote *Ratnāvalī* in the 7th century; Mahendravikramavarman, author of the 7th-century play *Bhagavad-Ajjukiya;* and Viśākhadatta, creator of the 9th-century drama *Mudrārākṣasa.*

Royal
patronage

In the 4th century BC, Kauṭilya, the chief minister of Emperor Candragupta, referred in his book on the art of government, the *Artha-śāstra,* to the low morals of players and advised the municipal authorities not to build houses in the midst of their villages for actors, acrobats, and mummers. But, in the glorious era of the Hindu kings during the first eight centuries after Christ, actors and dancers were given special places of distinction. This tradition continued in the princely courts of India even under British rule. *Kathākali* dance-drama, for instance, was created by the Raja of Kottarakkara, ruler of one of the states of South India in the 17th century. The powerful peshwas of the Marāthā kingdom in the 18th century patronized the *tamasha* folk theatre. Nawab Wajid Ali Shah (flourished mid-19th-century) was an expert *kathak* dancer and producer of Krishnalore plays in which his palace maids danced as the *gopīs* (milkmaids who were devotees of Krishna). Maharajas of Travancore and Mysore competed with each other for the excellence of their dance troupes. In the 20th century, the Maharaja of Banaras (Vārānasi) carried on this tradition by being patron and producer of the spectacular *rāmlīlā,* a 31-day cycle play on Rāma's life that he witnessed every night while sitting on his royal elephant. On special nights the spectators numbered more than 30,000.

Dance is a part of all Hindu rituals. Farmers dance for a plentiful harvest, hunters for a rich bag, fishermen for a good catch. Seasonal festivals, religious fairs, marriages, and births are celebrated by community dancing. A warrior dances before the image of his goddess and receives her blessings before he leaves for battle. A temple girl dances to please her god. The gods dance in joy, in anger, in triumph. The world itself was created by the Cosmic Dance of Lord Śiva, who is called Naṭarāja, the king of dancers, and worshipped by actors and dancers as their patron.

Religious festivals

Religious festivals are still the most important occasions for dance and theatrical activity. The *rāmlīlā kṛṣṇalīlā* and *rāslīlā* in North India (Uttar Pradesh, Delhi, Rājasthān, Haryana, and Punjab), the *chhau* masked dance-drama in Saraikela region in Bihār, and the *bhagavatha mela* in Melatur village in Tamil Nadu are performed annually to celebrate the glory of their particular deities. During the Daśaharā festival every village in North India enacts for a fortnight the story of Rāma's life, with songs, dances and pageants. The *jātrā* in West Bengal is a year-round dramatic activity, but the number of troupes swells to many thousands in Calcutta during the Pūjā festival. The hill and tribal people dance all night to celebrate their community festivals and weddings rich in masks, pageants, and carnivals. In far-flung areas of South Asia, people may not have seen a drama, but there will be hardly a person who has not witnessed or taken part in a community dance.

Audience participation

In folk theatre, traditional dance, classical music, and poetical symposia (especially the Urdu *mushā'irah*), performances are held in the open air or in a well-lit canopied courtyard so that the players can see the spectators and be motivated by their reactions.

For the usually all-night folk dramas, people come with their children, straw mats, and snacks, making themselves at home. At these performances there is a constant inflow and outflow of spectators. Some go to sleep, asking their neighbours to awaken them for favourite scenes. Stalls selling betel leaves, peanuts, and spicy fried things, adorned with flowers and incense and lighted by oil lamps, surround the open-air arena. The clown, an essential character in every folk play, comments on the audience and contemporary events. Zealous spectators offer donations and gifts in appreciation of their favourite actor or dancer, who receives them in the middle of the performance and thanks the donor by singing or dancing a particular piece of his choice. The audience thus constantly throws sparks to the performer, who throws them back. People laugh, weep, sigh, or suddenly fall silent during a moving scene.

In both folk and classical forms of drama, the performer may lengthen or shorten his piece according to audience response. During a *kathak* dance, the drummer, in order to test the perfection of the dancer, disguises the main beat of his drum by slurs and offbeats, a secret he shares with the audience and announces by a loud thump that is synchronized with the dancer's stamping of the foot. At this point in the dance the spectators shout, swaying their heads in admiration. They show their approval and disapproval through delighted groans or sullen headshakes as the performance goes on. In the *rāslīlā,* the audience joins in singing the refrain and marks the beat by hand clapping. At a climactic point the people rock and sway, rhythmically clapping and singing. These practices bind the performers, chanters, and spectators together in a sense of aesthetic pleasure.

Instrumental music and singing

Instrumental music and singing are integral parts of Indian dance and theatre. Musicians, chanters, and drummers sit on the stage in view, a tradition observed throughout almost all of Asia. They watch the dancer and play on their instruments following his movements, whereas in the West the movements of a ballerina are timed and controlled by the already-written music. An Indian dancer is constantly reacting to the accompanying musician, and vice versa. He may signal the chanters and drummers and even instruct them during the performance without spoiling its aesthetic effect.

In some classical dance forms, such as *kuchipudi,* the dancer sings in voiceless whispers as she dances. In *bhārata-nāṭyam* the dance movements are like sculpted music in space, and the accompanying musician is invariably a dance guru (teacher). In *kathak* the rhythmic syllables beaten out by the dancer with her feet are vocalized by the singer and then chirped out by the drummer. No folk dancing is complete without the use of drum and vocal singing. Women's folk singing such as the *giddha* in the Punjab and the men's *kīrtan* in West Bengal takes the form of dance when the rhythm becomes fast.

In folk theatre this relationship is even more apparent. *Rāslīlā* dance sequences are interspersed with the singing as a decorative frill, to accentuate emotional appeal, or to mark the climax of a song. The *yakṣagāna* hero gives a brisk dance number to announce his entry. In many folk forms of opera (*bhavai, terukkūttu,* and *nautanki*), the characters sing and dance at the same time or alternate. Ballad singers from the states of Orissa and Andhra Pradesh dramatize their singing by strong facial gestures and rhythmic ankle bells and execute dance phrases between the narrative singing. On the other hand, no one can imagine a dancer who is not at the same time a musician. This double aesthetic discipline enriches both of these arts, and the Indian audience is conditioned to this tradition.

INDIAN DANCE

Dance in India can be organized into three categories: classical, folk, and modern. Classical dance forms are among the best preserved and oldest practiced in the 20th century. The royal courts, the temples, and the guru to pupil teaching tradition have kept this art alive and unchanged. Folk dancing has remained in rural areas as an expression of the daily work and rituals of village communities. Modern Indian dance, a product of the 20th century, is a creative mixture of the first two forms, with freely improvised movements and rhythms to express the new themes and impulses of contemporary India.

The popularity of dance in 20th-century India can be judged from the fact that there is hardly any Indian motion picture that does not have half a dozen dances in it. In the typical "boy meets girl" film the heroine dances everywhere and anywhere. A film company may not have a script writer (in some cases the financier writes the story himself), but it must have a dance director. To provide ample dance opportunities, motion pictures have been made on the lives of poets, courtesans, and temple dancers and on mythological themes. For these the services of expert dancers are sought.

In the 20th century, classical dance has left the temples and royal courts and is now presented regularly on the stage in large cities. Rich industrialists, international hotels, and the wealthy families of the upper class are the chief patrons. It is not uncommon to have a classical dance recital by a major performer at a business dinner or for the annual function of a club. Some universities have dance as a regular subject in their curricula. Women learn it as a social grace, and young girls learn a few classical dances for greater eligibility in marriage. Folk dancing has also become more common as a contemporary cultural event in the cities. Most colleges have their folk-dance troupes, and even the police of the Punjab have their folk-dance groups to perform the *bhangra.* Folk dance, cut off from its rural settings, has lost much of its original vigour and beauty, but that is the inevitable result of cross-fertilization of regional cultures through folk-troupe exchanges at an interstate level.

Classical dance. *The dance-drama.* India has evolved through its classical and folk traditions a type of dance drama that is a form of total theatre. The actor dances out the story through a complex gesture language, a form that, in its universal appeal, cuts across the multilanguage barrier of the subcontinent. Some of the classical dance-drama forms (*e.g., kathākali, kuchipudi, bhagavatha mela*) enact well-known stories derived from Hindu mythology. The 20th-century dancers Uday Shankar and Shanti Bardhan have created ballets that were inspired by such traditional dance-dramas. Contemporary Indian directors and writers are re-examining traditional dance forms and are using these in their current works for greater psychological appeal and deeper artistic impact. Millions in villages are still entertained by dance-dramas. In spite of the popu-

'he
'āṭya-
āstra

larity of straight prose plays in the cities, the appeal of dance-drama is unquestionably deeper and more satisfying to the rural Indian, whose aesthetics is still rooted in tradition.

The chief source of classical dance is Bharata Muni's *Nāṭya-śāstra* (1st century BC to 1st century AD), a comprehensive treatise on the origin and function of *nāṭya* (dramatic art that is also dance), on types of plays, gesture language, acting, miming, theatre architecture, production, makeup, costumes, masks, and various *bhāvas* ("emotions") and *rasas* ("sentiments"). No other book of ancient times contains such an exhaustive study of dramaturgy.

Techniques and types of classical dance. According to the *Nāṭya-śāstra,* the dancer-actor communicates the meaning of a play through four kinds of *abhinaya* (histrionic representations): *angika,* transmitting emotion through the stylized movements of parts of the body; *vācika,* speech, song, pitch of vowels, and intonation; *āhārya,* costumes and makeup; and *sāttvika,* the entire psychological resources of the dancer-actor.

The actor is equipped with a complicated repertoire of stylized gestures. Conventionalized movements are prescribed for every part of the body, the eyes and hands being the most important. There are 13 movements of the head, seven of the eyebrows, six for the nose, six for the cheek, seven for the chin, nine for the neck, five for the breasts, and 36 for the eyes. There are 32 movements of feet, 16 on the ground and 16 in the air. Various positions of the feet (strutting, mincing, tromping, splaying, beating, etc.) are carefully worked out. There are 24 single-hand gestures (*asaṃyuta-hasta*) and 13 for combined hands (*saṃyuta-hasta*). One gesture (*hasta*) may mean over 30 different things quite unrelated to each other. The *patāka* gesture of the hand, for example, in which all the fingers are extended and held close together with the thumb bent, can represent heat, rain, a crowd of men, the night, a forest, a horse, or a flight of birds. The *patāka* hand with the third finger bent (*tripatāka*) can mean a crown, a tree, marriage, fire, a door, or a king. In *karkaṭa* ("crab"), one of the combined hand gestures, the fingers of the hands are interlocked, and this may indicate a honeycomb, yawning after sleep, or a conch shell. Of course, for each of these different meanings a *hasta* is given a different body posture or action.

The male or female classical dancer portraying a story in a solo performance simultaneously plays two or three principal characters by alternating facial expressions, gestures, and moods. Krishna, his jealous wife Satyabhāmā, and his gentle wife Rukmiṇī, for example, may be played by one person.

āva
d
sa

The aesthetic pleasure of Hindu dance and theatre is determined by how successful the artist is in expressing a particular emotion (*bhāva*) and evoking the *rasa.* Literally *rasa* means "taste" or "flavour" and is that exalted sentiment or mood that the spectator experiences after witnessing a performance. The critics do not generally concern themselves so much about plot construction or technical perfection of a poem or play as about the *rasa* of a particular work. There are nine *rasa:* erotic, comic, pathetic, furious, heroic, terrible, odious, marvellous, and spiritually peaceful. There are nine corresponding *bhāvas:* love, laughter, pathos, anger, energy, fear, disgust, wonder, and quietude.

Four distinct schools of classical Indian dance—*bhārata-nāṭya, kathākali, kathak,* and *manipuri*—exist in the 20th century, along with two types of temperament—*tāṇḍava,* representing the fearful male energy of Śiva, and *lāsya,* representing the lyrical grace of Śiva's wife Pārvatī. *Bhārata-nāṭya,* which takes its name from Bharata's *Nāṭya-śāstra,* has the *lāsya* character, and its home is Tamil Nadu, in South India. *Kathākali,* a pantomimic dance-drama in the *tāṇḍava* mood with towering headgear and elaborate facial makeup, originated in Kerala. *Kathak* is a mixture of *lāsya* and *tāṇḍava* characterized by intricate footwork and mathematical precision of rhythmic patterns; it flourishes in the north. *Manipuri,* with its swaying and gliding movements, is *lāsya,* and it has been preserved in Manipur state in the Assam Hills. In 1958 the Sangeet Natak Akademi (National Academy of Music, Dance and Drama) in New Delhi bestowed classical status on two other schools of dance—*kuchipudi,* from Andhra Pradesh, and *Odissi,* from Orissa. These two styles overlap the *bhārata-nāṭya* school and therefore are not as distinctly different in temperament and style as other forms.

The bhārata-nāṭya school. *Bhārata-nāṭya* (also called *dasi attam*) has survived to the present through the *devadāsīs,* temple dancing girls who devoted their lives to their gods through this medium. Muslim invasions from the north destroyed the powerful Hindu kingdoms in the south but could not disrupt their arts, which took shelter in the temples. After the 16th century the Muslims overpowered the south completely until the British came, thus giving a setback to Hindu dance. Slowly the institution of *devadāsī* fell into disrepute, and temple dancing girls became synonymous with prostitutes. In the latter half of the 19th century in Tanjore, Chinniyah, Punniah, Vadivelu, and Shivanandam, four talented dancers who were brothers, revived the original purity of *dasi attam* by studying and following the ancient texts and temple friezes, with missing links supplied by the socially spurned *devadāsīs.* Their popularized form of *dasi attam* was called *bhārata-nāṭya.*

A performance of *bhārata-nāṭya* lasts for about two hours and consists of six parts, beginning with *allarippu* (Telegu language, "to decorate with flowers"), a devotional prologue that shows off the elegance and grace of the dancer. The second part is *jātisvaram,* a brilliant blaze of *jāti*s ("dance phrases") with *svara*s ("musical sounds"). This is followed by *shabdam,* the singing words that prepare the dancer to interpret through *abhinaya* (gesture language) interspersed with pure dance. The fourth part is *varṇam,* a combination of expressive and pure dance. Then follow the *padam*s, songs in Telegu, Tamil, or Kanarese that the dancer dramatizes by facial expressions and hand gestures. The accompanying singer chants the line again and again, and the dancer enacts the clashing and contrasting meanings. Her virtuosity consists of exhausting all possible shades of suggestion. The performance ends with *tillānā,* a pure dance accompanied by meaningless musical syllables chanted to punctuate the rhythm. The dancer explodes into leaps and jumps forward and backward, from right and left, in a state of ecstasy. *Tillānā* ends with three clangs of the cymbals while the dancer executes a triple blaze of *jāti*s, thumping her feet with a jingling flourish of ankle bells.

Bhārata-nāṭya has attained world recognition as one of the most exquisite forms of classical dance. Its aspirants go to Tamil Nadu to learn from gurus who still live in villages. Because of its *lāsya* character, performing artists have always been women. But their teachers have invariably been old men who chant the lines to tiny cymbals, controlling the complex rhythm without dancing themselves.

The major 20th-century performers associated with the *bhārata-nāṭya* school of dance are T. Balasaraswathi, especially known for her *abhinaya* (expressive interpretation) of *padams*; Rukmini Devi, who popularized *bhārata-nāṭya* among the upper classes in the 1930s; Yamini Krishnamurthi; and Shanta Rao. Two of the most important gurus were Minakshisundaram Pillai, who injected vigour into *bhārata-nāṭya* by his choreography, and his son-in-law, Chokkalingam Pillai.

The kathākali school. *Kathākali* (*kathā,* "story"; *kali,* "performance") originated in the 17th century in Kerala, the lush tropical coastal strip of South India washed by the Arabian Sea. It was devised by the Raja of Kottarakkara, who, angry over the refusal of a neighbouring prince to allow his dancers to perform a Sanskrit dance-drama in his court, decided to create his own dance troupe using Malayalam, the spoken language of the people. This school of dance has its own *hasta*s, based on a regional text influenced by the *Nāṭya-śāstra* and later treatises. It also has marked elements of energetic ritualistic dances. The makeup has its roots in the grotesque Dravidian demon masks of the pre-Hindu period. Themes are taken mainly from the *Rāmāyaṇa,* the *Śiva-Purāṇa,* the *Bhāgavata-Purāṇa,* the *Mahābhārata,* and other religious texts. The superhuman characters represent primal forces of good and evil at war. Because of its terrifying vigour, men play all the roles.

Characters and costumes

Most *kathākali* characters (except those of women, Brahmins, and sages) wear towering headgear and billowing skirts and have their fingers fitted with long silver nails to accentuate hand gestures. The principal characters are classified into seven types. (1) *Pacca* ("green") is the noble hero whose face is painted bright green and framed in a white bow-shaped sweep from ears to chin. Heroes such as Rāma, Lakṣmaṇa, Krishna, Arjuna, and Yudhiṣṭhira fall into this category. (2) *Katti* ("knife"), haughty and arrogant but learned and of exalted character, has a fiery upcurled moustache with silver piping and a white mushroom knob at the tip of his nose. Two walrus tusks protrude from the corners of his mouth, his headgear is opulent, and his skirt is full. Duryodhana, Rāvaṇa, and Kichaka belong to this type. (3) *Chokannatadi* ("red beard"), power-drunk and vicious, is painted jet black from the nostrils upward. On both cheeks semicircular strips of white paper run from the upper lip to the eyes. He has black lips, white warts on nose and forehead, two long curved teeth, spiky silver claws, and a blood-red beard. (4) *Velupputadi* ("white beard") represents Hanuman, son of the wind god. The upper half of his face is black and the lower red, marked by a tracery of curling white lines. The lips are black, the nose is green, black squares frame the eyes, and two red spots decorate the forehead. A feathery gray beard, a large furry coat, and bell-shaped headgear give the illusion of a monkey. (5) *Karupputadi* ("black beard") is a hunter or forest dweller. His face is coal black with crisscross lines drawn around the eyes. A white flower sits on his nose, and peacock feathers closely woven into a cylinder rise above his head. He carries a bow, quiver, and sword. (6) *Kari* ("black") is intended to be disgusting and gruesome. Witches and ogresses, who fall into this category, have black faces marked with queer patterns in white and huge, bulging breasts. (7) *Minnukku* ("softly shaded") represents sages, Brahmins, and women. The men wear white or orange dhotis. Women have their faces painted light yellow and sprinkled with mica, and their heads are covered by saris.

Under a flower-decked canopy on a square, ground-level stage a tall brass worship lamp brimming with coconut oil burns brightly. The musicians and dancers bow before it before they start performing. Drummers standing in one corner pound the *cenda,* a barrel-shaped drum with a piercing, clattering sound suited for battle scenes, and continue throughout the performance, almost without respite.

Two men hold a 12-foot by six-foot (four-metre by two-metre) embroidered hand curtain from behind which the principal characters make their entrances. They dance, grab the trembling curtain, and give vivid facial expressions with fearful glances and grunts. This "peering over the curtain," called *tiranokku,* is a close-up that offers an actor full scope to display his art. At a climactic moment the curtain is whisked away and the character enters in full splendour. The performance lasts all night, the singers singing the text that the dancers act out in an elaborate gesture language.

