Time multiplexing. An additional process carried out at the transmitter is of utmost importance in the value of pulse code modulation. A multitude of independent signal messages may be sequentially combined for transmission over a common channel. In telephony, for example, a telephone signal (group of pulses) must be sent every 1/8,000 of a second; yet the transmission of the signal takes so little time that a large part of the 1/8,000 of a second is not used. By a process called time multiplexing, a number of signals, representing sequential parts of different telephone messages, can all be sent one after the other and sorted out again at the receiver. The process is diagrammed in Figure 17. Each of the four signal lines shown is successively (sequentially) sampled, the successive samples appearing on the common line following the sampler. In this example each signal line is assumed to be

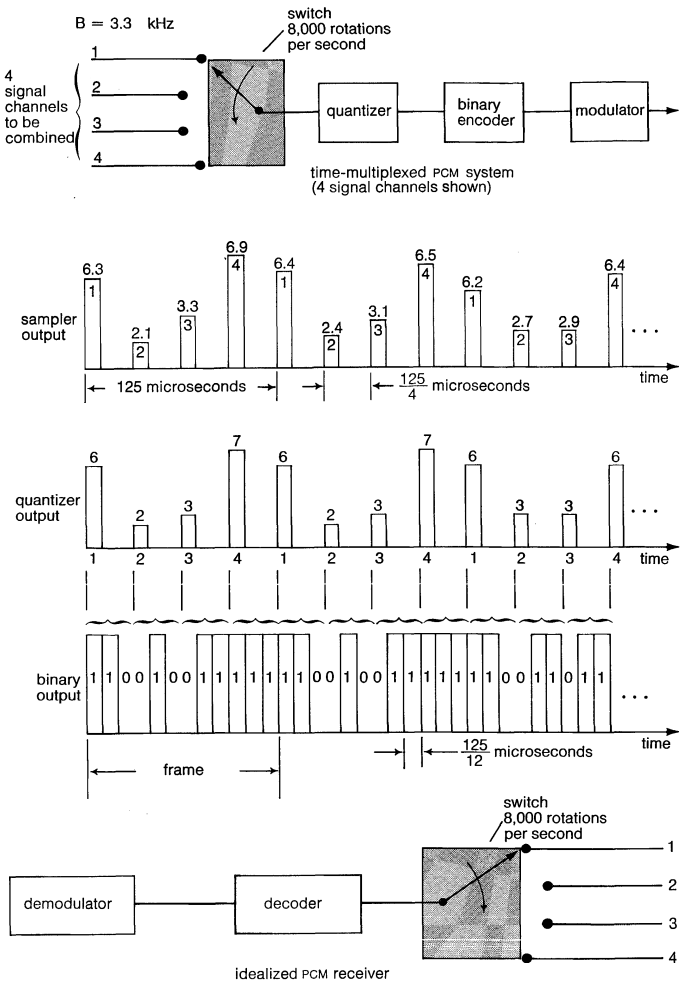

Figure 17: *Elements of a time-multiplexed pulse-code-modulation (PCM) system.*
At the top is a simplified block diagram of the sampler, quantizer, encoder, and modulator for a four-channel system. The analogue signal for each channel is successively sampled, quantized, and then converted to a binary output. At the bottom is a simplified block diagram of an idealized PCM receiver, consisting of a demodulator, decoder, and channel-switching arrangement synchronized with the transmitter sampling switch.

of the same bandwidth, so that the minimum sampling rate required is the same for each.

Versatility of PCM system

A single pulse-code-modulation system may carry several other kinds of signals besides voice. These other signals may not require a sampling frequency of 1/8,000 of a second; some data transmissions may have very slow fluctuations, requiring sampling only once an hour; a great number of such signals can be accommodated along with one or more voice transmissions. In such mixed transmissions, signals with the same bandwidth are first multiplexed into a single stream of samples; different band samples are then interleaved. The sequence of binary signals that represents one sample of each of the signals multiplexed is said to constitute a frame.

The number of signals time multiplexed into one stream varies from application to application. In one telemetering system used aboard a meteorological spacecraft, 544 inputs are multiplexed, of which 32 are sampled once every second, and 512 are sampled once every 16 seconds. Two levels of multiplexing are thus used. In a pulse-code-modulation system used for short-range telephone communication, 24 speech signals are time multiplexed for transmission over the same line. In PCM telegraph systems 660 telegraph channels are multiplexed. In many of these applications seven-bit analogue-to-digital conversion is used; that is, a group of seven bits represents a single sample of the transmitted information.

As more signal channels are multiplexed, the number of bits per second required to represent the composite data stream increases. The bandwidth required of the transmission medium goes up correspondingly, and the high-speed circuitry required to handle the flow ultimately limits the number of channels that may be multiplexed. The circuitry limitation has been changing rapidly, however, due to advances in digital technology. Integrated circuits and smaller electronic components and spacings have been bringing about a revolution in the speed or bandwidth of operation of these circuits.

In one type of telephone system 24 subscribers are time multiplexed into a single circuit. With an eight-kilohertz (thousands of cycles per second) sampling rate and seven-bit binary transmission, $24 \times 8{,}000 \times 7$ bits of information are transmitted every second. In practice an additional bit time interval is inserted after each seven-bit sequence, so that 1,536,000 ($24 \times 8{,}000 \times 8$) bits per second are actually transmitted. Laboratory demonstrations of systems carrying over 500,000,000 bits per second have been successfully carried out, and such systems may become commercially practicable in the near future. A system of this type could carry hundreds of simultaneous telephone conversations or six simultaneous television broadcasts. Television bandwidths are typically six megahertz (6,000,000 hertz). To sample six signals at twice this rate, using seven-bit analogue-to-digital conversion, would require over 500,000,000 bits per second. The bandwidth required is also of the order of 500 megahertz or more, thus bandwidth considerations play a key role in engineering a system. Coaxial cables, millimetre wave guides, and optical tubes are being considered as transmission media for such high-bandwidth systems.

The reception of time-multiplexed signals requires precise synchronization with the transmitter (Figure 17). After demodulation (removing the carrier frequency), the binary signals are decoded back into quantized signal form. Each signal is then sent to its appropriate destination (in the case of telephony the appropriate telephone line). Electronic switches precisely synchronized with those at the transmitter are used.

Insertion of synchronization processes

The synchronization problem is commonly handled by inserting in every frame a particular symbol or sequence of symbols that is readily recognized at the receiver. The receiver timing information necessary for synchronized switching is then derived from these synchronization pulses.

For telephone communication over short distances of 10 to 50 miles (16 to 80 kilometres), a system has been tested in which a network of 24 telephone subscriber lines are time multiplexed, sampled, and coded into pulse code modulation for carrier transmission. Each voice channel is first filtered to a bandwidth of 4,000 hertz, which determines the signal bandwidth, sampled and multiplexed at the 8,000-per-second rate. Seven-bit quantization and binary encoding are used. The binary pulses occupy half of the 0.65 microsecond's time allocated to them. Each seven-bit signal sequence is followed by an additional eighth time slot, which carries the exchange-area signalling information necessary to connect subscribers. In addition, a framing pulse is added at the end of each frame for synchronization.

Frequency multiplexing. As has been noted, the shift to a specified frequency is accomplished by varying, or modulating, a radio-frequency signal. This signal is called the carrier, and the resultant modulated carrier may be shown to possess frequency components or side bands (described later) in the vicinity of each carrier. If each group of signals modulates a different carrier, the resultant composite group consists of frequencies in the vicinity of each carrier. By spacing the carrier frequencies far enough apart, the signals can be kept distinct. When the group of signals is sent simultaneously from one point to another, the process of combining signals shifted in frequency is called frequency multiplexing. It is sometimes used in place of time multiplexing. More commonly a group of pulse-code-modulation signals, each consisting of a time-multiplexed sequence of signals, is in turn frequency multiplexed. The combination of time and frequency multi-

plexing thus results in the simultaneous transmission of many individual signals.

The use of frequency multiplexing is particularly common in telephone transmission. Each of the base band signals in a given set, whether time-multiplexed pulse code modulation or the original analogue telephone message, is first raised in frequency to an appropriate carrier, with the carriers spaced apart by at least twice the bandwidth so that the amplitude-modulated signal may be separately recovered. The frequency-multiplexed set, consisting of the sum of all of these signals, may then in turn modulate another, much higher frequency carrier for final transmission over the appropriate transmission medium.

Amplitude modulation. The simplest form of modulation is amplitude modulation (AM), in which the modulating signal slowly varies the amplitude of a carrier. The on–off binary signal sequence switches the carrier on and off.

Carrier and side bands

Physically, an amplitude-modulated signal consists of the carrier frequency plus two side bands separated from the carrier frequency by an amount equal to the frequency of the modulating (voice) signal. Each of these side bands, one above and one below the carrier frequency, carries all of the modulating information. The signal as a whole, therefore, carries with it superfluous information. It is possible to transmit one side band only, eliminating the carrier and the other side band, and still retrieve the modulating information intact.

Systems are in use in which the carrier is taken out before transmission; in systems of this type (suppressed carrier) the carrier is restored at the receiver. Special circuitry and techniques are required at the receiver in such systems. Since the economics involved make it impractical to build such receivers for widespread use, suppressed-carrier transmission is not used for normal radio broadcasting but is reserved for point-to-point communications and other shortwave radio applications, in which it achieves a substantial savings in transmitted power.

Suppressed-carrier systems with both side bands transmitted are commonly called double-side-band AM systems. Systems with one of the two side bands removed (filtered out) are called single-side-band systems and are in common use for all forms of point-to-point communications (radio and wire transmission, data, telephony, telegraphy). Since they too require insertion of a carrier at the receiver, they are not used in conjunction with home receivers. These systems provide still further power reduction and a reduction by one-half in bandwidth.

Frequency-multiplexed single-side-band systems are common in commercial practice. These systems range from those multiplexing simultaneously a few telegraph circuits to those combining many hundreds of telephone circuits.

Frequency modulation. In amplitude modulation, the amplitude of the carrier varies in accordance with the information-bearing, or modulating, signal. In frequency modulation (FM), on the other hand, the frequency of the carrier varies in accordance with the modulating signal. The resultant modulated carrier has a frequency spectrum centred about the unmodulated carrier frequency, again with upper and lower side bands, but the spectrum bears no simple resemblance to the spectrum of the modulating signal.

A simple form of frequency modulation occurs when the modulating signal is a pulse-code-modulation output. In this case the frequency of the carrier shifts between two values, one when a binary pulse is present in the modulating signal and the other when no pulse is present. As an example, in a typical telephone data set using frequency modulation, the two frequencies are 1,200 hertz and 2,200 hertz. At much higher radio frequencies, they could be any pair of frequencies in the desired band. Such a binary FM system is called a frequency-shift-keying (FSK) system. As the spacing between the two frequencies (or frequency deviation) is increased, the FM bandwidth increases accordingly. For small frequency deviations, however, the FM bandwidth corresponds to the AM bandwidth.

Frequency-shift keying

If a continuously varying (analogue) signal rather than the binary data signal is used as the modulating signal, the overall bandwidth of the modulated signal is approximately twice the frequency deviation plus twice the modulating signal frequency. The bandwidth is thus greater than for an AM system. An FM system in which the frequency shift is much greater than the modulating signal frequency is called a wide-band FM system. If the frequency shift is less, it is called a narrow-band FM system.

Even though frequency modulation requires wider bandwidths than the corresponding AM systems, it is employed as a modulation technique because wide-band FM signals are more effective than the equivalent AM signals in combatting noise and interference. The larger the modulation index (and hence the wider the bandwidth required for transmission), the more effectively FM performs.

Communications media

All telecommunications systems in use throughout the world follow some or all of the basic principles outlined above. They differ principally in the specific types of messages handled and the channels or media over which they are transmitted. When digital techniques are employed, once the various types of signals have been encoded into digital form and combined, they cannot be identified as to original source until they are decoded at their destination. The modulation technique (AM, FM) is selected after cost, power, bandwidth requirements, the availability of the proper transmitters and receivers, and the way the particular modulation technique is matched to the channel to introduce a minimum of distortion have been carefully considered. All possible combinations of the various techniques discussed are in fact in use in actual systems.

The three major communications media—wire, radio, and satellite—are discussed below, with examples of systems drawn from each. Wire transmission commonly refers to the transmission of electrical signals over various types of wire lines including open wire, multipair cable (twisted pairs), and coaxial cable. These lines are used to transmit voice frequencies, telegraph, low-speed data, and signalling for carrier systems (combining many voice or data signals by multiplex techniques). Radio transmission commonly refers to the transmission, through the air or space, of electrical signals in relatively narrow frequency bands. Satellite communications involves the use of man-made satellites travelling in Earth orbits to provide communication links between various points on the Earth.

RADIO COMMUNICATIONS

Because radio space is potentially available to any user, international and national regulations have evolved to limit usage, frequency bands available, and geographical limits of transmission. International radio regulations have been developed by the International Telecommunication Union in Geneva.

International Telecommunication Union

Two committees of the International Telecommunication Union are charged with studying technical and operating questions relating to telecommunications and issuing recommendations. These are the International Radio Consultative Committee (CCIR), dealing with radio communications, and the International Telegraph and Telephone Consultative Committee (CCITT), dealing with problems in telegraphy and telephony.

Among the regulations developed by the International Telecommunication Union are those pertaining to radio spectrum utilization, or allocations within particular frequency bands of the radio spectrum. The allocations are generally made on the basis of service type, or usage. The types of services include fixed service, involving radio communication between specified fixed points (point-to-point high-frequency communication and shortwave and microwave links are examples); mobile radio (aeronautical mobile, maritime, land mobile); radio navigation (aeronautical and maritime); broadcasting (AM, FM, and TV broadcasting intended for general public usage); amateur radio; space communications (telemetry, tracking, Earth-space communications as in satellite communications, and communications between space stations); radio astronomy; and standard frequency (radio transmission of specified frequencies of high precision for scientific and technical purposes).

These services are in general distributed in specific bands throughout the radio spectrum, from a few kilohertz to 40 gigahertz (40,000 megahertz). Each service in turn uses several of the modulation techniques mentioned.

In the U.S., for example, AM broadcasting is allocated the 535–1,605 kilohertz band, FM is allocated the 88–108 megahertz band, and television broadcasting is allotted four bands, 54–72 megahertz, 76–88 megahertz, 174–216 megahertz, and 470–890 megahertz (the ultrahigh frequency [UHF] band).

International point-to-point communications

Fixed, point-to-point communication, commonly used for international radiotelegraphy and radiotelephony, is allotted about 60 percent of the spectrum in the so-called HF (high-frequency) band from three to 30 megahertz. Transmission in this range depends on reflection from the ionosphere, a series of ionized layers of the atmosphere ranging in height from 30 to 200 miles (50 to 300 kilometres) above the Earth. Ionization is caused primarily by radiation from the Sun and so varies with height and in time. Transmission conditions thus change with time, resulting in received signals that fluctuate in amplitude. Special procedures are required for shifting frequencies within the high-frequency band as certain frequencies become unusable due to the changing conditions of the ionosphere. Diversity techniques (multiple frequencies, multiple transmitters and receivers, and multiple antennas) are used to combat fading.

High-frequency radiotelegraph systems commonly use either frequency-shift keying or single-side-band transmission with subcarriers. The data transmitted includes Morse, teletypewriter, and other signals. The international standard of signal transmission is 50 signal intervals per second (or 50 baud). With binary data transmission one baud is one bit per second. If one of four possible signals is transmitted every interval, as would be the case with four-frequency FSK, one baud would correspond to two bits in that interval. Automatic error-correction equipment keeps the number of errors in data transmission to less than one in 10,000 bits. Time-division multiplexing is extensively used, with either two or four 50-baud signals being multiplexed to form 100- or 200-baud channels respectively.

Single-side band systems

Single-side-band systems are employed for high-frequency radiotelephony. These systems use from three- to 12-kilohertz bandwidths, accommodating one to four voice channels respectively. In the four-voice-channel system, two channels are transmitted above and two below the carrier frequency. These voice channels can be used alternately to accommodate a group of frequency-division-multiplexed telegraph channels. In one technique, three single-side-band telegraph subcarriers (channels), each carrying 200 baud and requiring 340 hertz bandwidths, are spaced 340 hertz apart to cover a portion of the voice 2,465 hertz band. Each telegraph channel is in turn capable of accommodating four 50-baud teleprinter channels in time-multiplexed form. Facsimile and radiophoto transmission is also carried out with highfrequency communications channels (see above *High-speed data transmission*).

WIRE TRANSMISSION

Major wire lines. Wire lines transmit communications signals ranging from relatively narrow bandwidth telegraph and telephone (voice and data) to wide bandwidth, multiplexed signals and television. The major wire lines employed are open wire (bare-line conductors mounted on poles), multipair cables (aerial cables on poles, cables buried in the ground, underground cables in conduits, and submarine cables for water crossings), and coaxial cables. Each type provides progressively greater bandwidth and hence allows more signal channels to be transmitted (multiplexed).

A single open-wire pair may be used for carrier telephony up to a frequency of 150 kilohertz. In one typical carrier system, 12 voice channels, each requiring nominally four kilohertz, are frequency multiplexed using single-side-band techniques. Transmission in one direction is by means of the 40–88 kilohertz range, while transmission in the other direction uses the 100–148 kilohertz range.

Cable systems provide wider bandwidths than the open-wire systems (up to 500 kilohertz) and hence can accommodate more voice or telegraph channels. In one typical case, 24 voice channels are combined to form a composite single-side-band signal covering the range 40–140 kilohertz. Transmission in the reverse direction in this case is handled by using another pair of wires in the 164–264 kilohertz range.

Coaxial cables allow considerably more bandwidth, ranging into the megahertz range. As many as 600 voice channels may be combined by successive multiplexing to attain a final composite single-side-band signal with the 600 channels stacked side by side in frequency.

Accommodating telegraph channels. Any voice channel or group of channels could be used to accommodate a group of narrower bandwidth telegraph channels. Up to 24 telegraph channels may be multiplexed into one voice channel. Generally this is accomplished by frequency-shift-keying techniques. The spacing between signals in the final multiplexed group is 120 hertz for 60-word-per-minute telegraphy systems and 170 hertz for 100-word-per-minute systems. (M.Sch./Ed.)

SATELLITE COMMUNICATIONS

Communication satellites permit the exchange of live television programs between nations and continents. International telephone and data services are provided through Earth stations located in more than 100 countries, and a number of other satellite systems provide regional and domestic service, as well as communication with ships. The technique basically involves transmitting signals from an Earth station to an orbiting satellite. The equipment aboard the satellite receives these signals, amplifies them, and transmits them to a region of the Earth. Any station within this region can pick up the signals, thus providing a communication link.

The International Telecommunications Satellite Organization, usually referred to as Intelsat, is responsible for all international nonmilitary satellite communication outside the Soviet bloc. Intelsat also provides domestic service in a number of countries. A government-regulated private corporation known as the Communications Satellite Corporation (Comsat) is the U.S. member of Intelsat. An organization called Intersputnik manages satellite communication within the Soviet bloc.

Communication circuits via microwaves

Satellites provide communication circuits between widely separated locations via microwaves. To transmit television and telephone signals between population centres requires high-capacity circuits. As noted above, over land such circuits can be provided in many ways, including pairs of wires, coaxial cables, waveguides, optical fibres, and microwave radio relay systems. Improved submarine cables can carry thousands of telephone signals across oceans, but satellites can provide even greater capacity, in many cases at less cost per channel. Moreover, a satellite system can be put into service quickly, for it does not require the laying of wires or cables from one point to another or, as does a ground microwave system, the construction of intermediate relay or repeater stations. Once a satellite has been launched, communication between two points can be established merely by constructing two Earth stations, and one satellite can serve many stations.

Microwaves are launched from and received by parabolic (bowl-shaped) antennas. The waves diverge along straight lines in narrow beams; microwave repeaters or amplifiers, therefore, must be located within line of sight of one another. On land this can be achieved by using towers and hilltop locations, but transoceanic microwave systems were impossible until the stationing of satellites in the sky.

The width of a beam of microwaves is proportional to the ratio of the wavelength of the microwaves to the diameter of the antenna. Thus, a small antenna on a satellite will receive from or transmit to the part of the Earth that is visible from the satellite, nearly a complete hemisphere, while a larger antenna will receive from and transmit to a more limited region of the Earth's surface. Similarly, a large antenna at an Earth station will transmit to and receive from only the satellite to which it is pointed and not from other nearby satellites.

Development of satellite communications. Rockets were first seriously considered as a means for sending humans

through space by the Russian scientist Konstantin E. Tsiolkovsky and the U.S. scientist Robert H. Goddard early in the 20th century. The use of unmanned space vehicles has been appreciated only since World War II, when German V-2 rockets were used in air assaults on London. Although early proposals envisioned manned satellites, the great success of satellite communication has been achieved by the use of highly reliable unmanned satellites.

The theoretical stage. The idea of radio transmission through space is at least as old as the space novel *Ralph 124C41+* (1911), by the U.S. science fiction pioneer Hugo Gernsback. Yet the idea of a radio repeater located in space was slow to develop. In October 1942 the U.S. science fiction writer George O. Smith published the story "QRM Interplanetary" in the magazine *Astounding Science-Fiction.* Smith's "Venus Equilateral" radio repeater, in a position equidistant from Venus and the Sun, was used to relay signals between Venus and the Earth.

In 1945 the British author-scientist Arthur C. Clarke proposed the use of an Earth satellite for radio communication between, and radio broadcast to, points widely removed on the surface of the Earth. Clarke assumed a manned space station with living quarters for a crew, built of materials flown up by rockets. The station would be positioned at an altitude of about 22,300 miles (35,900 kilometres) so that its period of revolution about the Earth would be the same as the period of the Earth's rotation. This synchronous satellite, which would always appear in the same place in the sky, would be provided with receiving and transmitting equipment and directional antennas to beam signals to all or parts of the visible portion of the Earth. Clarke suggested the use of solar power, either a steam engine operated by solar heat or photoelectric devices. Three such space stations would provide broadcast to or communication among all locations on Earth except for the most remote regions of the Arctic.

Early plan for a manned space station

In a paper published in April 1955 the U.S. engineer-scientist J.R. Pierce analyzed various types of unmanned communication satellites. These included passive devices, such as metallized balloons and plane and corner reflectors, that would merely reflect back to Earth part of the energy directed to them. Active satellites, incorporating radio receivers and transmitters, were also considered. Pierce discussed satellites at synchronous altitudes, satellites at lower altitudes, and the use of the Earth's gravity to control the attitude or orientation of a satellite.

These two early papers by Clarke and Pierce showed that very modest powers would suffice for transoceanic communication.

Early satellites. The first satellite communication experiment was the U.S. government's Project SCORE (Signal Communication by Orbiting Relay Equipment), which launched a satellite on December 18, 1958. This satellite circled the Earth in an elliptical orbit, with a 112-mile (180-kilometre) perigee, its closest point to Earth, and an apogee, its greatest distance from Earth, of 926 miles (1,490 kilometres). The satellite operated in a real-time (immediate) and a delayed-repeater mode, in which messages were recorded on magnetic tape and retransmitted. SCORE functioned for 13 days, until its batteries ran down. It reentered the atmosphere and was destroyed on January 21, 1959.

Project SCORE

The U.S. Army Signal Corps's Courier project was a further development of the SCORE approach. Courier 1B was designed primarily to handle teletypewriter data and secondarily to handle voice and facsimile (photographs and drawings) messages. It was launched on October 4, 1960, into an orbit with a 602-mile (968-kilometre) perigee and a 1,215-kilometre apogee. It operated for 17 days.

Echo 1, a balloon 100 feet (30 metres) in diameter, made of a plastic called Mylar and coated with a thin layer of aluminum, was launched on August 12, 1960. The satellite was placed in an almost exactly circular orbit at an altitude of 995 miles (1,600 kilometres) and an inclination of 47.3°. The satellite stemmed from two sources: the construction of such a balloon by the U.S. engineer William J. O'Sullivan as a means for measuring the atmospheric density in a 995-mile orbit and from Pierce's proposal for a passive satellite in his 1955 article.

Echo 1

Communications tests carried out by reflecting radio signals from Echo 1's surface were completely successful. The first transmissions were made between terminals built on the East and West coasts of the United States. Bell Telephone Laboratories built a terminal in New Jersey, the U.S. National Aeronautics and Space Administration (NASA) paying for its use. A terminal on the West Coast was built at Goldstone, California, by NASA's Jet Propulsion Laboratory. Echo 1 was used for experimental telephone, data, and facsimile transmission. Signals from Echo 1 were detected in Europe, but no messages were transmitted across the ocean. Echo 1 remained in orbit for almost eight years and was a conspicuous object in the night sky. Echo 2, launched in 1964, remained in orbit for five years.

Echo 1 stimulated a great deal of interest in the development of active satellite communication and led American Telephone and Telegraph Company (AT&T) to build Telstar, launched on July 10, 1962. Telstar was an active satellite with a microwave receiver and transmitter. It was the first satellite to transmit live television and telephone conversations across the Atlantic, which it did on an experimental basis. Telstar was turned off on February 21, 1963. A second Telstar satellite was launched on May 7, 1963 and operated for about two years.

Telstar

NASA's Relay 1 satellite, built by the Radio Corporation of America (RCA), was launched into an elliptical orbit on December 13, 1962. This active satellite was successfully employed in a number of communication experiments. In September 1963 it was used, with the Syncom 2 satellite, to make a brief transmission between the United States, Brazil, and Nigeria.

Syncom 2, the first synchronous communication satellite, was launched on July 26, 1963. This simple but effective satellite was conceived by Harold A. Rosen of Hughes Aircraft Company. The satellite weighed only 86 pounds (39 kilograms); its light weight made insertion into a synchronous orbit possible with the small boosters available at the time. The satellite performed well.

First synchronous satellite

Syncom 3, launched on August 19, 1964, relayed the first sustained transpacific television picture from the opening ceremonies of the Olympic Games in Tokyo. The first commercial communication satellite, Intelsat 1 (Early Bird), launched on April 6, 1965, was a modified version of Syncom.

Other early experiments. In the early days of satellite communication it was not clear what techniques would prove to be practical or useful, and many were proposed and tested. The very earliest communication by means of a satellite made use of signals reflected from the Moon. As early as 1954 the U.S. Naval Research Laboratory transmitted voice messages in this way, and a naval communications link was established between Washington, D.C., and Hawaii in 1960. The goal of the West Ford project, which originated in 1958, was communication by reflection from a cloud of wires that had been launched into orbit; 44 pounds (20 kilograms) of wires were put into a 1,865-mile (3,000-kilometre) orbit in May 1963. Measurements were made of microwave signals reflected from them, but there was little further development of the project.

The success of Echo decided the issue in favour of man-made satellites, and the success of Telstar in favour of active satellites. The success of Syncom led to the universal use of active synchronous satellites for communication.