Well-known performers of *kathākali* include Guru Chandu Panikkar, Guru Kunju Kurup, Ramunni Nair, and Kalamandalam Krishna Nair. The dancers Guru Gopi Nath and Krishnan Kutty have both emphasized simplification of the use of towering headgear and thick-crusted, elaborate makeup, so that the art may be more commonly understood.

The kathak school. Kathak, born of the marriage of Hindu and Muslim cultures, flourished in North India under Mughal influence. *Kathak* dancers retain their 17th-century costumes but are steeped in Rādhā and Krishna love lore. Krishna, playing his flute in the Vṛndāvana woods on the bank of the Yamuna River, is surrounded by the *gopīs* ("milkmaids"). Their play is the eternal game of the god and his devotees, the hide-and-seek of man and woman. This spiritual relationship is deeply passionate, with erotic love-play. Slowly the dance degenerated and found shelter in bawdy houses, where nautch girls practiced the art to make themselves more tantalizing. In the beginning of the 20th century it was reclaimed and revived, however, mainly through the efforts of Kalkaprasad Maharaj, whose three sons Achchan, Lachchu, and Shambhu, perfected the art.

Because of its mixed *lāsya* and *tāṇḍava* temperament, *kathak* is popular with both females and males. In *bhāratanāṭya,* footwork is synchronized with hand gestures and eye movements, but *kathak* has no such rigid technique. It takes its movements from life, stylizes them, and adds complex rhythmic patterns. The mathematical precision in doubling and quadrupling the beat with quick transfers and shifts makes the onlookers dizzy.

Kathak performers

A female *kathak* dancer generally wears a brocade blouse, a long, wide, shimmering silk skirt, a transparent tissue scarf of gold threads, and a heavy cluster of ankle bells. A musician, generally the guru, sits beside the drummer on the floor and vocalizes the complicated syllables of the drum that the dancer beats out with her feet. *Kathak's* basic dance posture and some of the steps can be traced to the *rāslīlā* of Braj Bhoomi. The musical refrain, which is called *lehra,* provides the base on which the drummer and the dancer execute a rich tapestry of rhythmic patterns. Beats are called *mātrās* and the footwork *tatkar.* Important elements of the dance are *chakkars, torahs,* and *tihais. Chakkar* denotes whirling with great speed and stopping for a fraction of time after each whirl within the prescribed beat while at the same time maintaining the beauty of the form. *Torah* is a composition consisting of rhythmic syllables. *Tihai* is the repetition of a phrase of rhythmic syllables used to adorn the concluding part of a *torah.* There are two styles of *kathak:* Jaipur *gharana* and Lucknow *gharana.* While the Lucknow *gharana* excels in *bhāva,* the Jaipur *gharana* specializes in brilliance of footwork.

In the 20th century the major performers of *kathak* include Shambhu Maharaj, who specialized in *bhavapradarśan* ("display of emotion"), and Sunder Prasad, who concentrated on the *tala* and *layakari* aspects of the dance. Birju Maharaj, Gopi Krishan, Sitara Devi, and Damayanti Joshi all have important reputations in India as well as abroad.

The manipuri school. Manipuri has survived in the sheltered valley of Manipur in the Assam Hills. It remained aloof not only from foreign influences but also from the main Indian trends. Its isolation was broken only in the 1920s, when Rabindranath Tagore visited the valley and invited a leading guru of the area, Atomba Singh, to teach at his school in Santiniketan. The supple movements of *manipuri* dance were suitable for Tagore's lyrical dramas, and he therefore employed them in his plays and introduced the dance as a part of the curriculum at his institution.

The *manipuri* dancer wears a large, stiff skirt that is glittering with round mirror pieces and a shimmering gauze veil. Her hair is done up in a high rolled crown that is adorned with chains of white blossoms, and her luminous cheeks and forehead are decorated with dots of sandalwood paste.

Style of the *manipuri* dance

Known for its femininity, *manipuri* is marked by a slow, swooning rhythm. The dancer, with her hips thrust back and head tilted on one side, turns and sways and glides as if in a dream. The immobility of her face, like that of a mask, is in sharp contrast with the other three schools of dance, in which the face and eyes are a major source of expression.

The *manipuri* drummer, his naked torso in a white dhoti with a red border tucked up above his knees, dances while he plays on the drum. He slaps and thumps; the drum rumbles and howls and chuckles. Drunk with its rhythm, the drummer dances in wild, frenzied leaps. His energetic and electric movements are a masculine counterpart to the slow, undulating patterns woven by the female dancer.

Chief 20th-century exponents of *manipuri* include Atomba Singh, who preserved the tradition of *rās* dancing, and Amubi Singh.

The kuchipudi school. Kuchipudi dance-dramas owe their origin to the small village of Kuchipudi (Kuchelapuram) in Andhra Pradesh. Their form was originated in the 17th century by Sidhyendra Yogi, creator of the superb dance-drama *Bhama Kalapam,* which is the story of charming Satyabhāma, jealous wife of Lord Krishna. Sidhyendra Yogi taught the art to Brahmin boys of Kuchipudi and gave a performance with them in 1675 for the Nawab of Golconda, who was so pleased that he granted Kuchipudi to the Brahmin Bhavathas for the preservation of this art. Even in the 20th century every Brahmin of Kuchipudi is expected to perform at least once in his life the role of Satyabhāma as an offering to Lord Krishna.

The *kuchipudi* dance begins with worship rituals. A male dancer moves about sprinkling holy water, and then incense is burned. *Indra-dhvaja* (the flagstaff of the god Indra) is planted on the stage to guard the performance against outside interference. Women sing and dance with worship lamps, followed by the worship of Gaṇeśa, the elephant god, who is traditionally petitioned for success before all enterprises. The *bhagavatha* (stage manager-singer) sings invocations to the goddesses Sarasvatī (Learning), Lakṣmī (Wealth), and Paraśakti (Parent Energy), in between chanting drum syllables.

Two men hold up the traditional coloured curtain. A long gold-embroidered braid is hung on the curtain as a challenge to anyone among the spectators who dares to act and dance. If anyone should take up this braid, the hero playing the female character Satyabhāma will cut off "her" hair. The principal characters are introduced from behind the curtain after each one has done a brisk dance, and at that time the *bhagavatha* sings out the background and function of each. All roles are traditionally played by men (but in recent times by women also), and all the four elements of *abhinaya* are used—dance, song, costume, and psychological resources. Thus, *kuchipudi* differs from other classical dances in which the performers do not sing.

Among the major *kuchipudi* dancers of the 20th century are Guru Chinta Krishnamurthi, Vedantam Satyanarayana, and Yamini Krishnamurthi.

Odissi. Odissi, practiced in Orissa, claims to be over 2,000 years old and the true inheritor of the *Nāṭya-śāstra* tradition. It originated and was initially developed in the temples and later flourished in the courts as well. Many of the 108 basic dance units (*karaṇas*) mentioned in the *Nāṭya-śāstra* can be found only in *odissi,* and many of its dance poses are sculpted on the exterior of the temples of Bhubaneswar, Konārak, and Purī. Kelu Charan Mahapatra and Indrani Rehman are the principal 20th-century figures associated with *odissi.*

Bhagavatha mela, mohini attam, and kuṟavañci

semiclassical dance forms are *bhagavatha mela, mohini attam,* and *kuṟavañci.* Performed at the annual Narasimha Jayanti festival in Melatur village in Tamil Nadu, the *bhagavatha mela* uses classical gesture language with densely textured Karnatak music. Its repertoire was enriched by the musician-poet Venkatarama Sastri (1759–1847), who composed important dance-dramas in the Telugu language. *Mohini attam* is based on the legend of the Hindu mythological seductress Mohinī, who tempted Śiva. It is patterned on *bhārata-nāṭya* with elements of *kathākali.* It uses Malayalam songs with Karnatak music. *Kuṟavañci* is a dance-drama of lyrical beauty prevalent in Tamil Nadu. It is performed by four to eight women, with a gypsy fortune-teller as initiator of the story of a lady pining for her lover. Formally, it is a mixture of the folk and classical types of Indian dance.

Folk dance. Indian folk dances have an inexhaustible variety of forms and rhythms. They differ according to region, occupation, and caste. The half-naked Adivasis (aboriginal tribes) of central and eastern India (Murias, Bhīls, Gonds, Juangs, and Santāls) are the most uninhibited in their dancing. There is hardly a national fair or festival where these dances are not performed. The most impressive occasion occurs every January 26 on Republic Day, when dancers from all parts of India come to New Delhi to dance in the vast arena of the National Stadium and along a five-mile parade route.

Types of folk dances

It is difficult to categorize Indian folk dances, but generally they fall into four groups: social (concerned with such labours as tilling, sowing, fishing, and hunting); religious; ritualistic (to propitiate an angry goddess or demon with magical rites); masked (a type that appears in all the above categories).

The *kolyacha* is among the better known examples of social folk dance. A fisherman's dance indigenous to the Konkan coast of western central India, the *kolyacha* is an enactment of the rowing of a boat. Women wave handkerchiefs to their male partners, who move with sliding steps. For wedding parties young Kolis dance in the streets carrying household utensils for the newlywed couple, who join the dance at its climax.

The national social folk dance of Rājasthān is the *ghoomar,* danced by women in long full skirts and colourful *chuneri*s (squares of cloth draping head and shoulders and tucked in front at the waist). Especially spectacular are the *kacchi ghori* dancers of this region. Equipped with shields and long swords, the upper part of their bodies each arrayed in the traditional attire of a bridegroom and the lower part concealed by a brilliant-coloured papier-mâché horse built up on a bamboo frame, they enact jousting contests at marriages and festivals. Bawaris, by tradition a criminal tribe, generally are expert in this form of folk dance.

In the Punjab, the most electrifying social folk dance is the male harvest dance, *bhangra,* which is also popular in the Punjab province of Pakistan. This dance is always punctuated by a song. At the end of every line the drum thunders. The last line is taken up by all the dancers in a chorus. In ecstasy they spring, bellow, shout, and gallop in a circle, madly wiggling their shoulders and hips. Any man of any age can join.

The Lambadi Gypsy women of Andhra Pradesh wear mirror-speckled headdresses and skirts and cover their arms with broad, white bone bracelets. They dance in slow, swaying movements, with men acting as singers and drummers. Their social dance is imbued with impassioned grace and lyricism and is less wild than that of Gypsies in other parts of the world.

The bison-horn dance of the Muria tribe in Madhya Pradesh is performed by both men and women, who traditionally have lived on equal terms. The men wear a horned headdress with a tall tuft of feathers and a fringe of cowry shells dangling over their faces. A drum shaped like a log is slung around their necks. The women, their heads surmounted by broad, solid-brass chaplets and their breasts covered with heavy metal necklaces, carry sticks in their right hands like drum majorettes. Fifty to 100 men and women dance at a time. The male "bisons" attack and fight each other, spearing up leaves with their horns and chasing the female dancers in a dynamic interpretation of nature's mating season.

The Juang tribe in Orissa performs bird and animal dances with vivid miming and powerful muscular agility.

Religious folk dance

Some major examples of religious folk dances are the *dindi* and *kala* dances of Mahārāshtra, which are expressions of religious ecstasy. The dancers revolve in a circle, beating short sticks (*dindi*s) to keep time with the chorus leader and a drummer in the middle. As the rhythm accelerates, the dancers form into two rows, stamp their right feet, bow, and advance with their left feet, making geometric formations. The *kala* dance features a pot symbolizing fecundity. A group of dancers forms a double-tiered circle with other dancers on their shoulders. On top of this tier a man breaks the pot and splashes curds over the naked torsos of the dancers. After this ceremonial opening, the dancers twirl sticks and swords in a feverish battle dance.

Garabā, meaning a votive pot, is the best known religious dance of Gujarāt. It is danced by a group of 50 to 100 women every year for nine nights in honour of the goddess Ambā Mātā, known in other parts of India as Durgā or Kālī. The women move in a circle bending, turning, clapping their hands, and sometimes snapping their fingers. Songs in praise of the goddess accompany this dance.

Of the endless variety of ritualistic folk dances, many have magical significance and are connected with ancient cults. The *karakam* dance of Tamil Nadu state, mainly performed on the annual festival in front of the image of Māriyammai (goddess of pestilence), is to deter her from unleashing an epidemic. Tumbling and leaping, the dancer retains on his head without touching it a pot of uncooked rice surmounted by a tall bamboo frame. People ascribe this feat to the spirit of the deity, which, it is believed, enters his body. The Therayattam festival in Kerala is held to propitiate the gods and demons recognized by the pantheon of the Malayalis. The dancers, arrayed in awe-inspiring costumes and hideous masks, enact weird rituals before the village shrine. A devotee makes an offering of a cock. The dancer grabs it, chops off its head in one stroke, gives a blessing, and hands the bloody gift back to the devotee. This ceremony is punctuated by a prolonged and ponderous dance.

Masked folk dances

The greatest number of masked folk dances are found in Arunachal Pradesh (formerly North East Frontier Agency) union territory of India, where the influence of Tibetan dance may be seen. The yak dance is performed in the Ladākh section of Kashmir and in the southern fringes of the Himalayas near Assam. The dancer impersonating a yak dances with a man mounted on his back. In *sada topo tsen* men wear gorgeous silks, brocades, and long tunics with wide flapping sleeves. Skulls arranged as a diadem are a prominent feature of their grotesquely grinning wooden masks representing spirits of the other world. The dancers rely on powerful, rather slow, twirling movements with hops. The *chhau,* a unique form of masked dance, is preserved by the royal family of the former state of Saraikela in Bihār. The dancer impersonates a god, animal, bird, hunter, rainbow, night, or flower. He acts out a short theme and performs a series of vignettes at the annual Chaitra Parva festival in April. *Chhau* masks have predominantly human features slightly modified to suggest what they are portraying. With serene expressions painted in simple, flat colours, they differ radically from the elaborate facial makeup of *kathākali* or the exaggerated ghoulishness of the Nō and Kandyan masks. His face being expressionless, the *chhau* dancer's body communicates the total emotional and psychological tensions of a character. His feet have a gesture language; his toes are agile, functional, and expressive, like those of an animal. The dancer is mute; no song is sung. Only instrumental music accompanies him. In another form of *chhau,* practiced in the Mayūrbhanj district of Orissa, the actors do not wear masks, but through deliberately stiff and immobile faces they give the illusion of a mask. The style of their dance is vigorous and acrobatic.

Modern Indian dance. While in the West the theatrical elements of spoken words, music, and dance developed independently and evolved in the forms of drama, opera, and ballet, Indian theatrical tradition continued to combine the three in its dramas. Indian films still follow this rule (the heroine suddenly bursts into a song or dances for the hero), which offends Western sensibility, but in fact they are following their own classical and folk tradition. Recently, dance in the form of ballet with complex choreography in the Western sense has emerged as a distinct form.

Modern ballet

Modern Indian ballet started with Uday Shankar, who went to England to study the plastic arts and was chosen by the Russian ballerina Anna Pavlova to be her partner in the ballet *Radha and Krishna.* Young Shankar returned to India fired with enthusiasm. After studying the essentials of the four major styles of classical dance, he created new ballets with complex choreography and music, mixing the sounds from wooden clappers and metal cymbals with those of traditional instruments. He used classical and folk rhythms. Employing Western stage techniques, he presented his ballets with a skill and polish previously unknown to Indian audiences. These ballets included *Shiva-Parvati* and *Lanka Dahan* ("The Burning of Lanka"), in which he used wooden masks from Ceylon. In *Rhythm of Life* (1938) and in *Labour and Machinery* (1939), he employed contemporary political and social themes. He established a culture centre at Almora in 1939 and during its four years' existence created a whole generation of modern dancers.

Shanti Bardhan, a junior colleague of Uday Shankar, produced some of the most imaginative dance-dramas of the modern period. After founding the Little Ballet Troupe in Andheri, Bombay, in 1952 he produced *Ramayana,* in which the actors moved and danced like puppets. His posthumous production *Panchatantra (The Winning of Friends)* is based on an ancient fable of four friends (Mouse, Turtle, Deer, and Crow), in which he used masks and the mimed movements of animals and birds.

Mohan Khokar

"Ramayana," puppet-style modern dance-drama originally produced and choreographed by Shanti Bardhan, *c.* 1952.

Narendra Sharma and Sachin Shankar, both pupils of Uday Shankar, have continued his tradition. Other important figures who have shaped modern Indian dance include Menaka, Ram Gopal, and Mrinalini Sarabhai, who has experimented with conveying modern themes through the *bhārata-nāṭya* and *kathākali* styles.

Dance-training centres. Dance training in small academies and local *kala kendras* ("art centres") is available all over contemporary India. Most universities have introduced dance as a subject in their curricula. The gurus still impart specialized training to pupils who go to live with them in villages and learn the art over a number of years. But there are many state-run or public-financed training centres organized in the 20th century that attract students from all over the world. Among the most important of these are Kerala Kalamandalam (Kerala Institute of Arts), near Shoranūr; Kalakshetra at Adyar, Tamil Nadu; Kathak Kendra, a dance branch of the Bharatiya Kala Kendra in New Delhi; Triveni Kala Sangam (Centre of Music, Dance, and Painting), at New Delhi; Darpana Academy in Ahmadābād, Gujarāt; Visva-Bharati (founded by Rabindranath Tagore), at Santiniketan, West Bengal;

and the Jawaharlal Nehru Manipuri Dance Academy, at Imphāl.

INDIAN THEATRE

Classical theatre. Classical Sanskrit theatre flourished during the first nine centuries of the Christian era. Aphorisms on acting appear in the writings of Pāṇini, the Sanskrit grammarian of the 5th century BC, and references to actors, dancers, mummers, theatrical companies, and academies are found in Kauṭilya's book on statesmanship, the *Artha-śāstra* (4th century BC). But classical structure, form, and style of acting and production with aesthetic rules were consolidated in Bharata Muni's treatise on dramaturgy, *Nāṭya-śāstra.* Bharata defines drama as a

Bharata Muni's rules

> mimicry of the actions and conduct of people, rich in various emotions, depicting different situations. This relates to actions of men good, bad and indifferent and gives courage, amusement, happiness, and advice to all of them.

Bharata classified drama into ten types. The two most important are *nāṭaka* ("heroic"), which deals with the exalted themes of gods and kings and draws from history or mythology (Kālidāsa's *Śakuntalā* and Bhavabhūti's *Uttararāmacarita* fall into this caterory), and *prakaraṇa* ("social"), in which the dramatist invents a plot dealing with ordinary human beings, such as a courtesan or a woman of low morals (Śūdraka's *Mṛcchakaṭika,* "The Little Clay Cart," belongs to this type). Plays range from one to ten acts. There are many types of one-act plays, including *bhaṇa* ("monologue"), in which a single character carries on a dialogue with an invisible one, and *prahasana* ("farce"), which is classified into two categories: superior and inferior, both dealing with courtesans and crooks. King Mahendravikramavarman's 7th-century-AD *Bhagavad-Ajjukiya* ("The Harlot and the Monk") and *Mattavilāsa* ("Drunken Revelry") are examples of *prahasana.*

Types of classical theatre

There are three structural types of classical theatre: oblong, square, and triangular, each further divided into large, medium, and small sizes. According to the *Nāṭya-śāstra,* the playhouse was "like a mountain cave" with two floors at different levels, small windows so that outside noise and wind would not interfere with the acoustics, and a backstage for actors to do makeup, costumes, and offstage noise effects. Bharata disapproved of a large playhouse and recommended the medium-size structure meant for court productions.

The ancient Hindus insisted on a small playhouse, because dramas were acted in a highly stylized gesture language with subtle movements of eyes and hands. Hindu theatre differed from its Greek counterpart in temperament and method of production. The three unities rigidly followed by the Greeks were totally unknown to Sanskrit dramatists. Less time was consumed by a Greek program of three tragedies and a farce than by a single Sanskrit drama, with its subsidiary plots and wide variety of characters and moods. The Greeks laid emphasis on plot and speech, the Hindus on the four types of acting and visual demonstration. People were audiences to the Greeks and spectators to the Hindus. The aesthetic rules also differed. Aristotle's theory of catharsis bears no resemblance to Bharata's theory of *rasa.* The Greek conception of tragedy is totally absent in Sanskrit dramas, as is the aesthetic principle that prohibits any death or defeat of the hero on stage.

Kinds of Hindu production

There were two types of Hindu productions: the *lokadharmī,* or realistic theatre, with natural presentation of human behaviour and properties catering to the popular taste, and the *nāṭyadharmī,* or stylized drama, which, using gesture language and symbols, was considered more artistic. In *Śakuntalā* the king enters riding an imaginary chariot, and Śakuntalā plucks flowers that are not there; in "The Little Clay Cart" the thief breaks through a nonexistent wall, and Maitreya passes through Vasantasena's seven courtyards by miming.

A classical play traditionally opened with the *nāndī,* a benediction of eight to 12 lines of verse in praise of the gods, after which the *sūtra-dhāra* (stage manager) entered with his wife and described the place and occasion of the action. The last sentence of his prologue served as a bridge leading to the action of the play. In *Śakuntalā* he refers to the bewitching song of his wife, which has made him forget his surroundings as the pursuit of a deer has made the king forget his state affairs. At this point the king enters, riding his hunting chariot, and the spectators are plunged into action of the play.

The *vidūṣaka* (clown) is a noble, good-hearted, blundering fool, the trusted friend of the hero. A bald-headed glutton, comic in speech and manners, he is the darling of the spectators. With the decline of Sanskrit drama the folk theatre in various regional languages inherited the conventions of the opening prayer song, the *sūtra-dhāra,* and the *vidūṣaka.*

The only surviving Sanskrit drama is *kudiyattam,* still performed by the Cakkayars of Kerala. Some principles of the *Nāṭya-śāstra* are evident in their presentations.

The earliest available classical dramas are 13 plays edited in 1912 by Pandit Ganapati Sastri, who dug out their manuscripts in Trivandrum, the capital of Kerala state. These, ascribed to Bhāsa (1st century BC–1st century AD), include the one-act *Ūrubhaṅga* ("The Broken Thigh"), a tragedy that is a departure from Sanskrit convention, and the six-act *Svapnavāsavadatta* ("The Dream of Vāsavadattā").

The most acclaimed dramatist is Kālidāsa. Other important playwrights succeeding him include Harṣa, Mahendravikramavarman, Bhavabhūtī, and Viśakhādatta. An exception is King Śūdraka, whose work is perhaps the most theatrical in the entire Sanskrit range.

"The Litt Clay Cart

The title of "The Little Clay Cart" represents a departure from Sanskrit tradition, in which a *prakaraṇa* was generally named after its hero and heroine. *Mālavikāgnimitra,* for example, is the love story of Princess Mālavikā and King Agnimitra, *Vikramorvaśī* is the tale of King Purūravas and the heavenly nymph Urvaśī, and *Mālatī-Mādhava* is the love drama of Mālatī and Mādhava. Śūdraka, as if to mock tradition, chose an insignificant homely incident—the hero's son playing with a toy cart—and elevated this to the title.

"The Little Clay Cart" has a wide range of characters. The plot does not progress in a straight line but zigzags along a winding path. During its 10 acts the hero does not appear in four of them, the heroine is absent from three, and the lustful villain disappears after the first act until the eighth. Each act is an almost independent play. The device used to link the acts is that of ending them with subtitles that sum up their particular themes or plots.

"The Little Clay Cart" has been successful in the West, whereas Indian audiences, still fed on poetic-flavoured characters and romances of an ethereal type, have favoured *Śakuntalā.* Western audiences find "The Little Clay Cart" more in their own tradition of realism and individualized characterization. Its "lisping villain," gamblers, and rogues have something in common with Shakespeare's comic characters and Molière's crooks. "The Little Clay Cart" is better theatre, whereas *Śakuntalā* is better poetry.

Folk theatre. After the decline of Sanskrit drama, folk theatre developed in various regional languages from the 14th through the 19th centuries. Some conventions and stock characters of classical drama (stage preliminaries, the opening prayer song, the *sūtra-dhāra,* and the *vidūṣaka*) were adopted into folk theatre, which lavishly employs music, dance, drumming, exaggerated makeup, masks, and a singing chorus. Thematically it deals with mythological heroes, medieval romances, and social and political events, and it is a rich store of customs, beliefs, legends, and rituals. It is a "total theatre," invading all the senses of the spectators.

The most crystalized forms are the *jātrā* of Bengal, the *nautanki, rāmlīlā,* and *rāslīlā* of North India, the *bhavai* of Gujarāt, the *tamāshā* of Mahārāshtra, the *terukkūttu* of Tamil Nadu, and the *yakṣagāna* of Kanara.

Places and kinds of folk theatre

Folk theatre is performed in the open on a variety of arena stages; round, square, rectangular, multiple-set. The *bhavai,* enacted on a ground-level circle, and the *jātrā,* on a 16-foot (five-metre) square platform, have gangways that run through the surrounding audience and connect the stage to the dressing room. Actors enter and exit through these gangways, which serve a function similar to the *hanamichi* of the Japanese Kabuki theatre. In the *rāmlīlā,* the action sometimes occurs simultaneously at various levels on a multiple set. Actors in *nautanki* and *bhavai* sit on the stage in full view instead of exiting and sing or play an instrument as a part of the chorus. In the *rāmlīlā,* the actor playing Rāvaṇa removes his ten-headed mask when he is not acting and continues sitting on his throne, but for the spectators he is theatrically absent. Asides, soliloquies, and monologues abound. Scenes melt into one another, and the action continues in spite of change of locale.

In most folk forms the art of the actor is hereditary. He learns by watching his elders throughout childhood. He starts with drumming, then dancing, plays female roles, and then major roles.

All roles are played by men except that of the *tamāshā* woman, who is always a dancer-singer-actress. Recently, women have started playing female roles in the *jātrā* but have failed to achieve the artistic stature of their professional male counterparts.

In the *rāmlīlā* and *rāslīlā,* the principal characters—Rāma and Krishna—are always played by boys under 14, because tradition decreed they must be pure and innocent. They are considered representatives of the gods and are worshipped on these occasions. In the *rāmlīlā* the *vyas* ("director"), present on the stage throughout the performance, prompts and directs the characters loudly enough for the audience to hear. This is not regarded as disturbing because it is an accepted part of the tradition. Adult roles such as Rāvaṇa and Hanuman are sometimes played by the same individual throughout his life.

Of the nonreligious forms, the *jātrā* and the *tamāshā* are most important. The *jātrā,* also popular in Orissa and eastern Bihār, originated in Bengal in the 15th century as a result of the *bhakti* movement, in which devotees of Krishna went singing and dancing in processions and in their frenzied singing sometimes went into acting trances. This singing with dramatic elements gradually came to be known as *jātrā,* which means "to go in a procession." In the 19th century the *jātrā* became secularized when the repertoire swelled with love stories and social and political themes. Until the beginning of the 20th century, the dialogue was primarily sung. The length has been cut from all night to four hours. The *jātrā* performance consists of action-packed dialogue with only about six songs. The singing chorus is represented by a single character, the *vivek* ("conscience"), who can appear at any moment in the play. He comments on the action, philosophizes, warns of impending dangers, and plays the double of everybody. Through his songs he externalizes the inner feelings of the characters and reveals the inner meaning of their outer actions.

The *tamāshā* (a Persian word meaning "fun," "play," or "spectacle") originated at the beginning of the 18th century in Mahārāshtra as an entertainment for the camping Mughal armies. This theatrical form was created by singing girls and dancers imported from North India and the local acrobats and tumblers of the lower-caste Dombari and Kolhati communities with their traditional manner of singing. It flourished in the courts of Marāthā rulers of the 18th and 19th centuries and attained its artistic apogee during the reign of Bājī Rāo II (1796–1818). Its uninhibited *lavani*-style singing and powerful drumming and dancing give it an erotic flavor. The most famous *tamāshā* poet and performer was Ram Joshi (1762–1812) of Sholāpur, an upper class Brahmin who married the courtesan Bayabai. Another famous singer-poet was Patthe Bapu Rao (1868–1941), a Brahmin who married a beautiful low-caste dancer, Pawala. They were the biggest *tamāshā* stars during the first quarter of the 20th century. The *tamāshā* actress, commonly called the *nautchi* (meaning "nautch girl," or "prostitute") is the life and soul of the performance. Because of their bawdy elements, women never see *tamāshā* plays, nor do respectable men.

In the 20th century, *jātrā* and *tamāshā* both have become highly organized and are commercially run. Troupes are in heavy demand and work for nine months. Over 700 *tamāshā* troupes with 2,000 dancer-actresses tour the rural areas, providing a living for about 40,000 people. The *jātrā* is the most successful commercially. Its star actors draw more than any other professional actor in the theatrical centre of Calcutta.

Puppet
theatre
of North
India

Popular in North India are the *putliwalas* ("puppeteers") of Rājasthān, who operate marionettes made of wood and bright-coloured cloth. The puppet plays deal with kings, lovers, bandits, and princesses of the Mughal period. Generally, the puppeteer and his nephew or son operate the strings from behind, while the puppeteer's wife sits on her haunches in front of the miniature stage playing the drums and commenting on the action. The puppeteer chirps, whimpers, and squeals in animal–bird voices and creates battles and tragic moments, expresses pathos, anger, and laughter. In Andhra Pradesh the puppets, called *tholu bommalata* ("the dance of leather dolls"), are fashioned of translucent, coloured leather. These are projected on a small screen, like colour photographic transparencies. Animals, birds, gods, and demons dominate the screen. The puppeteer manipulates them from behind with two sticks. Strong lamps are arranged so that the size, position, and angle of the puppets change with the distance of the light. They are similar to the *wayang kulit* puppets of Indonesia but are much smaller and quicker moving.

In the absence of a powerful Indian city theatre (with the exception of a few in Calcutta, Bombay, and Tamil Nadu), folk theatre has kept the rural audiences entertained for centuries and has played an important part in the growth of modern theatres in different languages. The 19th-century dramatist Bharatendu Harishchandra, who was responsible for the birth of Hindi drama, used folk conventions—the opening prayer song, tableaux, comic interludes, duets, stylized speech—and combined these with Western theatrical forms in vogue at that time. Parsi companies adapted the popular folk techniques for their extravaganzas and were a major influence until the 1930s. Rabindranath Tagore, rejecting the heavy sets and realistic decor of the commercial companies, created a lyrical theatre of the imagination. Much influenced by the *baul* singers and folk actors of Bengal, he introduced the Singing Bairagi and the Wandering Poet (similar to the *vivek* of the *jātrā*) in his dramas. In the late 20th century, folk theatre has been viewed as a form that can add colour and vitality to contemporary theatre.

Modern theatre. Modern Indian theatre first developed in Bengal at the end of the 18th century as a result of Western influence. The other regional theatres more or less followed Bengal's pattern, and within the next 100 years they took the same meandering path, though they never achieved the same robust growth.

British
influence
on
Bengali
theatre

The British conquered Bengal in 1757 and influenced local arts by their educational and political systems. Their clubs performed Shakespeare, Molière, and Restoration comedies, introducing Western dramatic structure and the proscenium stage to the Indian intelligentsia. With the help of Golak Nath Dass, a local linguist, Gerasim Lebedev, a Russian bandmaster in a British military unit, produced the first Bengali play, *Chhadmabes* ("The Disguise"), in 1795 on a Western-style stage with Bengali players of both sexes. Subsequently, Bengali playwrights began synthesizing Western styles with their own folk and Sanskrit heritage. With growing national consciousness, theatre became a platform for social reform and propaganda against British rule. Among the most important playwrights were Michael Madhu Sudan (1824–73), Dina Bandhu Mitra (1843–87), Girish Chandra Ghosh (1844–1912), and D.L. Roy (1863–1913).

The success of Dina Bandhu Mitra's *Nildarpan* ("Mirror of the Indigo"), dealing with the tyranny of the British indigo planters over the rural Bengali farm labourers, paved the way for professional theatre. The actor-director-writer Girish Chandra Ghosh founded in 1872 the National Theatre, the first Bengali professional company, and took *Nildarpan* on tour, giving performances in the North Indian cities of Delhi and Lucknow. The instigatory speeches and lurid scenes of British brutality resulted in the banning of this production. To overcome censorship difficulties, playwrights turned to historical and mythological themes with veiled symbolism that was clearly understood by Indian audiences. The heroes and villains of these plays came to represent the Indian freedom fighter against the British oppressor. Girish's historical tragedies *Mir Qasim* (1906), *Chhatrapati* (1907), and *Sirajuddaulah* (1909) bring out the tragic grandeur of heroes who fail because of some inner weakness or betrayal of their colleagues. D.L. Roy emphasized the same aspect of nationalism in his historical dramas *Mebarapatan* (The Fall of Mebar), *Shahjahan* (1910), and *Chandragupta* (1911).

Girish introduced professional efficiency and showmanship. His style of acting was flamboyant, with fiery grace. Actors such as Amar Datta and Dani Babu carried his style into the early 1920s. The acting and production methods of the Star, the Minerva, and the Manmohan Theatres (all professional) were modelled on Girish's pioneer work.

The beginning of realism

The first elements of realism were introduced in the 1920s by Sisir Kumar Bhaduri, Naresh Mitra, Ahindra Chowdhuri, and Durga Das Banerji, together with the actresses Probha Devi and Kanka Vati. In his Srirangam Theatre (closed in 1954), Sisir performed two most memorable roles: the again Mughal emperor Aurangzeb and the shrewd Hindu philosopher-politician Cānakya. Sisir's style has been refined by actor-director Sombhu Mitra and his actress wife Tripti, who worked in the Left-wing People's Theatre movement in the 1940s. With other actors they founded the Bahurupee group in 1949 and produced many Tagore plays including *Rakta Karabi* ("Red Oleanders") and *Bisarjan* ("Sacrifice"), so far unattempted by any professional company.

Rabindranath Tagore (1861–1941), steeped in Hindu classics and indigenous folk forms but responsive to European techniques of production, evolved a dramatic form quite different from those of his contemporaries. He directed and acted in his plays along with his cousins, nephews, and students. These productions were staged mostly at his school, Santiniketan, in Bengal as a nonprofessional and experimental theatre. The Calcutta elite and foreign visitors were attracted to these performances.

A painter, musician, actor, and poet, Tagore combined these talents in his productions. He used music and dance as essential elements in his latter years and created the novel opera-dance form in which a chorus sat on the stage and sang while the players acted out their roles in dance and stylized movements. Sometimes Tagore himself sat on a stool acting as the *sūtra-dhāra* and chanted to the accompaniment of music and drum as the dancing players became visual moving pictures.

In northern and western India, theatre developed in the latter half of the 19th century. The Bombay Parsi companies, using Hindi and Urdu, toured all over India. Their spectacular showmanship, based on a dramatic structure of five acts with songs, dances, comic scenes, and declamatory acting, was copied by regional theatres. The Maharashtrian theatre, founded in 1843 by Visnudas Bhave, a singer-composer-wood-carver in the court of the Raja of Sāngli, was developed by powerful dramatists such as Khadilkar and Gadkari, who emphasized Marāthā nationalism. The acting style in Maharashtrian theatre remained melodramatic, passionately arousing audiences to laughter or tears.

In the south, the popularity of dance-dramas has not allowed theatrical realism to flourish. Tamil commercial companies with their song and dance extravaganzas have dominated Andhra Pradesh, Kerala, and Mysore. The most outstanding Tamil company since the independence of India in 1947 has been the T.K.S. Brothers of Madras, famous for trick scenes and gorgeous settings. Also famous is the actor-producer-proprietor Rajamanickam, who specializes in mythological plays with an all-male cast, using horses, chariots, processions, replicas of temples, and even elephants.

Urdu and Hindi drama

Urdu and Hindi drama began with the production of *Indrasabha* by Nawab Wajid Ali Shah in 1855 and was developed by the Parsi theatrical companies until the 1930s.

Parsi theatre was an amalgam of European techniques and local classical forms, folk dramas, farces, and pageants. Mythical titans thundered on the stage. Devils soared in the air, daggers flew, thrones moved, and heroes jumped from high palace walls. Vampire pits, the painted back cloth of a generalized scene, and mechanical devices to operate flying figures were direct copies of the 19th-century Lyceum melodramas and Drury Lane spectacles in London.

The star film actor Prithvi Raj Kapoor founded Prithvi Theatres in Bombay in 1944 and brought robust realism to Hindi drama, then closed down in 1960 with a sense of completion after many tours throughout India. Prithvi's sons, nephews, and old associates worked in his large company, which became a training centre for many actors who later joined the films. Among these was the outstanding stage actress Zohra Sehgal, a former dance partner of Uday Shankar in the 1930s who had tremendous emotional depth and range, rare in actresses on the Hindi stage. Out of Prithvi's eight productions, in which he always played the lead, the best was *Pathan* (1946), which ran for 558 nights. It deals with the friendship between a tribal Muslim khān and a Hindu dewan and is set in the rugged frontier from which Prithvi came. This tragedy of two archtypes in which the khān sacrifices his son to save the life of his friend's son had intensity of action, smoldering passion, and unity of mood and achieved the highest quality of realism on the Hindi stage to this day.

Among the actors who molded regional-language theatres are Shri Narayan Rao Rajhans (popularly known as the Bala Gandharva of the Mahārāshtra stage), Jayashankar Bhojak Sundari of Gujarāt, and Sthanam Narasimhrao of Andhra. All three specialized in female roles and were star attractions during the first quarter of the 20th century.

In the last half of the 20th century, two outstanding actor-directors are Ebrahim Alkazi, director of the National School of Drama in New Delhi, and Utpal Dutt, who founded the Calcutta Little Theatre Group in 1947, which originally performed plays in English and in 1954 changed to productions in Bengali. Dutt is an actor fully committed to the revolutionary ideology of the Chinese Communist leader Mao Tse-tung. He acts on open-air stages in rural areas of Bengal, where he exerts a strong artistic and political influence.

Since Lebedev in 1795 there has been a continuous stream of Western-trained actors and producers who have been revitalizing regional-language theatrical groups. Nawab Wajid Ali Shah had visiting French opera composers in his mid-19th-century court. Tagore did his first opera, *Valmiki Pratibha* ("The Genius of Vālmīkī"), in 1881, after returning from England, where he became familiar with Western harmonies. Prithvi Raj Kapoor, E. Alkazi, and Utpal Dutt all had their earlier training in English productions. Norah Richards, an Irish-born actress who came to the Punjab in 1911, produced in 1914 the first Punjabi play, *Dulhan* ("The Bride"), written by her pupil I.C. Nanda. For 50 years she promoted rural drama and inspired actors and producers, including Prithvi Raj Kapoor.