Satellite as a radio repeater. A typical communication satellite has a number of transponders, or repeaters, each providing a channel of information. Each transponder consists of a receiver tuned to a channel, or range, of frequencies lying in the uplink (receive) band of frequencies; a frequency shifter to lower the received microwaves to a downlink (transmit) range of frequencies; and a power amplifier to produce an adequate microwave output power. The number of transponders, or channels, indicates the communication capacity of a satellite. Typically, one channel (a half-circuit) can carry a colour television signal or 1,200 telephone voice signals in one direction.

Satellite capability

Propagation. As shown in Figure 18, electromagnetic waves are attenuated (*i.e.,* lose power) in passing through

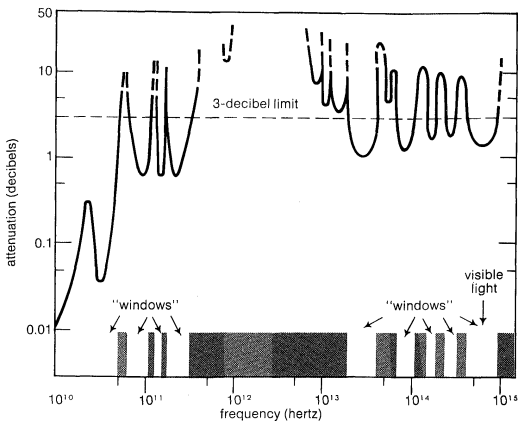

Figure 18: The attenuation of radio waves by the Earth's atmosphere as a function of frequency for an Earth-to-space signal. The chart assumes that the waves originate in clear weather at a high and dry location on the Earth and are directed upward toward space within 45° of vertical (see text).

the ionosphere and the lower atmosphere. In general, an atmospheric attenuation greater than three decibels (dB), corresponding to a loss of half of the transmitted power, is considered excessive. Deliberate attenuation, made by using high microwave frequencies for which atmospheric absorption is great, may be used in communication between military satellites in order to avoid interception of such signals on the ground. For satellite communication with Earth stations, however, only low microwave frequencies are suitable.

Rain also attenuates microwaves. In dealing with rain attenuation, it is useful to consider the attenuation in decibels that is exceeded 0.01 percent of the time, or 52.5 minutes a year. In a region that is neither very dry nor very rainy, the attenuation for this period of time exceeds 43 decibels at 28 gigahertz, 22 decibels at 19 gigahertz, nine decibels at 14 gigahertz, and only one decibel at four gigahertz. In regions where rain attenuation is a serious problem, two Earth stations can be used to communicate with one satellite (diversity), since it is less likely that rainfall will be heavy at both stations simultaneously. Diversity may be desirable at 12 gigahertz in some areas of the world. Except in very dry regions, diversity is necessary for reliable commercial service at 20 gigahertz.

Frequency allocations. Through international agreement, three major frequency bands have been assigned for nonmilitary satellite communication. Each band consists of an uplink (Earth station to satellite) and a downlink (satellite to Earth station) at a somewhat lower frequency. The lower frequency band is chosen for the more difficult downlink because rain and atmospheric attenuation are less at lower frequencies. Bands in service include the C band, which uses frequencies from 5.925 to 6.425 gigahertz for the uplink and frequencies from 3.7 to 4.2 for the downlink, and the K band, which uses frequencies from 14 to 14.5 gigahertz for the uplink and from 11.7 to 12.2 gigahertz for the downlink. There also is an assignment, with an uplink from 12.75 to 13.25 gigahertz and from 14 to 14.5 gigahertz and a downlink of from 10.7 to 11.7 gigahertz, that within the United States can be used only for international service. Another assignment has an uplink of 27.5–30 gigahertz and a downlink of 17.7–20.2 gigahertz. The 20-gigahertz downlink is vulnerable to rain and is no longer used commercially.

Major frequency bands

Characteristics of channels. The bandwidth of a transponder is commonly 36 megahertz (MHz). Such a channel will transmit about 1,200 telephone signals, each with a bandwidth of 4,000 hertz, or one television signal. The total bandwidth of 1,200 telephone signals is only 4.8 megahertz, and the 36-megahertz channel that is used to transmit these signals has seven and a half times this bandwidth. Either wide-deviation frequency modulation is used in satellite communication, or the telephone signals are transmitted as binary pulses by pulse-code modulation. In either case, the use of a broad band of radio frequencies reduces the transmitter power necessary to attain an adequate signal-to-noise ratio in the overall system.

Path loss and power requirements. The power necessary for satisfactory transmission between a satellite and the Earth depends on the total received power necessary at the input of the Earth-based receiver and on the fraction of the power transmitted from the satellite that is picked up by the Earth station antenna. This fraction is the ratio of the area of the receiving antenna on Earth to the area covered by the microwave beam on the Earth. A standard Earth station antenna, for example, has a diameter of about 30 metres. If the antenna beam from the satellite just covers the Earth, the 30-metre antenna receives about $^{4}/_{1,000,000,000,000}$ (4×10^{-12}) of the transmitted power, and the received signal is 114 decibels weaker than the transmitted signal. If the antenna beam of the satellite just covers the continental United States, the received power is about 103 decibels weaker than the transmitted power, or about 11 decibels (14 times) stronger than the power received from a satellite whose antenna beam covers the entire Earth. Because the path loss for transmitting between a pair of antennas is the same in either direction, it is also advantageous to use a narrow receiving beam on a satellite. Thus, it can be advantageous to use a satellite with narrow transmitting and receiving beams, pointed only toward those regions with which communication is desired. Advanced satellites, such as Intelsat 5, have global coverage beams for communicating with nations that have small amounts of traffic, as well as hemispheric and spot beams for areas of heavy traffic.

Types of beams

In order to get a narrow antenna beam, the antenna on the satellite must have a considerable area. The minimum beam width, measured in radians, that can be attained with an antenna of a given diameter is roughly equal to the wavelength divided by the diameter of the antenna. Thus, for a given beam width the diameter of the antenna must be greater at lower frequencies (longer wavelengths) than at higher frequencies. In order for the antenna beam to cover a limited area on Earth, the antenna on the satellite must be quite large (about 2.5 metres in width in Intelsat 5), and the feed, which directs the transmitted power toward the antenna dish or collects the received power from it, must consist of an array of microwave sources such as feed horns. The relative phases and amplitudes of the signals going to the feed horns determine the area of the Earth covered by the antenna beam. This area can be shifted by changing the phases of the signals to the feed horns, either mechanically or electronically. If the phases are shifted electronically, the beam can be made to scan, or hop, from one point to another. By dividing signals among the feed horns it is possible to produce several simultaneous beams aimed at different spots on the Earth. Figure 19 indicates the general configuration of some microwave antennas used for Earth stations and satellites.

The power that must be received at an Earth station for satisfactory operation of a communication satellite channel is proportional to the required ratio of the carrier (received power) to the noise. In normal operation the carrier-to-noise ratio is about 13 to 20 decibels. Signals can be received with some degradation in quality with a carrier-to-noise ratio as low as six or seven decibels, so the design carrier-to-noise ratio provides some protection against rain attenuation or other loss of signal strength.

Some noise in the receiver can be Johnson, or thermal, noise from rain; thermal noise from space is negligible unless the antenna is pointed at the Sun. Part of the noise comes from the receiver itself. Because Johnson noise is proportional to temperature in kelvins (K; −273.15° C), the noisiness of a receiver is specified by a noise temperature T, such that Johnson noise for temperature T added at the input of the receiver doubles the observed output noise. Thus, in the absence of rain noise power is proportional to the receiver noise temperature T. It is also proportional to the bandwidth, which for a satellite channel is about 36 megahertz (the noise power is $N = kTB$ watts, where B is the bandwidth in hertz and k is the Boltzmann constant [$k = 1.38062 \times 10^{-23}$ joule per degree]). The received power per channel is typically about 126 decibels less than a watt (2.5×10^{-13} watt).

Thermal noise

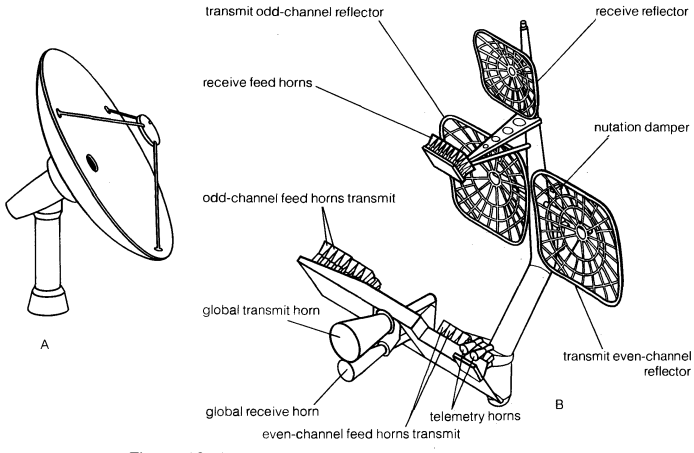

Figure 19: *Antennas.*
(A) Cassegrain Earth station antenna. The parabolic dish directs received microwaves to the convex secondary reflector, which in turn reflects the microwaves in a beam through a hole in the centre on the dish, where they are collected and sent to the receiver. (B) Antennas of the Intelsat 4A satellite. The large reflectors are illuminated by complex arrays of small horns so that the microwave beam covers only a portion of the Earth's surface.

The power received at an Earth station depends on the power transmitted by the satellite (usually from five to 10 watts per transponder), on the area of the Earth's surface covered by the satellite's transmitting beam, and on the area of the Earth station antenna. The gain G of an antenna is related to its area, being proportional to the area divided by the square of the wavelength. The "figure of merit" of an Earth station receiving system is defined as the ratio G/T, the ratio of antenna gain to receiver noise temperature. This ratio may be expressed in decibels. A typical Earth receiver noise temperature is 50 kelvins, and a typical antenna gain is 60 decibels, giving a figure of merit of 20,000, or 43 decibels.

The transmitter power on a satellite is limited by considerations of weight and life; it is important, therefore, that Earth stations have antennas with large areas and that they have low-noise receivers. It is of little use to provide the receiver on a satellite with low-noise receivers because noise at between 200 and 300 kelvins is received from the Earth. Large Earth station antennas can be used for transmitting to satellites as well as receiving from them, and high powers can be used in transmitting (about three kilowatts [kW] for all channels combined).

Limitations. The maximum amount of communication available from satellites is limited by the number and bandwidth of frequency assignments and by other considerations. For a given bandwidth the amount of communication can be increased several ways. Sending independent signals on two polarizations doubles the communication capacity. The first use of two polarizations was on the domestic satellites Satcom, launched on December 12, 1975, and Comstar, launched on May 13, 1976. In addition, using narrow beams from satellites to various regions of the Earth allows reuse of the same frequencies.

The more satellites that can be used simultaneously in synchronous orbit, the greater the total communication capacity. Larger, and hence more directive, Earth station antennas allow the simultaneous use of more satellites. Some Intelsat satellites are spaced as closely as 3° from other satellites. Satellites spaced as far as 14° apart can interfere, however, if small Earth station antennas and correspondingly high powers are used. The U.S. Federal Communications Commission (FCC) has proposed that domestic satellites be spaced 2° apart, even though this spacing is considered too close by some experts.

Satellite technology. Communication satellites are put into orbit by means of rocket launch vehicles, or boosters. During insertion into orbit control is maintained partly by inertial guidance, using gyroscopes and accelerometers, and partly by microwave radar observations, by means of which the position and velocity of the vehicle is determined and commands are given for correcting the orbit.

Launch sequence. Satellites are put into synchronous orbits in the plane of the Equator from sites that do not lie on the Equator. This requires adjusting the plane of the orbit during or after the initial launch phase. The first, or boost, stage lifts the satellite out of the atmosphere and gives it considerable velocity. When this stage burns out, it is separated from the satellite and other stages, falls to Earth, and is destroyed as it passes through the atmosphere. The fairing, which protects the payload (the satellite and associated final stages) as it passes through the atmosphere, is jettisoned. The second stage is then fired, putting the satellite into an intermediate orbit. After the second stage is jettisoned, it remains in orbit for some time. The perigee stage is then fired and ejected; this puts the satellite in an inclined elliptical orbit, an orbit whose apogee is at synchronous altitude (22,310 miles [35,900 kilometres] above the surface of the Earth). While the satellite is in this transfer orbit, tests are performed, and the satellite is positioned for the firing of the apogee motor, which is commonly built into the body of the satellite. (The Titan IIIC transtage can eject into synchronous orbit, so that no apogee motor is needed.) At the apogee of the transfer orbit, the apogee motor is fired, which puts the satellite in a circular synchronous orbit. Satellite antennas and the solar panels can then be extended and the satellite put into its final physical configuration.

Control of attitude and station

The orbit at this point will not be exactly right, nor will the satellite have the correct attitude (point in the right direction). Throughout the life of the satellite the attitude must be controlled and the station kept (the orbit adjusted), because irregularities in the gravitational fields of the Earth, Sun, and Moon—as well as the pressures of light from the Sun and of the solar wind—tend to change the attitude and station.

Launch vehicles. Advances in satellite communication have been made possible by the development of powerful boosters that can launch heavier satellites. In the early 1960s Syncom was launched by a Delta vehicle, which at that time was just able to insert the 86-pound (39-kilogram) satellite into a synchronous orbit. By the 1980s the Delta vehicle could launch a satellite such as the 1,210-pound (550-kilogram) SBS (Satellite Business System). Heavier satellites, such as Intelsat 5, which weighs almost 4,410 pounds (2,000 kilograms), can be launched with the Atlas-Centaur. Military satellites have been launched with these vehicles, and several at a time have been launched with the more powerful Titan IIIC.

Figure 20 shows the relative sizes of various launch vehicles. All of the launch vehicles used through the early 1980s—the Delta, Atlas-Centaur, and Titan—have been refinements and developments of military ballistic missiles—the Thor, Atlas, and Titan, respectively. The Japanese N launch, in some ways similar to the U.S. Delta, is a civilian vehicle. The French Ariane, which has made several successful flights, is a civilian vehicle with capabilities somewhat greater than the Delta or Atlas-Centaur; in its most powerful configuration it should be capable of launching two communication satellites, and a number of commitments have been made to use the Ariane to launch commercial satellites. The U.S. STS (Space Transportation System), or space shuttle, is a manned vehicle; the manned portion is recoverable through a gliding landing on an airfield, and the solid rocket shells through descent into the ocean by parachute. The space shuttle itself can put a payload consisting of several satellites into a low Earth orbit. Propulsion such as the Inertial Upper Stage (IUS) or propulsion incorporated in the satellite itself is necessary for insertion into synchronous orbit.

The reusable U.S. space shuttle

The space shuttle is designed to put up to about 66,150 pounds (30,000 kilograms) into a low orbit. Manned space shuttle flights might make it possible to assemble or to repair large communication satellites in low Earth orbit. Assembly in orbit would be extremely expensive, however, and does not appear to be necessary. Space shuttle plans provide no means for sending astronauts into synchronous orbit, where they would have to go in order to repair communication satellites. In addition, communication satellites have proved to be very long-lived; they tend

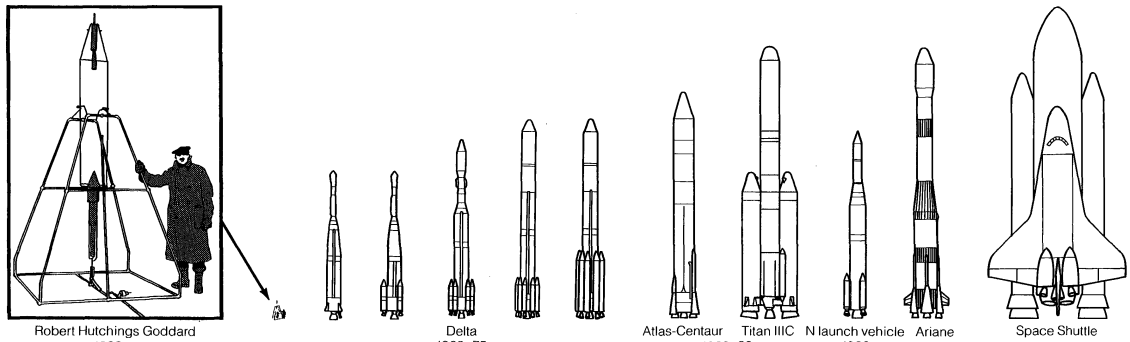

Figure 20: Relative sizes of launch vehicles.
From Harold A. Rosen, *Hughes Aircraft Space Telecommunication;* used with permission from Hughes Aircraft Co. Space and Communications Group

to become obsolete before they wear out. Repair costs may greatly exceed the cost of launching a new satellite. (See also EXPLORATION: *Space exploration.*)

Attitude control and station keeping. In the Syncom and Intelsat 1 satellites, the entire satellite, including the antenna, spun stably around the axis of maximum moment of inertia. Adjustments in axis of spin, or attitude, in rate of spin, and in orbit, or station keeping, were made by an ingenious scheme in which either of two jets were pulsed on briefly. One jet had an off-centre axial thrust and could be used to control both the axis of spin and the plane of the orbit. The other jet had a radial thrust and could be used to alter orbital speed and hence to adjust the period and the eccentricity of the orbit. This scheme of pulsed jet control, which was invented by Harold A. Rosen and Donald Williams, has been used in most later satellites in which the body of the satellite spins in order to attain a stable attitude. Two sets of pulsed jets are provided to guard against failure.

Attitude control by pulsed jets

Intelsat 3, launched in 1968, and all subsequent spinning satellites have had motor-driven, despun platforms at one end, so that antennas can be pointed stably at some point on Earth. Pointing is usually achieved by means of an optical or infrared Earth sensor, which provides a reference for pointing at the Earth. In Intelsat 4, 4A, and 5 and in Comstar a Sun sensor and a clock are used as well. Pointing also can be done by ground command. Pointing is attained by attitude control and by regulating the rate of the motor that drives the despun platform.

Early spinning satellites had a serious disadvantage. A spinning body is stable only if it spins about its axis of maximum moment of inertia; a lossy damper (such as sloshing fluid) will then diminish any periodic nutation, or nodding, of the axis. If the spin is not about the axis of maximum moment of inertia, the damper will cause the nutation to increase rather than diminish, and the satellite will tumble. This arrangement suggested that spinning satellites had to be short along the axis of spin and that only a small satellite could be fitted into a fairing of practical diameter. Anthony Iorillo found theoretically that, if the damping were put in the despun platform rather than in the body of the satellite, the satellite could spin stably around an axis that was not the axis of maximum moment of inertia; his discovery made longer, narrower spinning satellites possible. This feature was first incorporated in a military satellite, Tacsat (tactical communication satellite), launched in 1969, and has been used in most subsequent spinning satellites.

The alternative to attitude control by spinning the body of the satellite and despinning the antenna platform is to control the attitude of the body of the satellite with respect to the Earth (body stabilization). If all three axes of the body are stable with respect to the Earth, as is necessary in pointing an antenna at a particular point on Earth, the satellite must have three-axis stabilization. Three-axis stabilization has been used in many types of space vehicles. A satellite with such stabilization must use jets for station keeping and for gross corrections of attitude. Routine maintenance and corrections of attitude are made by means of spinning inertia wheels. These have a stabilizing effect, and small changes in the rate of spin can cause the body of the satellite to rotate. All Soviet communication satellites, starting with the first Molniya satellite in 1965, have been body-stabilized. The first U.S. operational satellites to use three-axis stabilization were RCA's Satcom, launched in 1975; the LES (Lincoln Experimental Satellite) 8 and 9, launched in 1976; FLTSATCOM (Fleet Satellite Communications), a military satellite launched in 1978; and Intelsat 5, launched in 1980.

Three-axis stabilization

In spinning satellites the solar cells that provide electric power cover the outer cylindrical surface. As the satellite spins, half of the cells are shadowed from the Sun, and most do not face the Sun directly. In a three-axis stabilized satellite the solar cells are placed on panels that can be rotated so that they directly face the Sun. Erecting the solar panels and the antenna arrays on a three-axis stabilized satellite, however, are more complicated operations than deploying the antennas on a spinning satellite. During the 1980s, of U.S.-made satellites, more spinning satellites were in operation and under construction than three-axis stabilized satellites. Further, Intelsat 6, unlike Intelsat 5, was designed to be a spinning satellite.

Electronic technology. Solar cells are the universal source of electric power in operational communication satellites, although some experimental satellites have used thermoelectric generators heated by radioisotopes. A synchronous satellite, which is eclipsed by the Earth during two 44-day seasons each year, for times as long as 70 minutes, carries secondary batteries to provide power during the eclipse. The power necessary for the operation of a communication satellite is considerable; the solar cells of Intelsat 4A, for example, provide 600 watts.

The most common source of microwave power for transmitting signals from communication satellites is the traveling-wave tube. Transistors have been used in some transmitters, but they are not as efficient for microwave frequencies as are traveling-wave tubes. Linearity is another consideration when signals from Earth stations must be transmitted through the same transponder. As improvements are made, the transistor or some other solid-state amplifier may eventually replace the traveling-wave tube, the last vacuum tube used in communication satellites.

As was noted, it is important to have a low-noise receiver at an Earth station in order to reduce the signal power that must be transmitted from the satellite. In some early satellite experiments a very low-noise microwave amplifier, called a maser, was used. The maser is expensive, for it must operate at the temperature of liquid helium, only slightly above absolute zero. The signal received from a satellite is weakest during a rainstorm. Unfortunately, during a rainstorm a considerable amount of Johnson noise is received, corresponding to a temperature of more than 200 kelvins. For this reason there is little advantage in using a receiver with a noise temperature below the 50 kelvins that can be attained with a parametric amplifier. Thus, parametric amplifiers rather than masers are used even in large and costly Earth stations.

Almost all electronic functions in satellites are carried out by means of solid-state devices, especially transistors, which are used to generate and amplify signals and to operate various control functions. LSI and VLSI (large-scale integration and very large-scale integration) circuits,

in which many complex on–off or digital functions are performed by a silicon chip about 1/16 square inch (0.4 square centimetre) in size, have come to play an increasingly important part in satellite communication.

Echo suppressors

An important advance has been the production, by Western Electric, of an LSI chip that can be used to cancel echoes. Telephone calls that are transmitted by satellite reach a home or an office over a single pair of wires that transmits the voice to and from the telephone. A speaker can often hear a faint echo of his own voice. If this is much delayed, talking becomes difficult. For this reason, in circuits longer than 1,490 miles (2,400 kilometres), echo suppressors are used to prevent or reduce an incoming signal while a speaker is talking. In satellite communication it takes a signal almost 0.3 second to reach the satellite and return to Earth, and echoes of one's voice are heard about 0.6 second after speaking. When echo suppressors are used in a circuit with so great a time delay, they sometimes cause a speaker to miss remarks of the other party. Tests show that satellite circuits with echo suppressors are rated by users as considerably inferior to usual telephone circuits. The echo-cancelling chip can detect the presence of echoes by comparing the incoming signal with the outgoing signal and can add artificial echoes that cancel those present in the communication circuit. This arrangement makes satellite circuits comparable in quality to ordinary telephone circuits. The idea of cancelling echoes is an old one, but it became economically feasible only through LSI.

Although satellites use both wide-deviation frequency modulation (FM) and digital transmission of voice by pulse-code modulation in order to conserve power and reduce interference, the trend is toward digital transmission. In part this is a general trend in all voice communication, in switching as well as in transmission. Digital transmission also is more efficient than FM when more than one Earth station uses the same satellite repeater. If several FM signals are sent through one repeater, the transponder must operate at a reduced power level in order to reduce nonlinearities that cause one signal to interfere with the others. In digital transmissions Earth stations can be assigned different, short repetitive time intervals for their transmissions (time-division multiplex), and the repeater can operate at full power.

Time-division multiplex requires that Earth stations operate synchronously and send out bursts of data at specific times, so as not to interfere with one another. Besides being more efficient, time-division multiplex makes it easy to switch between channels groups of data that occur in particular time intervals. Time-division switching makes the use of satellite communication much more flexible, and it is becoming a standard feature of satellites. This function, of course, requires complex digital operations, for which LSI and VLSI are ideally suited.

LSI and VLSI also can be useful in controlling the antenna beam position in satellites. The beam direction can be changed by shifting the phases of the microwave signals sent to various feed horns that illuminate the antenna dish, or reflector. For use in satellites all solid-state devices, including LSI and VLSI, must be highly reliable, and they should not be harmed by the low-level but penetrating radiation that is found at synchronous altitudes.

Satellite systems. Several satellites of the same or of different designs used in communicating among a group of Earth stations form a satellite communication system. A system may provide international communication, as does the Intelsat system, or both international and domestic communication; the Soviet Intersputnik organization provides communication within the Soviet Union and among countries of the Soviet bloc. Other satellite systems provide regional or domestic communication. Some systems, such as the Marisat and Marecs and a number of military satellites, provide mobile communication, primarily to ships. Other satellites serve military uses only. Several experimental satellites have been launched, and there are some satellites reserved for use by amateur radio operators.

Intelsat. The first use of communication satellites was to provide international communication. When the U.S. Congress passed the Communications Satellite Act in 1962, creating Comsat and giving it a U.S. monopoly on international satellite communication, no clear provision was made for supplying other forms of satellite service.

Intelsat

International satellite communication required the participation of other nations. Intelsat originated as a joint venture in August 1964, when 11 countries signed agreements to form a global communication system. It has become an international legal entity in which about 100 countries hold investment shares. Comsat is the designated U.S. participant in Intelsat, which is responsible for the design, development, and maintenance of the space segment of the global telecommunication system. Earth stations used for international communication are owned and operated by entities in the countries in which they are located.

Nations that are not members of Intelsat, including those that cannot join because they are not recognized by the United Nations, can obtain satellite communication through Comsat General, a domestic subsidiary of Comsat. An example is Taiwan, which has a large international telecommunications traffic.

By the 1980s the Intelsat system included about 400 Earth stations with some 500 antennas, located in approximately 150 countries. By the mid-1980s Intelsat was providing about 20,000 two-way telephone circuits that were leased full time and a great deal of television and other transmission.

The advance in satellite communication has been outstanding. For example, Intelsat 1, launched in 1965, has one transponder, which provides 240 two-way telephone circuits or one television channel. Intelsat 5, launched in 1980, provides 12,000 telephone circuits and two television channels. Intelsat 1 operates in the 6/4-gigahertz band only. In Intelsat 5 the 6/4-gigahertz frequencies are used four times, and the 14/11-gigahertz frequencies are used twice. Intelsat 5 also has six communication antennas: two global-coverage beams, two hemispheric beams, and two steerable spot beams. The specifications for additional Intelsat satellites provide for even greater capabilities.

Molniya satellites

Soviet satellites. There are two major types of Soviet satellites. The Molniya satellites, first launched in 1965, are placed in elliptical orbits with a 65° inclination. At this angle the perigee moves very slowly, and the apogee remains in the Northern Hemisphere. Under suitable conditions, the angular velocity near apogee roughly matches the angular velocity of the Earth, and the satellite appears almost stationary in the sky. The satellite is positioned over the Soviet Union every other revolution for about eight hours. Due to its inclination, the Molniya satellite is visible in the most northerly regions of the Soviet Union, where a synchronous satellite would be below the horizon. The second type of Soviet communication satellite is the Statsionar. It is a synchronous satellite and was first launched in 1975.

By the end of 1979, 75 Molniya satellites had been launched, of which 28 were known to be out of service. Only one of the 14 synchronous satellites launched was no longer operating. Technical details of Soviet satellites are known only in part. Their communication capacity appears to be less than that of Intelsat satellites.

Domestic systems. Some domestic satellite systems have been established because the communication they provide would be difficult to obtain in any other way. Canada's Telesat system provides communication to the sparsely populated regions of the Northwest Territories as well as to the nation's urban areas. Indonesia's Palapa system provides communication among many islands that would be hard to link otherwise.

Domestic satellite systems in the United States add communication capacity to a range of other communication channels. Such satellite service has several advantages. In the distribution of programs for cable television the same signal must be sent simultaneously to stations in many parts of the country. The transmission of plates from which newspapers and magazines can be printed simultaneously in many locations is a similar application. Satellites can provide many additional long-distance circuits more quickly than laying cables or building ground microwave systems. Once in place, a satellite system can

be used to supplement other long-haul facilities when they become overloaded because of regional changes in traffic or because of disasters. The SBS, for example, provides large industries with private networks in which the Earth station is on company premises, thus avoiding the use of cables or ground microwave systems to link the networks to communication facilities.

Canada

Canada's Telesat system uses satellites, called Anik, built by U.S. companies. Three Anik A satellites were in service by the early 1980s; the first was launched in 1972. They have antennas with beams that cover Canada and have 12 transponders. One Anik B satellite, launched in 1978, has 12 transponders in the 6/4-gigahertz band that cover all of Canada and six transponders in the 14/12-gigahertz band that serve a fourth of the nation. Advanced Anik satellites have been designed.

Indonesia

The first two satellites of Palapa A, Indonesia's satellite system, were launched in 1976 and 1977. They are of the Anik A type, and the antenna beams cover some 3,000 islands. The larger and more powerful Palapa B system is designed to use both polarizations and to have 24 transponders.

United States

The United States has the greatest number of domestic satellites. Western Union launched two Westar satellites in 1974 and one in 1979. These operate in the 6/4-gigahertz band and have 12 transponders. The antennas cover the conterminous United States and, with less power, Alaska and Hawaii.

RCA launched Satcom satellites in 1975, 1976, and 1981. These operate in the 6/4-gigahertz band, use both polarizations, and have 24 transponders. Half of the transponders are used in conjunction with separate antennas so that they cover Hawaii as well as the rest of the United States; the other transponders cannot be used for traffic with Hawaii.

Four Comstar satellites were in service by the early 1980s; the first was launched in 1976. They are Comsat General satellites, but their entire communication capacity is leased by AT&T. The satellites operate in the 6/4-gigahertz band and use both polarizations to provide 24 transponders. Communication is provided within all of the United States, including Alaska, Hawaii, and Puerto Rico. In 1981 AT&T ordered three advanced communication satellites, called Telstar 3, which can operate in a higher frequency and have an increased life expectancy of 10 years, instead of the average seven years.

SBS is a joint venture of Comsat General, Aetna Life and Casualty, and IBM (International Business Machines). It launched its first satellite in 1980 and its second in 1981. SBS satellites operate with small ground terminals that use antennas with diameters of 5.5 and 7.7 metres. They provide high-speed networks for large organizations that have multiple, dispersed locations, and they supply data, telephone, teleconferencing and other communication services. The organization using the service owns the Earth station and the rest of the ground-based communication equipment. Service to smaller enterprises is under way. The SBS satellites operate in the 14/12-gigahertz range. The antenna beams cover the United States and the lower part of Canada.

Maritime communication. In general, mobile satellite communication is difficult because of the problem of placing microwave antennas on vehicles. Some narrowband communication can be provided by ultrahigh frequency (UHF) using essentially nondirectional antennas, but the amount is limited. In contrast to automobiles and airplanes, ships are suitable platforms for microwave antennas of moderate size; the first commercial mobile service was to ships.

Marisat system

The Marisat system, developed by Comsat General, began serving both the U.S. Navy and commercial shipping in 1976. Three satellites were launched, operating in three frequency ranges. The UHF capability, in the 300/250-megahertz band, was leased by the U.S. Navy for five years. Commercial maritime traffic is carried in the 1.6/1.5-gigahertz range. The 6/4-gigahertz range is used for commercial communication links between satellites and Earth stations on both coasts of the United States. Each satellite provides 16 voice and 88 telex channels in the high-power mode (60 watts transmitter power), eight voice and 44 telex channels in the medium-power mode (27 watts), and one voice and 44 telex channels in the low-power mode (seven watts). By 1980 ships flying the flags of more than 35 nations were using Marisat, and more than 460 shipboard terminals had been commissioned for operation with the satellites.

Inmarisat (International Maritime Satellite Organization) was established in July 1979; Comsat was designated the U.S. participant. Marecs, the first Inmarisat satellite, was launched in 1981 from French Guiana, using an Ariane vehicle. Marecs are designed to communicate between shore and satellite in the 6/4-gigahertz band and between ship and satellite in the 1.6/1.5-gigahertz band. By 1982 Marecs had become the primary satellite for Atlantic communication and with Comsat's Marisat was used for the primary Indian and Pacific coverage; Inmarisat provided worldwide maritime service to about 1,200 ships.

Military satellites. In 1960 ARPA (Advanced Research Projects Agency of the U.S. Department of Defense) proposed an elaborate military communication satellite called Advent. The satellite proved far beyond the state of the art and was abandoned in 1962. In June 1965 the Department of Defense directed the U.S. Air Force to launch simple near-synchronous satellites in equatorial orbits. Some 26 of these IDCSP (Initial Defense Communication Satellite Program, later renamed Initial Defense Satellite Communication System [IDSCS]) satellites were launched from 1966 to 1968, usually eight at a time, using the Titan IIIC vehicle. Although these satellites provided useful communication, they were soon outdated.

Tacsat, a large and elaborate communication satellite, was launched for the U.S. Air Force early in 1969 but failed at the end of 1972.

By the early 1980s the major U.S. military communication satellites were the DSCS 2 and FLTSATCOM satellites. The DSCS 2 satellite, of which 10 had been successfully launched by 1981, is a spinning satellite with both global coverage and spot beam antennas. It has a capacity of 1,300 two-way voice circuits. The uplink frequency band ranges from 7.9 to 8.4 gigahertz; the downlink varies from 7.25 to 7.75 gigahertz. The FLTSATCOM satellite began operation in 1978, and by 1981 five had been launched. Each satellite provides high-frequency communication between military forces through more than 20 channels.

Eight LES satellites of various types were launched from 1965 through 1976. These were used to explore various frequencies and to conduct experiments with steerable antenna beams and in nulling against jamming.

The initial requirement of U.S. military satellites was that they provide adequate and reliable communication. The armed forces have become more and more dependent on satellite communication for both strategic and tactical use, but it had become increasingly apparent by the 1980s that existing military satellites would be vulnerable in a number of ways during a war: to jamming by high-power ground-based jammers; to destruction of ground facilities that are used in connection with satellite station keeping and internal operation; to high-altitude nuclear explosions, whose electromagnetic fields and radiation could destroy or cause errors in the operation of satellite electronic equipment; and, finally, to enemy antisatellite weapons. In the future military communication satellite systems will diverge increasingly from commercial systems in several respects.

IDSCP satellites were used to provide early communication for the North Atlantic Treaty Organization (NATO). Two NATO satellites were launched in 1971 and 1972, and three NATO 3 satellites were launched in 1976, 1977, and 1978. The NATO 2 satellites are spinning satellites, with an antenna coverage optimized for NATO use. The up-band is 7.976–8.005 gigahertz, and the down-band is 7.257–7.286 gigahertz. The NATO 3 satellite has one global beam antenna and one spot beam antenna for Europe; it operates in about the same frequency band as NATO 2. Skynet 1 and 2 are British satellites. They were launched in 1969 and 1974 and are similar to DSCS 2.

Amateur satellites. From 1961 to 1978 the United States successfully launched eight OSCAR (Orbiting Satellite

Carrying Amateur Radio) satellites for the use of amateur radio operators; by 1980 five remained. OSCAR 7 has two channels: a 145.85–145.95-megahertz uplink with a 29.40–29.50-megahertz downlink and a 432.125–432.175-megahertz uplink with a 145.925–145.975-megahertz downlink. In 1978 the Soviet Union launched two RS satellites for amateur use.

Experimental satellites. In addition to early experimental satellites such as Echo, Telstar, and Syncom, a large number of other experimental satellites have been launched. NASA launched a series of ATS's (Applications Technology Satellite) that were used mainly to explore various technological features and to gather data on microwave propagation. The last satellite in the series, ATS 6, was used in an experiment in India for direct broadcasting of educational programs to receiving equipment in numerous villages.

Direct television broadcasts

There were several joint ventures in the mid-1970s. Two French–German Symphonie satellites were launched in 1974 and 1975. These three-axis stabilized satellites have global and spot beams in the 6/4-gigahertz band and four transponders. The CTS (Communications Technology Satellite), or Hermis, a U.S.–Canadian experimental satellite launched in 1976, operates in the 14/11-gigahertz band. It has a high-power (200 watts) transmitter for use with small Earth stations, as well as a transmitter of moderate power. Among other options, it can transmit FM television with up to three simultaneous channels.

Other programs include the Italian Sirio, launched in 1977, with beams that cover Europe. The European Space Agency's OTS (Orbital Test Satellite), a three-axis satellite, was launched in 1978. It operates in the 14/12-gigahertz band, uses dual polarization, two European spot beams, and six repeaters of various bandwidth.

Japan had two major experimental programs by the late 1970s. The CS, or Sakura satellite, launched in 1977, has six repeaters in the 30/20-gigahertz band and two repeaters in the 20/18-gigahertz band. The BSE (Medium-Scale Broadcasting Satellite for Experimental Purposes), or Yuri satellite, was launched in 1978 and operates in the 14/12-gigahertz range. It can transmit two FM high-power (100 watts) colour television signals to Japan for experimental broadcasting to homes.

Disadvantages and prospects. Satellites cannot provide separate circuits to individual homes and offices, as can telephone wires, cables, and optical fibres. Although the SBS can link various corporate locations, wires, cables, or fibres must connect individual users to the Earth station. Thus cables compete successfully with satellites between Europe and the United States, and cables with optical fibres are expected to perform even more successfully. The amount of communication that satellites can provide is limited further by the number of orbital positions and the frequencies available.

Limitations

Although it was suggested early in the history of satellite communication, the advantages of direct broadcasting of television signals from satellites to individual users has been questioned. The U.S. experimental Intelsat 4 (1974) was used for a time by India to broadcast educational programs to villages. The joint U.S.-Canadian CTS satellite (1976) had a transmitter powerful enough to transmit television signals to small Earth stations. The Japanese Yuri satellite (1978) was capable of transmitting television signals to small rooftop antennas, but part of the motivation for doing this was a law that required television service to all parts of Japan, a country with regions where cable is uneconomical and reception from Earth-based transmitters impractical. In the United States, by the early 1980s, a number of people had erected antennas to pick up cable and network television programs relayed by satellite. One satellite alone relayed 24 channels, but tens of channels were available from other satellites. (J.R.P./Ed.)

Telecommunications networks

Where communication between a large number of information sources is desired, the sources must be organized into some form of network, as direct connections between any two among a large number would obviously be uneconomical and technically difficult. Generally there are two aspects to the problem of network organization in a geographically distributed communications system. Since most sources (such as an individual telephone subscriber) are idle a good portion of the time, it is possible first to combine or concentrate communications traffic in a localized area. Interconnections are then provided between the various concentration points to effect the appropriate distribution of the signals. Network organization involves the design of systems to carry out the concentration and distribution of traffic in an economical manner, with a minimum of time delay.

The time-multiplexing and frequency-multiplexing techniques discussed earlier are schemes for combining signals from various sources. There is no concentration involved, however, since a channel (whether in time or in frequency) is always allotted to each source.

Telephone and telegraph networks are prime examples of well-established communications networks. They consist of both public and private systems. There exist as well many other types of data-gathering and distribution networks—telemetry networks used in the remote control and operation of geographically distributed industrial processes, communications networks for railroads, and automobile traffic control in large cities. Time-shared computer systems and computerized airline reservation and bank transaction systems, along with cable television (CATV), also are forms of modern data-gathering and distribution networks.

Types of networks

A multitude of data-concentration techniques and various types of network distribution systems are in existence or in the process of being developed. Two major classes, the telephone network and message (digital-data) networks, are described here.

TELEPHONE NETWORKS

A telephone subscriber is usually connected by way of a loop (two- or four-wire line) to a local telephone exchange or end (central) office. End offices are in turn interconnected via a hierarchy of switching centres. The connection medium between centres is called a trunk, which consists physically of cable, coaxial cable, or microwave-radio links.

A typical incoming telephone call is routed at its end office into an appropriate outgoing trunk. With the message destination known, various alternative routes are available. Under the modern direct-distance-dialing system, five classes of switching centres (see Figure 21) come into play. The class 5, or end, offices are the lowest in the hierarchy. They interconnect customers' lines directly and are connected to other end offices and, by trunk, to

Hierarchy of switching centres

From *Transmission Systems for Communications;* Bell Telephone Labs

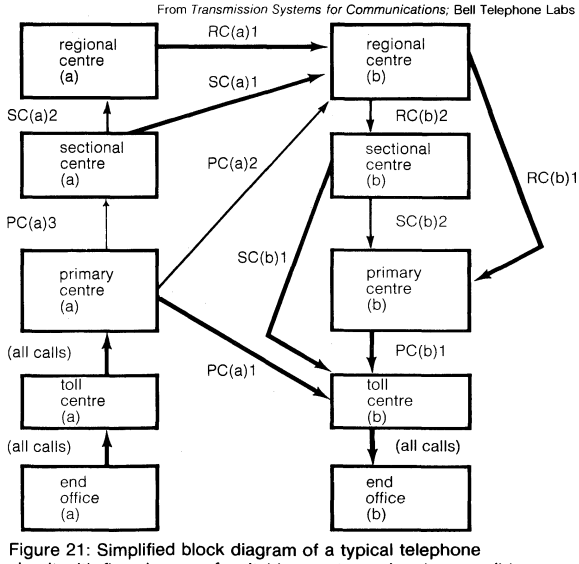

Figure 21: Simplified block diagram of a typical telephone circuit with five classes of switching centres, showing possible alternate routings of a call from end office (a) to end office (b). The order of preference for routing from a given office is indicated by number (see text).

a higher office in the hierarchy. Class 4 switching centres, called toll centres, lead to the higher centres.

A typical set of possibilities for routing a call between an end office in one city and the destination end office in another city is shown in Figure 21. The order of choice in leaving a particular centre is indicated by number. Thus, primary centre 1 is connected directly, via a high-usage trunk, to toll centre 2, which in turn connects to the destination end office. This would be the first choice in routing to end office 2. If this trunk is fully occupied, the route via regional centre 2 is used. If this in turn is unavailable, the route via sectional centre 1 is used. In practice a maximum of seven different links may be allowed.

Automatic switching

Automatic switching using alternate routes provides large economies in connection. High-usage groups are provided between any two offices that carry a sufficiently high mutual traffic.

Figure 22 is an example of a simplified telephone system connecting a group of cities. Various types of channels are used for the interconnecting trunks: coaxial cable, microwave radio, multipair cable, and open-wire line. Each of these carrier systems in turn uses various types of frequency-division-multiplexed schemes to combine many message channels. In the figure, PCM indicates pulse code modulation and PBX a private branch exchange.

Various hierarchies of frequency-division multiplexing, combining individual message channels into groups, then further into mastergroups and supergroups, have been developed following recommendations of the International Telegraph and Telephone Consultative Committee and other organizations.

Microwave-radio communications account for about one-half the trunk mileage in the U.S. In these systems the groups of frequency-multiplexed messages treated earlier

From *Transmission Systems for Communications;* Bell Telephone Labs

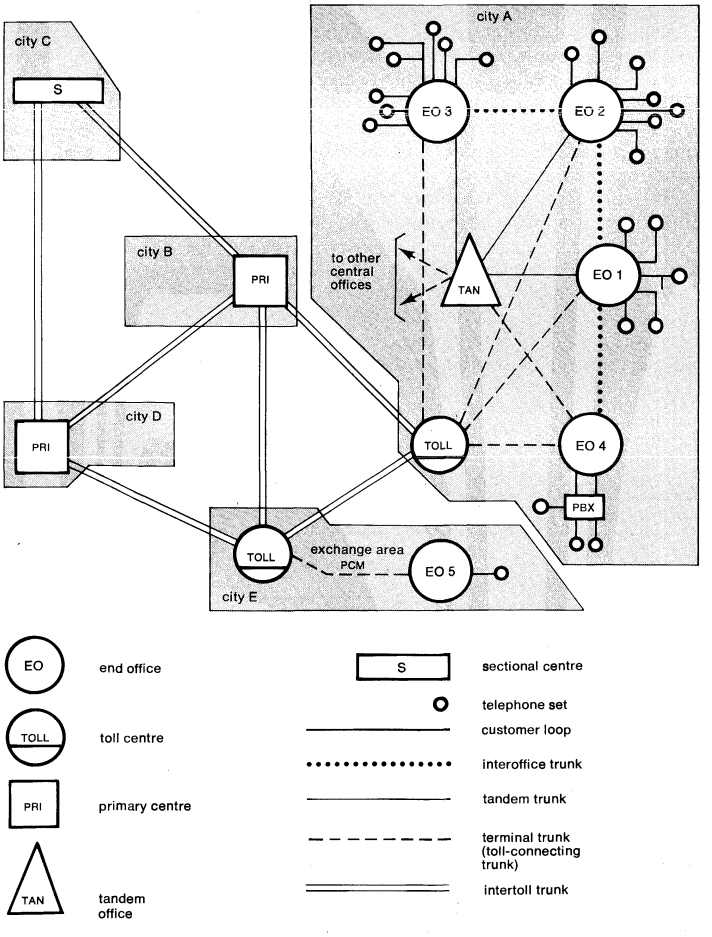

Figure 22: Simplified telephone system for interconnecting a block of cities. The intertoll trunks may be microwave radio, coaxial cable, multipair cable, or open-wire lines and may utilize various types of multiplexing. The exchange area trunk may utilize a pulse-code-modulation (PCM) system.

are most commonly used to frequency modulate carriers in the microwave range. The most common carrier frequencies used are 6,000 and 11,000 megahertz for short-haul transmission (up to 250 miles [400 kilometres]) and 4,000 and 6,000 megahertz for long-haul transmission (up to 4,000 miles [6,400 kilometres]). Overall bandwidths available in these bands are 500 megahertz for the four- and six-gigahertz bands (one gigahertz equals 1,000 megahertz) and 1,000 megahertz for the 11-gigahertz band. Only a fraction of this bandwidth is actually used. For a microwave system, three mastergroups and one supergroup, with a total of 1,860 message channels, are combined to form the modulating signals. The bandwidth of this overall group is on the order of eight megahertz.

Common carrier frequencies

The extremely high frequencies used in microwave transmission enable relatively small antennas to be employed for focussing the energy. Signals are transmitted line of sight between relay stations located 20–30 miles (30–50 kilometres) apart. These repeaters serve to repower the signal periodically. In long-distance transmission the receiver at a relay station converts the microwave FM signal to 70 megahertz. It is then amplified, as much as possible of the noise and interference are removed, and the signal is converted back to the desired microwave frequency for retransmission. Four antennas are commonly used at any one station: two for reception (one for each direction) and two for retransmission.

Switching and dialling. The procedure that enables telephone messages to be placed into a system and switched into a trunk is called switching. As noted earlier, a loop commonly connects the subscriber to a telephone exchange (end office). This loop (using two-wire transmission) provides a path for the two-way speech signals as well as the signals used for ringing, switching, and supervisory functions. The telephone set on the customer's premises consists of a transmitter for converting voice energy into electrical energy, a receiver for performing the reverse process, and appropriate circuitry for carrying out the necessary additional functions.

The conversion from acoustic to electrical energy is accomplished by varying the resistance of carbon granules held between a cup and a diaphragm. Lifting the telephone headset off its hook connects a battery current from the central office to the subscriber's set. This current, flowing through the granules, is varied, or modulated, in accordance with varying pressure on the diaphragm. The telephone receiver is similar in function to a loudspeaker: the varying portion of the loop current passes through a winding on a permanent magnet, causing the magnetic field to vary accordingly, and this in turn changes the force on a diaphragm, causing it to vibrate in accordance with the current fluctuations. The diaphragm moves the air in front and the vibrations are picked up by the ear as a sound wave.

The local exchange office to which a telephone is connected must make the connection between the telephone and an appropriate outgoing trunk. The connection is made by a switching system located at the exchange office. Switching systems have been classified according to the type of switches used (stepping switches, rotary, panel, crossbar); or whether they are electromechanical, electronic, or combinations. A connection must be made at the intersection of an incoming wire and an appropriate outgoing wire.

Since the number of trunks is typically much smaller than the number of subscriber lines, there is a great deal of line concentration, which in turn is possible because an individual customer uses his phone only a small portion of the time.

The appropriate connection is obtained from the number dialled in by the subscriber. A typical seven-digit code allocates four digits (for a maximum of 10,000 possibilities) to a subscriber loop in any one exchange. The exchange itself is identified by the first three digits. The seven numbers are transmitted to the exchange via the subscriber loop by appropriate dialling. In the common dial system each digit dialed sends a different number of pulses to the office. These address digits either control the settings of switches or, in more modern systems, are stored and then

Push-button dialling

used to set up a circuit. In push-button dialling now being introduced, as each button is pushed a two-frequency tone is generated and sent to the central office. The resultant train of tones is interpreted as equivalent dial pulses at the central office and used to set the appropriate switches.

The seven digits allow 9,000,000 telephone numbers to be assigned. Where needed, additional "area code" digits can be assigned; at present three such additional digits are in use in the United States and Canada and two in the U.K.; for international dialling, two international code digits precede the country number and an additional digit to show the language of the party calling.

Typical automatic switching systems in operation include the step-by-step system, used throughout the world for local exchanges and private branch exchanges, accommodating up to 10,000 lines; various crossbar systems for local offices, with up to 30,000 lines; and a computer-controlled electronic switching system capable of handling up to 60,000 lines, employed for both local and toll service exchanges.

Video-telephone service. Early in the 1970s the Bell System introduced video-telephone service. The equipment consists of a 12-button push-button telephone; a display unit with picture (viewing) tube, camera tube, and loudspeaker; a control unit with a microphone; and associated circuitry. The picture signal consists of 250 lines, displayed 30 times per second on a 5.5-inch by 5-inch (14-centimetre by 13-centimetre) screen. The bandwidth required to transmit the signal is one megahertz. The voice-only portion of the telephone call and the voice portion of the video service use normal two-wire subscriber loops. Two more pairs of wires are needed in a telephone cable, however, for the picture signals, one pair for each direction of transmission. Picture (video) signals are switched separately at the central office to which they are connected. Because of this additional switching requirement, not all switching systems can accommodate the system.

For transmission beyond six miles (9.7 kilometres), the picture, voice, and interoffice information are all encoded at a local office into a 6.3-megabit-per-second digital pulse-code-modulation signal. To accomplish this the signal is sampled some 2,000,000 times per second. Three binary digits per sample are then used to produce a six-megabit rate. Voice and data signals of much lower bandwidth are also digitized and then intermixed with the video bits.

Three bits per sample provide representation of the signal by eight amplitude levels, resulting in a coarse and grainy picture. A modified form of pulse code modulation called differential PCM is used to improve picture quality. In this system, the difference between successive amplitude samples is encoded and sent. If the signal is changing slowly, as is normally the case in a picture signal, the encoder signal is often close to zero. More of the eight quantization levels can thus be allocated to this region and fewer to the higher amplitude region, which occurs less often and only when rapid motion is taking place on the screen.

Most 6.3-megabit-per-second encoded video-phone signals are transmitted over microwave radio or coaxial cable trunks. With microwave, up to three such digital signals plus necessary synchronizing signals are sent over one channel. For this purpose, the three signals plus synchronizing signals are sequentially time multiplexed (interleaved), providing a multiplexed bit rate of 20.2 megabits per second. This binary digital stream is then further encoded into a four-level digital stream of 10.1 megabits per second. Each successive pair of binary digits is combined to form one of four possible levels. The encoding results in one-half the bandwidth requirement but reduces signal immunity to noise and distortion. The four-level pulse train is then used to frequency modulate a carrier for transmission over a microwave system.

Encoding for coaxial transmission

Encoding for coaxial transmission is somewhat different. The noise level is less than for microwaves, and there is no signal fading as there is in radio transmission. Eight-level digital transmission can be used to reduce the required bandwidth.

DATA-MESSAGE NETWORKS

Telegraph networks have traditionally provided the capability for data transmission in the form of written messages (see above *Telegraph*). The 1960s, however, saw an explosive growth in data generation and transmission, brought on by the widespread use of high-speed computers. Stock market and bank transactions are rapidly consummated via data-transmission facilities, airline reservations are routinely processed via geographically widespread data networks, and large companies carry out business and bookkeeping transactions via high-speed data networks.

Techniques for efficiently processing, transmitting, and routing these data messages are still undergoing refinement. Much of the data is currently transmitted over the public telephone networks or private, leased voice-quality lines. More engineering effort, however, is going into the development of high-speed data-transmission and switching facilities.

Data-transmission facilities can be conveniently classified into categories of public switched networks or private (leased) lines or networks.

Regular public telephone systems may be used for the transmission and routing of data. Teletypewriters and other low-data-rate (so-called sub-voice-grade) equipment transmitting at up to 150 bits per second can be connected to a teletypewriter exchange service (TWX). Each subscriber has his own dial-up number and is listed in a national directory. Several TWX channels plus telephone circuits can be sent over one voice channel on the telephone network after combining at the local telephone exchange to which they are connected.

Higher data rate signals, at 1,200 bits per second and 2,400 bits per second (voice-grade signals), representing computer or other data-source outputs, may be transmitted by converting the signals into a form suitable for transmission over the telephone network. One device for this purpose uses both frequency-shift-keying (FSK) and phase-shift-keying (PSK) techniques.

Voice-grade signals

The use of voice-grade telephone lines limits the rate of transmission of digital data. Distortion introduced by these lines may be readily corrected in voice signals since the ear is relatively insensitive to distortion of voice signals over a wide range. This distortion is harmful to rapidly varying digital signals, however, introducing many errors at the receiver if not corrected. The problem arises because a connection between two distant points may be routed differently at various times. The transmission characteristics and hence distortion introduced vary with different routing and require different amounts of equalization (correction).