India's genius still lies in its dance-dramas, which have a unique form based on centuries of unbroken tradition. There are very few professional theatre companies in the whole of India, but thousands of amateur productions are staged every year by organized groups. Out of this intense experimental activity, the Indians hope a contemporary national theatre will emerge, influenced by Western techniques but distinctly Indian in flavour.

ntres
ining

Many centres for theatrical training have been established in the 20th century. Among the most important are the National School of Drama and the Asian Theatre Institute in New Delhi, Sangeet Natak Akademi (National Academy of Music, Dance, and Drama) in New Delhi, and the National Institute for the Performing Arts in Bombay. Bharatiya Natya Sangh, the union of all Indian theatre groups, was founded in 1949 and is centered in New Delhi. Affiliated with UNESCO's branch of the International Theatre Institute, it organizes drama festivals and seminars, as well as serving as a centre for information.

SRI LANKA (CEYLON)

The ritualistic dances of Sri Lanka have attained world fame for their weird mystical beauty. Literary drama has not flourished, because the monks of predominantly Buddhist Sri Lanka shunned theatre. Dramatic activity found expression in exorcism ceremonies and masked dramas that employed mime, song, dance, acrobatics, and bits of prose dialogue. Heavily influenced by India, Sri Lanka's Kandyan dance and *kōlam* plays have South Indian origins. But over the centuries these have been transformed and now have a distinctly Sri Lankan character.

It is difficult to divide Sri Lankan performing arts into dance and drama, because a *kōlam* play uses dance and song, and the devil dance has bits of improvised prose dialogue.

Dance. *Devil dance.* The Buddhists of Sri Lanka still believe in supernatural beings and the healing power of magical rites. Their devil dancing is the expression, however, of pre-Buddhist beliefs.

The devil dance is performed to cure a person gripped by disease, insanity, or bad luck believed to be caused by some malignant spirit and to propitiate demons and deities to bring good fortune. The dancers belong to a lower-caste community and are professional. During their performance the patient lies to one side. Several palm-leaf shrines are constructed outside his house, each dedicated to a particular demon to lure him into the arena. The role of the Vesamuni, king of all demons, is played by the chief exorcist.

Three types of supernatural beings have to be appeased: demons, deities, and others that are half demon, half deity. The most terrible is Riri Yakka (Demon of Blood), who inhabits cremation grounds and graveyards and rides a pig. His belly is smeared with blood, and he has a monkey's face and four clawed hands that hold a parrot, a sword, a rooster, and a human head.

ostumes
f the
evil
ancers

The dancers, all men, each wear around their heads a red cloth fringed with long ribbons of palm leaves hanging down like female hair, a strip of cloth around their chests, 22 yards (20 metres) of thin white cloth wound so skillfully around their hips that it never comes loose during an entire night of violent activity, and clusters of bells fitted around their calves to make a deafening jingle. Their appearance is half female, half male.

The dance is punctuated by little pieces of mimes and magical actions, with naked-chested drummers pounding to the accompaniment of a chorus of singers. The climax is reached when the dancers, holding flaming torches in both hands, whirl and spin, forming circles of fire around themselves. The flames lick their bodies, but they remain unsinged. The dancers leap and dive through the air in seeming defiance of gravity. In this surcharged atmosphere they pause to put on masks representing various demons. These have terrifying expressions. They romp and stomp in circles, describing their identity and purpose of visiting. The particular demon associated with the malady enters the patient's body. The chief exorcist questions, threatens, torutures, beseeches, and offers bribes to appease the demon until it finally leaves and its victim is healed.

The *sanni yakku* dance, exorcising the disease demon, has a series of humorous impersonations. One is of the demon as a beautiful woman, then as a pregnant woman, and finally as a mother. The exorcists ask questions about her pregnancy, and she lists all the respectable men of the village.

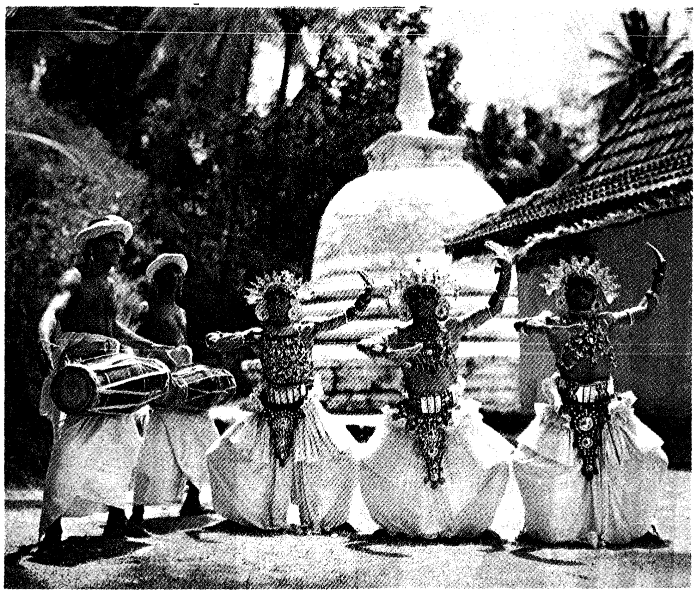
Out of many devil-dance ceremonies, most picturesque and important are the *kohomba kankariya* (or "ritual of the god Kohomba"), performed to ensure prosperity and to get rid of pestilence, and the *bali,* danced to propitiate the heavenly beings.

Kandyan dance. The *kandyan* dance, shorn of occult ceremonies, is highly sophisticated and refined. It flourished under the Kandyan kings from the 16th through the 19th centuries, and today it is considered the national dance of Sri Lanka. It has four distinct varieties: The *pantheru, naiyadi, udekki,* and *ves* (the most artistic and renowned). Its energetic movements and postures are reminiscent of India's *kathākali.* Besides the above four styles, there are 18 *vannamas* (dance enactments) including the *gajaga vannama,* depicting the elephant; the *hanuma vannama,* the monkey; and the *mayura vannama,* the peacock. These beautiful animal movements and abstract impersonations have been distilled and perfected over several hundred years.

The
vannamas

Hindu mythological themes were originally the subjects of *kandyan* dances, the most popular being Rāma's crossing over to Laṅkā with the help of his monkey general and his reunion with Sītā. Gradually, stories of kings and legendary heroes and mimes of birds and forest beasts were introduced. The Kandyan kings elevated the dance to such beauty and skill that the Buddhists began admitting it into their temple courtyards as a tribute to the glory of their religion. It became a part of the annual August Perahera festival, in which a procession of gilded elephants, palanquins, saffron-robed monks, drummers, and chanters move majestically to the Temple of the Tooth in Kandy, where Buddha's tooth is enshrined. The *kandyan* dancers are a glittering attraction as they perform en route to the temple.

Ewing Krainin—Stockpile



Kandyan dancers and drummers from Sri Lanka.

A *kandyan* dancer wears a pagoda-like conical silver headpiece with glistening forehead fringe and huge earpieces, many-stranded bead necklaces of silver and ivory across his naked torso, beaten-silver epaulets on his biceps, and hollow silver anklets filled with silver beads to make them rattle. He spins with sudden leaps and reaches violent climaxes of geometric patterns. The sudden right and left turns of his head make the onlookers dizzy. When telling a story, he sings descriptive passages and enacts them with spurts of dancing.

Masked drama. Out of the four folk-drama forms—*kōlam, sokari, nadagam,* and *pasu*—the most highly de-

The *kōlam*

veloped and significant is the *kōlam,* in which actors wear brightly painted and intricately carved wooden masks. The word *kōlam* is of Tamil origin and means "costume," "impersonation," or "guise." The performance consists of the masked representation of many isolated characters, such as kings, demons, deities, hunters, animals and birds, the washerman, the police constable, a pregnant woman—a British Museum manuscript concerning the *kōlam* lists 53 such characters. The most terrifying masks are of the demons, with twisted faces, protruding tusks, and cavelike nostrils for snorting fury. The *nāga* demon has a long, flaming, red tongue and dozens of cobras writhing around his head. Some old masks have only one large bulging eye, with a cobra hissing out from one nostril. The design of these masks lies between the strongly stylized tribal masks of Africa and the highly polished, sophisticated masks of the Japanese Nō Theatre. Five basic colours are used—red, blue, yellow, green, and black, the last two for lower rank characters. Exaggerated comicality, distortions, bulges, nightmarish whimsy, bright colours, and artful carving of the masks have been significant factors in keeping this form of drama alive.

The *kōlam* is performed once a year for seven to ten nights, starting at night after dinner and lasting through the early hours of the morning. The performance is generally held in the open courtyard of a house, to the accompaniment of two drummers, an instrumentalist, and a singing chorus with leader. After songs in praise of Lord Buddha and others (including the patron of the show), the *sabhapati* (master of ceremonies) describes the origin of *kōlam*—how an Indian king's pregnant wife expressed a desire to see a masked dance-drama and how a troupe was invited from a distant court. The *sabhapati* then introduces the masked characters as they enter and describes their various vocations and backgrounds.

Out of many, two plays are especially famous: the *Sandakinduru Katava* and the *Gothayimbala Katava.* The former deals with the legendary idyllic love between a half-human, half-bird couple singing and dancing in a forest. The King of Banaras comes hunting and, attracted by the beautiful Kinduri, kills her husband and makes advances to her. Rejected, he is ready to kill her when Lord Buddha appears and brings her husband back to life. In the *Gothayimbala Katava* the beautiful wife of the warrior Gothayimbala bathing in a pond attracts the attention of a demon, who falls in love with her. The enraged husband comes and chops off the demon's head, which, because of its magical power, reunites itself with the body every time it is cut off. Finally, the forest deity comes and rescues the warrior.

The recorded history of *kōlam* is not very old. There is only one known early eye witness account of *kōlam,* that of John Callaway, who in 1829 published 185 verses of a play with a description of the performance and some sketches of the masks and a brief introduction concerning the masquerade. According to Callaway, the dancers did not sing. The chanters described the characters in the third person and sometimes exclaimed to draw the attention of the audience to a particular action. The earliest *kōlam* text is preserved in the Colombo National Museum on palm leaves; another is in the British Museum inscribed on paper. The oldest printed text, edited in 1895 by A.G. Perera, is in the Colombo National Museum Library.

Masks are made of the light woods kaduru (Strychnos nux vomica) and ruk-attana (*Alstonia scholaris*) and after 50 years start decaying; consequently, the earlier masks are no longer in existence.

There has been an important revival of interest in drama in Sri Lanka since independence. E.R. Sarachchandara, a scholar of traditional Ceylonese theatre, has been responsible for a major breakthrough in revitalizing and adapting for the modern stage traditional dramatic forms such as the *kōlam.* Several new playwrights have become prominent in the mid-20th century. Foremost among them is Henry Jayasena. A producer-writer-actor, Jayasena has written and staged plays in Sinhalese and translations of foreign plays. But modern theatre is still very weak.

DANCE AND THEATRE IN KASHMIR

The Vale of Kashmir, predominantly populated by Muslims, has remained aloof from the main cultural currents of India. The ancient caves and temples of Kashmir, however, reveal a strong link with Indian culture at the beginning of the Christian Era. At one time the classical dances of the south are believed to have been practiced. When Islām was introduced, in the 14th century, dancing and theatrical arts were suppressed, being contrary to a strict interpretation of the Qur'ān. These arts survived only in folk forms and were performed principally at marriage ceremonies. The popular *hafiza* dance performed by Kashmiri women at weddings and festivals to the accompaniment of *sufiana kalam* (devotional music of the Muslim mystics known as Ṣūfīs) was banned in the 1920s by the ruling maharaja, who felt this dance was becoming too sensual. It was replaced by the *bacha nagma,* performed by young boys dressed like women. A popular entertainment at parties and festivals, it is also customarily included in modern stage plays.

In contrast to its natural scenic richness, Kashmir is theatrically a pauper. Theatrical productions are generally amateurish, since there is no regular performing company or any tradition of civic theatre.

Bhand jashna

There is only the *bhand jashna* ("festival of clowns"), a 300- to 400-year-old genre of Kashmiri folk theatre. Performed in village squares, it satirizes social situations through dance, music and clowning.

The Kashmiri-language theatre was founded in 1947, when a new national consciousness, the aftermath of the independence of the Indian subcontinent from Britain, inspired playwrights and folk actors to dramatize topical events and create a "visual newspaper" for the people. Left-wing propaganda plays such as *Zamin Sanz* ("Who Owns the Land?") and *Jangbaaz* ("The Warmonger"), though mediocre, had topical interest. Notable among those who tried their hand at writing for the stage is the poet Nadim, author of two operas, *Bambur-yambarzal (The Bumblebee)* and *Himal Nagraj (The Beautiful Woman and the Snake Prince).*

Since the 1960s, the Jammu and Kashmir Academy of Art, Culture, and Languages has been struggling to promote theatre in the Kashmiri and Dogri languages, but with little success. Its emphasis is on literary dramas and folk-dance festivals of regional appeal.

PAKISTAN

Muslim culture has frowned upon the performing arts, with the result that there is no Arabic or Persian classical theatre. The only possible sources of drama were the Persian passion plays dealing with the martyrdom of Ḥuysayn (grandson of Muḥammad) in the desert of Karbalā' in 680 AD, which have inspired some Urdu playwrights. Pakistan, a Muslim country, therefore either had to find a theatrical heritage in Urdu and Bengali theatre, which had been flourishing in India long before the partition, or look to the West. It did both. The Urdu-language theatre of Pakistan had started in the Lucknow court of Nawab Wajid Ali Shah in 1855 and was nurtured by both Muslim and Hindu artists. In Pakistan the *kathak* style is preferred because of its strong Muslim flavour and Mughal court associations. Cut off from Hinduism and its lore, Pakistani performers use these Indian classical dance styles to interpret the aspirations of a young nation, while their folk dances express the character of Pakistan's rural culture.

Khaṭak

Folk dance. Pakistan's dances are virile and explosive. *Bhangra* and Khaṭak are the most popular. Khaṭak is a dance of the tribal Pathans, known for their hospitality and feuds in the rugged hills of the northwest. It originated in zealous preparations for raids and celebrations of victories. In the 20th century, any joyous event is the occasion for this community dance. The Pathans, dressed in baggy *salwars,* embroidered waistcoats, and skullcapped turbans, perform it holding a rifle in both hands. In a frenzy they spin and somersault, float and whirl, with sudden bursts of swordplay to the accompaniment of drums and pipes. Because of its popularity, Khaṭak is presented to visiting dignitaries and for this purpose has been refined into choreographed productions.

Bhangra, folk dance of the Punjab region of Pakistan and India.

Lustig—FPG

male
nces

Important dances by women are the *sammi, kikli, giddha,* and *luddi.* Except for the *sammi,* which has a slow rhythm accompanied by a sad song because of its association with the tragic love legend of Princess Sammi and Prince Dhola, all the other forms are charged with energy and fast rhythms. The *kikli* is performed by teen-age girls in groups of two. The partners cross their arms, interlock their fingers, and, touching the toes of their feet, stretch backward and whirl. The *giddha* is danced in a circle, the participants keeping the rhythm by clapping their hands. Two women impulsively leave the circle, jump into the centre, and perform a hilarious mimetic dance enacting a *boli* (two-line song) and again join the circle to dance in a ring and allow another couple to take the centre. In the *luddi,* women click their fingers and clap their hands, moving in a circle by jumps and half-turns and accelerating their rhythm by stamping their feet.

Performing arts in the Punjab. The genius of Punjabis finds expression in love stories, lusty dancing, and humour. The *mirasi*s (professional wits), *naqalia*s (mummers), and *domani*s (female singer-actresses) are professional performers belonging to the lower classes. They exploit all the tricks of exaggeration, absurdity, malapropism, comic gags, and lewd references. In the performance of a *naqal* (comic sketch), two people constitute a troupe. The leader holds a leather folder and slaps his foolish partner, who leads his master to a hilarious situation through absurd replies. Expert in mime and clowning, these character types are distantly related to the Western court fool and the commedia dell'arte.

Theatre in Pakistan. Urdu theatre grew out of a spectacular production of *Indrasabha* ("The Heavenly Court of Indra"), an operatic drama written by the poet Agha Hasan Amanat and produced in 1855 in the palace courtyard of the last Nawab of Oudh, Wajid Ali Shah. The story deals with the love of a fairy and Prince Gulfam. The fairy takes her lover to heaven where the angry and jealous Indra hurls him down to earth. Finally, the fairy, through her songs and dances, wins the heart of Indra, and the two lovers are united. Wajid Ali Shah, an expert *kathak* dancer and author of many valuable treatises on stage techniques, composed some of the melodies and dances for his production and used folk conventions, gorgeous costumes, elaborate settings, and gold-inlaid masks. *Indrasabha* was a fantastic success; it was translated into almost all the regional languages, with many local variants. Its characters—Sabaz Pari (Green Fairy), Kala Deo (Black Devil), Lal Deo (Red Devil)—became a part of the theatrical vocabulary of the subcontinent.

Parsi theatre. During the second half of the 19th century, Urdu was the main spoken and written language of the northern half of the subcontinent and understood in almost all the principal cities. The Parsis (originally Zoroastrians from Iran who settled on the coast of Bombay), comprising a wealthy community with sharp business acumen, were the pioneers in establishing a commercial theatre, that lasted from 1873 to 1935 and influenced all the other regional theatres. Though located mainly in Bombay and Calcutta, the Parsi companies toured the subcontinent with huge staffs, sets, and an army of players.

The best known playwright of this period is Agha Hashr (1876–1935), a poet-dramatist of flamboyant imagination and superb craftsmanship. Among his famous plays are *Sita Banbas,* based on an incident from the *Rāmāyaṇa; Bilwa Mangal,* a social play on the life of a poet, whose blind passion for a prostitute results in remorse; and *Aankh ka Nasha* ("The Witchery of the Eyes"), about the treachery of a prostitute's love, with realistic dialogue of a brothel. Many of Hashr's plays were adapted from Shakespeare: *Sufayd Khūn* ("White Blood") was modelled on *King Lear,* and *Khūn-e Nāḥaq* ("The Innocent Murder") on *Hamlet.* His last play, *Rustam-o-Sohrab,* the tragic story of two legendary Persian heroes, Rustam and his son Sohrab, is a drama of passion and fatal irony.

Parsi
productions

Productions by Parsi theatrical companies were large-budgeted affairs. Plays opened with the actors in full makeup and costume, their hands folded and eyes closed, singing a prayer song in praise of some deity, and generally ended in a tableau. Sometimes at curtain call the director rearranged the tableau in a split second and offered a variant. Actors were required to know singing, dancing, music, acrobatics, and fencing and to possess strong voices and good physical bearing. In improvised auditoriums with bad acoustics and packed with more than 2,000 people, actors' voices reached the farthest spectator. Plays began at 10 o'clock and lasted until dawn, moving from comedy to tragedy, from pathos to farce, from songs to the rattle of swords, all interspersed with moral lessons and rhyming epigrams. The droll humour and realism of the comic interludes remain unsurpassed in contemporary Urdu drama. Important playwrights of this period were Narain Prasad Betab, Mian Zarif, and Munshi Mohammed Dil of Lucknow. All took inspiration from Hindu mythology and Persian legends, transforming these tales into powerful dramas.