With a voice signal, random variation in distortion is tolerable as long as some average equalization is introduced, but this is not the case with digital signals. Adaptive equalizers—*i.e.*, correction networks introduced at the destination to compensate automatically for deleterious transmission characteristics—are employed to correct the problem. With these equalizers, transmission rates as high as 9,600 bits per second may be possible over the telephone network. The higher transmission rates are accomplished by combining several successive binary digits in a binary data stream and transmitting one of a multiple set of amplitudes or phases of a pulsed carrier. This reduces the required bandwidth, enabling the signal to be transmitted over a three-kilohertz bandwidth line.

Worldwide public teletypewriter service is available through Telex. Telex was introduced in Canada in 1956 and in the U.S. in 1957 and is now combined with the Bell System TWX. The system operates at 66 words per minute (50 baud, or 50 bits per second). Each subscriber has his own number and may dial any other number in his own country, just as with the telephone system.

Private-line data communications

Private-line systems for data communications have come into widespread use in the past decade. These may provide point-to-point communications or, in the case of large systems, network switching as well. They provide an advantage over public systems in that they are assigned (dedicated) to a specific purpose or customer and hence may be specially conditioned to provide superior performance. Voice-grade private lines transmit 2,400 and 4,800 bits per second with conditioning, and adaptive equalization features allowing up to 9,600 bits per second are available.

Private wide-band data channels allowing 500,000-bits-

per-second transmission or higher are also currently available.

When many message sources are to be interconnected in one common private network, switching and routing techniques must be incorporated. Unlike telephone (voice) data, different message sources to be interconnected may have vastly different data rates, data statistics, and data-transmission requirements. The data sources to be switched into the same network may include a telemetry signal that is transmitted continuously at a few bits per second, a teletypewriter producing 50 bits per second intermittently, and a satellite computer communicating at a high data rate with a master computer. Unlike the telephone network, in which direct transmission is required and a busy signal is given when the destination or trunks are all occupied, many data messages may be stored until transmission becomes possible. Priority classifications may be set up, with certain messages allowed to go through and others temporarily held up. Some sources may be regularly queried as to whether immediate transmission is required or can come through as facilities become available.

The strategies of combining or concentrating sources with different data rates, of temporarily storing certain messages, and of determining how to connect the sources and how to route them can all be accomplished by computer, and the trend is in the direction of completely automatic computer-message switching.

Several methods are available for connecting many data terminals to one central point or computer. The methods include connection of the terminals to a computer in a time-shared mode or to a local exchange before retransmission elsewhere. In the so-called roll-call polling technique, a computer successively asks, or polls, each terminal in prearranged order whether a message is to be transmitted. If the answer is yes, polling stops and the message is transmitted. Polling then continues with the next terminal. If the answer is no, the computer goes on to the next terminal. Some terminals may be interrogated more than once in a particular sequence, and priorities are often introduced. In the hub polling technique, the terminals are all connected in a line. The first terminal is polled by the computer. If it has nothing to send, the polling message is forwarded down the line to the next terminal. The computer resumes control only when a particular terminal down the line has something to transmit. At the end of the transmission, the computer resumes the polling at the next terminal, which in turn forwards the message down the line. In the contention, or asynchronous, technique, an individual terminal requests transmission when needed. If a transmission channel is available, transmission proceeds. If not, the channel waits its turn in line.

Roll-call polling

In these techniques, as in the method of concentrating low-speed data for retransmission at a higher rate, data storage becomes significant. Devices, called buffers, used to provide this function include magnetic tape, disc, and other kinds of memory devices. Paper tape has long played the same role in teletypewriter systems.

Error control. It has been noted that errors occur in data transmission. More specifically, in binary transmission a 1 may be received as a 0 or vice versa or two adjacent levels may be confused in multilevel phase or amplitude pulse transmission, because of noise added during transmission or on reception of a pulse signal, signal distortion during transmission, signal fading during transmission, and other effects. Much of modern communications research involves the search for new communications systems and techniques that will provide improved error performance. Appropriate signal design and encoding at the transmitter and unique modulation techniques all play a role. Different receiver configurations and processing techniques are also compared on the basis of their error performance.

If noise is the predominant perturbing effect of the transmission medium, frequency modulation provides improvement over amplitude modulation. If fading plays a significant role, single-side-band transmission is usually preferred. Errors may occur in fading when the signal level drops to a level comparable to that of the noise. At this point an FM system deteriorates rapidly compared to an AM system. The FM improvement is possible only when the signal level is high compared to the noise. If noise is the limiting factor in systems performance, the receiver incorporates a matched filter, whose frequency response is just that of the binary signal pulses received.

Noise appearing at the receiver antenna is the predominant deteriorating effect in space communications. In telephone data transmission, however, it is the signal distortion introduced during transmission that plays the major role. Particular types of pulse shapes at the transmitter are used to minimize the distortion. Repeaters spaced at relatively short distances along the transmission path prevent distortion from building up. Equalizers, both of the fixed type and the adaptive type mentioned earlier, reduce the distortion as well.

Signal distortion

With all of these improved techniques, errors still occur, and error-detection and correction techniques are necessary. By appropriately coding a binary pulse-code-modulation sequence, for example, it is possible to detect errors and even to correct them. In such a scheme additional binary digits (redundant bits) are added at the transmitter to the binary message stream in a controlled manner. There are many techniques for adding the redundant bits and determining the optimum number to use, and significant improvements in performance can be realized by their use.

It is possible, by inserting a large number of redundant bits, actually to locate the error in question and correct it. With still more redundant bits two or more errors may be corrected. The disadvantage is that as more redundant bits are added the transmission rate is reduced accordingly. Thus if five redundant bits are added to 10 message bits, there is a one-third reduction in the data rate.

Coded binary transmission has been used in recent space probes. At the large distances involved, the signal power returned is so small compared to the noise received at the Earth receiving-station antennas that the binary pulses must be stretched out over a relatively long time to provide enough signal energy to overcome the noise. The use of coded transmission reduces the errors or allows a faster rate of transmission for the same error rate.

As an example, the signal received from a space vehicle 1,000,000 miles (1,610,000 kilometres) out in space may be on the order of 10^{-16} watt. If the distance is increased by 10,000,000 miles (16,100,000 kilometres), the received power is about 10^{-18} watt. To keep the average number of errors to less than one in 100,000 binary digits—a common design figure—the maximum data rate is 1,000 bits per second. At 1,000,000 miles each bit must last at least 0.001 second to ensure enough signal energy. If the distance is increased to 10,000,000 miles, the maximum data rate is only ten bits per second. Thus, normal voice communication with existing techniques is not possible at these distances.

Increasing data rate. A theorem from information theory, developed in 1948 by U.S. scientist Claude Shannon, is invoked to increase the data rate. Shannon proved that for a communications channel with white noise added (random noise the intensity of which is constant at all frequencies), there exists an upper limit to the information rate in bits per second that may be transmitted over the channel. This he called the capacity of the channel. Packing more bits per second into the channel than this theorem allows increases the probability of an error being introduced. By using a data rate less than the allowed upper limit of capacity, however, the error rate can be made to approach zero with appropriate encoding. The theorem does not tell how this encoding may be carried out, and much of the error-correction encoding effort has gone into this question of finding good codes.

The capacity of the channel depends on three parameters: the bandwidth of the channel (the maximum frequency component it can transmit), the signal power received, and the noise power measured at the same point as the signal. In particular, as the bandwidth gets larger, the capacity increases to a maximum value directly proportional to the ratio of signal power to noise intensity.

Such considerations may be applied to the three-kilohertz voice channel used with the public telephone network. In this case, unlike in space communications, distortion plays

a greater role than noise. A channel capacity, however, can be found for it. Typically, it is on the order of 20,000 bits per second or higher. In data networks of the future, with the individual links especially devised for data rather than voice, the rate may be expected to increase considerably. Coding techniques have been investigated for a different type of noise than that which appears in space channels. In the telephone channel, noise bursts tend to occur because of faulty switches in exchanges and lightning bursts. These bursts may last for many bits, wiping out all signal pulses while they last. Various error-control techniques and codes have been developed to handle the problem.

The Art of the Theatre

Although a wide range of entertainment is presented in arenas called theatres, the art of theatre is concerned almost exclusively with live performances in which the action is precisely planned to create a coherent and significant sense of drama. Though the word theatre is derived from the Greek *theaomai,* "to see," the performance itself may appeal either to the ear or to the eye, as is suggested by the interchangeability of the terms spectator (which derives from words meaning "to view") and audience (which derives from words meaning "to hear"). Sometimes the appeal is strongly intellectual, as in Shakespeare's *Hamlet,* but the intellectual element in itself is no assurance of good theatre. A good performance of *Hamlet,* for example, is extremely difficult to achieve, and a poor one is much less rewarding than a brilliant presentation of a farce. Moreover, a good *Hamlet* makes demands on the spectator that may be greater than he is prepared to put forward, while the farce may be enjoyed in a condition of comparative relaxation. The full participation of the spectator is a vital element in theatre.

There is a widespread misconception that the art of theatre can be discussed solely in terms of the intellectual content of the script. Theatre is not essentially a literary art, though it has been so taught in some universities and schools. For many years the works of the Greek dramatists, Shakespeare, and other significant writers such as Schiller were more likely to be studied than performed in their entirety. The literary side of a theatrical production works most effectively when it is subordinated to the histrionic. The strongest impact on the audience is made by acting, singing, and dancing, followed by spectacle—the background against which those activities take place. Later, on reflection, the spectator may find that the meaning of the text has made the more enduring impression, but more often the literary merit of the script, or its "message," is a comparatively minor element.

Yet it is often assumed that the theatrical experience can be assimilated by reading the text of a play. In part, this is a result of the influence of theatrical critics, who, as writers, tend to have a literary orientation. Their influence is magnified by the fact that serious theatre cannot be made widely available; for each person who sees an important production, thousands of others will know it only through the notices of critics. While reviewers in the popular papers may give greater credence to such elements as acting and dancing, critics in the more serious journals may be more interested in textual and thematic values. Such influences vary from country to country, of course. In New York City a critic for one newspaper, *The New York Times,* may determine the fate and historical record of a production, assuring it a successful run or forcing it to close overnight. In London, audiences have notoriously resisted the will of the critics, and in some cities, such as Moscow, reviews may take many weeks to appear.

This is not to say that the contribution of the author to the theatrical experience is unimportant. The script of a play is the basic element of theatrical performance. In the case of many masterpieces it is the most important element. But even these dramatic masterpieces demand the creative cooperation of artists other than the author. The dramatic script, like an operatic score or the scenario of a ballet, is no more than the raw material from which the performance is created. The actors, rather than merely reflecting a creation that has already been fully expressed in the script, give body, voice, and imagination to what was only a shadowy indication in the text. The text of a

play is as vague and incomplete in relation to a fully realized performance as is a musical score to a concert. The Hamlets of two great actors probably differ more than two virtuoso renditions of Bach's *Goldberg Variations* possibly can. In general, the truly memorable theatrical experience is one in which the various elements of performance are brought into a purposeful harmony. It is a performance in which the text has revealed its meanings and intentions through skillful acting in an environment designed with the appropriate measure of beauty or visual drama.

This article contains a treatment of the art of theatre in the most general terms, an attempt to illuminate what it is and why it has been regarded as a fundamental human activity throughout history. It also deals with the roles of the director and the actor in producing the desired aesthetics. The theatrical traditions of the various cultures of the world are considered at length in articles such as THEATRE, THE HISTORY OF WESTERN; AFRICAN ARTS; EAST ASIAN ARTS; SOUTHEAST ASIAN ARTS; and in articles on the literatures of various nations—*e.g.,* ENGLISH LITERATURE, RUSSIAN LITERATURE. A more extensive treatment of the elements of theatre can be found in THEATRICAL PRODUCTION. The genres of dramatic literature are discussed in LITERATURE, THE ART OF: *Drama.*

The art of theatre

Roots of Western theatre in Athenian drama

Exactly how the theatre came into being is not known. While it is indisputable that the traditions born in ancient Athens have dominated Western theatre and the theories of Western drama up to the present, it is impossible to state with certainty what the theatre was like even a few years before the appearance of Aeschylus' earliest extant play, *Persians* (472 BC). Legend attributes the invention of the dithyramb, the lyrical ancestor of tragedy, to the poet Arion of Lesbos in the 7th or 6th century BC, but it was not until the creation of the Great (or City) Dionysia in Athens in 534 that tragic drama established itself. The Dionysiac festivals were held in honour of Dionysus, a god concerned with fertility, wine, and prophecy. Dionysiac celebrations, held in the spring, were traditionally occasions for frenzy, sexual license, and ecstatic behaviour welcoming the return of fertility to the land after the winter (reflected dramatically in the *Bacchants* by Euripides). The Great Dionysia was a more formal affair, with its competition in tragedy, but its religious purpose is often cited as a pointer to the origin of drama itself.

Origins in religious rites

In the theories that see drama as a development from primitive religious rites, the dramatist is often described as a descendant of the priest. Theatrical representation could have arisen first from the substitution of an animal for a human sacrifice, say a goat for a virgin or a young warrior. In time, the formula of the sacrifice might have been enacted ritualistically without the actual sacrifice of the animal. (The word tragedy is descended from the Greek *tragōidia,* meaning "song of the goats.")

Considered in such a way, the most famous of Greek tragedies, *Oedipus the King* by Sophocles, can be seen as a formalistic representation of human sacrifice. Oedipus becomes a dramatic embodiment of guilt; his blinding and agony are necessary for the good of all Thebes, because it was by killing his father and marrying his mother that he first brought the gods' curse upon his people. Aristotle felt that the representation on stage of Oedipus' suffering was a means of vicarious purgation, or cleansing, for the spectators.

But other explanations for the origin of drama have been offered. Mimesis, the artistic representation or imitation of an event, has been discerned in such primitive rituals as war dances, which are intended to frighten the enemy and put courage into the hearts of the participants. These dances may imitate the battle itself, or at least the way in which the participants hope to see the battle develop.

The origins of drama have also been attributed to simple storytelling, as when the storyteller adopts a false voice or adds characterization through movement and costume. In such terms, the art of theatre could be described at its most fundamental as the presence of an actor before an audience.

Whatever the primary motivation, the first systematic elaboration of theatre can be seen through the work of the Greek playwrights of 5th-century-BC Athens. Aeschylus apparently inherited a form that consisted of a single actor responding to or leading a chorus. His innovation is generally considered to have been the use of a second actor, and it was either Aeschylus or Sophocles who added a third actor as they competed each year for prizes in the Great Dionysia. Once a third actor had appeared, the chorus gradually declined, and it was the multiplying individual characters who assumed importance. In this way, classical Greece left to posterity a measure of specialization among theatrical performers.

Drama reflecting the rise and decline of civilizations

Beyond these formal elements, however, classical drama offers a pattern of development that has been reenacted continually in other cultures throughout history. The rapid rise and decline of drama in ancient Athens paralleled the rise and decline of the Athenian civilization itself. Great periods of achievement in theatre have tended to coincide with periods of national achievement, when man's breadth of vision expands to encompass the cosmos, as in Elizabethan England. Conversely, periods of excessive materialism, such as those of the decay of ancient Greece or ancient Rome, tend to produce theatre in which ostentation, spectacle, and vulgarity predominate.

Probably more than in other arts, each theatrical style represents an amalgamation of diverse heritages. Although the Greek theatre has long had the most direct influence on Western culture, many later innovations have been borrowed from previously remote cultures such as India, Bali, and Japan. A fundamental difference between borrowings from Greek theatre and borrowings of a more recent and exotic nature is that the techniques of Greek performance have not been handed down with the texts. Most of what is known about the actual performance of Greek plays is the result of scholarly and archaeological research. Information about the nature of the music and of choral dances, for example, is very skimpy.

Influence of Oriental theatre

In the Oriental theatre, on the other hand, techniques as well as texts have survived. For example, the Nō theatre of Japan has been handed down through families of performers with little change for 600 years. In addition to the instructions for performers contained in India's *Nāṭyaśāstra,* there is a major descriptive treatise on music,

giving guidance on musical techniques. The *Nāṭya-śāstra,* which may be as old as Aristotle's *Poetics* (4th century BC), is a book with very specific injunctions to performers, including dancers. Some of its techniques may be found in surviving theatre forms such as the kathakali dance in Kerala, India. In turn, some of these techniques have been assimilated by such Western directors as Jerzy Grotowski and Peter Brook. With other writers and directors consciously exploiting techniques and traditions from such forms as Kabuki and Nō, new relationships are inevitable.

There is little doubt that the Greek theatre, with its literary emphasis, has provided Western theatre with a sense of continuity in stories, themes, and formal styles. The plays themselves are regularly revived, with discernible references to specifically modern concerns. It is also notable that the Greek theatre has served as a model for such great writers as Racine and Corneille in France and Eugene O'Neill in the United States. When Arthur Miller's *Death of a Salesman* (1949) touched its audiences with awe and pity in the manner of Aristotle's prescriptions, critics debated whether the play could be genuinely tragic in the Greek sense, given that it had no nobler a protagonist than the salesman Willy Loman.

Implicit in all developments since Athenian drama reached its peak in the 5th century BC has been the measure of the greatness of the Greeks. That the heights which they achieved have never been equaled stands as a powerful argument against an easy belief in the constant progress of mankind.

THEATRE AS EXPRESSION

Mimesis in theatre. The art of the theatre is essentially one of make-believe, or mimesis. In this respect it differs from music, which seldom attempts to imitate "real" sounds—except in so-called program music, such as Tchaikovsky's *1812 Overture,* which suggests the sounds of a battle. In this respect, the art of narrative in literature is much closer to that of the theatre. In a story, considerable attention must be paid to plausibility. Even if the story is not intended to be believed as having actually happened, plausibility is essential if the story is to hold the auditor's attention. The principal factor in plausibility is not precise correspondence with known facts but inner consistency in the story itself.

Importance of maintaining plausibility

Drama also requires plausibility, but in drama it must be conveyed not by a narrator but by the actors' ability to make the audience "believe in" their speech, movement, thoughts, and feelings. This plausibility is based on the connection between the impression made by the actors and the preconceptions of the auditors. If the character Hamlet is to be plausible, the actor must make his audience believe that Hamlet could conceivably be as he is presented. This does not mean that the actor must make his audience believe that he literally is Hamlet, merely that he is plausibly and consistently making-believe to be Hamlet. The aim of a performance is not to persuade spectators that a palpable fiction is fact, that they are "really" there, out on those bitterly cold battlements of Hamlet's castle at Elsinore. Indeed, they are far freer to appreciate the play and to think about it if they are not "really" present. Knowing all the time that it is a figment, they are willing to enter into the make-believe, to be transported, if it is sufficiently convincing. Yet they know that, however thrilling or pleasurable the rapture, it may be shattered at any moment by some ineptitude or mistake on the stage or by a coughing neighbour in the audience.

That is the basic rule, or convention, of the make-believe of the theatre. The actor breaks the basic rule of the game if he forgets his words, or laughs at private jokes, or is simply incompetent, or is unsuited to his part. No audience can accept a vulgar, lumpish, elderly Hamlet, because Hamlet is a young prince whose lines are consistently thoughtful and witty. Yet it is not necessary that the actor playing Hamlet should "really" be all these things; he need only give the impression of being princely, witty, elegant, and young enough to sustain the credulity of the people sharing the make-believe. That credulity can extend a considerable way; several times in her old age the actress Sarah Bernhardt played Hamlet.

Degrees of realism in performance

Thus, in every performance there must be realism in some degree. At certain epochs and in certain kinds of plays the aim has been to be as realistic as possible. But even the most realistic production (*e.g.,* Anton Chekhov's play *The Cherry Orchard* in Konstantin Stanislavsky's production at Moscow) made immense concessions to theatrical artifice. Conversation in real life often leads nowhere; it is full of inconclusive, meaningless, boring passages. It does not necessarily attempt, as every word in Chekhov's play must, to fit into a story, to be part of the expression of a theme, or to introduce and reveal a group of characters.

Though most commercial, light comedies continue to be written and acted as realistically as possible, realistic theatre fell out of fashion in the first half of the 20th century in response to the advent of motion pictures. Just as realistic painting declined when photographs began to achieve similar effects mechanically, so did staging that attempted to reproduce the actual world in every detail decline when such effects became commonplace in films.

Even before the introduction of motion pictures, the theatre was moving toward extravagantly nonrealistic theatrical effects, from the puppet-inspired theatre of Alfred Jarry, author of *Ubu roi* (1896), to the Symbolist dramas of Maurice Maeterlinck, Edward Gordon Craig's concept of the *Übermarionette* ("Superior Puppet") and theatrical surrealism. The most unrealistic productions, however, inevitably retained certain quite realistic features; the actors still had to be recognizably human, no matter how fantastic the script and settings might be.

Theatre as social expression. In different contexts, different aspects of humanity have seemed important and have therefore been stressed in theatrical representation. Renaissance drama, for instance, emphasized the individuality of each character, while in 17th-century theatre, which was much more restricted in its philosophy and in its setting, man was presented not as a creature proclaiming his unique importance in the universe but rather as one adapted to the quite limited environment of 17th-century society. The greatness of the Elizabethan theatre was the universality of its outlook and the breadth of its appeal; these have never been regained. Since the latter part of the 17th century the art of the theatre has been concerned with smaller themes and has aimed at a smaller section of society.

From the 17th to the 19th century, the theatre's leading characters were persons of breeding and position; the "lower classes" appeared as servants and dependents, mostly presented in low comedy. Rustics were almost automatically ridiculous, although sometimes their simplicity might be endearing or pathetic. The 17th-century plays of Molière are a good deal more egalitarian than English plays of similar date, or even of a century later; but even Molière never allowed the audience to forget that his plays were about, and for, persons of high station. A very clear line is drawn between employers and employed, and the latter, though often more intelligent, never seem to belong to quite the same species.

Upper-class audience of 17th–19th-century drama

By the middle of the 19th century European theatre had become at least as much a middle-class as an aristocratic entertainment. Nevertheless, it was still thought important, especially in London, that the actors suggest gentility. George Bernard Shaw, in *Our Theatres in the Nineties* (1932), remarked that to be employed in a good production it was far less important that a young actor be talented than that he speak "well" and be beautifully dressed. The plays that succeeded throughout Europe were plays about men and women of good social position, and the plots were concerned with some infringement, usually sexual, of the genteel code of behaviour; *The Second Mrs. Tanqueray* (1893) by Arthur Wing Pinero is an example.

After the Russian Revolution of 1917 the Soviet theatre broke with gentility. The heroes and heroines of Soviet theatre were splendid, muscular, idealistic workers. In western Europe, however, gentility continued in the 1920s and '30s to be the dominant aim of the fashionable theatre. In New York City it received a setback at the time of the Great Depression of the 1930s. At a famous series of productions at the New York Group Theatre, the director Harold Clurman was in conscious revolt against

the oppressive bourgeois gentility of the day. The theatre was not spectacularly successful, however, and it stayed in existence for no more than a few years.

In Europe it was not until after World War II that the theatre made efforts to reflect and to interest a wider section of society. By that time, however, audiences at all levels had lost the habit of theatregoing and were fast losing the habit of moviegoing, as television was becoming the popular medium of drama—indeed, of all entertainment. Theatre began to be directed not to any one class in society or to any one income group, but rather toward anyone who was prepared for the energetic collaboration in the creative act that the art demands.

ELEMENTS OF THEATRE

The theatrical hierarchy. Theatrical art demands the collaboration of the actors with one another, with a director, with the various technical workers upon whom they depend for costumes, scenery, and lighting, and with the business people who finance, organize, advertise, and sell the product.

Collaboration among so many types of personnel presupposes a hierarchy. In the commercial theatre the most powerful person is usually the producer (until recently known as the manager in the British theatre, which has now adopted the American usage). He is responsible for acquiring the investment that finances the production. The rehearsal of the play is conducted by the director (formerly known in Britain as the producer), who is responsible for interpreting the script, for casting, and for scenery and costumes. Under his general direction a stage manager, possibly with several assistants, looks after the organization of rehearsal and the technical side of the performance—light and curtain cues, properties, sound effects, and so on.

Producers, directors, and stage managers

Naturally, the hierarchy varies somewhat in different circumstances. In the state-subsidized National Theatre of Great Britain, for example, the apex of the pyramid is an artistic director, who is more concerned with guiding the policy of the theatre than with details of administration or the preparation of any single production—though he may, of course, also assume responsibility for the preparation of a number of productions.

The dominant expression so far as the audience can tell is nearly always that of the actor with the most important part. It may, therefore, be wondered why theatres are no longer dominated by actor-managers, as they were in 19th-century London, where Sir Henry Irving managed the Lyceum for 21 years (1878–99) as its artistic director, administrator, producer-director, and leading actor. Since Irving's day theatrical business has become infinitely more costly and complicated. Budgets in Irving's time were only a fraction of what they became a century later. A single Broadway musical can now cost in excess of $5,000,000, while the running costs of organizations such as the Royal Shakespeare Company rise to many millions of pounds each year. In addition, there are complicated negotiations with trade unions.

Although the leading actor seems completely to dominate the performance, he is often only a mouthpiece: the words he speaks so splendidly were written by somebody else; the tailor and wigmaker must take some credit for his appearance; that he should play the part at all was usually not his own idea but that of a producer or director.

Even before the actors assemble for the first rehearsal, the producer, director, designer, and—if he is available—the author have conferred on many important decisions, such as the casting and the design of scenery and clothes. In the commercial theatre, the capacity of the theatre that is selected determines the budget and therefore the scale of the production. (Different considerations affect the planning of programs in the subsidized theatre, including responsibility to new writing, to the national heritage, and to a balanced repertoire.) Certainly the most lively part of the work still lies in the period of rehearsal, but much of it has been determined before it begins.

Although it might be supposed that the author would be the best person to direct a play, he usually is not, for several reasons. First, authors are apt to love their brainchildren not wisely but too well; and, like most parents, they are not usually the most impartial judges of their plays' character and quality. Also, authors rarely combine a knowledge of their own craft with a good working knowledge of the quite different craft of direction.

The role of the audience. It is partly because it is a collaborative art, involving so much compromise, that the theatre seems often to lag behind other arts, expressing dated views in a dated manner. There is another reason too: the theatre depends more than most arts upon audience response. If the house is not full, not only does the performance lose money, but it loses force. It is unusual for new ideas, even for new ways of expressing old ideas, to be popular. With few exceptions, people apparently do not go to the theatre to receive new ideas; they want the thrilling, amusing, or moving expression of old ones.

Spectators' lack of response to new ideas

If a performance is going well, the members of its audience tend to subordinate their separate identities to that of the crowd. This phenomenon can be observed not only at the theatre but also at concerts, bullfights, and prizefights. The crowd personality is never as intelligent as the sum of its members' intelligence, and it is much more emotional. Intelligent members of an audience lose, to an extraordinary degree, their powers of independent, rational thought; instead, unexpected reserves of passion come into play. Laughter becomes infectious; grave and solid citizens, as members of an audience, can be rendered helpless with mirth by jests that would leave them unmoved if they were alone.

This being the case, theatre audiences are virtually incapable of an intellectual consideration of the ideas presented to them unless those ideas are already familiar. Familiar ideas can be received effortlessly while the emotional or thrilling or amusing aspects of the presentation are enjoyed. This is why the effectiveness of a theatrical performance never depends solely upon the excellence of a text. Laurence Olivier's performance as Shakespeare's *Richard III* was more exciting than his performances in many superior works of Shakespeare. Theatrical art succeeds to the degree that excitement is engendered in the audience, a factor that is unrelated to the intellectual merits of the text.

The effect of theatre structure. From the 17th to the 20th century few dreamed of building a theatre in other than the now traditional proscenium style. This style consists of a horseshoe auditorium in several tiers facing the stage, from which it is divided by an arch—the proscenium—which supports the curtain. Behind the curtain, the backstage machinery facilitates quick changes of illusionistic scenery. This type of theatre was developed for Italian opera in the 17th century. From the proscenium theatre's introduction, productions of plays of all themes have tended to exploit the audience's pleasure in its dollhouse realism.

The dominance of the proscenium

The proscenium theatre separates the audience from the performers. In the theatres of Elizabethan England, the actors performed in the very midst of their audience. Their theatre had evolved from the courtyards of inns, in which a raised platform was erected for a stage. Some members of the audience stood around it while others watched from windows and galleries surrounding the inn yard.

In the early years of the 20th century, the English actor-manager William Poel suggested that Shakespeare should be staged so as to relate the performers and the audience as they had been on the Elizabethan stage. His ideas slowly gained in influence, and in 1953 just such an "open" stage, with no curtain and with the audience sitting on three sides of it, was built for the Stratford Shakespearean Festival in Ontario. A considerable success, it had a strong influence on subsequent theatre design.

The open stage proved suitable not only for Elizabethan plays but also for a wide repertoire. Probably it will never completely replace the proscenium, which remains more suitable for the countless plays that were written with such a stage in mind, such as the comedies of Molière or the highly artificial comedies of Richard Brinsley Sheridan and Oscar Wilde. On the other hand, the more realistic plays of Ibsen, Shaw, and Chekhov, all written for the proscenium theatre, lend themselves well to the open stage.

Advantages of the "open" stage

There are three solid reasons for preferring the open stage. First, more people can be accommodated in a given cubic space if arranged around the stage instead of just in front of it. This is important not merely for the economic advantage of a larger capacity but also for artistic reasons—the closely packed audience generates more concentration and excitement.

A second reason for preferring the open stage is that the actors are nearer to more of their audience and can therefore be better heard and seen. This point is contested by adherents of the proscenium stage, who claim that the actor at any given moment must have his back turned to a large part of the house and, as a result, must be more difficult to see and hear. If the open stage is used efficiently, however, the actor's back will never be turned to anyone for more than a few seconds at a time.

The third reason is that members of an audience seated all around the stage are far more aware of the presence of the others than is the case in an opera house. The performance thereby is appreciated more as an event jointly shared and created by the audience and the actors.

Since the arguments for the open stage were first made, theatres such as the Arena Stage in Washington, D.C., have been designed "in the round" so that the audience completely surrounds the stage. Other theatres have followed the example of Grotowski's Polish Laboratory Theatre by taking as the starting point an "empty room," in which a different environment may be constructed for each production, radically altering the relationship between actors and audience for each play.

The proscenium has come to be associated so closely with creating "illusion" that it has led to a misconception about the function of drama and to a misdirection of the energies of dramatists, players, and audiences. The single-minded attempt by the actors to create, or by the audience to undergo, illusion reduces drama to a form of deception.

The art of the theatre is concerned with something more significant than creating the illusion that a series of quite obviously contrived events are "really" happening. *King Lear* is far more complex and interesting than that. Art is concerned not with deception but with enlightenment. The painter's art helps its audience to see and the musician's art helps it to hear in a more enlightened way: Rembrandt and Bach are trying not to deceive their audiences but to express and to share their deepest thoughts and feelings. Similarly, the art of the theatre is concerned with expressing the most profound thoughts and feelings of the performers about the story they are enacting, so that the audience may partake in the ritual event.

Art as enlightenment

The influence of writing and scholarship. Like the other arts, the theatre has been the subject of a great deal of theoretical and philosophical writing, as well as criticism, both of a journalistic and of a less ephemeral character. Members of the theatrical profession have probably been influenced by the work of scholars and theorists more than they realize. Scholarship has made Shakespeare's work, for example, far more intelligible and coherent. On the other hand, many of the scholarly debates over small points seem irrelevant in the theatre.

A commendable example of scholarship is the emendation of Mrs. Quickly's description of Falstaff's death in Shakespeare's *Henry V* (Act II, Scene 3), from "a table of green fields," which, in the context, seems unintelligible, to "a [*i.e.*, he] babbled of green fields," which is not only comprehensible but touching. But it scarcely alters the way in which an actress will speak this phrase. It is one descriptive phrase among five or six others relating his fumbling with the sheets, playing with flowers, and smiling at his fingers' ends. It may be the greatest description of the moment of death in all literature; in the course of performance, however, an audience does not follow even so great a passage as this word by word.

A compelling actor playing Hamlet can ask whether 'tis nobler in the mind to suffer the "eggs and bacon" of outrageous fortune and few will be aware that he has not said "slings and arrows." And if Mrs. Quickly says "a table of green fields" with good accent and discretion, the musical flow and emotional effect of this marvelous speech will hardly be diminished.

Until recently, scholars and professionals in the English-language theatre lived almost completely segregated from one another. The tradition is rather different in continental Europe, where for many years the dramaturge has been a vital part of the state theatre companies. A dramaturge is usually a writer, critic, or scholar who advises the theatre on literary points, editing classic texts and perhaps translating foreign plays. With the establishment of the National Theatre of Great Britain in 1962, the idea of a dramaturge was transplanted to Britain, the critic Kenneth Tynan becoming part of the theatre management in 1963. Other British theatres, such as the Royal Shakespeare Company and the Glasgow Citizens' Theatre, have fruitfully married scholarship, in the form of a dramaturge, to their planning of productions.

Fruitful marriage of scholarship and production

Much journalistic criticism is marred by a reviewer or critic who wants to be just without being dull. Justice demands reason and moderation, but such qualities are often less interesting to read than high-coloured opinion. Shaw was perhaps the greatest theatrical and musical critic in English, but he again and again strayed, in the pursuit of readership, into exaggeration, prejudiced partisanship, and facile jokes at the expense of actors, as in his *Our Theatres in the Nineties.*

THE PLACE OF THEATRE IN CONTEMPORARY LIFE

Work, leisure, and theatre. In general, mankind has regarded as serious the activities that help him to survive and to propagate the species. At all levels of sophistication, however, mankind's serious pursuits offer opportunities for entertainment. The ablest members of the human species have never made a clear-cut distinction between work and play. The best workers enjoy their work, be it surgery, carpentry, housework, or fieldwork. They engage themselves in work that permits, even demands, an expression of their invention and ingenuity. Indeed, the most valuable workers are not the most strenuous but rather the most ingenious and resourceful; and as their tasks increase in complexity and responsibility, the need for intelligence and imagination increases. These qualities are also expressed in the play of such people.

Combining work and self-expression

In the times and places in which theatre has become frivolous or vulgar or merely dull, intelligent and imaginative people have stayed away from it. This was the case in London during the first half of the 19th century. A similar movement away from the theatre by the intelligentsia occurred in New York City in the middle of the 20th century, as fewer and fewer serious productions were undertaken. While Broadway became primarily devoted to musicals or star vehicles, interest in serious theatre developed in the smaller and more specialized Off-Broadway and Off-Off-Broadway theatres.

Of the many theories and philosophies propounded about the purposes of theatrical art, from the *Poetics* of Aristotle onward, most presuppose that the theatre is directed toward an elite consisting of the wealthier, more leisured, and better educated members of a community. In these theories, popular theatre is assumed to be noisily cheerful and egregiously sentimental, with easy tunes, obvious jokes, and plenty of knockabout "business." In the 20th century, however, the distinctions between social classes have become progressively more blurred. Egalitarian manners became fashionable, indeed obligatory, and the theories that gave serious art a role exclusively for the upper classes lost much of their force.

Paradoxically, while more people are enjoying more leisure than ever before, there has not been a proportional increase in theatrical attendance. Those engaged in the professions or employed in a managerial capacity, unlike the aristocrats of earlier times, generally allow themselves little leisure time. Of those engaged in industry, whose leisure time has increased, the enormous majority are engaged in dull and repetitive tasks that leave them tired and apathetic at the end of the day. Comparatively few make imaginative, intelligent, and decisive use of their leisure.

The decline in theatrical attendance

The theatre's efforts to appeal to the whole community generally have been futile. There exists an ever-widening gulf: on one side, a small, enthusiastic, and highly vocal minority clamours for art galleries, symphony concerts,

and drama; on the other, the vast majority is apathetic to such serious art.

The role of subsidy. A serious theatre, with or without massive public attendance, must be sustained by other financial support. Public funds have been used for this purpose throughout Europe and in much of Asia. The assumption behind such a subsidy is the realistic one that a serious theatre is now too costly to pay its way.

In Great Britain in 1940, under the threat of imminent invasion in World War II, the government took the first steps toward subsidizing theatre by guaranteeing a tour of the Old Vic Theatre against loss. Subsequently, with the establishment of the Arts Council of Great Britain in 1946, its support of theatre increased continually. By the last quarter of the 20th century many millions of pounds were committed each year to supporting a network of regional theatres, small touring groups, so-called fringe theatres, and the "centres of excellence," meaning the National Theatre, Royal Shakespeare Company, English National Opera, and opera at Covent Garden. Subsidy in Britain was the means by which the British theatre industry became the strongest in the world, both as a significant export and as a chief tourist attraction.

Until the middle of the 20th century, private patronage was still the sole support of legitimate theatre in the United States, but eventually charitable support was encouraged by a structure of tax allowances and by philanthropic organizations such as the Ford Foundation. With few exceptions, however, professional theatre in the United States remained strictly a commercial business. Nonprofit regional theatres gradually created an alternative to Broadway, but while the regional theatres have established faithful and discerning audiences, the record of the commercial theatre has been blotted by numerous instances of greed and irresponsibility and an absence of a longer view than immediate personal advantage. Unions have sometimes pressed demands that have made professional theatrical production economically difficult.

Academic theatre. A significant factor for some years has been the theatrical activity conducted by the universities with departments of drama. Their theatres, often handsomer and better equipped than professional houses, present plays of all sorts. Millions of people attend performances in university theatres each year, and in serious planning and choice of programs the academic theatre's standards are far superior to professional theatre, since the aim is educational. Unfortunately, many leading parts, whether in classics or in potboilers, call for assured and authoritative actors, between 35 and 50 years of age.

Problems of academic theatre

Academic theatre, therefore, is handicapped at the outset by the immaturity of most of its student-actors, though professional actors are sometimes hired for special productions or to become actors-in-residence.

A more serious drawback is that the direction of drama departments and of university theatres is often entrusted to academics, chosen in most instances for scholarly rather than theatrical distinction. Furthermore, most college theatres operate on extremely low budgets, and, while money without taste and intelligence cannot create good theatre, taste and intelligence without money can seldom do so either. The highest standards can, in certain instances, be achieved by sheer ingenuity, but, in general, shoestring budgets result in that desperate air of "making do"—almost a trademark of academic theatre.

It is a common error in universities to suppose that the mere production of a masterpiece must amount to an educational experience for players and audience alike. It is not so. Incompetent acting and direction can reduce the greatest masterpiece to suffocating, excruciating tedium. Moreover, in many schools, the theatre must be economically self-supporting, and each season one of the successful Broadway musicals of yesteryear is put on to redeem the losses incurred by Shakespeare, Molière, and O'Neill.

In Britain, the universities still, with few exceptions, have been slow to find a place for theatrical art in the curriculum. They frequently continue to take the view that if university students want to act, they must join a club and act in their spare time. But in the 1960s British universities began to come together for annual festivals of student theatre, and many are the professional careers that began with a university group at the Edinburgh Festival.

The search for an audience. In Great Britain, government subsidy has been applied in varying fashion to attract wider audiences to the theatre. Theatre-in-education companies have been formed to tour schools, with both classical and new or improvised plays. (Although rarer, similar companies can be found in the United States and Canada, such as the Living Stage in Washington, D.C., an offshoot of Arena Stage.) Probably the most significant investment has been in the regional theatres, where the intention has been to provide audiences with not only a wide-ranging repertoire but also the opportunity to develop regional voices. The Royal Shakespeare Company and the National Theatre have also made regional tours a significant part of their planning, but London is still the theatre centre of Britain and the audience remains a minority.

In the Soviet Union the statistics of popular interest in art and literature are impressive, but the level of creative work is kept low by censorship. Artistic creation is compelled to conform to party policy, and the political machinery often manipulates popular opinion. In the theatre, success can sometimes be assured to productions that are politically acceptable, denied to those that are not.

In both the East and the West tremendous efforts are being made toward more fruitful use of the leisure time that technology has made available. But by the second half of the 20th century, theatre had become a regular leisure-time activity of only a small minority. Although the civilized world generally regarded a serious theatre as an essential activity, deserving of public support, the mere existence of an intelligent and imaginative theatre does not ensure such support. This can probably be achieved only by profound changes of belief concerning the purpose not merely of theatre but of human existence.

Endurance of theatre in the age of technology

Live theatre has demonstrated an unexpected tenacity in the face of competition from film, television, video, and other popular entertainments such as rock concerts. At one time theatre lovers feared that a new generation of actors, directors, and technicians without professional experience of the theatre would precipitate a decline in theatrical art; on the contrary, many people most identified with movies have taken large risks to perform on the stage, so that actors such as Dustin Hoffman, Martin Sheen, and Lauren Bacall have brought to the theatre precisely those qualities of risk and commitment that make live performance so challenging.

Other factors that contribute to the perpetuation of theatre include the theatrical classics themselves, the classic dramas of different epochs and different cultures such as Molière's *Tartuffe* (1664), Racine's *Phèdre* (1677), Ibsen's *Peer Gynt* (published 1867), Shaw's *Saint Joan* (1923), Brecht's *Mother Courage and Her Children* (1939)—the instances could be multiplied countless times without exhausting the great works of the human spirit. Such works were written for the stage and can only be given full expression by stage representation.

Inadequacy of screen adaptations

Adaptations for the screen or television of material that was conceived in terms of the stage remain merely adaptations. If the original is a work of genius, the adaptation must seem presumptuously inadequate. Although Laurence Olivier's film adaptations of Shakespeare's *Henry V, Hamlet, Richard III,* or *Othello* were justified in that thousands of people who would not otherwise have had the opportunity saw the adapted plays magnificently performed, those who saw both the stage and the film versions can testify to the superiority of the theatrical experience. The texts were necessarily garbled and hashed, and the acting and direction were adapted to suit a medium for which the originals were not conceived. Some part of the public will always believe that it is as important to see fine performances of theatrical masterworks as to see the originals of great achievements in painting, sculpture, and architecture, rather than mere photographic reproductions. As long as this is the case, there is a good reason for the continued existence of a live theatre.

Another reason for believing in the survival of theatre is that the live theatre can achieve a sense of occasion impossible for canned events. This sense of occasion is

a heightening of everyday people and occurrences into a new vividness and significance: not just the heightening of characters and events of the drama but also a heightening of the people who take part, spectators as much as performers. This can occur more effectively if the occasion is a great one, if the house is large and full, if the audience appears to be distinguished, and if celebrated performers are taking part. But the sense of occasion can be achieved more simply, more subtly, and less expensively. What matters is that, when the performance begins, the audience should be excited, receptive, and ready. Yet the heart of the occasion lies not in the auditorium, however bedizened with celebrity, but on the stage. There, a troupe is about to create either a new work or a new interpretation of a classic. The sense of occasion is at its strongest when the cast is distinguished, but even unknown players in obscure performances can create it.

The participating audience

Activity is required of the theatre audience if the performance is to succeed; the audience is required to share with the performer, to assist him in the act of creation. In films and in television, mistakes can be eliminated, unsuccessful scenes can be reshot, even rewritten, and the whole work can be manipulated, edited, titivated, and set before the public with every detail in place. The product has been prefabricated without the cooperation of its audience, which is therefore reduced to the status of a mere consumer. In the theatre, on the other hand, every audience helps to create or to destroy the performance. To some extent, audiences get the performance they deserve.

Moreover, in every live performance is the imminence of disaster. An actor must be skillful and an audience must be imaginative if Macbeth, seeing a phantom dagger in the air, or Othello, falling down in an epileptic seizure, is to be moving and impressive instead of merely ludicrous. Yet it is precisely this hairbreadth division between the sublime and the ridiculous that creates the sense of occasion.

Some dozens of immortally great expressions of the human spirit have been written for performance by live actors for live audiences and cannot be adequately experienced in any other medium. This is why, in spite of economic difficulties, in spite of far smaller technical resources and far greater distributive problems, the live theatre must survive. (T.G./N.Ch.)

Directing

The craft of controlling the evolution of a performance out of material composed or assembled by an author is called directing. The performance may be live, as in a theatre and in some broadcasts, or it may be recorded, as in motion pictures and the majority of broadcast material. The term is also used in film, television, video, and radio to describe the shaping of material that may not involve actors and may be no more than a collection of visual or aural images.

In the theatre there was for a time a confusion of terminology between British usage and that of the United States. The director (as distinct from an old-time actor organizing rehearsals of a play in which he himself appears) emerged during the 19th century, and, like his actors, he worked for an employer who engaged both on contract. The employer, in Britain, came to be known as the manager, while the person directing the action was known as the producer. In the United States the producer has always been the one who engages the actors and finances the production, while the artist who directs the actors and shapes the performance is known as the director. With the advent of films these terms were applied to the new industry, and the American usage eventually found its way into the London theatre. It has since been absorbed by British broadcasting and British regional theatres as well and is now applied generally, although the original British usage is found in many earlier books.

Role of the director

The role of the director varies a great deal, not only according to the medium in which he works but also according to whether or not he works with actors. There is always common ground between directors of drama, whatever the medium, because their success depends not only upon knowledge of the specialized form but also upon understanding of acting and human nature. Traditionally the director is responsible to the play in the same way a symphony conductor is responsible to the score. In some experimental theatres that responsibility expands to include "devising" not only the performance but also the text of a play, partly through improvisations with the actors, with or without the collaboration of an author. In all directing there is a tension between content and form. Because there are many opportunities for jugglery with technical tricks, directors can be tempted toward virtuosity at the expense of meaning. In the musical theatre, for example, directors may attempt to compensate for a weak script by dazzling the audience with mechanically sophisticated sets and elaborate lighting designs. The justification for such measures is highly debatable; in any event, the value of immediate effect must be balanced against that of enduring significance, for the two are often mutually exclusive.

The non-Western context

Outside the Western world, the development of the director's power originally followed the Western pattern only in the performance of Western or Western-type plays, but, more recently, non-Western directors have come to have an influence on traditional non-Western forms. Indigenous Oriental theatre, as typified by the classical theatre of China and the Nō and Kabuki theatres of Japan, is rooted in tradition; its aim is not discovery but rather the perfect presentation of what was discovered long ago. In China's Peking opera before the Communist revolution, techniques were handed down from father to son for generations. In the Nō theatre, and to a lesser extent in the Kabuki, the positions of the performers on their acting platforms and the precise timing of their stylized gestures and vocalizations have all been fixed for centuries. In such traditions a director in the Western sense would be superfluous. But the incorporation of modern lighting and film techniques has strengthened the director's influence generally, as can be seen in the Kabuki theatre, where such widely traveled artists as Ichikawa Ennosuke III have been controversial in Japan for their use of innovative techniques.

19TH-CENTURY DIRECTING

The director as a dominant force began to be recognized in the late decades of the 19th century. His function of guiding the actors, however, was probably being regularly practiced as early as the 4th century BC, when the Greek political orator Demosthenes is said to have been given lessons in speech by an actor named Polus. It is a reasonable assumption that, from the beginning of the existence of an acting profession, it became customary for the most experienced performers to give advice and instruction to their less experienced colleagues: actors are seldom as confident as their performances can suggest, and they need repeated confirmation that their abilities approach their self-imposed standards. Such confirmation is likely to be sought from the most respected member of the company. There is a limit, however, to the value of the help given by a fellow actor; the perspective needed to see all the possibilities of performance is usually attainable only from a viewpoint outside the cast. The importance of this perspective is well illustrated in Hamlet's advice to the players, yet it was well over 200 years after Shakespeare's death before acting companies officially ceased to direct themselves from within.

As Hamlet's advice might indicate, however, directorial control has existed in some form in most theatre productions. The German practice of appointing an *Intendant* to run a theatre company is an early example of the function now referred to in the British theatre as artistic director, combining practical and artistic control over the work of a dramatic company. Goethe, for example, was appointed *Intendant* of the court theatre at Weimar in 1791; his prime concern was a formal balance of production elements, with emphasis on clarity of diction. So strong was his directorial style that the playwright Heinrich von Kleist blamed him entirely for the disastrous first production of his now classic comedy *Der zerbrochene Krug* (*The Broken Jug*) in 1808. It was not until the end of the 19th century that the Goethe-inspired formality of speech made way for greater realism.

In England the first professional director to coordinate the acting, decor, sound effects, and lighting of a production without also performing in it was probably Madame Vestris, who in 1830 controlled the Olympic Theatre in London. At her injunction, the company abandoned certain restrictive traditions of dress that had encouraged staginess and artificiality by inhibiting individuality of characterization. At the same time, she introduced varying degrees of realism into her productions, such as interior settings with real doors and windows (instead of painted ones) and sophisticated stage machinery.

Early directors in the United States

By the 1870s Augustin Daly, although a leading actor in the United States, was also achieving fame for the very personal direction he was giving his company in New York City. Daly's even more famous successor, David Belasco, started his career as an actor and concentrated on directing and play doctoring after the 1880s. He had a flair for vivid staging and is probably the best known director in American theatre history, but he had little or no influence on acting and left behind him no tradition. It was left to an eccentric amateur in Germany to establish an acting company that was eventually to lead to profound changes in theatrical methods throughout the Western world. The Duke of Saxe-Meiningen's actors aimed to achieve a psychological depth of characterization that was quite new for playgoers, and the company also paid meticulous attention to detail in their settings and in the way they managed crowd scenes. In their second tour of Russia in 1890 they had a great influence on Konstantin Stanislavsky, who was beginning to think along the same lines. A few years later, Stanislavsky and V.I. Nemirovich-Danchenko, who had by then established the Moscow Art Theatre, learned further from Anton Chekhov, a playwright so concerned with conveying the inner realities of human nature that his works could not be acted successfully except through entirely new directorial methods.

Meanwhile, in Scandinavia, France, England, and Germany there appeared realistic writers whose plays also called for deeper and subtler acting; thus, a "theatre of significance" grew up alongside the "theatre of entertainment" in those countries, leading to the emergence of original and creative directors. Prominent among these were Harley Granville-Barker in England and André Antoine in France. By the turn of the century nearly all professional productions presented in Europe and America were directed by professional directors—though another two decades were to pass before directors were universally acknowledged in theatre programs.

20TH-CENTURY DIRECTING

Diversity and complexity of modern directing

The craft of the theatre director has become a matter of considerable diversity and complexity in the 20th century. The responsibilities include the style of acting in particular productions, the interpretation of the play, the guidance of the actors in exploring their parts, and sometimes, though controversially, a complete control over their performances. The director also exercises overlordship in matters of decor, costuming, and lighting (sometimes he functions himself in these three areas, but union restrictions in certain countries, notably in the United States, prevent this in commercial productions, even though they allow him the final word). Incidental music, if any, and choreography in a musical play are also under his control, as are visual and sound effects.

These, the director's theatrical instruments, are more numerous and sophisticated than they were in the 19th century. Moreover, the actor is now much more aware of the techniques of voice and speech, so that the director needs at least a theoretical knowledge of how a performer achieves the fully expressive tonal octave of which he should be capable. He must also be sensitive to the rhythms and dynamics of speech and how these are affected by emotion and situation; through the contrasts resulting from these, he can create in performance a pattern that appeals both to the mind and to the senses. A great deal depends, too, upon the composition of his stage pictures, which must never remain static for long, and on how and when his actors move. The function of a modern director might be summed up like this: he creates a succession of focal points that must irresistibly attract the attention of the audience; then, through the quality of the acting, he tries to ensure that these focal points are as relevant as he can possibly make them.

Directorial styles. The backgrounds of individual directors—some have been actors, some stage managers, some have entered the theatre from other professions—have shaped their styles. Yet style in a director is difficult to gauge. It is much affected by material, and the director may be labeled by facile critics according to the kind of production with which he has been most obviously associated. Max Reinhardt was famous in two continents largely because of *The Miracle* (premiered 1911), a play of no great distinction that owed much of its success to his spectacular treatment. His less publicized interpretation of Luigi Pirandello's *Six Characters in Search of an Author,* a psychological play requiring no scenery, was, however, at least as typical of this distinguished Viennese director. The name of Stanislavsky is inextricably linked with that of Chekhov, and he is commonly believed to have been the perfect interpreter of the great Russian playwright. The belief is due less to a full understanding of Chekhov on the part of Stanislavsky than to the fact that Stanislavsky wrote repeatedly and at length about the kind of acting that Chekhov's plays needed. We know from the former's prompt script of *The Seagull* and from Chekhov's letters that the two men differed over some fundamental questions of artistic judgment. Chekhov's letters and Nemirovich-Danchenko's last production of *The Three Sisters* (1938), which continued to be performed for more than 20 years, suggest that the Russian playwright was far better served by Stanislavsky's more reticent partner.

Difficulty of gauging directorial style

The success with which a director has carried out his task is not easily assessed by either playgoer or critic. Both can be deceived by exciting scenery or bold theatrical effects into overvaluing these tools of the trade and forgetting their purpose, which is to ensure an imaginative interpretation of what the author has written. Louis Jouvet, the distinguished 20th-century French director, once wrote:

> There are two kinds of director: the one who expects everything from the play, for whom the play itself is essential; and the one who expects nothing except from himself.

There is much truth in this statement, provided the extremes are not taken too seriously.

Peter Brook of the Royal Shakespeare Company seemed to expect little from the author when he did an outstanding production of *Titus Andronicus* in 1955. If he had put greater faith in Shakespeare and had not eked out the script with a multitude of happy theatrical inventions, the public would have been the poorer. On the other hand, Brook's treatments of Shakespeare's great plays have not invariably been happy; these do not need eking out and rather seem to ask that director and actors build a testament to Shakespeare's poetry and grandeur.