Imtiaz Ali Taj (1900–70) was a bridge between Agha Hashr and contemporary Pakistani playwrights. His *Anarkali* (1922), the tragic love story of a harem girl, Anarkali, and Crown Prince Salim (son of Akbar the Great), unfolds the love-hate relationship of a domineering emperor and his rebellious son. Brilliant in treatment and character analysis, this play has been staged hundreds of times by amateur groups and has entered the list of Urdu classics.

In the absence of a professional company, Urdu theatre has found it difficult to strike roots. After 1947 many Muslim actors and writers were absorbed by the Indian film industry in Bombay, and they found it difficult to adjust their great talent to amateur theatrical clubs. All the same, plays have been staged in Karāchi, Lahore, and Rāwalpindi. The best productions have been those dealing with topical themes—refugee problems, new adjustments, the corrupt bureaucracy, the Kashmir issue, and other sociopolitical issues. Agha Babar in Rāwalpindi produced *Burra Sahib* (1961: "The Big Boss"), an adaptation of Gogol's *Government Inspector,* setting it in Pakistan. *Tere Kuce se Jub Hum Nikle* ("Thrown Out of Your Lane"), by Naseer Shamshi, describes the pathetic condition of an aristocratic family in Delhi that is forced to leave home because of communal riots. In *Lal Qile se Lalukhet Tak* ("From the Red Fort to Lalukhet"), by Khwajah Moinuddin, the comedy arises out of the pitiable condition of the refugees who leave their well-settled existence in Delhi dreaming of prosperity, take a tedious journey, and arrive homeless in Karāchi to find shelter in thatched hovels. Ali Ahmed, an avant-garde actor-director in Karāchi, presents his plays with polished stagecraft and esoteric appeal.

Lahore remains the centre of amateur theatre based on the tradition of the late directors A.S. Bokhari and G.D.

Sondhi, both former principals of the Government College in Lahore. In 1942 G.D. Sondhi built the Open-Air Theatre, situated on a small artificial hillock in the Lawrence Gardens and perhaps the best in all of South Asia. It has remained the centre of dramatic contests and festivals and is a favourite of visiting dancers and actors.

The actor-playwright Rafi Peer, with his knowledge of Western theatre as a result of his training in Berlin in the 1930s, has helped to develop Pakistani theatre. Professional in approach, he has produced radio and stage plays and has been a critical colleague of A.S. Bokhari and Imtiaz in the revival of amateur theatre.

Radio and television plays. Plays are being written for radio and television that are readily adaptable for the stage, and vice versa. Saadat Hussan Mantoo (1912–55), the greatest writer of short stories and author of over 100 radio plays and features, is still the model for contemporary writers for plot construction, bitter realism, and whimsical dialogue. His collection of plays (1942–45), including *Mantoo ke Dramay* ("Mantoo's Plays"), *Ao* ("Come"), and *Teen Aurten* ("Three Women"), have flashes of the then-unborn Theatre of the Absurd.

More dramas are written in Urdu today than are staged. The turnover is large because of their generally amateurish character and short runs. There is no major professional centre for the training of actors, nor a school for stagecraft and production. Notwithstanding, the young directors and playwrights have been enthusiastic about establishing a permanent Urdu stage.

BANGLADESH

East Bengal continued the folk *jātrā* and used this form for themes concerning current political problems and historical events. A successful example of the latter is *Nawab Sirajuddaulah,* which deals with the fall of the last Muslim ruler of Bengal in 1757 through betrayal by his ambitious brother-in-law Mīr Jaʿfar, who joined the British. This *jātrā* is popular with both rural and urban audiences. Tales of Muslim kings and lovers from Persian legends also have been rendered into *jātrās*.

Contemporary theatre inherits the tradition of the prepartition Bengali stage. The poet-playwright Nazrul Islam followed the tradition of Tagore's verse plays and dance operas. Inspired by left-wing ideology, he wrote for the People's Theatre in East Bengal, championing the cause of the poor farmer. He has dealt with psychological problems and inner tensions in his *Shilpi* ("The Artist"), in which the artist is torn between love for his wife and for his art. Especially popular are historical themes of political significance, inspiring Muslims who for centuries were subjugated by the Hindus of East Bengal. Ebrahim Khan wrote *Kamal Pasha* (1926), a play about the Turkish liberator, a symbol of hope and reawakening, and *Anwar Pasha,* about the downfall of Anwar (Enver), who could not cope with the new historical forces.

Bangladesh has a solid acting tradition and a rich repertoire of Bengali plays. Its amateur stage has professional actors, and it retains the impassioned lyricism and power of the mainstream of Bengali tradition. (B.Ga.)

Visual arts

VISUAL ARTS OF THE INDIAN SUBCONTINENT

Indian art is the term commonly used to designate the art of the Indian subcontinent, which includes the present political divisions of India, Kashmir, Pakistan, and Bangladesh. Although a relationship between political history and the history of Indian art before the advent of Islām is at best problematical, a brief review will provide a broad context. The earliest urban culture of the subcontinent is represented by the Indus Valley civilization (*c.* 2500–1800 BC), which possessed several flourishing cities not only in the Indus Valley but also in Gujarāt and Rājasthān. The circumstances in which this culture came to an end are obscure. Although there is no clear proof of historical continuity, scholars have noticed several striking similarities between this early culture and features of later Indian civilization. The period immediately following the urban Indus Valley civilization is marked by a variety of essentially rural cultures. A second urbanization began to occur only around the 6th century BC, when flourishing cities started to reappear, particularly in the Gangetic Basin. The Buddha lived and preached in this period, which culminated in the great Maurya Empire, whose relatively few works are the earliest surviving remnants of monumental art. The Maurya dynast Aśoka (died 238 BC) is considered the greatest of Buddhist kings; and the majority of the monuments of the next 500 years appear to be dedicated to the Buddhist faith, though iconographical and other details suggest that the art also drew heavily on popular religion.

The Maurya Empire spread over almost all of what is modern India and Pakistan. Territories as extensive were never possessed by any other dynasty. With its fall, the empire broke up into a number of states ruled by many dynasties, some of which acquired considerable power and fame for varying periods of time. Among these, the Śuṅgas (*c.* 2nd–1st century BC) in the north and the longer-lived Sātavāhanas in the Deccan and the south are particularly noteworthy. Though these kings were Hindu by religion, Buddhist monuments form the great majority of surviving works.

Toward the end of the 1st century BC, northern India was subjected to a series of invasions by Scythian tribes, resulting finally in the establishment of the vast Kushān (Kuṣāṇa) empire, of which Mathurā was an important centre. The new rulers seemed to have followed Indian faiths, the great emperor Kaniṣka (*c.* AD 78) being a devout Buddhist. The schools of Gandhāra and Mathurā flourished during their rule, and, though much of the work is dedicated to the Buddhist religion, the foundations of later Hindu iconography were also laid in this period. While the Kushān dynasty was sovereign in the north, the Sātavāhanas continued to rule in the south. The bulk of the work at Amarāvatī was produced during their hegemony.

The Golden Age of India

Around the mid-4th century, the Gupta dynasty, of indigenous origin, rapidly expanded its power, uprooting the last remnants of foreign rule and succeeding in bringing almost all of northern India under its sway. In the Deccan there arose at the same time the equally powerful Vākāṭakas, with whom the Guptas appear to have had friendly relations. The period extending from the 4th through the 5th centuries is marked by the most flourishing artistic activities. In addition to the Buddhist monuments, there are the first strong indications of specifically Hindu patronage. Works of remarkable beauty and elegance were produced in this period, which is commonly called the Golden Age of India.

The disintegration of these two empires toward the close of the 5th and the 6th centuries ushered in what has been called the medieval period (*c.* 8th–12th centuries), marked by the appearance of a large number of states and dynasties, often at war with each other. Their rise to power and their decline was part of a constantly recurring process, for none of them was able to hold onto a position of even relative paramountcy for any extended period of time. In the north, the great dynasties were the Gurjara-Pratīhāras, whose empire at its greatest equalled that of the Guptas; the Pālas, who ruled chiefly over northeastern India; and various other dynasties, such as the Kalacuris, the Candelas, and the Paramāras of north central India, the Cāhamānas of Rājasthān, the Cālukyas of Gujarāt. In the Deccan, also, several dynasties rose and fell, the most powerful of which were the Cālukyas of Bādāmi, the Rāṣṭrakūṭas, and the Cālukyas of Kalyāṇī. They were often at war not only with their powerful neighbours to the north but also with the great Pallava and Cōḷa kingdoms of southern India. Most of the dynasties of medieval India were Hindu, though some Jaina and a very few Buddhist kings are also known. The various faiths, however, existed in comparative harmony; and Buddhist and Jaina monuments continued to be built, though most of the surviving works are Hindu.

Although the effects of constant struggle were not as devastating as one might expect, largely as a result of the institutionalization of war and its confinement to appropriate castes, the Hindu kingdoms fell easy prey to the Islāmic invasions, which began as early as the 8th century

AD but gathered strength only in the 11th century. By the end of the 12th century, almost all of northern India had been conquered. Islāmic advances in the south were checked for a while by the Vijayanagara dynasty, but with its collapse almost all of India fell under various degrees of Islāmic hegemony. Large Hindu kingdoms enjoying differing degrees of independence continued to exist chiefly in Rājasthān and portions of southern India, but overall political supremacy was vested with the Islāmic states. The Muslim powers were also divided into many kingdoms, despite attempts made by the sultanate of Delhi, and later by the Mughals, to achieve paramountcy over large portions of India. These attempts were successful only for short periods of time. Although the initial impact of Islām on Indian art was generally destructive, Islāmic influences entering India were gradually transformed in the new environment and eventually resulted in the flowering of an extremely rich and important aspect of the Indian genius.

cenden- of the ıropean wers

The ascendency of the European powers in the 18th century, culminating in the establishment of the British Empire, laid the foundation of modern India's contacts with the West. As a whole, the European advent was marked by a relative insensitivity to native art traditions, but rising nationalism attempted a conscious revival of Indian art toward the end of the 19th century. In modern times, the absorption of European influence is a more natural, freer process that affects artistic development in a vital and profound way.

General characteristics. *The unity of Indian art.* Indian art is spread over a subcontinent and has a long, very productive history; but it nevertheless shows a remarkable unity and consistency. Works produced in the several geographical and cultural regions possess decidedly individual characteristics but at the same time have sufficient elements in common to justify their being considered manifestations of a general style. The existence of this style is evidence of the essential cultural unity of the subcontinent and to the uninterrupted contact between the various geographical units, at least from the historical period onward. Developments in one area have been quickly reflected in the others. The regional idioms have contributed to the richness of Indian art, and the mutual influences exercised by them have been responsible for the multi-faceted development of that art throughout the course of its long life.

The style of Indian art is largely determined not by a dynasty but by conditions of time and space. It has, essentially, a geographical rather than a dynastic basis, which is to say that the evolution of regional schools appears to have been largely independent of any particular dynasty that happened to rule over a specific region. The style does not change because of the conquest of one area by another dynasty; rather the influences exercised by one area on another are usually through the agency of factors other than conquest. Instances in which dynastic patronage changed the nature of a style are very few and confined mostly to the Islāmic period. The political history of India is itself quite vague, and the areas in possession of a dynasty at various points in its history are even less susceptible to precise definition. For all these reasons, the classification of Indian art adopted here is not based on dynasties, for such a division has little meaning. Nevertheless, names of certain dynasties are used, for these have passed into common usage. When this is done, however, the name must be understood as little more than a convenient way of labelling a particular period.

The materials of Indian art. Indian art employs various materials, such as wood, brick, clay, stone, and metal. Most wooden monuments of the early period have perished but have been imitated in stone. Clay and brick were also abundantly used; but, particularly in later times, the favoured material seems to have been stone, in the dressing (facing and smoothing) and carving of which the Indian artist attained great excellence. The material may have influenced the form somewhat, but essentially Indian art tends to impose the form on the material. Thus, materials are generally regarded as interchangeable: wooden and clay forms are imitated in stone, and stone is imitated in bronze, and in turn stone sculpture assumes qualities appropriate to metal. It is as though the nature of the material presented a challenge that had to be met and overcome. At the same time, Indian art stresses the plasticity of forms; sculpture is generally characterized by emphatic mass and volume; architecture is often sculpture on a colossal scale; and the elements of painting, particularly of the early period, are modelled by line and colour.

Emphasis on the plasticity of forms

Indian and foreign art. Thanks to its geographical situation, the Indian subcontinent has been constantly fed by artistic traditions emanating from West and Central Asia. The Indian artist has shown a remarkable capacity for accepting these foreign influences naturally and assimilating and transforming them to accord with the nature of his own style. The process occurred frequently: in the Maurya period; in the two centuries after Christ, when the Kushān dynasty attained imperial supremacy in the north; and at a much later period, in the 16th century, when the Mughals patronized a new school of architecture and painting.

Just as India received influences, so it transmitted its own art abroad, particularly to Ceylon and the countries of Southeast Asia. Developments of great importance were therby precipitated in Ceylon, Burma, Thailand, Indonesia, and Indochina, where the reinterpretation of Indian influences resulted in the creation of works of great originality.

Indian art and religion. Indian art is religious inasmuch as it is largely dedicated to the service of one of several great religions. It may be didactic or edificatory as is the relief sculpture of the two centuries before and after Christ; or, by representing the divinity in symbolic form (whether architectural or figural), its purpose may be to induce contemplation and thereby put the worshipper in communication with the divine. Not all Indian art, however, is purely religious, and some of it is only nominally so. There were periods when humanistic currents flowed strongly under the guise of edificatory or contemplative imagery, the art inspired by and delighting in the life of this world.

Although Indian art is religious, there is no such thing as a sectarian Hindu or Buddhist art, for style is a function of time and place and not of religion. Thus it is not strictly correct to speak of Hindu or Buddhist art, but, rather, of Indian art that happens to render Hindu or Buddhist themes. For example, an image of Vishnu and an image of Buddha of the same period are stylistically the same, religion having little to do with the mode of artistic expression. Nor should this be surprising in view of the fact that the artists belonged to nondenominational guilds, ready to lend their services to any patron, whether Hindu, Buddhist, or Jaina.

Religion, symbolism, and abstraction

The religious nature of Indian art accounts to some extent for its essentially symbolic and abstract nature. It scrupulously avoids illusionistic effects, evoked by imitation of the physical and ephemeral world of the senses; instead, objects are made in imitation of ideal, divine prototypes, whose source is the inner world of the mind. This attitude may account for the relative absence of portraiture and for the fact that, even when it is attempted, the emphasis is on the ideal person behind the human lineaments rather than on the physical likeness.

The artist and patron. Works of art in India were produced by artists at the behest of a patron, who might commission an object to worship for spiritual or material ends, in fulfillment of a vow, for the discharge of virtues enjoined by scripture, or even for personal glory. Once the artist received his commission, he fashioned the work of art according to his skill, gained by apprenticeship, and the written canons of his art, which possessed a holy character. There were prescribed rules for proportionate measurement, iconography, and the like, often with a symbolic significance. This is not to say that the individual artist was invariably aware of the symbolic meaning of the prescribed standards, based as these were on complex metaphysical and theological considerations; but the symbolism nevertheless formed part of the fabric of his work, ready to add an extra dimension of meaning to the initiated and knowledgeable spectator.

In these conditions it is not surprising that the artist as a person is for the most part anonymous, very few names of artists having survived. It was the skill with which the work of art was made to conform to established ideals, rather than the artist who possessed the skill, that held the place of first importance.

The appreciation of Indian art. According to Indian aesthetic theory, a work of art possesses distinct "flavours" (*rasa*), the "tasting" of which constitutes the aesthetic experience. Because the work of art operates at various levels, granting to the spectator what he is capable of receiving by virtue of his intellectual and emotional preparation, the appreciation of the beauty of form and line is considered an appropriate activity of the educated and cultured man. The supreme aesthetic experience, however, is believed to be much deeper and cognate to the experience of the Godhead. From this point of view, the work of art is in a sense irrelevant and unnecessary for a person at a high level of spiritual progress; and for the devout layman its excellence is measured by its efficacy in promoting spiritual development.

Architecture. The favoured material of early Indian architecture appears to have been wood, but little has survived the rigours of the climate. Wooden forms, however, affected work in other mediums and were sometimes quite literally copied, as, for example, in early cave temples of western India. The principles of wooden construction also played an important part in determining the shape of Indian architecture and its various elements and components.

Effect of wooden forms on other mediums

Baked or sun-dried brick has a history as ancient as that of wood; among the earliest remains are buildings excavated at sites of the Indus Valley civilization. The use of brick is once again evident from about the 6th century BC, and its popularity was undiminished in subsequent centuries. Many brick monuments have been discovered, particularly in areas in which good clay was easily available, such as the Gangetic Basin. Although more durable than wood, few brick buildings from before the 5th century AD have survived in a good state of preservation.

Traditions of stone architecture appear to be more recent than wood or brick, the earliest examples of the use of dressed stone for building purposes not predating the 6th century BC. The Indian architect, however, soon gained great proficiency in its use, and, by the 7th century AD, the use of stone for monumental buildings of considerable size had become quite popular. The preference for stone can also be seen in Islāmic monuments of India, which contrast markedly with the brick and tile structures popular in neighbouring West Asia.

Most surviving examples of Indian architecture before the Islāmic period are of a religious nature, consisting mainly of Buddhist shrines, or *stūpa*s, and temples. Monastic residences give some idea of civil architecture, but, surprisingly, very few examples of palaces and secular dwellings have been found.

Indus Valley civilization (c. 2500–1800 BC). From excavated remains, it is clear that the Indus Valley civilization possessed a flourishing urban architecture. The major cities associated with the civilization, notably Mohenjo-daro, Harappā, and Kalibangan, were laid out on a grid pattern and had provisions for an advanced drainage system. The residential buildings, which were serviceable enough, were mainly brick and consisted of an open patio flanked by rooms. For monumental architecture, the evidence is slight, the most important being a "sacred" tank (thought to be for ritual ablution) and associated structures. Corbel vaulting (arches supported by brackets projecting from the wall) was known, and, to a limited extent, timber was used together with brick; whatever architectural ornamentation existed must have been of brick or plaster.

The Maurya period (c. 321–185 BC). The state of Indian architecture in the period between the Indus Valley civilization and the rise of the Maurya Empire is largely unknown since most work was done in such perishable material as wood or brick. Excavations at Rājgīr, Kauśāmbī, and other sites, however, testify to the existence of fortified cities with *stūpa*s, monasteries, and temples of the type found at the later Maurya sites of Nagarī and Vidiśā; and there is evidence of the use of dressed stone in a palace excavated at Kauśāmbī. Considering the power of the Maurya Empire and the extensive territory it controlled, the architectural remains are remarkably few. The most important are *stūpa*s (later enlarged) such as a famous example of Sānchi; the ruins of a hall excavated at the site of Kumrāhar in Patna (ancient Pāṭaliputra), the capital city; and a series of rock-cut caves in the Barābar and Nāgārjunī hills near Gayā, which are interesting because they preserve in the more permanent rock some types of wooden buildings popular at that time.