Possibly the best directors cannot be made to fit into categories. Tyrone Guthrie (1900–71), in 45 years of directing every kind of play, progressed from an almost perverse disregard of authors to an ungrudging respect for them. His work ranged from Shakespeare to Aeschylus and took in Gilbert and Sullivan on the way. In viewing the totality of Guthrie's work, what emerges most strongly is an irrepressible comedic originality. The ability to discern comedy inevitably lurking behind the obvious sorrows of existence is evidence of more than maturity; it also demonstrates the director's knowledge of dramatic ways and means, for the face behind the mask is in the best writers always discernible, and in the less good it is still there, to be forcibly exposed. The discovery of the comedy that is latent gives a highlight to good dialogue and the impression at least of an extra dimension to any writing that might otherwise seem featureless.

The need for diversity

Diversity is demanded of a director working in the traditional repertoire of the European classical theatre. Trevor Nunn of the Royal Shakespeare Company may have achieved his most memorable Shakespearean production with his intense, small-scale *Macbeth* (1976), a production designed for fewer than 200 spectators, but he was no less successful in 1980 in staging an epic dramatization of Charles Dickens' novel *Nicholas Nickleby,* which un-

folded its story for more than eight hours. It was after demonstrating his mastery of classical theatre—including a production in 1978 of Chekhov's *Three Sisters,* notable for its precise observation of detail and its melancholy humour—that Nunn went on to direct major commercial productions in the musical theatre, including Andrew Lloyd Webber's *Cats* (1981) and the roller-skating spectacle *Starlight Express* (1984). Laurence Olivier, the first director of the National Theatre of Great Britain, became known for his command of a wide range of theatrical styles and was particularly remarkable for his capacity to direct a play in which he also acted the leading part. This is a rare talent. It is extremely difficult for the actor-director to maintain creative objectivity while becoming immersed at the same time in his own personal creation.

Ingmar Bergman, though best known internationally for his work in film, has had considerable impact in Europe with his stage productions, not only in his native Sweden but also in Germany. He is a master of the art of drama in a multitude of forms and techniques and among the most profound directors of modern times. His emendations to the classic plays of Europe and of his fellow Scandinavians are respectfully regarded even by those who do not agree with them. Part of the success of Bergman's productions is due to his handling of actors and the admiration that he inspires in them. Consequently, the best performers throughout the world have regarded an invitation to work for him as an accolade.

Conditions in the American theatre have not encouraged such diversity, and the best known stage directors in the United States have tended to be closely associated with particular writers or kinds of writing. Thus, Elia Kazan remains identified with the early great successes of Tennessee Williams and Arthur Miller; Mike Nichols with sophisticated comedy; José Quintero with productions of Eugene O'Neill; and Harold Prince with Broadway musicals.

In the second half of the 20th century the chief development in the art of directing has been a strengthening of international influences. Ariane Mnouchkine, for example, directing her own company in Paris, did not hesitate to present plays by Shakespeare as Oriental spectacles, borrowing most successfully from the Kabuki theatre. Where research into the art of acting has been a major interest of directors, there have been surprising convergences from very different traditions, so that when Suzuki Tadashi's Waseda company from Tokyo arrived in Europe in 1972, it found itself being compared in its intense physicality to Jerzy Grotowski's Polish Laboratory Theatre from Wrocław in Poland, though the two companies had been founded independently in the early 1960s.

International influences

Although aware of the more exotic techniques available to a theatre director in the late 20th century, Peter Stein in West Berlin concentrated in the 1970s and '80s on some particularly fruitful European conventions, including elaborating the traditions of historical research established by the Duke of Saxe-Meiningen's company and Stanislavsky in Russia. Stein's work with West Berlin's Schaubühne company included group visits to Greece for research on Greek tragedy and to England to prepare for productions of Shakespeare; on those occasions the research itself was dramatized by Stein and the company into complementary performances aimed at helping to illuminate the respective plays. Their work represents perhaps the most thorough synthesis of the directorial ideas of such diverse theorists as Bertolt Brecht—advocating a cool rationality in the theatre—and Antonin Artaud—proposing a visceral "theatre of cruelty."

National conditions affect directorial vitality. The vast size of the United States and its hesitation to accept the cultural asset of professional drama, except in a very few cities, polarized the American theatre in the post-World War II period. At one extreme Broadway dominated—highly professionalized but dependent upon the limited vision of speculative investors and demanding little of imaginative directors. Its intellectual sterility encouraged the opposite extreme of Off Broadway and Off-Off-Broadway, where there was both experiment and imagination but also unfortunately much professional incompetence.

Inhibitors to imaginative directing

A promising development was the establishment of regional theatres in and around the bigger centres of population. Pioneering theatres such as the Arena Stage in Washington, D.C., and the Alley Theatre in Houston, Texas, provided forums not only for a wide repertoire of world theatre but also for new playwrights and directors. As Broadway continued its decline, the regional theatres continued to grow in importance; "schools" of acting, directing, and playwriting emerged in Chicago, San Francisco, Los Angeles, and other cities.

The scarcity of good directors poses the question as to why modern dramatists should not direct their own plays, as Racine and Molière did in the 17th century. Contemporary writers seem more introverted and tend to lack both the stagecraft and the desire to inspire a company of actors. The contemporary English playwright Harold Pinter is a notable exception. An actor himself, he is as good a director as he is a playwright. In Italy, Pirandello established himself as a director uniquely able to realize his own advanced ideas of drama, rather as Brecht later did with the Berliner Ensemble. Dario Fo followed in that tradition, bringing to his own political comedies such as *Accidental Death of an Anarchist* (1970) the fruits of his studies of the traditional Italian commedia dell'arte. Other modern exceptions have included Harley Granville-Barker and George Bernard Shaw, who saw to it that their plays were performed as they wished them to be. Moreover, they both had a marked effect on English acting and laid the foundations for its 20th-century preeminence in the English-speaking world. Shaw, in particular, inspired many a young performer with the understanding of stress, cadence, and rhythm, and even today his stage directions (with most dramatists these are no more than generalized indications and are useless for practical purposes) are models of instructive lucidity from which a director departs only at his peril.

The director's relation to the actor. A proper comprehension of and respect for the actor is indispensable to direction of the highest quality, since the acting in the theatre greatly outweighs such elements as settings, lighting effects, and visual ideas. On this point Jouvet and Shaw both have written aptly. The former said: "The profession of director suffers from the disease of immodesty." And the latter, hardly famous for underestimating his own abilities, advised in *The Art of Rehearsal:*

> Do not forget that though at the first rehearsal you will know more about the parts than the actors, at the last rehearsal they ought to know more about them than you, and therefore have something to teach you about them.

If a director has antagonized his actors and has not, on the contrary, stimulated their imagination so that they have become confidently creative, then failure for him is almost inevitable.

The task is difficult. To communicate with any particular group of actors requires the most balanced judgment. Unlike the orchestral conductor, to whose aims the theatrical director's are closely analogous, he cannot control actual performance. Neither can he, except rarely, tell his actors precisely and in every detail exactly what he wants of them. The minutiae are solely their concern, just as in a concerto they are the concern of the soloist (all actors, basically, are soloists, and their creative powers generally are inhibited by drill sergeant methods). Actors need at least the illusion that their own imaginations have full freedom. To direct by guile is therefore most often the key to success.

The rehearsal process. The director's efforts are naturally affected by the length of time given to rehearsals. These vary according to economic pressures, national customs, and union rules. In some countries, notably the United States, the actors' union has used its powers to escalate salaries and limit working hours. The American director is consequently hard put to find enough time to achieve the depth and polish to which he aspires. His limit may stretch to four weeks on Broadway and to a mere one or two weeks outside New York City. In many parts of Europe, subsidized theatre has been long established, and where this is so conditions are better. Rehearsals can last five or six weeks and may even extend into months. Despite unionization, the length of the rehearsal day for

Time limitations

serious drama in Great Britain is left up to the artists themselves. The working day is long and four weeks is usually considered enough time, but it is not uncommon for productions at the National Theatre or the Royal Shakespeare Company to begin through workshops months before the opening performance.

Directorial capacities for patience and self-control usually are put to the test in the last few days of rehearsal. For weeks the company has worked together, and it should have at last reached a result that seems very close to fruitful consummation. The actors may have rehearsed, as in many European countries, on the very stage on which they are to perform. If they are working in Great Britain or the United States, they may have worked in nothing better than a room. In either case, a time must come when scenery, probably incomplete, appears and almost inevitably looks unlike what was expected. The actors have scarcely adjusted themselves to this when the lighting has to be set and cues established. Suddenly, the marvelous magic world that the artists have built and come to inhabit as their own is shattered: the technicians have arrived. There is retrogression and despondency as door handles come off in the actors' hands and complicated speeches written to be spoken to the dying rays of a setting sun are repeated over and over again while the sun obstinately refuses to set. At this point the entire production must be reborn and all its disparate components brought together in rhythm and harmony. The best served artists are those in countries where subsidy permits extended technical rehearsals. In West Germany, eastern Europe, and Scandinavia, artists and technicians may be given a week or more in which they can work together onstage before the first dress rehearsal. The allotted time in the United States may be less than 24 hours.

Casting. There is a crucial responsibility at the other end of the production schedule, before rehearsals even begin. It is the casting process, which is often regarded as an art in itself. An error in casting can be fatal, no matter how much imagination, hard work, and money have been invested in the production. The responsibility should always be the director's, but it is often usurped by the producer in theatres oriented toward the box office, and it has become a frequent habit with the latter to seek either the "right type" for the part or a well-publicized "name," irrespective of the ability to act. The wisest casting often works by opposites, so that a hot-blooded character is best played by an actor whose own personality is cool and objective. Then, as a director of the Royal Academy of Dramatic Art in London observed:

> Two contrary elements fuse harmonically to create a character in depth [who] becomes "real" precisely because he is made up of opposite elements in the same way as people are in life.

Casting, the planning of schedules, and the coordination of differing streams of creativity become more complex in production outside the field of straight drama. The rehearsal period in musicals, for example, is longer, and the strain is greater not so much on the director's artistic resources (for he has a great many helpers) but on his powers of leadership. The presence of a choreographer, with a conductor and an orchestra, the cost of which in Britain and the United States prohibits the use of musicians before the dress rehearsal, in addition to a heightened emphasis on lighting and visual effects, all contribute to creating a vast potential for discord. The director must resolve these and even turn them to advantage. All large-scale entertainments, including most modern musicals, reach the ears of the audience by means of electronic amplification. This introduces the alien element of the sound engineer, who is likely to be more technocrat than artist and may require tactful handling.

Clearly, the director of live entertainment needs to be a person of many qualities, some of which are in conflict with one another. Of all the necessary characteristics, patience perhaps is one of the most important. Unlike directors in other media, the theatre director is both artist and maintenance supervisor: in a long run it is his duty to watch the show at least every two or three weeks, thus ensuring that all that happens on the stage continues to be true to the original intentions. Such recurring watchfulness calls for critical balance and powers of endurance not easily found. (J.B.F./N.Ch.)

Acting

Acting is generally agreed to be a matter less of mimicry, exhibitionism, or imitation than of the ability to react to imaginary stimuli. Its essential elements remain the twin requisites enunciated by the French actor François-Joseph Talma in his tribute to the actor Lekain (1825): "an extreme sensibility and a profound intelligence." For Talma it is sensibility that allows an actor to mark his face with the emotions of the character he is playing and to convey the intentions of the playwright, the implications of the text, and the movements of the "soul" of the character. Intelligence—the understanding of the workings of the human personality—is the faculty that orders these impressions for an audience.

The essential problems in acting—those of whether the actor actually "feels" or merely imitates, of whether he should speak naturally or rhetorically, and of what actually constitutes being natural—are as old as theatre itself. They are concerned not merely with "realistic" acting, which arose in the theatre of the 19th century, but with the nature of the acting process itself.

The ephemeral nature of acting has left it without many practical foundations and only a few theoretical traditions. In the middle of the 18th century the German critic and dramatist Gotthold Ephraim Lessing drew attention to this difficulty: "We have actors but no art of acting." In an artistic field where the measures of greatness are traditionally the subjective reports of witnesses or critics, the understanding of the art has naturally remained in dispute. It remains as true today as when stated by George Henry Lewes in his *On Actors and the Art of Acting* (1875):

> I have heard those for whose opinions in other directions my respect is great, utter judgments on this subject which proved that they had not even a suspicion of what the art of acting really is.

Difficulty of definition

Efforts to define the nature of an art or craft usually are based upon the masterpieces of that field. Without that necessary reference point, vague speculations and generalizations—without proof of validity—are likely. In the visual, musical, and literary arts, this foundation exists; the work of the great masters of the past and the present serves not only to elucidate the art but also to create standards to emulate. It is difficult to imagine what the present state of comprehension of music would be if only the music of today were available, and the achievements of Monteverdi, Bach, Beethoven, and Mozart had to be known only by hearsay. Yet, this is precisely the situation that exists in acting. The actor, in the words of the 19th-century American actor Lawrence Barrett, "is forever carving a statue of snow." That is why the understanding of acting has not equaled the appreciation of it and why the actor's creative process has defied comprehension.

THEORIES OF TRADITIONS

The actor as creative artist and interpreter

Throughout the history of theatre, debate has continued over the question of whether the actor is a creative artist or simply an interpreter. Since the actor's performance is usually based on the play, and the dramatist is conceded to be a creative artist, it is sometimes concluded that the actor must be only an interpretive artist. Some modern exponents of the actor's creativity have indirectly accepted this view and have turned, therefore, to nonverbal theatre. But others deny that this recourse to primitivism is necessary in order to make acting a creative art. When composers like Schubert or Schumann created musical settings for the poems of Heine or Goethe, their music did not lose its essentially creative nature. Verdi used Shakespeare's Othello and Falstaff for his great operas, but his music is no less creative for that. When an artist merely imitates the work of another artist in the same medium, that may properly be called noncreative; the original artist has already solved the basic problems of execution, and his pattern is simply followed by the imitator. Such a work can be considered merely an exercise in skill (or in execution). An artist in one medium who uses an

art work of another medium as subject matter, however, must solve the problems posed by his own medium—a creative achievement. It is therefore quite proper to speak of a character as if he were the actor's creation—of John Gielgud's "Hamlet," for example, or John Barrymore's or Jonathan Pryce's. Because a medium offers the potential for creativity, of course, it does not follow that all its practitioners are necessarily creative: there are imitative artists in every medium. But acting can only be understood after it is first recognized as a creative medium demanding a creative act. In "The Art of Acting" the American drama teacher Brander Matthews remarked,

> The actor needs to have under control not only his gestures and his tones, but all other means of stimulating sensibility and these should be ready for use at all times, wholly independent of the words of the text.

In the same work he quoted with approval the words of the great 19th-century Italian tragedian Ernesto Rossi that a "great actor is independent of the poet, because the supreme essence of feeling does not reside in prose or in verse, but in the accent with which it is delivered." And even Denis Diderot, the French philosopher of the 18th century whose famous *Paradox of Acting* (written 1773–78; published 1830) is dealt with below and who was himself a dramatist, stated:

> even with the clearest, the most precise, the most forceful of writers, words are no more, and never can be more, than symbols, indicating a thought, a feeling or an idea; symbols which need action, gesture, intonation, and a whole context of circumstances, to give them full significance.

If the art of acting is regarded as merely interpretive, the external elements of the actor's skill tend to be emphasized, but, when acting is recognized as a creative art, it leads inevitably to a search for the deeper resources that stimulate the actor's imagination and sensitivity. This search presents difficult problems. The actor must learn to train and to control the most sensitive material available to any craftsman: the living organism of a human being in all of its manifestations—mental, physical, and emotional. The actor is at once the piano and the pianist.

Acting should not be confused with pantomime, which is a form of external movements and gestures that describes an object or an event but not its symbolic significance. Similarly, the actor is not to be mistaken for an imitator. Many of the best imitators are unable to act in their own person or to create a character that is an extension of themselves rather than an imitation of someone else. Neither is acting mere exhibitionism; the capacity for "showing off" or entertaining at parties is quite different from the talent demanded of the actor—the ability to put oneself into another character, to create through performance a nonexistent event and bring it to its logical fulfillment, and to repeat this performance not only when one is in a favourable mood but also at specified times and places, regardless of one's own feelings on each occasion.

Genuine and feigned emotion. The most famous instance of supposed acting in ancient Greece was that of the actor Polus performing in the *Electra* of Sophocles, at Athens in the 4th century BC. The plot requires Electra to carry an urn supposed to contain the ashes of Orestes and to lament and bewail the fate she believed had overtaken him. Accordingly, Polus, clad in the mourning garb of Electra, took from the tomb the ashes and urn of his own son (who had recently died), embraced them as if they were those of Orestes, and rendered not the appearance or imitation of sorrow but genuine grief and unfeigned lamentation. Rather than mere acting, this was in fact real grief being expressed.

Rival traditions of acting

From antiquity, rival traditions of acting can be discerned—one stressing the externals of voice, speech, and gesture and the other looking to the actual emotional processes of the actor. Aristotle defined acting as "the right management of the voice to express the various emotions," and this primacy of the voice as the actor's outstanding medium has been widely accepted. "Dramatic ability," he said further, "is a natural gift, and can hardly be taught. The principles of good diction can be so taught." Aristotle did not fall into the common mistake of thinking that acting is only good diction; rather, he simply recognized that diction, unlike acting, can be taught. He was well aware of something more than diction in acting but he knew no way of training it. Aristotle saw good acting resulting either from a great natural quickness of parts or an enthusiasm allied to madness. "By the first of these, we mold ourselves with facility to the imitation of every form; by the other, transported out of ourselves, we become what we imagine."

The dichotomy noted in ancient Greece persisted through ancient Roman theatre and into modern times. On the one hand, there was a recognition of the need for the actor to be affected by the sensations he wishes to arouse in others; on the other hand, a need was also seen for a precise system of expression—the peculiar look, tone, and gesture appropriate to every emotion of the mind.

Beginning of modern acting

Modern European acting began with the Italian commedia dell'arte, the earliest mention of which is in 1545. Until then, the actor was limited to illustrating the text by means of a narrow scheme of gesture and rhetorical speech. But in the commedia dell'arte the actor used only an outline, a plot; he improvised the play, giving free rein to the actor's art, developing his own characters or masks that he repeated in each play. Each character became an extension of the actor's own personality but elastic enough to respond to innumerable dramatic situations; thus, actors began to develop the distinctive stage character of the theatre, whereas previously the emphasis had been on its literary aspects. Since this demanded high skill, the actors joined into companies—in which, incidentally, women began to take major roles for the first time, female characters having traditionally been portrayed by men. The actors became professional, and, by doing so, they stimulated the development of modern drama.

The essential requisite for the drama is its performance. The dramatist's creation finds its fulfillment not in the writer's study but on the stage. This fulfillment can best be achieved through the contribution of the professional actor. Nonetheless, after the formation of acting companies, actors continued to learn by doing. Their schools were professional companies; their classroom, the stage; their teachers, the audience and their fellow players. Schools of dramatic art, isolated from theatres or companies, are a relative innovation in Europe and the Americas.

In contrast, ancient traditions of actors' training have continued unbroken for many centuries in India and Japan, where particular types of theatrical experience are prescribed. India's textbook for actors, the *Nāṭya-śāstra,* has provided specifications for the representation of emotions down to the smallest gesture for nearly 2,000 years, and its influence is still visible in such dramatic forms as *kūḍyāṭṭam,* which has carried on the traditions of Sanskrit drama for about a thousand years, and in the kathakali dance drama, a relative newcomer that emerged contemporaneously with Shakespeare. The Nō theatre of Japan, presently divided into five distinct schools, is directly descended from the theatre of Zeami Motokiyo (1363/64–1443), an actor and author of Nō plays who codified the form in 21 treatises, the most influential of which is the *Fūshi kaden* (1400–18; "Appearance of Flower Transmission"), also known as the *Kaden sho.* Zeami's teachings, originally intended for his descendants in the Kanze school of Nō, are both philosophical and practical regarding actors' training, and his concerns for constant training and discipline anticipate many modern approaches to acting.

Diderot's "Paradox of Acting." The most significant statement on acting is Diderot's *Paradox of Acting.* Because of its polemic brilliance, it remains the most widely known essay on the subject. In the 20th century it provided the guiding precepts for the influential work of the French director and actor Louis Jouvet. Outside France it has found little acceptance within the profession, though its famous paradox—that in order to move the audience the actor must himself remain unmoved—is still highly regarded.

However disputable the solutions it proposes, Diderot's essay contains an excellent description of the actor's problem. What bothered Diderot was the unsolved problem of how the actor, if he were full, really full, of feeling, could play the same part twice running with the same spirit and

success and yet be worn out and cold as marble at the third performance. Diderot confirmed this phenomenon by noting "the unequal acting of players who play from the heart. Their playing is alternately strong and feeble, fiery and cold, dull and sublime." This was the case with an actress who in her day was the outstanding example of emotional acting. "She comes on the stage without knowing what she is going to say; half the time she does not know what she is saying; but she has one sublime moment." Diderot knew that actors do feel and experience; but he also knew that some actors refused to recognize the need for craft, for training.

Diderot asked how the actor, if he is himself while he is playing, is to stop being himself: how he is to catch just the point at which he is to stay his hand? Diderot demanded unity in a performance; he demanded respect for the author's concept, and he understood the difficulty of repeating a performance. He demanded a definite course to the passion—a beginning, a middle, and an end. In Diderot's day, however, the problem of developing a technique for creating inspiration in the actor remained unsolved.

The difficulty of solving the problem is illustrated by the work of the 19th-century French teacher François Delsarte, whose influence was widespread not only in France but also in the United States. Delsarte became dissatisfied with routine acting techniques. He observed their mechanical and stultifying character and realized that under the stress of natural instinct or emotion, the body assumes appropriate attitudes and gestures quite different from those described by his teachers. But when he attempted to formulate laws of speech and gesture, on the basis of years of diligent observation and study, he created a series of elaborate pictorial descriptions that were just as mechanical as those he had originally criticized. Knowledge of affective behaviour had not advanced far enough to serve as an aid in solving the problem of the actor: there was still too little understanding of human behaviour, of the relation between the conscious and unconscious, and of the role of the senses.

Delsarte's laws of speech and gesture

Stanislavsky's contribution. It is in this context that the enormous contribution in the early 20th century of the great Russian actor and theorist Konstantin Stanislavsky can be appreciated. Stanislavsky was not an aesthetician but was primarily concerned with the problem of developing a workable technique. He applied himself to the very problems that Diderot and others had believed insoluble: the recapture and repetition of moments of spontaneity or inspiration, which could not be controlled and repeated at will even by many of the greatest actors. In his work as director of the Moscow Art Theatre, he often experienced those flashes of intuition or inspiration that stimulate the imagination and turn something that one understands with the mind into an emotional reality and experience. Stanislavsky described such a moment occurring at a low point in the rehearsals for Chekhov's *Three Sisters,* when "the actors stopped in the middle of the play, ceased to act, seeing no sense in their work." Suddenly something incomprehensible happened: an accidental sound, of someone nervously scratching his fingernails on the bench on which he sat, reminded Stanislavsky of a scratching mouse, setting off an entire sequence of previously unconscious memories that put the work at hand into a new spiritual context.

Later, in examining parts he had played, Stanislavsky became aware of how much his characterizations had been based unconsciously on his memories. With the passing of time, however, the memories and the feelings aroused by them were lost, and he began to repeat mechanically the fixed appurtenances of the role—the movements of the muscles, the mimetics of the face, eyes, arms, and body, and the physical signs of absent emotion. This led him to the perception that creativeness on stage demands a condition that he called "the creative mood." To the genius on stage, this condition almost always comes of itself, and less talented people receive it less often. Although everyone on stage received the creative mood sometimes, none seemed able to control it with his own will.

The role of the creative mood

Stanislavsky's description of the problem thus far had reached the point at which all previous examinations had stopped. By going further and inquiring into technical means for controlling the creative mood, Stanislavsky laid the foundation for the modern approach to the actor's problem. Stanislavsky had no intention of creating inspiration by artificial means; rather, he wanted to learn how to create favourable conditions for the appearance of inspiration by means of the will. He emphasized that other artists may create whenever they are of a mind or feel inspired, but that "the artist of the stage must be the master of his own inspiration and must know how to call it forth when it is announced on the poster of the theatre." If he is unable to find a conscious path to unconscious creativeness, the actor is forced to rely on the superficial aspects of scenic craft and theatrical cliches.

Stanislavsky believed that the problem could be solved through advanced psychology, especially the concept of "affective memory" described by the French psychologist Théodule Ribot in the 1890s. Although there has been confusion and misunderstanding about it, and its very existence has been questioned, the concept of affective memory is of prime importance for the understanding of how spontaneous and emotional experiences occur and can be repeated on the stage.

Affective memory is the reliving of a past experience—with the accompanying positive or negative response—triggered by an analogous experience in the present. Something that has brought pain is anticipated with displeasure the second time. This displeasure, which is felt immediately, rather than remembered, is like a residue of previous appraisals. Affective memory may be linked directly to the memory of a traumatic experience, as the same situation or a similar one recurs, or to an experience that bears little apparent relation to the original, if the memory has been repressed. Of course, affective memories may stem from pleasant experiences as well as unpleasant ones. The concept of affective memory has found a place in several schools of psychology, including the Freudian and the Pavlovian, though different explanations have been offered.

The concept of affective memory is essential to an understanding of how the actor functions and the faculties that have to be trained to develop his talent. It is his unusually sensitive affective memory that enables the actor to respond to events that must be imagined on the stage and to repeat performances. This point was stressed by Stanislavsky's great pupil Yevgeny Vakhtangov, who emphasized that literal emotion—emotion that derives from the presence of an object that actually stimulates it—cannot be controlled and cannot be relied upon to provide the level of response that is required in every performance.

The use of affective memory is not limited only to acting. Wordsworth defined poetry as originating from "emotion recollected in tranquility." Marcel Proust, in a long passage in *Swann's Way,* brilliantly described the working of affective memory and illustrated precisely the way in which it can be recalled. Instances of its presence can be multiplied from all the arts—literary, visual, or musical. But, though in the other arts it can function unconsciously, the actor must learn to use it consciously to satisfy the unique conditions under which he must create.

The "Method" is the name by which the totality of Stanislavsky's ideas have become most widely known in the United States, where they were chiefly promulgated by the director, actor, and teacher Lee Strasberg, first through the Group Theatre, established in the 1930s, and later through the Actors Studio in New York City. The Method represents a development of Stanislavsky's procedures based not only on his writings but also on his actual achievement in his major productions. It includes the work of Vakhtangov, who demonstrated that Stanislavsky's ideas apply to the essential problems of the actor in any style and not only to the realistic style most often associated with them. The Method became widely known in the mid-20th century largely through the work in films of actors such as Marlon Brando, Rod Steiger, and Geraldine Page, who had studied at the Actors Studio. These actors made a powerful impression and showed a remarkable ability to bridge the gap between stage, screen, and television to an extent that aroused excitement and

Stanislavsky's "Method"

interest in the rest of the world. So strong was the fusion of performer and role that many of the traits of the character were confused with those of the actor, which led to serious misunderstanding. But at mid-20th century an American style of acting was being born.

Critics who feel that the Method was only one of Stanislavsky's continually developing theories now generally refer to the more complete tradition of Stanislavsky's thought and work as the "System." While the term Method can apply to Stanislavsky's work up to the early 1920s, it largely ignores his later developments—in particular, his embrace of the "method of physical action" in the 1930s. This was a technique that put greater emphasis on the body, with the reasoning that there is a physical aspect to thought and a mental aspect to action; by concentrating on the physical requirements of a part, an actor would become aware of a character's reasoning. In regard to rehearsal, Stanislavsky described his intentions thusly: "Start bravely, not to reason but to act. As soon as you begin to act you will immediately become aware of the necessity of justifying your actions."

The lesson of the Method seemed to be that a character could best be built from the inside out, using, among other techniques, affective memory, which would allow the actor consciously to draw upon genuine emotions from the past. In practice, however, the development of the "method of physical action" arose from Stanislavsky's continued questioning of his own research and was founded on the various discoveries of his own career. The System as it evolved is far from its popular image as a simple technique for introspective character development dependent for success on the personality of the actor; it is rather a process designed for the constant renewal of the actor through the renewal of the Method itself.

Later developments. Stanislavsky was fully aware of alternative ideas regarding the work of the actor; he encouraged, for example, the early work of such a resolute experimentalist as Vsevolod Meyerhold. Meyerhold set out, in rebellion against Stanislavsky's naturalism, to train actors for the production of highly stylized plays, such as the Symbolist dramas of Maurice Maeterlinck. His synthesis of styles gave rise to a training system known as "biomechanics." Borrowing from the commedia dell'arte, as well as such alien influences as Japanese Kabuki, Meyerhold sought to create an actor of athletic accomplishment who could be used by the director as a formal element in the production of a play.

The ideas of Artaud, Brecht, and Grotowski

The theatre since World War II has been influenced chiefly by the ideas of Antonin Artaud, Bertolt Brecht, and Jerzy Grotowski. Artaud, a French avant-gardist director, actor, and playwright, exerted an enormous posthumous influence on contemporary theatre through his writings. There he proclaimed the "theatre of cruelty," which is based on the extreme development of gesture and sensory responses by the actors so that they can communicate with the audience at a more profound psychological level than is possible through words. Artaud's ideas achieved international attention in the 1960s through the productions of Peter Brook and the Royal Shakespeare Company, especially *The Persecution and Assassination of Jean-Paul Marat as Performed by the Inmates of the Asylum of Charenton Under the Direction of the Marquis de Sade,* which called for emotional states verging on hysteria from most of the cast during each performance.

Contrary to the opinion of many, Artaud thought of the theatre not as a psychological but as a plastic and physical domain and of the actor as an "athlete of the heart." For every feeling, every mental action, and every leap of human emotion, there is a corresponding breath that is appropriate to it. Grotowski has pointed out that, if Artaud's principles are analyzed in a practical way, they lead to "stereotyped gestures, one for each emotion." Questionable as some of Artaud's specifications might be, his achievement was to remind actors and directors that in addition to an internal truth, which the early work of Stanislavsky emphasized, there was such a thing as an external truth: what the audience sees is what it believes and feels.

Through his plays and the remarkable productions of the Berliner Ensemble in East Berlin in the 1950s, which represent the most important contribution to theatre of the post-Stanislavsky period, Bertolt Brecht generated ideas about acting that have received wide prominence and have usually been counterposed to those of Stanislavsky. Whereas in Stanislavsky-inspired productions the actors often seem to be exaggerating their individuality, Brecht's characters struck many observers as existing primarily as representatives of a class—in some cases showing self-effacement to the point of dehumanization. Brecht himself, however, denied that his ideas were opposed to those of Stanislavsky. Calling his approach epic realism, he stressed that the stage of a realistic theatre must be peopled by live, three-dimensional, self-contradictory people, with all their passions, unconsidered utterances, and actions. Brecht mentioned some of Stanislavsky's procedures to which he felt indebted—the creation of the given circumstances that motivate the beginning of an event, the emphasis on creating the activity of the day that helps to define the actor's behaviour, and the individualizing of the characters that make up a mass.

Brecht's epic realism

Brecht's most significant contribution to concepts of acting was his theory of the *Verfremdungseffekt,* usually translated into English as "alienation effect," though it has also been translated as "distanciation." The aim of the technique, as Brecht described it, was to "make the spectator adopt an attitude of inquiry and criticism in his approach to the [incidents portrayed]. . . . The actor does not allow himself to become transformed on stage into the character he is portraying. He is not Lear, Harpagon, Schweik; he shows them."

Through maintaining a distance between the actor and the character, it should become possible for actors to comment implicitly upon the characters they are playing, even to address the audience directly about the character. By abandoning the concept of total transformation, the actor can speak his part "like a quotation," though "at the same time he obviously has to render all the quotation's overtones, the remark's full human and concrete shape; similarly the gesture he makes must have the full substance of a human gesture even though it now represents a copy." A Brechtian actor must not only have the ability to assume in a convincing manner the character he is portraying, but he must also be able to step aside from the character, providing commentary as necessary while sustaining the believability of the situation.

Grotowski's "poor theatre"

Following Brecht and Artaud, the Polish director Jerzy Grotowski made the most thorough effort to rediscover the elements of the actor's art. From the early 1960s to the mid-1970s it was Grotowski's work with the Polish Laboratory Theatre that most stimulated and excited theatre professionals, though not all were in sympathy with the stripped-away concept of staging that he called "poor theatre." He rejected the idea that theatre should attempt to match the spectacle and effects of film and television and declared that the primary element of theatre is the relationship between actor and spectator. The theatre can exist without makeup and without a separate stage; it can exist without lighting and sound effects; but "it cannot exist without the actor-spectator relationship of perceptual, direct, 'live' communion."

Although he credited Stanislavsky with having posed the most important questions, Grotowski was not satisfied either with Stanislavsky, who let natural impulses dominate, or with Brecht, who was too much concerned, Grotowski felt, with the construction of the role. To Grotowski, the actor is an individual who works in public with his body, offering it publicly. The work with the actor's instrument consists of physical, plastic, and vocal training to guide him toward the right kind of concentration, to commit himself totally, and to achieve a state of "trance." The actors concentrate on the search for "signs," which express through sound and movement those impulses that waver on the borderline between dream and reality. By means of such signs, the actor's own psychoanalytic language of sounds and gestures is constructed, in the same way as a great poet creates his own language.

In his search for the basic elements of acting, Grotowski turned to the French actor Charles Dullin's rhythm ex-

ercises, Stanislavsky's "method of physical action," and Meyerhold's biomechanics and to the training techniques of the Peking opera, India's kathakali dance, and the Japanese Nō theatre. He emphasized, however, that he and his company were not merely accruing techniques but were using physical and mental exercises to free the actor from blocks, eliminating obstacles between the inner impulse and the outer reactions.

THE ACTOR'S QUALIFICATIONS AND TRAINING

In view of the diversity of approaches to the actor's problems, it may seem difficult to arrive at any useful generalizations that are valid for all of them. Even among theatre groups that approach the production of a play from a fixed style or a fixed scale of expression, as in Kabuki and classic Oriental theatre generally, the same basic concerns are apparent. The following is an attempt to set down an approach that has proved successful in a variety of professional procedures.

The qualifications of the actor are generally thought to be a good physique, a retentive memory, an alert brain, a clear, resonant voice with good articulation, and controlled breathing. While looks and the even more important element of personality are undoubtedly factors, their characteristics are difficult to determine; they are usually recognized after the actor has become successful rather than before. Many actors do not possess them offstage but seem to ignite them as soon as they begin to perform. The central element of the actor's talent, as differentiated from his means, is a special sensibility ("fire," "enthusiasm," "spirit," in the words of 18th-century theoreticians), an ability to respond to imaginary stimuli and situations, which makes it possible for him to enter into the experience and emotions of the character he is to represent. These elements have always been recognized as distinguishing the great actor but were assumed to be beyond the reach of the ordinary actor; they were regarded as elements "born in him" and not susceptible to training. This is precisely the area of the modern training of the actor.

Looks and personality

The first stage in the training of the actor's control of his physical, mental, and psychical resources is the ability to relax. Because this ability seems to have little to do with the final achievements in acting, it is often disregarded, but it is basic to any expenditure of will and energy on his part. In a state of physical or mental tension, or both, the actor cannot think, the commands he gives himself are not transmitted, sensation is stifled, and expression is inhibited. The process of relaxation serves to clear the actor of the unnecessary pressures that he has accumulated before the moment of acting begins, to free him of blocks or interferences that may inhibit sensory responses. Physical and mental energies are comparatively easy to train, but sensory control is much more difficult. Relaxation is not a static state or effort. Often in the initial stages of training the actor is subject to strong eruptions of unconscious impulses. He must learn to continue the relaxation, to force his will to maintain his effort on the action of the nerves and the muscles.

The role of concentration

The converse of relaxation is concentration. Everything the actor does demands concentration. His training proceeds by work with imaginary objects: working with real objects often leads to pantomimic or to physical imitation, but the actor may begin with them in order to learn how to respond with his entire organism and to apply such responses to his work with imaginary objects—the real medium of the stage—as he would to real ones. This capacity to respond to stimuli that come not from outward reality but from the promptings of one's own imagination may be seen to some extent in every human being; something akin to it is found in psychology in the study of conditioned reflexes, of automatic and spontaneous reactions, and of behaviour patterns. In heightening the sensory awareness and stimulating the senses to respond more strongly in life, the actor acquires the ability to recreate any object, sensation, or experience in the imagination.

In strengthening his concentration, the actor uses not only will but also a process of self-awareness by which he trains the instrument that is his body and voice to respond to his commands. The very process of concentration and of commitment and involvement must include awareness. The more the actor learns to master concentration, the more aware he becomes.

The actor's sense of truth

An additional factor is the development of the actor's sense of truth—a faculty particularly stressed by Stanislavsky and by followers of his System. The growth of self-awareness is useless if it is not accompanied by a correct evaluation of what is true and what is false. If the actor must rely on outside judgment and remain dependent on it, he may become insecure and lose his spontaneity and responsiveness. His mastery of inner relaxation and concentration helps him achieve a combination of spontaneity, commitment, and awareness. Thus, the actor's involvement and his awareness, rather than being in opposition to each other, are in accord.

The actor's sense of truth is also involved in another major area of the actor's training—his work with actions (the way he behaves physically on the stage), sometimes called the "business" of the actor. Some idea must supply an incentive or intention to pull together what could otherwise be a series of disconnected and unrelated physical deeds. Some purpose, some aim must motivate the actor's will and energy. Any performance thus may be seen as a series of actions—as the score of the play—which must be carried out not simply physically but logically and truthfully. They must accomplish their purpose anew each night at every performance rather than merely repeating the external movements.

To develop spontaneity, to train himself to behave logically and truthfully, and to listen and respond to his partner, the actor practices improvisation—dramatizing contrived situations without a script. Improvisation is of enormous importance in the process of training and also of performance. It teaches the actor to speak rather than to read his lines, and it breaks his unconscious adherence to conventional theatrical patterns of behaviour. It forces him to use his senses and often to discover not only the logic but also the significance of a scene. It compels the actor to work creatively and prevents him from reverting to skillful but mechanical repetition.

By means of exercises that may be remote from the actual roles he plays—such as the "song and dance" (in which a song is rendered syllable by syllable unrelated to the way in which it would usually be sung, thus helping to break the unconscious habits of the actor that affect his performance) or, conversely, the spoken "inner monologue" (in which the actor speaks out what is happening to him at the moment, unrelated to the play), or others—the actor not only intensifies his capacity for experience, but also frees his blocked, or inhibited, impulses. He is enabled to deal with his own subjection to automatic habitual forms of behaviour and mannerisms and to acquire new means of expression, corresponding to the true nature and strength of his impulse.

The basic means of the actor, which have traditionally served as the primary area of his training, are voice and body gesture. The actor's voice must be flexible and expressive of all situations and experiences. It must be able to deliver a "poor" voice or a vulgar, rough, angry, or harsh voice. It must vary as much as the events to be created. His attitudes must be those of the character—of a human who may be ill at ease, slovenly, awkward, debilitated, or natural—giving no indication that it is being accomplished by a skilled craftsman. The methods used to train these tools of the actor derive from other fields, such as from the training of the singer's voice and of some forms of dance and pantomime. These contain many useful exercises for the strengthening of the respective muscles of the voice and body. But while the technical accomplishment in the singer and in the dancer may represent a large part of what is appreciated in their performances, in the actor the very fact of the accomplishment must remain hidden. Technical accomplishment should go unnoticed by the audience.

Voice and body training

THE ACTOR'S APPROACH TO HIS ROLE

Stanislavsky suggested that the actor, in approaching his work on a scene, ask himself four questions: (1) who he is (character), (2) where he is (place), (3) what he is doing

there (action and intention), and (4) what happened before he came there (given circumstances). The answers to these questions provide the actor with the necessary background for his performance, helping him to create the scene. In approaching the play in its entirety, the actor must subject his role to more intense analysis: he must search for the spine, or the kernel, of the play as well as its division into separate sections or units of actions. He must discern the beats of the play (*i.e.,* the smallest units of dramatic action into which each role can be divided) as well as the rhythms of the play as a whole, and he must determine what adjustments must be made in his performance for each of the other characters. For some plays an additional element is necessary: the overall mood, or pervading texture, that surrounds the play or out of which the play stems. The attempt to determine it, however, may lead to an excess of verbal and mental gymnastics that are of little actual value, unless the actors have been trained in the proper procedures. The actors must act out the elements involved in the analysis in order to receive any concrete benefit from it; otherwise it may remain superficial or merely intellectual.

Collaboration with the director

Another area deserving attention is the rehearsal process. This is primarily the time in which the director's conception of the play must be harmonized with those of the actors; it is of immense importance that the actor approach the rehearsal in a creative frame of mind, ready to enlarge both his own and his colleagues' interpretations. Without a logical sequence of rehearsals, the actor's creativity cannot be properly stimulated. Without an understanding of the psychology of the rehearsal procedure, much of the work of the actor and the director may be defeated in production. There are, for example, significant possibilities in the reading rehearsal, in which the actors, usually seated in a circle, read aloud from the script and discuss its meanings as they proceed through it. There is enormous value in improvisation, when it is understood and used correctly. The relation between the individual actor and the ensemble is welded during the rehearsals, and it is during rehearsals that the director "blocks" the scenes and the actors memorize their lines.

Styles of performance. In an effort to bring new life to plays of the past and present and to advance the imaginative possibilities of theatre, there has been a rediscovery of "style" in the 20th century. Style is the attribute of any complete achievement; it is not merely the manners and customs of a particular period. Such manners may be more strikingly elegant compared with those of the present, but they remain only manners. The Elizabethan form of theatre had conflicting styles within it, judging from a description of them in *Hamlet,* and so did the Greek and the French classical theatre. Even in Kabuki and Nō theatre there have been conflicts of styles like those in Western theatre.

Style is not, as is sometimes assumed, the opposite of realism. Neither is it necessarily characterized by an expansiveness or broadness in acting. Style is the angle from which reality is observed. It is an attribute of all creative activity—not just of period or classic plays. The search for the specific content and reality of a play leads to style. The search for style in itself or in the traditions of the past often leads to empty forms.

Just as style should not be identified with a particular period, neither should it be associated with specific playwrights. Such terms as Shakespearean style or Chekhovian style actually refer to the theatrical conventions traditionally associated with those dramas—a rhetorical and "larger than life" manner in the first and a static "mood" in the latter. These elements are little related to style; otherwise great Shakespearean and Chekhovian productions could be re-created generation after generation in precisely the same way. The fact is that those dramas must be continually re-created from the new views of each emerging generation.

The term style is often used incorrectly in reference to the theatrical conditions that simulate the original concept, structure, and dynamics of a play. The rediscovery in the 20th century of the Shakespearean stage, for example, led to a new quickness and fluidity, a nearly cinematic technique, in presenting Shakespeare's plays, but these techniques should not be interpreted as the original and therefore correct style of production. Shakespeare continues to be presented in a vast range of styles, even by the Royal Shakespeare Company, which has offered *A Midsummer Night's Dream* as a circus and *The Merry Wives of Windsor* as a 1950s suburban morality play.

Practice has shown that the use of methods traditionally associated with particular types of theatre may bring a fresh understanding to totally unrelated theatrical forms. Ariane Mnouchkine's use of Oriental styles in her Paris productions of Shakespeare, for example, was particularly successful in transmitting the ideas of Shakespeare to a French audience notoriously dubious of Shakespeare's charms.

Techniques of performance. The fundamentals of the actor's art remain the same no matter how bizarre the dramatic context: the actors may portray abstractions, for example, as in Stanislavsky's 1908 production of Maurice Maeterlinck's allegorical fantasy *The Bluebird;* they may play a band of actors producing a play, which they then proceed to perform in a vivid theatrical fashion, as in Yevgeny Vakhtangov's production of *Turandot,* a play by the 18th-century Italian Carlo Gozzi; they may invade the stage as people who demand that their story be told to an audience, as in Pirandello's *Six Characters in Search of an Author;* or they may assume the distorted attitudes appropriate to an expressionist world, as in the classic horror film *The Cabinet of Dr. Caligari* (1919).

Acting in motion pictures and television

The growth of motion pictures, especially the rise of the "talkies," beginning in 1927, greatly affected acting, as theatre talent was diverted from the stage. The requirements of acting in motion pictures, television, theatre, and opera are basically the same, although some of the techniques are different. It is possible to put strips of film together and create a performance that never was actually given. The performance is created by the director rather than by the actor. There have been performers in motion pictures who were thus completely products of the camera and contributed little from an acting point of view, depending rather on their physical charms and personality. Others, however, have been authentic actors, who developed a style perfectly suited to the medium; Charlie Chaplin, for example, ranks as one of the greatest actors of all time in any medium.

Despite the technical demands that are unique to each medium, the properly trained actor moves easily from one medium to another without any diminution of his talent. In the past, those who were trained in the rhetorical and theatrical gesture approach sometimes found difficulty in making the transition to films. The theatre can diminish the impact of action and voice, requiring a heightened intensity to project emotion and meaning to the audience. The camera, however, exaggerates action and emotion. Some actors find it difficult to perform scenes out of sequence, as is usually done in films, and for other actors the close-up can be intimidating. But the fact is that actors training for films usually use the same exercises as theatrical actors—working with imaginary objects and partners, performing appropriate physical and psychological tasks, and others. Moreover, most of the preeminent actors of the 20th century, such as Laurence Olivier, John Gielgud, Louis Jouvet, Katharine Hepburn, Dustin Hoffman, and Al Pacino, have been outstanding in both film and theatre.

The contemporary theatre is characterized by many plays that demand more dynamic and more imaginative physical actions of the actors than previously and that utilize a diversity of audiovisual effects and multimedia devices, particularly in musicals. Under the need to fulfill these demands, acting could easily revert to its old-fashioned externalized forms. In addition, the development of repertory theatres in North America, Britain, and elsewhere, with their eclectic repertoires and their combinations of contemporary and classic plays, could lead to a search for meretricious "style" rather than for genuine content. These pitfalls may be avoided, however, in much the same way as those that faced the actor in previous epochs, by understanding the true fundamentals of the art of acting.

(Le.S./N.Ch.)

BIBLIOGRAPHY

Art of theatre: Few works deal extensively with the aesthetics of theatre as a body of knowledge or theory unrelated to particular productions, schools of playwriting, or historical periods. Notable modern exceptions are ANTONIN ARTAUD, *The Theatre and Its Double* (1958; originally published in French, 1938), which considers theatre in its broadest implications and has had enormous influence on avant-garde theatre since World War II; and JERZY GROTOWSKI, *Towards a Poor Theatre* (1968, reissued 1975), an elucidation of personal artistic values by the director-teacher whose Polish Laboratory Theatre has been among the most controversial and innovative theatres of the century. The ideas of one of the 20th century's most important playwrights and directors emerge in *Brecht on Theatre: The Development of an Aesthetic,* edited and translated by JOHN WILLETT (1964, reissued 1978). A tendentious view of the shaping of 20th-century theatre by an influential director emerges in ERWIN PISCATOR, *The Political Theatre,* translated and edited by HUGH RORRISON (1978; originally published in German, 1929).

Perceptive analyses of aesthetic points of view represented in theatrical production include MORDECAI GORELIK, *New Theatres for Old* (1940, reprinted 1975), a classic work on staging and design that covers the late 19th century and first four decades of the 20th; BERNARD SHAW, *Our Theatres in the Nineties,* 3 vol. (1932, reprinted 1954), an incisive contemporary view of drama in the 1890s; and the writings of such major 20th-century critics as Harley Granville-Barker, Stark Young, George Jean Nathan, and Kenneth Tynan. Personal histories by leading theoreticians and practitioners, including KONSTANTIN STANISLAVSKY, *My Life in Art,* translated from the Russian (1924, reissued 1980); and HAROLD CLURMAN, *The Fervent Years: The Story of the Group Theatre and the Thirties* (1957, reissued 1983), carry implicit commentaries on the art of theatre. KONSTANTIN STANISLAVSKY, *An Actor Prepares,* translated from the Russian (1936, reissued 1980); and TOBY COLE (comp.), *Acting: A Handbook of the Stanislavski Method,* rev. ed. (1955, reprinted 1971), though specialized, develop aesthetic points of view that have underlain much of the theatrical production in the West during the 20th century. A classic study of the aesthetic intentions of theatre is contained in FRANCIS FERGUSSON, *The Idea of a Theatre* (1949, reprinted 1972); while PETER BROOK, *The Empty Space* (1968, reprinted 1981), is a brilliant analysis of theatrical values as manifested in such diverse areas as commercialized drama, the popular, or "rough," theatre, and the dedicated avant-garde, or "holy," theatre. A detailed examination of the development of experimental theatre in the 20th century can be found in CHRISTOPHER INNES, *Holy Theatre: Ritual and the Avant Garde* (1981).

An overview—outdated but still singular—of the many different forms and aesthetic conditions of Oriental theatre is contained in FAUBION BOWERS, *Theatre in the East* (1956, reprinted 1980). Discussions of the conditions under which theatrical forms have emerged appear in many works, including SIR JAMES FRAZER, *The Golden Bough,* 3rd ed., 12 vol. (1907–15), available also in numerous later editions, both complete and abridged, and those of Margaret Mead and other anthropologists. Finally, such periodicals as *Drama Review* (quarterly; formerly, *Tulane Drama Review*), *Theatre Arts* (1939–64), and *Theatre Quarterly* (1971–81), contain important reportorial, critical, and philosophical writing on theatre as both an artistic and a social expression.

(N.Ch./Ed.)

Directing: Many of the most useful guides to directing are biographical in nature, or they document productions of individual directors. A good, if partial, overview of the development of directing from the time of the Meiningen Players is EDWARD BRAUN, *The Director and the Stage: From Naturalism to Grotowski* (1982). *Peter Hall's Diaries: The Story of a Dramatic Battle,* edited by JOHN GOODWIN (1983), presents an intensely personal picture of the role of the artistic director of the National Theatre of Great Britain; HAROLD CLURMAN, *On Directing* (1972), is a personal testament to the practical details of the discipline by one of America's most important directors; and *A Casebook on Harold Pinter's The Homecoming,* edited by JOHN LAHR and ANTHEA LAHR (1971), documents the direction, design, intention, and reception of one of Pinter's most important plays. JIM HILEY, *Theatre at Work: The Story of the National Theatre's Production of Brecht's Galileo* (1981), is a complete documentation of a production by John Dexter. HARLEY GRANVILLE-BARKER, *Prefaces to Shakespeare* (1930; also available in later multivolume editions), is an analysis of the theatrical, as well as the obvious poetic, values to be discovered by anyone staging Shakespeare's plays. An important statement extending the Stanislavsky tradition to more experimental strains of the Soviet theatre and placing them in historical context is EDWARD BRAUN, *The Theatre of Meyerhold: Revolution and the Modern Stage* (1979, reissued 1986). JOHN WILLETT, *Brecht in Context: Comparative Approaches* (1984), is a thoughtful bringing together of the elements that shaped Brecht's ideas of theatre, from music and design to politics; RICHARD SCHECHNER, *Environmental Theater* (1973), is a fundamental statement by a radical American director and theorist; and *Twentieth Century Polish Theatre,* edited by BOHDAN DROZDOWSKI (1979), examines the work of several influential avant-gardists.

JOHN FERNALD, *Sense of Direction: The Director and His Actors* (1968), is a detailed examination of the way a director works with actors, including analyses of scenes from classic plays, showing how to approach them as a director; ELSIE FOGERTY, *Speech Craft: A Manual of Practice in English Speech* (1930), is a guide to what actors should be able to do and the mistakes they can make; TYRONE GUTHRIE, *A Life in the Theatre* (1959, reprinted 1985), presents personal revelations about directing and the theatre; G. WILSON KNIGHT, *Shakespearean Production,* new ed. (1963, reprinted 1981), is a first-class complement to Granville-Barker's *Prefaces;* RICHARD L. STERNE, *John Gielgud Directs Richard Burton in Hamlet* (1967), shows how a great Shakespearean directed this play over a period of four weeks' rehearsal. Other works include JOANN GREEN, *The Small Theatre Handbook: A Guide to Management and Production* (1981); ANDREW MCCALLUM, *Fun with Stagecraft* (1981); and ANN PASTERNAK SLATER, *Shakespeare, the Director* (1982).

(J.B.F./N.Ch.)

Acting: Although the literature on actors and acting is overwhelming, most of it is of little informational value. The best anthology, with useful notes and bibliography, is TOBY COLE and HELEN KRICH CHINOY (eds.), *Actors on Acting: The Theories, Techniques, and Practices of the Great Actors of All Times as Told in Their Own Words,* rev. ed. (1970). The most valuable individual statements are those of Luigi Riccoboni, F.J. Talma, and William Gillette; some of these are reprinted completely in *Papers on Acting,* edited by BRANDER MATTHEWS (1958), which also includes the polemic between Henry Irving and C. Coquelin. A useful introduction to the literature is EDWIN DUERR, *The Length and Depth of Acting* (1962), though flawed by the inability to relate theory to practice.