The *stūpa*

The *stūpa,* the most typical monument of the Buddhist faith, consists essentially of a domical mound in which sacred relics are enshrined. Its origins are traced to mounds, or tumuli, raised over the buried remains of the dead that were found in India even before the rise of Buddhism: *Stūpa*s appear to have had a regular architectural form in the Maurya period: the mound was sometimes provided with a parasol surrounded by a miniature railing on the top, raised on a terrace, and the whole surrounded by a large railing consisting of posts, crossbars, and a coping (the capping on the top course), all secured by tenons and mortices in a technique appropriate to craftsmanship in wood. The essential feature of the *stūpa,* however, always remained the domical mound, the other elements being optional.

Along with *stūpa*s were erected roofless, or hypaethral, shrines enclosing a sacred object such as a tree or an altar. Temples of brick and timber with vaulted or domical roofs were also constructed, on plans that were generally elliptical, circular, quadrilateral, or apsidal (*i.e.,* having an apse, or semicircular plan, at the sanctum end). These structures have not survived, but some idea of their shape has been obtained from the excavated foundations and the few examples imitating wooden originals that were cut into the rock, notably the Sudāmā and the Lomas Ṛṣi caves in the Nāgārjunī and Barābar hills near Gayā. The latter has an intersesting entrance showing an edged barrel-vault roof (an arch shaped like a half cylinder) in profile supported on raked pillars, the ogee arch (an arch with curving sides, concave above and convex toward the top) so formed filled with a trellis to let in light and air. The interiors of most caves are highly polished and consist of two chambers: a shrine, elliptical or circular in plan with a domed roof (Sudāmā cave); and an adjacent antechamber, roughly rectangular and provided with a barrel vault. Remains of structural buildings have been excavated at Bairāt and Vidiśā, where wood and brick shrines with timber domes and vaults once existed. A temple (No. 40) at Sānchi was apsidal in plan and perhaps had a barrel-vault roof of timber.

A hall excavated at Kumrāhar in Patna had a high wooden platform of most excellent workmanship, on which stood eight rows of 10 columns each, which once supported a second story. Only one stone pillar has been recovered, and it is circular in shape and made of sandstone that has been polished to a high lustre. The capitals that topped them must have been similar to others found in neighbouring Lohanipur and almost certainly consisted of one or two pairs of addorsed (set back to back) animals, recalling Persepolitan examples. Indeed, there is much about Maurya architecture and sculpture to suggest Iranian influence, however substantially transformed in the Indian environment.

Early Indian architecture (2nd century BC–3rd century AD). Except for *stūpa*s, architectural remains from the 2nd century BC (downfall of the Maurya dynasty) to the 4th century AD (rise of the Gupta dynasty) continue to be rare, indicating that most of the work was done in brick and timber. Once again, examples cut into the rock and closely imitating wooden forms give a fairly accurate idea of at least some types of buildings in this period.

The *stūpa*s become progressively larger and more elaborate. The railings continue to imitate wooden construction and are often profusely carved, as at Bhārhut, Sānchi II, and Amarāvatī. These were also provided with elaborate gateways, consisting of posts supporting from one to three architraves, again imitating wooden forms and covered with sculpture (Bhārahut, Sānchi I, III). In the course of time an attempt was made to give height to the *stūpa*s by multiplying the terraces that supported the dome and by increasing the number of parasols on top. In Gandhāra and southeastern India, particularly, sculptured decoration was extended to the *stūpa* proper, so that terraces, drums, and domes—as well as railing—were decorated with figural and ornamental sculpture in bas-relief. *Stūpa*s in Gandhāra were not provided with railings but, instead, had rows of small temples arranged on a rectangular plan.

Vest ndian :ave emples

Cave temples of western India, cut into the scarp of the Western Ghāts and stretching from Gujarāt to southern Mahārāshtra, constitute the most extensive architectural remains of the period. Two main types of buildings can be distinguished, the temple proper (*caitya*) and the monastery (*vihāra, saṅghārāma*). The former is generally an apsidal hall with a central nave flanked by aisles. The apse is covered by a half dome; and two rows of pillars, which demarcate the nave, support a barrel-vault roof that covers the rest of the building. In the apsidal end is placed the object to be worshipped, generally a *stūpa,* the hall being meant for the gathered congregation. In front of the hall is a porch, separated from it by a screen wall provided with a door of considerable size, together with an arched opening on top clearly derived from wooden buildings of the Lomas Ṛṣi type and permitting air and dim light to filter into the interior. Other influences of wooden construction are equally striking, particularly in the vaulting ribs that cover the entire ceiling and that are sometimes actually of wood, as at Bhājā, where the pillars are also raked in imitation of the exigencies of wooden construction. The pillars are generally octagonal with a pot-shaped base and a capital of addorsed animals placed on a bell-shaped, or campaniform, lotus in the Maurya tradition. The most significent example is at Kārli, dating approximately to the closing years of the 1st century BC. The Bhājā *caitya* is certainly the earliest, and important examples are to be found at Beḍsā, Kondane, Pītalkhorā, Ajantā, and Nāsik. Toward the end of the period, a quadrilateral plan appears more and more frequently, as, for example, at Kuda and Sailarwāḍī.

In addition to the *caitya,* or temple proper, numerous monasteries (*vihāra*s) are also cut into the rock. These are generally provided with a pillared porch and a screen wall pierced with doorways leading into the interior, which consists of a "courtyard" or congregation hall in the three walls of which are the monks' cells. The surviving rock-cut examples are all of one story, though the facade of the great monastery at Pitalkhorā simulates a building of several stories.

Monasteries carved into the rock are also known from Orissa (Udayagiri-Khandagiri), in eastern India. These are much humbler than their counterparts in western India, and consist of a row of cells that open out into a porch, the hall being absent. At Uparkot in Junāgadh, Gujarāt, is a remarkable series of rock-cut structures dating from the 3rd–4th century AD, which appear to be secular in character and in all probability served as royal pleasure houses.

The large number of representations of buildings found on relief sculpture from sites such as Bhārhut, Sānchi, Mathurā, and Amarāvatī are a rich source of information about early Indian architecture. They depict walled and moated cities with massive gates, elaborate multi-storied residences, pavilions with a variety of domes, together with the simple, thatched-roofed huts that remained the basis of most Indian architectural forms. A striking feature of this early Indian architecture is the consistent and profuse use of arched windows and doors, which are extremely important elements of the architectural decor.

The Gupta period (4th–6th centuries AD). Dating toward the close of the 4th and the beginning of the 5th century AD is a series of temples that marks the opening phase of an architecture that is no longer content with merely imitating wooden building but initiates a new movement, ultimately leading to the great and elaborate temples of the 8th century onward.

Two main temple types have been distinguished in the Gupta period. The first consists of a square, dark sanctum with a small, pillared porch in front, both covered with flat roofs. This type of temple answers the simplest needs of worship, a chamber to house the deity and a roof to shelter the devotee. Temple No. 17 at Sānchi is a classic example of this flat-roofed type. The plain walls are of ashlar masonry (made up of squared stone blocks), composed of sizable blocks, which are spanned by large slabs that constitute the ceiling. The pillars of the porch have a campaniform lotus capital, one of the last times this form appears in Indian architecture. Another temple of this type is the Kaṅkālī Devī shrine at Tigowā, which has more elaborate pillars, provided with the overflowing vase, or the vase-and-foliage (*ghaṭa-pallava*), capital that became the basic north Indian order.

Two main temple types of the Gupta period

It is the second type of temple that points the way to future developments. It also has a square sanctum, or cella, but instead of a flat roof there is a pyramidal superstructure (*śikhara*). Among the most interesting examples are a brick temple at Bhītargaon and the Vishnu temple at Deogarh, built entirely of stone. The pyramidal superstructure of each consists essentially of piled-up cornice moldings of diminishing size, which are decorated primarily with *candraśālā* (ogee arch) ornament derived from the arched windows and doors so frequently found in the centuries immediately before and after Christ. The sanctums of both temples are square in plan, with three sides provided with central offsets (vertical buttress-like projections) that extend from the base of the walls right up to the top of the *śikhara* (spire); the section of the central offset that extends across the wall is conceived in the form of a niche, in which is placed an image. The Deogarh temple is also noteworthy for the large terrace with four corner shrines (now ruined) on which it is placed, prefiguring the quincunx, or *pañcāyatana,* grouping (one structure in each corner and one in the middle) popular in the later period. The doorway surround, too, is very elaborate, carved with several bands carrying floral and figural motifs. At the base of the surround are rows of worshippers, and in the crossette (projection at the corner) on top are images of graceful river goddesses.

Carved sandstone doorframe of the Vishnu temple at Deogarh, Uttar Pradesh, India, 5th century AD.

The Pārvatī Devī temple at Nācnā Kuṭṭhārā, also of this period, is interesting for the covered circumambulatory provided around the sanctum and the large hall in front. When first discovered, the temple had an entire chamber above the sanctum (which subsequently collapsed). Though provided with a door, there seems to have been no access to it; thus, for all practical purposes it constituted a false story and, aside from a symbolic meaning,

Early Indian architecture and sculpture

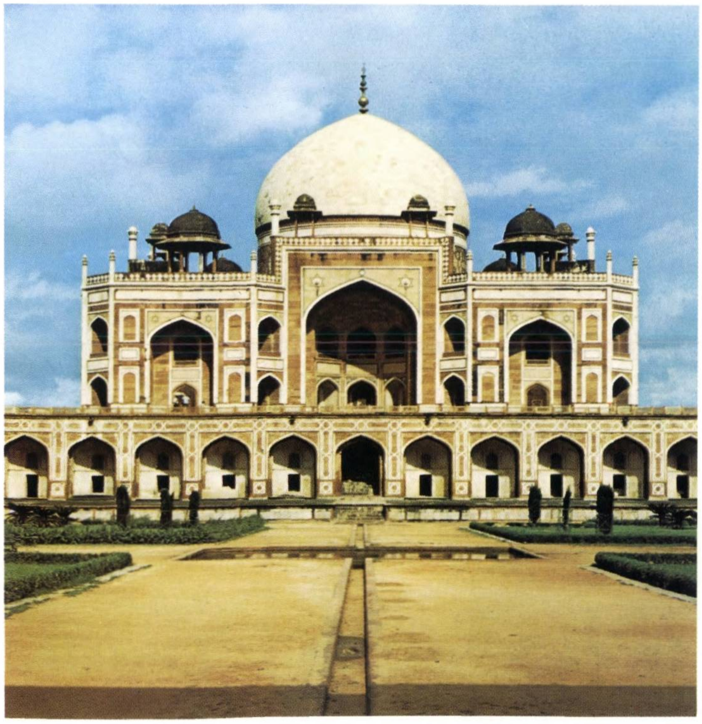
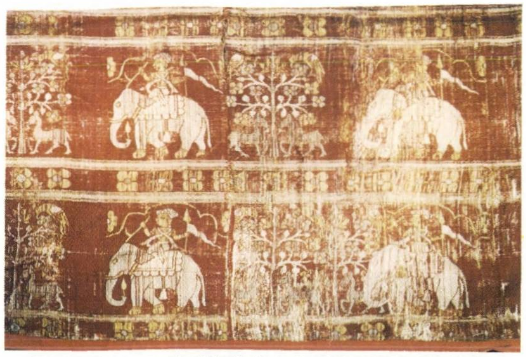
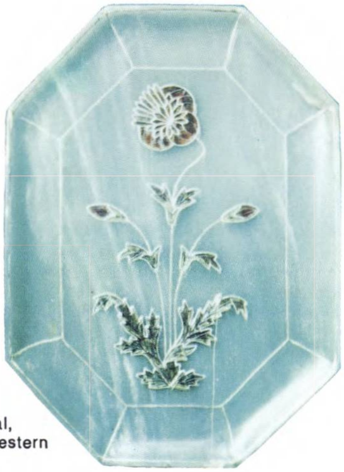
Mughal architecture and decorative arts



The tomb of Humāyūn at Delhi, red sandstone and marble, *c.* AD 1564.



Detail of a silk tapestry, Mughal, early 17th century AD. In the Prince of Wales Museum of Western India, Bombay.



Jade dish inlaid with semiprecious stones and gold, Mughal, mid-17th century AD. In the Prince of Wales Museum of Western India, Bombay.

served no other purpose than to emphasize the importance of the sanctum. The principle of gaining height not by the superimposition of ornamental cornice moldings with *candraśālā* decoration but by the multiplication of stories, each imitating the story below, also distinguished the later architectural style of southern India.

The great Mahābodhi temple at Buddh Gaya, commemorating the spot where the Buddha attained enlightenment, though burdened with later restorations, is essentially a temple of this period. It has a particularly majestic *śikhara,* decorated with ornamental niches and *candraśālā*s, rising over a square sanctum to a great height.

Along with temples, *stūpa*s continued to be built. These also aspired to height, which was achieved by multiplication and heightening of the supporting terraces and elongating the drum and dome. A good example of this new form is the Dhamekh *stūpa* at Sārnāth. Along more conventional lines, but quite elaborate, are the brick *stūpa*s in Sind, notably a fine example at Mīrpur Khās.

The rock-cut temple and monastery tradition also continued in this period, notably in western India, where the excavations—especially at Ajantā—acquire extreme richness and magnificence. The monasteries are characterized by the introduction of images into some of the cells, so that they partake of the nature of temples instead of being simple residences. Temples with an apsidal plan and barrel-vault roofs, however, soon went out of fashion, and are found very rarely in the subsequent period. The early 5th-century cave temples at Udayagiri, Madhya Pradesh, are similar to the simple flat-roofed temples with a hall and are not descended from ancient traditions as preserved in western India.

Medieval temple architecture. Architectural styles initiated during the 5th and 6th centuries found their fullest expression in the medieval period (particularly from the 9th to the 11th centuries), when great stone temples were built. Two main types can be broadly distinguished, one found generally in northern India, the other in southern India. To these can be added a third type, sharing features of both and found in Karnataka and the Deccan. These three types have been identified by some scholars with the *nāgara, drāviḍa,* and *vesara* classes referred to in some Sanskrit texts, though the actual meaning of these terms is far from clear. In spite of the havoc wrought by the destructive Islāmic invasions, particularly in the Indo-Gangetic Plains, an extremely large number of monuments have survived in almost every other part of India, particularly in the south, and these continue to be discovered and recorded to the present day.

Period of the great stone temples

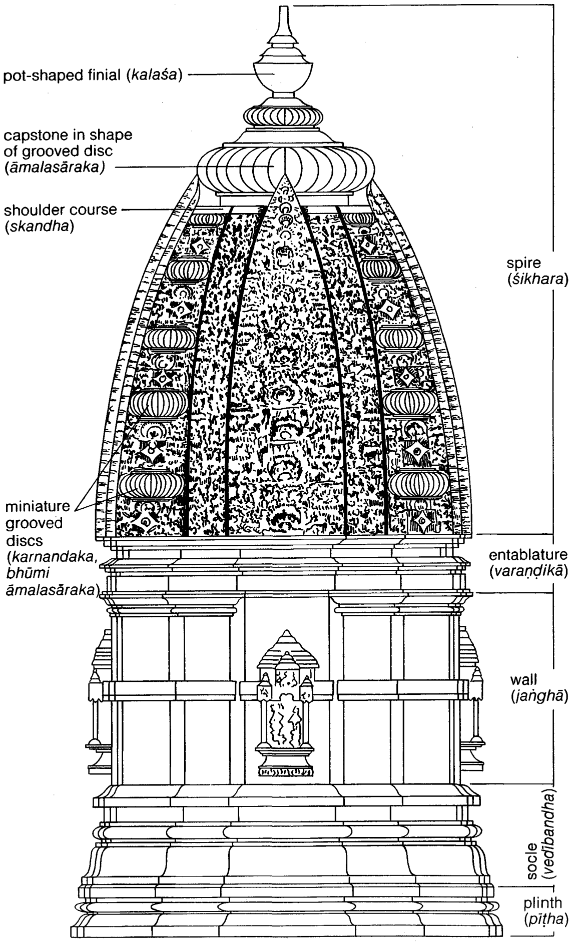
Medieval temple architecture: North Indian style. North Indian temples generally consist of a sanctum enshrining the main image, usually square in plan and shaped like a hollow cube, and one or more halls (called *maṇḍapas*), aligned along a horizontal axis. The sanctum may or may not have an ambulatory, but it is invariably dark, the only opening being the entrance door. The doorway surrounds are richly decorated with bands of figural, floral, and geometrical ornament and with river-goddess groups at the base. A vestibule (*antarāla*) connects the sanctum to the halls, which are of two broad types: the *gūḍhamaṇḍapa*s, which are enclosed by walls, light and air let in through windows or doors; and open halls, which are provided with balustrades rather than walls and are consequently lighter and airier. The sanctum almost invariably, and the *maṇḍapa*s generally, have *śikhara*s; those on the sanctum, appropriately, are the most dominant in any grouping. Internally, the sanctum has a flat ceiling; the *śikhara* is solid theoretically, though hollow chambers to which there is no access must be left within its body to lessen the weight. The ceilings of the halls, supported by carved pillars, are coffered (decorated with sunken panels) and of extremely rich design.

The sanctum is often set on a raised base, or a plinth (*pīṭha*), above which is a foundation block, or socle (*vedībandha*), decorated with a distinct series of moldings; above the *vedībandha* rise the walls proper (*jaṅghā*), which are capped by a cornice or a series of cornice moldings (*varaṇḍikā*), above which rises the *śikhara.* One, three, and sometimes more projections extend all the way from the base of the temple up the walls to the top of the *śikhara.* The central offset (*bhadra*) is the largest and generally carries an image in a niche; the other projections (*rathas*), too, are often decorated with statuary.

The entire temple complex, including sanctum, halls, and attendant shrines, may be raised on a terrace (*jagatī*), which is sometimes of considerable height and size. The attendant shrines—generally four—are placed at the corners of the terrace, forming a *pañcāyatana,* or quincunx, arrangement that is fairly widespread. The temple complex may be surrounded by a wall with an arched doorway (*toraṇa*).

Śikhara types

The *śikhara* is the most distinctive part of the North Indian temple and provides the basis for the most useful and instructive classification. The two basic types are called *latina* and *phāmsanā.* Curvilinear in outline, the *latina* is composed of a series of superimposed horizontal roof slabs and has offsets called *latā*s. The edges of the *śikhara* are interrupted at intervals with grooved discs, each one demarcating a "story." The surface of the entire *śikhara* is covered with a creeper-like tracery, or interlaced work, composed of diminutive ornamental *candraśālās.*



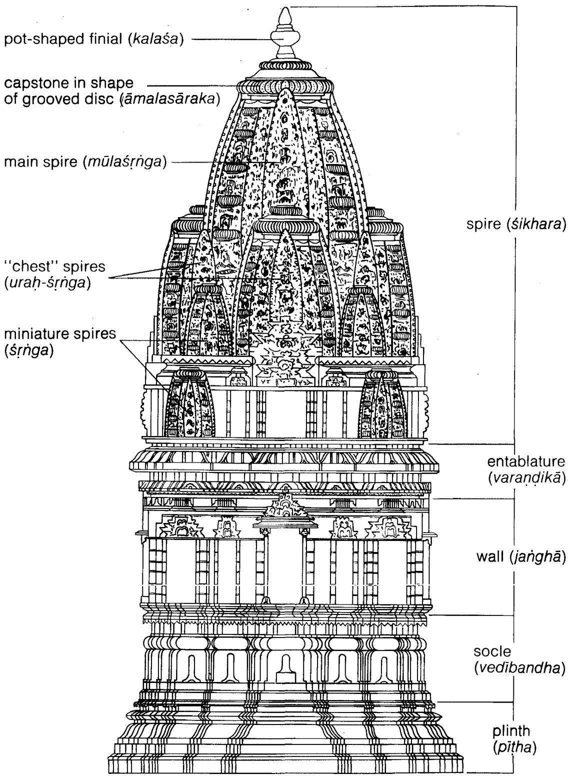
pot-shaped finial (kalaśa)
capstone in shape of grooved disc (āmalasāraka)
shoulder course (skandha)
spire (śikhara)
miniature grooved discs (karnandaka, bhūmi āmalasāraka)
entablature (varaṇḍikā)
wall (jaṅghā)
socle (vedibandha)
plinth (pīṭha)

Elevation of a North Indian temple with the *latina* type of superstructure.

The *śikhara* is truncated at the top and capped by a shoulder course (*skandha*), above which is a circular necking (*grīvā*), carrying a large grooved disc called the *āmalasāraka.* On it rests a pot and a crowning finial (*kalaśa*).

Unlike the *latina,* the *phāmsanā śikhara* is rectilinear rather than curvilinear in outine, and it is lower in height. It is composed of horizontal slabs, like the *latina,* but is capped by a bell-shaped member called the *ghaṇṭā.* The surface of this type of *śikhara* may have projections, like the *latina śikhara,* and be adorned with a variety of architectural ornament.

From the 10th century onward, the *śekharī* type of spire, an elaboration of the *latina* type, became increasingly popular. In its developed form it consisted of a



pot-shaped finial (*kalaśa*)
capstone in shape of grooved disc (*āmalasāraka*)
main spire (*mūlaśṛṅga*)
"chest" spires (*uraḥ-śṛṅga*)
miniature spires (*śṛṅga*)
spire (*śikhara*)
entablature (*varaṇḍikā*)
wall (*jaṅghā*)
socle (*vedībandha*)
plinth (*pīṭha*)

Elevation of a North Indian temple with the *śekharī* type of superstructure.

central *latina* spire (*mūlaśṛṅga*) with one or more rows of half spires added on the sides (*uraḥ-śṛṅga*) and the base strung with miniature spires (*śṛṅgas*). The corners, too, are sometimes filled with quarter spires, the whole mass of carved masonry recalling a mountain with a cluster of subsidiary peaks.

The *latina* and *śekharī* spires are generally found on the sanctum, while the *phāmsanā* and its variants are usually confined to the *maṇḍapas,* or halls. The sanctum spires also have a large and prominent projection in front (*śukanāsā*), generally rising above the vestibule (*antarāla*). These projections are essentially large ogee arches of complex form, which often contain the image of the presiding deity.

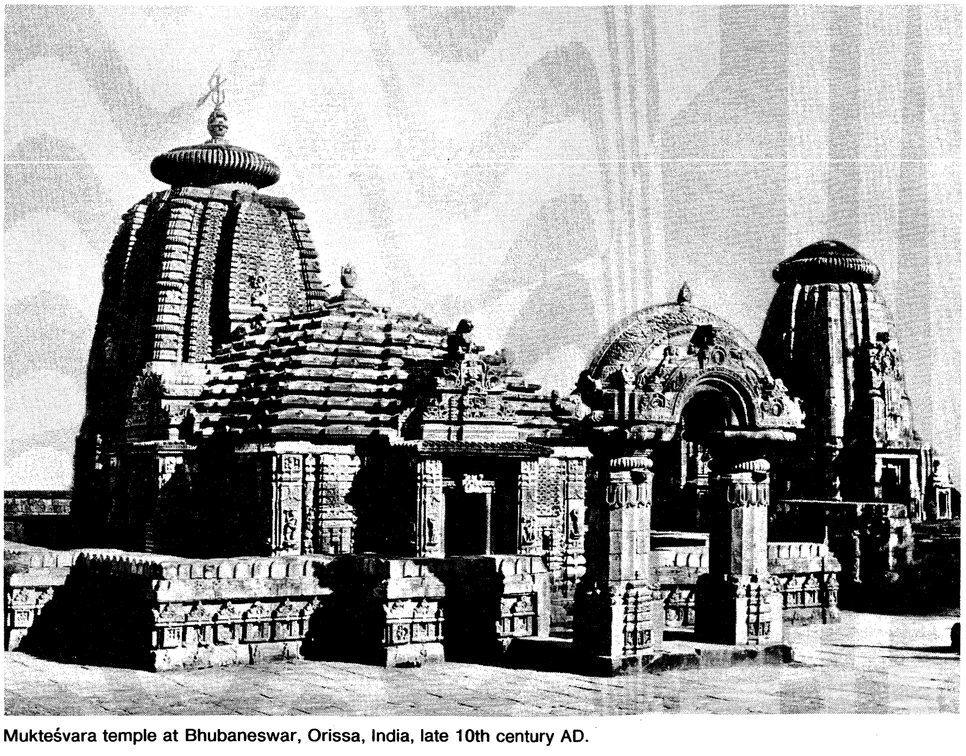
The *bhūmija* *śikhara*

A particularly rich and pleasing variety of North Indian *śikhara,* popular in Mālwa, western India, and northern Deccan, is the *bhūmija* type. It has a central projection on each of the four faces, the quadrants so formed filled with miniature spires in vertical and horizontal rows right up to the top.

Although basically reflecting a homogeneous architectural style, temple architecture in northern India developed a number of distinct regional schools. A detailed elucidation of all has yet to be made, but among the most important are the styles of Orissa, central India, Rājasthān, and Gujarāt. The style of Kashmir is distinct from the rest of northern India in several respects, and hardly any examples of the great schools that flourished in modern Uttar Pradesh, Bihār, and Bengal are left standing. The North Indian style also extended for some time into the Karnataka (formerly Karṇāṭa) territory, situated in the southern Deccan, though the architecture of Tamil Nadu was relatively unaffected by it.

Medieval temple architecture: North Indian style of Orissa. The greatest centre of this school is the ancient city of Bhuvaneśvara, in which are concentrated almost 100 examples of the style, both great and small, ranging in date from the 7th to the 13th century. Among the earliest is the Paraśurāmeśvara temple (7th–8th century), with a heavy, stately *latina śikhara,* to which is attached a rectangular *gūḍhamaṇḍapa* with double sloping roofs. The walls are richly carved, but the interiors, as in almost all examples of the style, are left plain. The Mukteśvara temple (10th century), which has a hall with a *phāmsanā* roof, is the product of the most exquisite workmanship. The enclosing wall and the arched entrance, or *toraṇa,* are still present, giving a clear idea of a temple with all its parts fully preserved. The Brahmeśvara temple, which is dated on the basis of an inscription to the mid-10th century, is a *pañcāyatana,* with subsidiary shrines at all of the corners. The most magnificent building, however, is the great Liṅgarāja temple (11th century), an achievement of Orissan architecture in full flower. The *latina* spire soars to a considerable height (over 125 feet [40 metres]); the wall is divided into two horizontal rows, or registers, replete with statuary; and the

P. Chandra



Mukteśvara temple at Bhubaneswar, Orissa, India, late 10th century AD.

attached hall is exquisitely and minutely carved. The most famous of all Orissan temples, however, is the colossal building at Konārak, dedicated to Sūrya, the sun god. The temple and its accompanying hall are conceived in the form of a great chariot drawn by horses. The *śikhara* over the sanctum has entirely collapsed; and all that survives are the ruins of the sanctum and the *gūḍhamaṇḍapa,* or enclosed hall, and also a separate dancing hall. Of these, the *gūḍhamaṇḍapa* is now the most conspicuous, its gigantic *phāṃsanā śikhara* rising in three stages and adorned with colossal figures of musicians and dancers.

Because the Orissan style usually favours a *latina śikhara* over the sanctum, the *śekharī* spire of the Rājrānī temple (11th century) at Bhuvaneśvara (Bhubaneswar) is quite exceptional. Of particular interest as a late survival of early building traditions is the Vaitāl Deul (8th century), the sanctum of which is rectangular in plan, its *śikhara* imitating a pointed barrel vault. Besides Bhuvaneśvara, important groups of temples are to be found at Khiching and Mukhalingam.

Medieval temple architecture: North Indian style of central India. The area roughly covered by the modern state of Madhya Pradesh was the centre of several vigorous schools of architecture, of which at least four have been identified. The first flourished at Gwalior and adjacent areas (ancient Gopādri); the second in modern Bundelkhand, known in ancient times as Jejākabhukti; the third in the eastern and southeastern parts in the ancient country of Ḍāhala, of which Tripurī, near modern Jabalpur, was the capital; and the fourth in the west, in an area bordering Gujarāt and Rājasthān in the fertile land of Mālava (Mālwa).

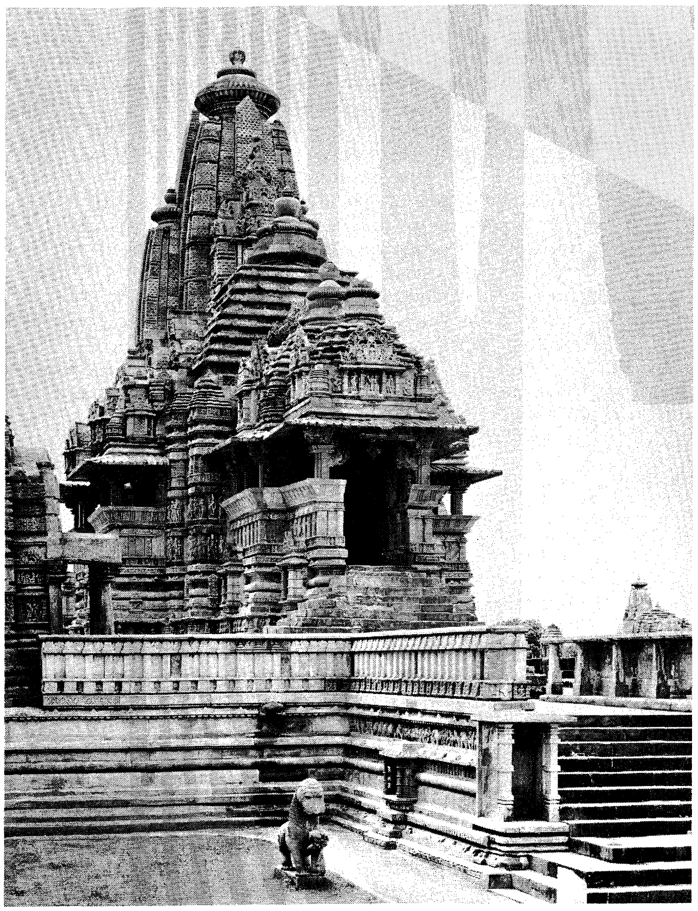
The Gwalior temples

The earliest examples in the Gwalior area are a group of small shrines at Naresar, a few miles from Gwalior proper; dating to the 8th century, the shrines have *latina* spires and sparsely ornamented walls. In the 9th century a series of magnificent temples was built, including the Mālā-de at Gyāraspur, the Śiva temples at Mahuā and Indore, and a temple dedicated to an unidentified mother goddess at Barwa-Sāgar. The period appears to have been one of experimentation, a variety of plans and spires having been tried. The Mālā-de temple is an early example of the *śekharī* type in its formative stages; the Indore temple has a star-shaped plan; and the Barwa-Sāgar example has a twin *latina* spire over a rectangular sanctum. The masonry work is of the finest quality and the architectural ornament is crisply carved. (The figural sculptures are few.) The temple at Umrī, with a *latina* spire, is small and exquisitely finished; but the largest and perhaps the finest temple is the Telī-kā-Mandir on Gwalior Fort, rectangular in plan and capped by a pointed barrel vault, recalling once again the survival of ancient roof forms. The walls are decorated with niches (empty at present) topped by tall pediments (triangular gable ornament).

The style of this region became increasingly elaborate from the 10th century, during the supremacy of the Kacchapaghāṭa dynasty. The many examples from this period are distinguished by a low plinth and rich sculptural decoration on the walls. Outstanding among them are the Kākan-maḍh at Suhāniā (1015–35) and the Sās-Bahū temple (completed 1093) in Gwalior Fort. The several temples at Surwāyā and Kadwāhā, though smaller in size, are distinguished for their extremely rich and elegant workmanship.

The style is best represented by a large group of temples at Khajurāho, the capital of the Candella dynasty, though examples are also to be found in Mahoba and at several other sites in the Jhānsi district of Uttar Pradesh, notably Chāndpur and Dudhai. All of the distinctive characteristics of the fully developed style can be seen in the Lakṣmaṇa temple at Khajurāho (dated 941), which is a *pañcāyatana* placed on a tall terrace enclosed by walls. The sanctum has an ambulatory and, facing it, a series of halls, including the *gūḍhamaṇḍapa,* a porch, and a small intermediate hall. Both the ambulatory and the *gūḍhamaṇḍapa* are provided with lateral, balconied arms, or transepts, which let in light and air. Each hall has its own pyramidal *śikhara,* all skillfully correlated to ascend gradually to the main *śekharī* spire over the sanctum. Extraordinary richness of carving, both in the interior and on the exterior, where the walls carry as many as three rows of sculpture, and a skillful handling of the main spire to suggest ascent are distinguishing features of the style. The largest temple of the group, very similar to the Lakṣmaṇa, is the Kandāriyā Mahādeo; and among the most distinguished are the Viśvanātha and the Pārśvanātha temples. The Dūlādeo temple, which does not have an ambulatory, represents the closing phase of the group and probably belongs to the 12th century.

The Lakṣmaṇa temple



Lakṣmaṇa temple at Khajurāho, Madhya Pradesh, India, *c.* AD 941.

P. Chandra

The earliest temples of the Ḍāhala area, dating from the 8th–9th century, are the simple shrines at Bāndhogarh, which consist of a sanctum with *latina* spire and porch. To the 10th century, when the local Kalacuri dynasty was rapidly gaining power, belong the remarkable Śiva temples at Chandrehe and Masaun, the former being circular in plan, with a *latina* spire covered with rich *candraśālā* tracery. The Golā Math at Maihar has the more conventional square sanctum, with a very elegant *latina śikhara,* the walls of which are adorned with two rows of figural sculpture. There must have existed at Gurgī a large number of temples, though all of them now are in total ruin. Judging from a colossal image of Śiva-Pārvatī and a huge entrance, which have somehow survived, the main temple must have been of very great size. Another important site is Amarkantak, where there are a large group of temples, the most important of which is the Karṇa. Although generally of the 11th century, they are quite simple, lacking the rich sculptural decoration so characteristic of the period. By contrast, the Virāṭeśvara temple at Sohāgpur, with an unusually tall and narrow *śekharī* spire, is covered with sculptural ornamentation as rich as that of Khajurāho.

Temples o the Mālava area

The Mālava region, ruled largely by the Paramāra dynasty, appears to have been the first to develop the *bhūmija* type of *śikhara* (10th century). The finest and most representative group of these structures is at Un. Though, unfortunately, they are considerably damaged, judging from the remains, they must have been very elegant structures. The best preserved and easily the finest *bhūmija* temple is the Udayeśvara (1059–82), situated at Udaipur in Madhya Pradesh. The *śikhara,* based on a stellate plan, is divided into quadrants by four *latās*, or offsets, each one of which has five rows of aediculae. The large hall has three entrance porches, one to the front and two to the sides, and walls that are richly carved. The whole complex, including seven subsidiary shrines, is placed on a broad, tall platform. The Siddheśvara temple at Nemāwar (early 12th century) is even larger than the Udayeśvara, though the proportions are not as well balanced and the quality of the carving is inferior. Structures in the *bhūmija* manner continued to be made in Mālava up to the 15th century; the Malvai temple at Alīrājpur is a good example of the late phase.

From Mālava, the *bhūmija* style spread to the neighbouring regions. To the north in Rājasthān, the Mahānāleśvara temple at Menāl (*c.* 11th century), the Sun temple at Jhālrapātan (11th century), the Śiva temple at Rāmgarh (12th century), and the Uṇḍeśvara temple (12th century) at Bījoliān are important examples. To the west, in Gujarāt, are temples at Limkheda and Sarnāl of the 11th and 12th centuries. The style was particularly favoured in Mahārāshtra, to the south. Among surviving examples, the most impressive is the Ambarnāth temple near Bombay (11th century); Balsāṇe and Sinnar also have pleasing temples. The style continued up to the 16th century, many examples having been found in north Deccan and Berār. The *bhūmija* style also spread to the east of Mālava; the Bhāṇḍ Dewal at Arang (11th century), for example, is a Ḍāhala adaptation.

Medieval temple architecture: North Indian style of Rājasthān. A group of temples at Osiān, dating to about the 8th century, represents adequately the opening phases of medieval temple architecture in Rājasthān. They stand on high terraces and consist of a sanctum, a hall, and a porch. The sanctum is generally square and has a *latina* spire. The walls, with one central and two subsidiary projections, are decorated with sculpture, often placed in niches with tall pediments. The halls are generally of the open variety, provided with balustrades rather than walls, so that the interiors are well lit. The surrounds of the doorway sanctum are quite elaborate, with four or five bands of decoration and the usual river-goddess groups at the base. The pillars, with *ghaṭa-pallava* (vase-and-foliage) capitals, are also decorated, richness of sculpture and architectural elaboration being a characteristic of this group of monuments. The Mahāvīra temple, which is the largest, belongs to the 8th century, though renovated in later times, when the *toraṇa* (gateway) and the *śikhara* were added. Other important temples are Harihara Nos. 1, 2, and 3 and two temples dedicated to Vishnu. The ruined Harshat Mātā temple at Ābānerī, of a slightly later date (*c.* 800), was erected on three stepped terraces of great size and is remarkable for the exquisite quality of the carving. Some of the finest temples of the style date from the 10th century, the most important of which are the Ghaṭeśvara temple at Bāḍolī and the Ambikā Mātā temple at Jagat. The simple but beautiful Bāḍolī temple consists of a sanctum with a *latina* superstructure and an open hall with six pillars and two pilasters (columns that project a third of their width or less from the wall) supporting a *phāmsanā* spire. Only the central projections of the sanctum walls are decorated with niches containing sculpture. A large open hall was built in front of the temple at a later date. The Ambikā-Mātā temple at Jagat, of the mid-10th century, is exceptionally fine. It consists of a sanctum, a *gūḍhamaṇḍapa,* or enclosed hall, and a parapeted porch with projecting eaves. The walls of the sanctum and the hall are covered with fine sculpture, the superstructures being of the *śekharī* and the *phāmsanā* types.

rowing esem-lance etween yles of āja-hān and ujarāt

Temples, too numerous to mention, dating from the 10th and—to an even greater extent—the 11th century onward, are found throughout Rājasthān. The styles of Rājasthān and neighbouring Gujarāt during these centuries grew closer and closer together until the differences between them were gradually obliterated. This coalescence resulted in the emergence of a composite style found throughout Gujarāt and Rājasthān. Temples situated in the two areas are discussed separately here, but this is for the sake of convenience and does not signify any real stylistic difference.

The temples at Kirāḍu in Rājasthān, dating from the late 10th and 11th centuries, are early examples of the style shared by Rājasthān and Gujarāt. The Someśvara temple (*c.* 1020) is the most important and clearly shows the movement toward increasing elaboration and ornamentation. Each of the constituent parts became more complex; the moldings of the plinth, for example, are multiplied to include bands of elephants, horses, and soldiers. The walls are covered with sculpture, and the spire is of the rich *śekharī* type. Situated in Rājasthān, but again in the composite style, are the extraordinarily sumptuous temples known as the Vimala Vasahī (1031) and the Lūṇa Vasahī (1230) at Mt. Ābū. The Vimala Vasahī consists of a sanctum, a *gūḍhamaṇḍapa,* and a magnificent assembly hall added in mid-12th century. The plain, uncarved exterior walls of the rectangular enclosure of the temple have on the inside rows of cells containing images of divinities. The interiors are very richly carved, the coffered ceilings loaded with a wealth of detail. The Lūṇa Vasahī is even more elaborate, though the quality of the work had begun to decline perceptibly.

Traditional architecture continued even after the Islāmic invasions, particularly during the reign of Rāṇā Kumbhā of Mewār (*c.* 1430–69). During this period, the tall nine-storied Kīrttistambha and other temples at Chitor and also the great Chaumukha temple at Ranakpur (1438) were built.

The temple at Gop

Medieval temple architecture: North Indian style of Gujarāt. Gujarāt was the home of one of the richest regional styles of northern India. A temple at Gop (*c.* 600), with a tall terrace and a cylindrical sanctum with high walls capped by a *phāmsanā* roof, and other temples in Saurāshṭra show the formative phases of the style. Its distinctive features are clear in an interesting group of temples from Roḍā (*c.* 8th century). The sanctum is square in plan and has *latina* spires that are weighty and majestic. The walls are relatively plain, with niches, housing images, provided only on the central projection. The masonry work is exceptionally good, a characteristic of Gujarāt architecture throughout its history. The Rāṇakdevī temple at Wadhwān, of the early 10th century, is also characterized by plain walls and a *latina* spire, while the Śiva temple at Kerākoṭ has a *śekharī* spire and also a *gūḍhamaṇḍapa.* The great Sun Temple at Modhera, datable to the early years of the 11th century, represents a fully developed Gujarāt style of great magnificence. The temple consists of a sanctum (now in ruins), a *gūḍhamaṇḍapa,* an open hall of extraordinary richness, and an arched entrance in front of which was the great tank. The Navalakhā temple at Sejakpur continued this tradition. The Rudramāla at Siddhapur, the most magnificent temple of the 12th century, is now in a much ruined condition, with only the *toraṇa* (gateway) and some subsidiary structures remaining. Successively damaged and rebuilt, the Somanātha at Prabhāsa Patan was the most famous temple of Gujarāt, its best known structure dating from the time of Kumārapāla (mid-12th century). It has been now dismantled, but a great temple built at the site in recent years testifies to the survival of ancient traditions in modern Gujarāt.

The hills of Satrunjaya and Girnār house veritable temple cities. Most of the shrines, which are of late date, are picturesque but otherwise of little significance. With the Islāmic conquest, the Gujarāt architect adapted his considerable skills to meet the needs of a patron of different religion and quickly produced a totally successful Indian version of Islāmic architecture.

Medieval temple architecture: North Indian style of Karnataka. The North Indian style was largely confined to India above the Vindhyas, though for a short period it also flourished in a region of southern India known as Karnataka from ancient times and now largely part of Karnataka (formerly Mysore) state. Here, temples of the northern and the southern styles are found next to each other, notably at Aihole and Pattadkal. The earliest appears to be the Lāḍh Khān at Aihole, closely related to the 5th-century temple at Nāchnā Kutharā in northern India. The northern style was also cultivated at Pattadkal, where the most important examples are the Kāśīviśvanātha, the Galaganātha, and the Pāpanātha. Ālampur, now in Andhra Pradesh, has eight temples of the northern style with *latina* spires. These belong to the late 7th and early 8th centuries and are the finest and among the last examples of the northern style in southern India.

Distinct architectural style of Kashmir

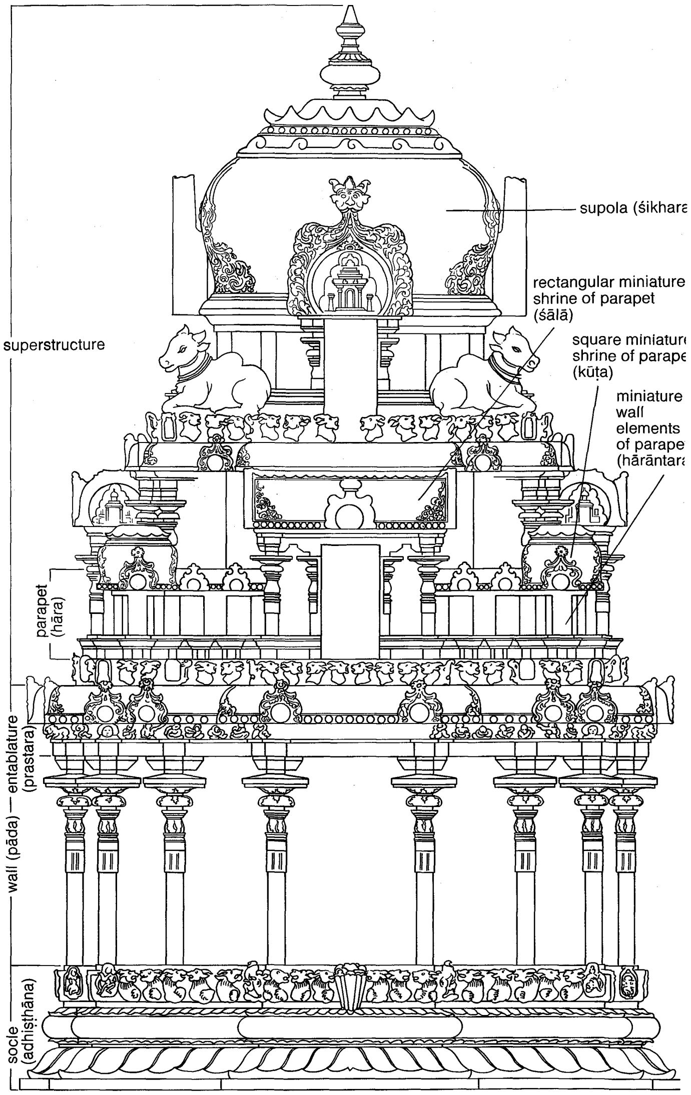
Medieval temple architecture: North Indian style of Kashmir. The architectural style of the Kashmir region is quite distinct: unlike other regions, in which the sanctum usually has a *latina* or *śekharī* spire, the roof of the Kashmir sanctum is of the *phāmsanā* type, with eaves raised in two stages. The greatest example to survive is the ruined Sun Temple at Mārtanḍ (mid-8th century), which, though its *śikhara* is missing, gives a good idea of the characteristic features of the style. The temple is placed in a rectangular court enclosed by a series of columns. Access to the court is through an imposing entrance hall, the walls of which have doorways with gabled pediments and a trefoil (shaped like a trifoliate leaf) recess. The Avantisvāmī temple of the mid-9th century, now quite ruined, must have been similar, though much more richly ornamented. The style continued up to the 12th century; the Rilhaṇeśvara temple at Pāndrenṭhan is a comparatively well-preserved example of this period.

Medieval temple architecture: South Indian style. The home of the South Indian style, sometimes called the drāviḍa style, appears to be the modern state of Tamil Nadu; examples, however, are found all over southern India, particularly in the adjoining regions of Karnataka and Andhradeśa, now largely covered by the states of Karnataka and Andhra Pradesh. Both Andhradeśa and Karnataka developed variants, particularly Karnataka, which evolved a distinct manner, basically South Indian but with features of North Indian origin. The Karnatic style extended northward into Mahārāshtra, where the Kailāsa temple at Ellora is the most famous example.

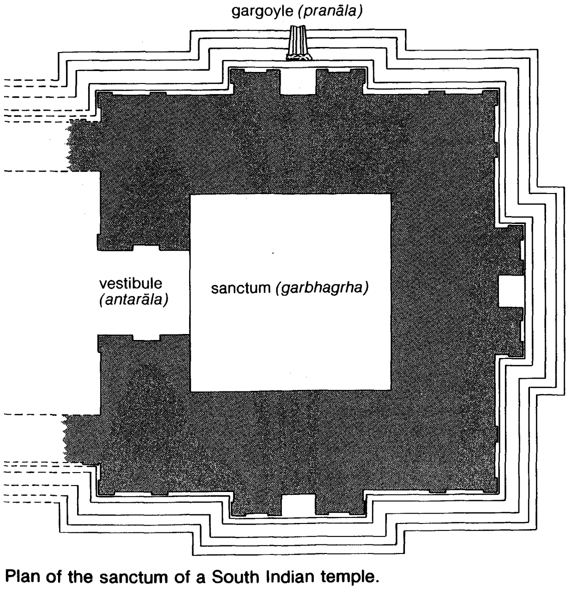
A typical South Indian temple consists of a hall and a square sanctum that has a superstructure of the *kūṭina* type. Pyramidal in form, the *kūṭina* spire consists of stepped stories, each of which simulates the main story and is conceived as having its own "wall" enclosed by a parapet. The parapet itself is composed of miniature shrines strung together: square ones (called *kūṭas*) at the corners and rectangular ones with barrel-vault roofs (called *śālās*) in the centre, the space between them connected by miniature wall elements called *hārāntaras*. (Conspicuous in the early temples, these stepped stories of the superstructure with their parapets became more and more ornamental, so that in the course of time they evolved into more or less decorative bands around the pyramidal superstructure.) On top of the stepped structure is a necking that supports a solid dome, or cupola (instead of the North Indian grooved disc), which in turn is crowned by a pot and finial. The walls of the sanctum rise above a series of moldings, constituting the foundation block, or socle (*adhiṣṭhāna*), that differ from North Indian temples; and the surface of the walls does not have the prominent offsets seen in North Indian temples but is instead divided by pilasters. In the Karnatic version, particularly from the late 10th century onward (sometimes called the *vesara* style), this arrangement of the superstructure is loaded with decoration, thus considerably obscuring the component elements. At the same time, these elements—particularly the central offset with its subsidiaries that carry *candraśālā* motifs—are so manipulated that they tend to form distinct vertical bands, in this respect closely recalling the *śikharas* of northern India.

The design of the hall-temple roofed by a barrel vault, popular in the centuries before and after Christ, was adopted in southern India for the great entrance buildings, or *gopuras*, that give access to the sacred enclosures in which the temples stand. Relatively small and inconspicuous in the early examples, they had, by the mid-12th century, outstripped the main temple in size.

Medieval temple architecture: South Indian style of Tamil Nadu (7th–18th century). The early phase, which, broadly speaking, coincided with the political supremacy of the Pallava dynasty (*c.* 650–893), is best represented by the important monuments at Mahābalipuram. Besides a fine group of small cave temples (early 7th century), among the earliest examples of their type in southern India, there are



Elevation of a South Indian temple with the *kūṭina* type of superstructure.



Plan of the sanctum of a South Indian temple.

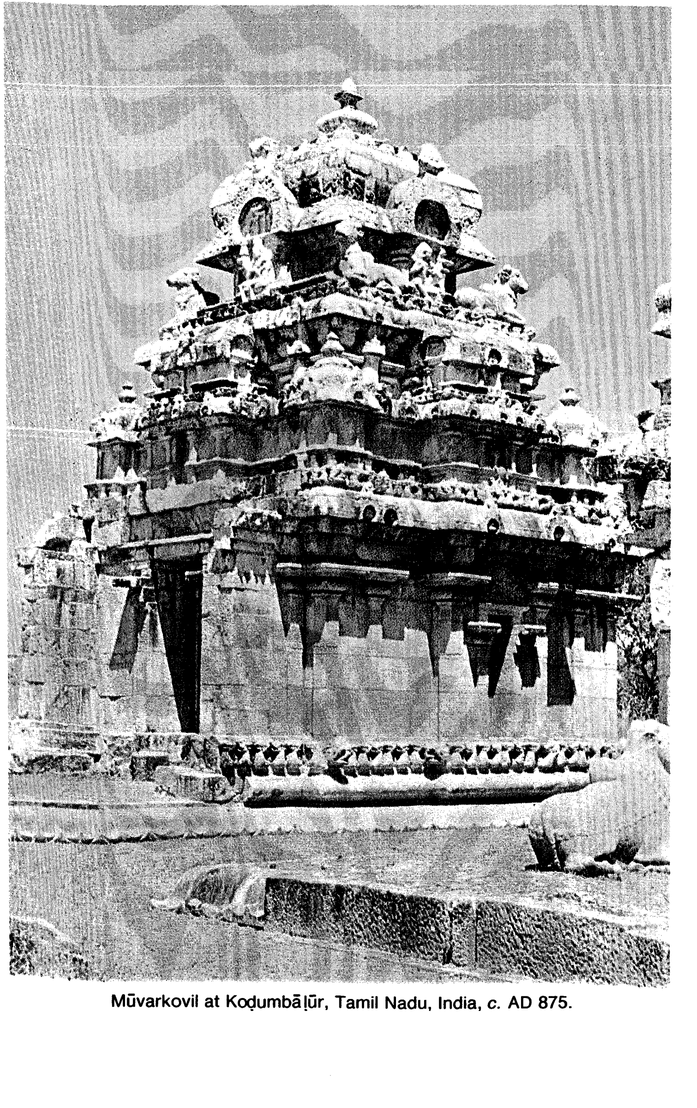
he Shore
emple

here several monolithic temples carved out of the rock, the largest of which is the massive three-storied Dharmarāja-ratha (*c.* 650). The finest temple at this site and of this period is an elegant complex of three shrines called the Shore Temple (*c.* 700), not cut out of rock but built of stone. The Tālapurīśvara temple at Panamalai is another excellent example. The capital city of Kānchipuram also possesses some fine temples—for example, the Kailāsanātha (dating a little later than the Shore Temple), with its stately superstructure and subsidiary shrines attached to the walls. The enclosure wall has a series of small shrines on all sides and a small *gopura.* Another splendid temple at Kānchipuram is the Vaikuṇṭha Perumāl (mid-8th century), which has an interesting arrangement of three sanctums, one above the other, encased within the body of the superstructure.

The 9th century marked a fresh movement in the South Indian style, revealed in several small, simple, but most elegant temples set up during the ascendancy of the Cōḷa and other contemporary dynasties. Most important of a large number of unpretentious and beautiful shrines that dot the Tamil countryside are the Vijayālaya Cōḷīśvara temple at Nārttāmalai (mid-9th century), with its circular sanctum, spherical cupola, and massive, plain walls; the twin shrines called Agastyīśvara and Cōḷīśvara, at Kīḷaiyūr (late 9th century); and the splendid group of two temples (originally three) known as the Mūvarkovil, at Koḍumbāḷūr (*c.* 875).

These simple beginnings led rapidly (in about a century) to the mightiest of all temples in the South Indian style, the Bṛhadīśvara, or Rājarājeśvara, temple, built at the Cōḷa capital of Thanjāvūr. A royal dedication of Rājarāja I, the temple was begun around 1003 and completed about seven years later. The main walls are raised in two stories, above which the superstructure rises to a height of 190 feet (60 metres). It has 16 stories, each of which consists of a wall with a parapet of shrines carved in relatively low relief. The great temple at Gaṅgaikoṇḍacōḷapuram, built (1030–40) by the Cōḷa king Rājendra I, is somewhat smaller than the Bṛhadīśvara; but the constituent elements of its superstructure, whose outline is concave, are carved in bolder relief, giving the whole a rather emphatic plasticity. The Airāvateśvara (1146–73) and Kampahareśvara (1178–1223) temples at Dārāsuram and Tribhuvanam follow the tradition of the 11th century but are smaller and considerably more ornate. They bring to a close a great phase of South Indian architecture extending from the 11th to the 13th century.

P. Chandra



Mūvarkovil at Koḍumbāḷūr, Tamil Nadu, India, *c.* AD 875.

From the middle of the 12th century onward, the *gopuras*, or entrance buildings, to temple enclosures began to be greatly emphasized. They are extremely large and elaborately decorated with sculpture, quite dominating the architectural ensemble. Their construction is similar to that of the main temple except that they are rectangular in plan and capped by a barrel vault rather than a cupola, and only the base is of stone, the superstructure being made of brick and plaster. Among the finest examples are the Sundara Pāndya *gopura* (13th century) of the Jambukeśvara temple at Tiruchchirāppalli and the *gopuras* of a great Śiva temple at Chidambaram, built largely in the 12th–13th century. Even larger *gopuras*, if not of such fine quality, continued to be built up to the 17th century. Such great emphasis was placed on the construction of *gopuras* that enclosure walls, which were not really necessary, were especially built to justify their erection. In the course of time several walls and *gopuras* were successively built, each enclosing the other so that at the present day one often has to pass through a succession of walls with their *gopuras* before reaching the main shrine. A particularly interesting example is the Ranganātha temple at Srīrangam, which has seven enclosure walls and numerous *gopuras*, halls, and temples constructed in the course of several centuries. The *gopuras* of the Mīnākṣī temple at Madurai are also good representative examples of this period.

In addition to the *gopuras*, temples also continued to be built. Although they never achieved colossal size, they are often of very fine workmanship. The Subrahmaṇya temple of the 17th century, built in the compound of the Bṛhadīśvara temple at Thanjāvūr, indicates the vitality of architectural traditions even at this late date.

Rock-cut
cave
temples
of South
India

Medieval temple architecture: South Indian style of Karnataka. The early phase, as in Tamil Nadu, opens with the rock-cut cave temples. Of the elaborate and richly sculptured group at Bādāmi, one cave temple is dated 578, and two cave temples at Aihole are early 8th century. Among structural temples built during the rule of the Cālukyas of Bādāmi are examples in the North Indian style; but, because the Karnataka region was more receptive to southern influences, there are a large number of examples that are basically South Indian with only a few North Indian elements. The Durgā temple (*c.* 7th century) at Aihole is apsidal in plan, echoing early architectural traditions; the northern *latina śikhara* is in all probability a later addition. The Mālegitti Śivālaya temple at Bādāmi (early 8th century), consisting of a sanctum, a hall with a parapet of *śālās* and *kūṭas* (rectangular and square miniature shrines), and an open porch, is similar to examples in Tamil Nadu. The Virūpākṣa at Pattadkal (*c.* 733–746) is the most imposing and elaborate temple in the South Indian manner. It is placed within an enclosure, to which access is through a *gopura;* and the superstructure, consisting of four stories, has a projection in the front, a feature inspired by the prominent projections, or *śukanāsā,* of North Indian temples. Belonging to the 9th century is the triple shrine (the three sanctums sharing the same *maṇḍapa,* or hall) at Kambaḍahalli and the extremely refined and elaborately carved Bhoganandīśvara temple at Nandi. The Chāvuṇḍarāyabasti (*c.* 982–995) at Śravaṇa-Beḷgoḷa is also an impressive building, with an elegant superstructure of three stories.

With the 10th century, the Karnatic idiom begins to show an increasing individuality that culminates in the distinctive style of the 12th century and later. The Kalleśvara temple at Kukkanūr (late 10th century) and a large