Basic to modern understanding are the above-mentioned works of Stanislavsky, as well as his *Building a Character* (1949, reissued 1979), and *Creating a Role* (1961, reissued 1981), English trans. edited and abridged by ELIZABETH REYNOLDS HAPGOOD. *Stanislavski's Legacy: A Collection of Comments on a Variety of Aspects of an Actor's Art and Life,* rev. and expanded ed., edited and translated by ELIZABETH REYNOLDS HAPGOOD (1968, reissued 1971), collects further fragments of his thoughts on acting and its critics, as well as his memories of Anton Chekhov. Also useful are ROBERT LEWIS, *Method or Madness?* (1958); LEE STRASBERG, "Acting and the Training of the Actor," in JOHN GASSNER, *Producing the Play,* rev. ed. (1953); ROBERT HETHMON (ed.), *Strasberg at the Actors Studio* (1965); RICHARD BOLESLAVSKI, *Acting: The First Six Lessons* (1933, reprinted 1980); and JEAN BENEDETTI, *Stanislavski, an Introduction* (1982). For a proper appreciation of Stanislavsky's approach, the work of his pupil Yevgeny Vakhtangov is essential, a brilliant description of which is in NIKOLAI GORCHAKOV, *The Vakhtangov School of Stage Art* (1959?; originally published in Russian, 1957). Contributions on acting that add dimensions to the study of the art come from JOSEPH CHAIKIN, *The Presence of the Actor* (1972, reprinted 1980); CHARLES MAROWITZ, *The Act of Being* (1978); MICHEL SAINT-DENIS, *Theatre: The Rediscovery of Style* (1960); VIOLA SPOLIN, *Improvisation for the Theater* (1963, reissued 1983); JOHN HODGSON and ERNEST RICHARDS, *Improvisation,* new rev. ed. (1974, reprinted 1979); and MICHAEL CHEKHOV, *To the Actor: On the Technique of Acting* (1953, reissued 1985).

Essential texts on Oriental theatre include J. THOMAS RIMER and MASAKAZU YAMAZAKI (trans.), *On the Art of the No Drama: The Major Treatises of Zeami* (1984); and JISHO HACHIMONJIYA, *The Actors' Analects,* edited and translated by CHARLES J. DUNN and BUNZO TORIGOE (1969), a collection of "advice and notes" by Kabuki actors of the 17th century. Modern Japanese ideas are explored in SUZUKI TADASHI, *The Way of Acting,* trans. from Japanese (1986). British acting tradition is analyzed in ANTONY SHER, *Year of the King: An Actor's Diary and Sketchbook* (1985), a revealing memoir of his creation of the role of Richard III for the Royal Shakespeare Company; SIMON CALLOW, *Being an Actor* (1984); and LAURENCE OLIVIER, *On Acting* (1986), a book on craft.

No history of acting can be written without a knowledge of what acting consists of and the creative processes involved. German students have in specialized studies and dissertations tried to formulate methods for studying the actor's work by examining critical descriptions, stage directions, and iconographical material. A bibliography is available in HANS KNUDSEN, *Methodik der Theaterwissenschaft* (1971).

The History of Western Theatre

Western theatre encompasses a vast range of styles, genres, themes, and functions. It also includes diverse methods of acting, directing, and production. This article reviews the origins and development of the various traditions of the Western theatre, with attention given to each of these elements. The significant theatrical traditions of non-Western cultures are covered in AFRICAN ARTS: *Performing arts;* EAST ASIAN ARTS: *Dance and theatre;* SOUTH ASIAN ARTS: *Dance and theatre;* and SOUTHEAST ASIAN ARTS: *The performing arts.*

For a discussion of drama as a literary form, see LITERATURE, THE ART OF: *Drama,* and the articles on individual national literatures. For detailed information on the arts of theatrical performance and stagecraft, see THEATRE, THE ART OF THE and THEATRICAL PRODUCTION. (Ed.)

The article is divided into the following sections:

The origins of Western theatre 531
- Preclassical antiquity 531
  - Ritual beginnings
  - Nature worship
  - Shamanism
- Ancient Egypt 532
- Ancient Greece 532
  - Dramatic genres
  - The theatre

The origins of Western theatre

PRECLASSICAL ANTIQUITY

Ritual beginnings. Notwithstanding its great diversity of styles, forms, themes, and functions, the theatre of today has its roots in a basic need to give meaning to the workings of the universe. This suggests that theatre is a social art based on doubt and questioning. From earliest times, man has sought to understand the cycle of nature, the progression from birth to death, and the forces that drive him. Indeed, this understanding has been necessary to man's survival on Earth, particularly when his environment has become hostile or he has had to face natural cataclysms.

The lack of documentary evidence makes it impossible to determine exactly how theatre began, though it is generally believed to have evolved from religious rituals. But it is difficult to decide at which point ritual became theatre. Important clues as to the nature of theatre in prehistoric times can, however, be found by examining the many patterns of drama and ritual that exist throughout the world today, especially in primitive societies.

Nature worship. The most widely held theory about the origins of theatre is that it evolved from rituals created symbolically to act out natural events, thereby bringing them down to human scale and making the unknown more easily accessible. Individuals would express themselves through rhythmic movement using some kind of adornment to depersonalize the body. The earliest known evidence of this is in the cave paintings and engravings at Les Trois Frères in southern France. Dating from the Late Paleolithic Period (about 40,000–10,000 BC), these ancient manifestations of art depict half-human, half-animal figures in animated poses. The figures appear to be dancers wearing the heads and skins of animals, suggesting the early use of mask and costume. Certainly the mask has been one of the most potent means of transcending one's own being or of representing other planes of existence, and in many parts of the world it holds great power and fascination to this day.

The natural elements were given personalities, which were in turn abstracted as spirits and gods. By wearing masks and moving in certain patterns, individuals could impersonate these deities. Sacred dances were performed to influence the course of nature—to bring rain, to facilitate a good harvest or a hunt, and to drive out evil. But one of the most important patterns was the enact-

ment of the cycle of the seasons, dramatized by a battle in which winter gave way to spring. A year-king figure was ritually killed and supplanted by a new king. At first this was probably a human sacrifice of propitiation; later the killing was mimed. In a further development of this theme, the two kings were reduced to a single figure who underwent a process of repeated death and resurrection. This interpretation is used to explain the mock battles in such continuing folk traditions as the European mummers plays or the multiple deaths and rebirths of such figures as the Padstow Horse in Cornwall, England.

Shamanism. A second theory proposes that theatre evolved from shamanistic rituals that manifested to the audience a supernatural presence, as opposed to giving a symbolic representation of it. In this case the shaman, as actor/priest, was able to put himself into a trance and become a medium with the other world. He was believed to travel in the spirit world or be actually possessed by spirits. One of the main activities of shamanism, which is still practiced today, is the exorcism of evil spirits, and this can often involve trance dances in which the shaman performs acrobatics, juggling, or vigorous dancing for long periods, demanding a facility and stamina that would not normally be possible. Fire-walking, fire-eating, and other acts of apparent self-torture, performed while in a trance, are taken as further demonstrations of the supernatural. They represent the opposite pole from illusionism, in which such acts are achieved by trickery. Sometimes puppets are used by shamans as manifestations of supernatural forces in the giving of divinations or oracles. Masks also are an important part of shamanism: it is believed that by putting on a mask the dancer becomes possessed by the spirit represented and takes on the functions of that spirit. The use of body paint and elaborate costumes helps further in the personification of the spirit or demon.

The demon play

These ritual elements gave rise to an archetypal genre known as the demon play, a primitive dance drama in which the force of good exorcises the force of evil. The demon play is still performed in various guises in parts of Asia. An interesting component, which also occurs in later Western theatre, is the use of clowns—often deformed—to parody the more serious figures.

The residue of both functions—impersonator of natural forces and medium with the other world—can be detected in the role of the Western actor today. Shamanism emphasizes the special skills that actors have traditionally developed and that set them apart from the rest of society. It also shows the way the actor's techniques can help to transport imaginatively the audience beyond the actual space where the performance takes place. The "nature worship" theory expresses the idea that disguise is one of the fundamental aspects of the actor's art. Indeed, when an individual addressing a gathering modifies his manner, voice, or appearance, the event becomes theatrical rather than actual. This also conforms to Aristotle's definition of theatre as "an imitation of an action"; *i.e.,* not the action itself. Shamanism, on the other hand, is not an imitation but a direct manifestation.

In cultures where the ritual elements of theatre have remained intact—in South India and Bali, for example—the performances of plays and dance dramas have acquired an aura of deep respect and almost awesome power over their audience. However, where the ritual has continued in empty form long after the full significance of its content has been lost, as in modern performances of mummers plays or the Padstow Horse, it becomes little more than a quaint entertainment. The development of Western theatre lies between these two extremes and polarizes into its two primary types of experience—tragedy and comedy.

ANCIENT EGYPT

In ancient Egypt, religious ritual moved toward a more explicitly theatrical enactment. The pantheon of animal-headed gods and the stories of the soul's journey after death into the other world provided rich material for ceremonies and rituals in which priests were thought to have impersonated the deities by wearing stylized masks and reciting hymns and prayers. Carvings depicting masked dancers, dated at 3500 BC, have been found in Egypt.

The so-called Pyramid Texts have been assembled from fragments of prayers found carved on the walls of royal tombs of the Old Kingdom (from *c.* 2686–*c.* 2160 BC). The most important of these involved the god Osiris. He was the subject of what was known as the Abydos passion play, a yearly ritual performed during the period of the Old Kingdom and until about AD 400. The Abydos passion play depicts the slaying of Osiris and his followers by his brother Seth, the enactment of which apparently resulted in many real deaths. The figure of Osiris, symbolically represented in the play, is then torn to pieces by Seth, after which his remains are gathered by his wife Isis and son Horus, who subsequently restore him to life. The play thus follows the pattern of birth, death, and resurrection, and it also echoes the cycle of the seasons.

The Abydos passion play

Ritual dramas like this were performed to ensure the fertility of women, cattle, and crops and to invest the spirit of the community and its leaders with vitality for the new year. Myths relating to Osiris and Horus were especially important because the pharaoh, while alive, was believed to be an incarnation of Horus, and, after his death, he was believed to be Osiris. By the time the Greek historian Herodotus saw the Abydos passion play on a visit to Egypt in 450 BC, he could record that there was also a tradition of popular drama that used comic elements (*e.g.,* Horus, born as a baby but growing to enormous size and developing a voracious appetite), though it still confined itself to religious themes.

Investigators have discovered another text preserved on papyrus scrolls. Known as the Book of the Dead (from about 1800 BC), it reads very much like an oratorio. Although there is no evidence that it was actually performed, the ritual is full of theatrical elements. It describes the journey of the soul, brought after death by the jackal-headed god Anubis into the Hall of Truth, where the dead man's heart is weighed against a feather. If the heart, made light by goodness, does not outweigh the feather, then the soul is brought before Osiris and granted immortality.

ANCIENT GREECE

Dramatic genres. The first time theatre truly freed itself from religious ritual to become an art form was in Greece in the 6th century BC when the dithyramb was developed. This was a form of choral song chanted at festivals in honour of Dionysus, the god of wine, fruitfulness, and vegetation. Originally, it celebrated his rejuvenation of the earth; later, it drew on Homeric legends for its subject matter. According to Greek tradition, the actor and playwright Thespis invented the drama when he augmented the chorus of the dithyramb with a single actor who wore masks to portray several different characters. With the possibility of dialogue between the actor and the chorus, more complex themes and modes of storytelling could be developed. In 534 BC, at Athens' first dramatic festival, one of Thespis' tragedies won the prize. (Derived from the Greek *tragos,* meaning "goat," the term *tragedy* may have referred to a goat as the prize or as an animal sacrifice made at the festival.) Thereafter, tragedies were performed annually as part of the festival of Dionysus.

The tragedies of Aeschylus

The earliest surviving texts of plays are seven tragedies by Aeschylus dating from the first half of the 5th century BC. Adding a second actor and reducing the chorus from 50 to 12, Aeschylus laid the foundation for an aesthetics of drama that was to influence subsequent plays for well over 2,000 years. Tragedy, it was considered, should deal with illustrious figures and significant events. The plays, which were based on legends or remote history (though given the appearance of truth), were interpreted so as to convey some religious, moral, or political meaning. The entire cosmos was depicted in the drama, represented on a vertical structure: above was the seat of the gods, below was the place of exile and punishment, and in the middle was the flat circle of the Earth, represented by the circular stage, where the action unfolded.

The universal scale of Greek drama was reflected in one of its most characteristic features, the interaction between chorus and protagonist. The function of the chorus was to generalize the particular events by observing and interpreting the action of the play as a kind of ideal spectator.

It provided, as it were, the social background, which in turn gave resonance to the actions of the main characters. Sometimes the chorus would have a particular point of view (as in *Bacchae,* where it represents the followers of Bacchus), while at other times it could be the mouthpiece of the poet. Long speeches and songs made up much of the plays, though these were made more dramatic by the dancing of the chorus. The visual aspect of Greek tragedy was very important, a fact that is easily forgotten as only the words survive.

Sophocles and Euripides

The conventions Aeschylus developed were refined by Sophocles, who brought the chorus up to 15 and added a third actor, thereby making possible a much larger number of characters. Euripides, in his turn, brought greater realism to characterization and strengthened dramatic action by reducing the role of the chorus. The dramatic unities of time, place, and action were usually observed in Greek tragedy by attempting to make the action complete in itself, without superfluities, within a single circuit of the Sun, and in one location. The lack of scene change and the limited number of actors available meant that much of the action, particularly murders and other deaths, took place offstage.

In time, the masks worn by the actors and chorus became more expressive, and their conventionalized representation of character types (old king, young king, old nurse, etc.) meant that each character was instantly recognizable when he entered. The masks also helped to make the portrayal of female characters by male actors more plausible, as well as to make the facial features clearly discernible by the large audience.

The principle occasion for drama was the Great Dionysia (or City Dionysia), a spring festival devoted mainly to tragedy. The *archon,* a city official, chose the poets who were allowed to compete, and for each of them there was a *choregos,* a wealthy man who as part of his civic duties would pay for and organize the production. The actors were paid by the state. Each poet was required to offer three tragedies and a satyr play (a bawdy comic comment on the main theme of the tragedies). The tragedies could be separate plays on a linked theme or a trilogy on one theme. The only surviving complete trilogy is Aeschylus' *Oresteia.* The poet directed his plays, composed the music, and arranged the dances. In the early tragedies, he was also the main actor.

Comedy (from Greek *kōmos,* meaning "revel") was presented competitively in Athens from 486 BC at the Lenaea winter festival, though it fused much earlier traditions of popular entertainment, mime, phallic rites, and revelry in honour of Dionysus. Ancient shamanistic ceremonies also may have influenced its development. Old Comedy, of which Aristophanes was the chief exponent, was highly satirical. It was characterized by wildly imaginative material (in which the chorus might represent birds, frogs, wasps, or clouds) that was blended with a grotesque, vulgar, and witty tone, which could still accommodate poetry of great lyrical beauty. The bawdiness of the plays was emphasized by the actors' costumes, which featured jerkins with padded stomachs and large phalli. As in tragedy, masks were worn, though exaggerated for comic effect.

Old Comedy

With the decline of tragedy after Euripides' death in 406 BC and the defeat of Athens in 404 BC, comedy increased in popularity. It began to evolve through the transitional Middle Comedy to the style known as New Comedy, established about 320 BC during the time of Alexander the Great. Only fragments by one writer, Menander, survive from this period, but they indicate a swing away from mythological subjects toward a comedy of manners, concentrating as they do on the erotic adventures of young Athenians and centring on urban family life. Gone were the boisterousness, the religious influence, and the long choruses of the earlier drama. The new, gentler style was reflected in the use of more realistic costumes and masks and in the increasing use of scenery.

New Comedy

The theatre. The outdoor setting for performances of Greek drama traditionally comprised three areas: a large circular dancing floor (*orchēstra* in Greek) on which the action took place and in the centre of which was an altar to Dionysus; behind this, a scene-building and dressing room (*skēne* in Greek, whence "scene"), a low architectural facade to which painted scenery could be fitted, sometimes on revolving panels (*periaktoi*); and around the *orchēstra,* a semicircular auditorium cut into a hillside and fitted initially with wooden benches and later with stone or marble seats. The steep rake and layout of the auditorium enabled audiences of from 10,000 to 20,000 to sit in reasonable proximity to the players. They also enhanced the acoustics. An important stage device used in tragedy during the 5th century BC was the crane (*mēchanē*), which served to fly in the gods (*deus ex machina*) at the end of the play.

ROME

If the quality of theatre is reflected in the values of the civilization out of which it grows, then this is vividly illustrated by the fate of theatre in Roman times. Suffering from vulgarized public taste and a complete lack of originality, nearly all of the Roman plays were imitations or loose translations of Greek dramas, even to the extent of their being performed in Greek costume. Eventually, after 400 years of competing with chariot races, gladiatorial fights to the death, and the spectacle of criminals and Christians being torn apart by wild animals, theatre came to an apparent end.

Several factors must be taken into account in explaining why this happened, but perhaps the main reason lay in the political cynicism with which Roman authorities used circuses and public games, at which theatrical performances took place, to divert the public from economic and political dissatisfaction. The number of official festivals proliferated. In 240 BC, when drama was first included, the games lasted less than a week. By the 1st century AD there were 60 days of games throughout the year, and 300 years after that, 175 days were devoted to games, with plays being performed on 100 of them. Most of these festivals were secular, and theatre soon lost its close ties with religious ritual, degenerating into theatricality and crude spectacle for its own sake.

Native traditions. In spite of the lack of originality shown by dramatists, there were in Italy a number of native comic traditions that helped to shape the style of Roman comedy. The Fescennine verses (*fescennia locatio*) were bawdy, improvised exchanges sung by clowns at local harvest festivals and marriage ceremonies. These are thought to have combined with a tradition of performances by masked dancers and musicians from Etruria to form *saturae,* medleys consisting of jests, slapstick, and songs. The historian Livy says that in 364 BC these Etruscan players were summoned to Rome at a time of pestilence to appease the gods with their dancing and music.

Phlyax plays

From the areas of southern Italy and Sicily settled by the Greeks came the *phlyax* plays in the 4th century BC. Named for the Phlyakes (literally "Gossip Players"), these were burlesques and travesties of mythology and daily life and probably improvised. They were performed on a raised wooden stage with an upper gallery, and the actors wore grotesque costumes and masks similar to those of the Greek Old Comedy. Acrobatics and farcical scenes were a major ingredient of the *phlyax.* The Oscan inhabitants of Campania, in the Neapolitan region of Italy, also had a long tradition of farces, parodies, and political satires influenced by Greek models, which became popular in Rome during the 3rd century BC. This genre was known as *fabula Atellana* ("Atellan play," Atella being the name of a Campanian town). The significance of the *fabula Atellana* is that it introduced a set of stock characters, such as Maccus and Bucco, which were thought to be the direct ancestors of many of the Italian commedia dell'arte characters. The actors wore masks, improvised their dialogue, and worked slapstick routines and other buffoonery into the plots.

Imitation of Greek models. In the literary theatre, plot invention and characters were largely taken from Greek plays. Livius Andronicus, a Greek living in Rome, was the first to adapt Greek plays (in 240 BC), and his example was followed in 235 BC by the poet Gnaeus Naevius, a native of Campania. Naevius can be regarded as the first native Italian playwright, and the genre of comedies he founded was called *fabula palliata* ("play in Greek dress"). His

less successful tragedies on Roman history were known as *fabulae praetextae* ("plays in the Roman toga"). Naevius' attempts at satire were audacious enough to land him in prison, which is probably why the noted poet Quintus Ennius, who followed him as a dramatist, limited himself to safe adaptations of Greek tragedies, mostly those of Euripides.

In the 2nd century BC, the two most important comic writers of the Roman theatre, Plautus and Terence (who came from lower class backgrounds), were both influenced by the New Comedy of the Greeks, and their plays retained the Greek setting and costume. Plautus, who had few literary pretensions but a sharp sense of wit and wordplay, blended the comic style of Menander with the *fabula Atellana* to produce vigorous farces about mistaken identities, sexual intrigues, and the mischief of household servants. His 21 surviving plays (of a total of about 130) were in turn to inspire playwrights for centuries to come, including Shakespeare. The braggart soldier, Miles Gloriosus, became one of Plautus' most imitated characters. Terence, who closely followed the style of Menander, aimed at a more discerning audience. His comedies are noted for their grace and delicacy, and they avoided the buffoonery that attracted Plautus.

The works of Plautus and Terence

Seeds of decay. The audience that followed Terence's plays was a small and exclusive one. From the start Roman theatre was dependent on popular taste in a way that had never been known in Greece. If a play failed to please, the manager of the festival was obliged to return part of the subsidy from public funds. Thus, even in Republican times, there was some anxiety to give the public what it wanted, and this proved to be the sensational, the spectacular, and the crude. Huge amphitheatres such as the Colosseum in Rome were built throughout the empire as evidence of the power and grandeur of Rome, but not of its artistic life and energy. The general public preferred boxers, beasts, and mock sea battles to drama. Actors and dramatists were tempted to adapt their style of presentation accordingly. Where it had once been subtle, the acting became coarse and declamatory. The actors took to wearing built-up shoes (*cothurni*) and bigger masks in order to make themselves appear larger than life. Some of the small number of tragedies that were staged were filled out with long processions of animals, gaudy costumes, and elaborate effects, all emphasizing the hollowness of both theatre and audience.

Theatre buildings themselves became grander in the 1st century BC. Erected on flat ground, the raked semicircular auditorium was a freestanding structure of great engineering complexity. With the elimination of the chorus from plays, the *orchēstra* was no longer needed other than as a space for important guests to sit, and the action took place on a wide, raised stage backed by an imposing architectural facade, the *scaenae frons,* which was often two or three stories high. A drop curtain at the front of the stage facilitated scene changes, and the audience could be protected from harsh sunlight by a huge awning. The comfort was unrivaled, but it came too late; what took place on these stages had become trivial and degrading. It is not surprising that serious people avoided the theatres and writers were alienated from them.

One reaction against the excesses of the theatre was the custom of reading tragedies aloud to select gatherings of intellectuals. It is thought that this was the purpose behind the tragedies of Seneca, a Stoic philosopher and statesman under the emperor Nero in the 1st century AD, for there is no record of any of his works having been produced. While his plays lack the craftsmanship of the Greeks, Seneca's importance lies in the fact that he was the principal medium through which Renaissance writers became acquainted with Greek tragedy. His division of the plays into five acts, his exaggeration of the melodramatic and violent aspects of the originals, his emphasis on rhetoric, and his preoccupation with the conflict between passion and reason helped to shape the Elizabethan drama and French Neoclassical tragedy that followed more than a millennium later.

The tragedies of Seneca

Mime and pantomime. After Seneca, serious dramatic literature in Rome virtually ceased, and the newly erected stone theatres were taken over by mime (Latin *mimus*) and pantomime (*pantomimus*) as the level of public taste steadily fell. Pantomime grew out of the wreckage of tragedy as a kind of burlesque ballet in which a chorus chanted the story to musical accompaniment, while a solo actor used mime, gesture, and dance to portray the various characters in a succession of masks. Particular emphasis was placed on the erotic elements of the story.

Of more interest is the mime, which was derived from the Greek mime traditions and the *fabula Atellana.* By the 2nd century BC, it had a large following in Rome. Mime was characterized by great diversity: sometimes the shows were tragicomic dramas, but most often they were indecent burlesques on the gods in which female performers also took part. They featured acrobatics, songs, and slapstick routines. Companies ranged from itinerant groups of six players to the troupe of 60 actors recorded in AD 169. Although the performers were highly skilled (some of them achieved widespread fame), mime contented itself with easy targets, pandering to the taste of the emperor. By the time of the Christian persecutions under Nero and Domitian, mimes were used to ridicule the Christian faith on stage. In *Centunculus,* for example, a clown was baptized and martyred, being grotesquely crucified in a way calculated to burlesque his faith. Sometimes the shows were spiced with sexual acts and real executions on stage. At the end of the Roman era, mime actors were performing throughout the empire, but after the triumph of Christianity the theatre of the day was abominated by the Church Fathers as an art so debased as to have lost any relevance to the general good of society. In the 5th century all performers of mime were excommunicated, and in the following century the theatres were closed.

Diversity of mime performances

The old Roman Empire was Christianized and became divided in two: one based in Rome, the other in Constantinople (modern Istanbul). There being no other outlet for the expression of the supernatural and the cycle of the seasons, semitheatrical religious festivals, magnificent rituals, and processions became once more the principal means of community celebration. These were particularly elaborate in the Byzantine Church, centred in Constantinople. Meanwhile the mimes dispersed. Though the church did its best to prohibit them through the Middle Ages, they managed to carry on their intriguing art illicitly, finding audiences wherever they could. Mime, therefore, preserves the only dramatic continuity between the classical world and modern Europe. The texts and theoretical treatises of the classical world were all to lie largely unused for more than 900 years. The failure of the Roman theatre was that it had lost its seriousness of purpose; the surviving plays were comparatively tired and unimaginative imitations that did not carry the dramatic forms forward to create an important theatrical movement. Yet, in what survived, sufficient elements were present to stimulate a new and powerful theatre during the Renaissance.

Medieval theatre

POPULAR TRADITIONS AND SECULAR THEATRE

During the Middle Ages, theatre began a new cycle of development that strangely paralleled the emergence of the theatre from ritual activity in the early Greek period. Whereas the Greek theatre had grown out of Dionysian worship, the medieval theatre originated as an expression of the Christian religion. The two cycles would eventually merge during the Renaissance, but for centuries before that the theatre was left to grope its way blindly through the Dark Ages. It meant a completely fresh start. The decadence of what remained of the Roman theatre had so offended the upright barbarian invaders, who had no sophisticated culture of their own with which to replace it, that their reaction was to try to prohibit it. Their efforts, however, were not wholly successful.

Between the classical and the medieval periods, theatre was kept alive by the slenderest of threads—the popular entertainers who had dispersed to wander, alone or in small groups, throughout Europe. These were the mimes, acrobats, dancers, animal trainers, jugglers, wrestlers, minstrels, and storytellers who preserved vital skills that sur-

vive in the theatre today. They also brought a duality to theatre that still exists: popular theatre and the literary theatre were to grow side by side, feeding off and nourishing each other. During the late Middle Ages these popular entertainers found a more secure place at royal courts and in the households of the nobility, where they acted, sang, and played music at their masters' festivities. The written texts that they developed for performance were, especially in France, literate and often sharply satirical.

Folk play

A further, though minor, influence on the development of theatre was the folk play. This dramatic form had two main sources. One was the symbolic ritual dramas of the seasons such as the Plow Monday play (English Midlands), in which a plow was decorated and pulled around the village (thought to have originally been a fertility god carried around the fields on a plow), or the European folk drama of the Wild Man of the Woods, in which a figure covered with leaves, representing winter, was ritually hunted and "killed." The other source was the mimetic elements in dances held at village feasts. The Morris dance (probably Moorish in origin; from Spanish *morisco*), famed in England but also performed in medieval continental Europe, was strongly mimetic and had dramatic elements in its use of the fool or clown character. It can also be linked with ancient trance dances in its occasional use of the hobbyhorse. The various forms of sword dance found in Europe are another example.

Both ritual and mimetic dance came together in the mummers plays that emerged during the late Middle Ages. The essential elements were some kind of fight in which one of the combatants was killed and the revival of the fighter by a healer or doctor. This pattern also reflects the cycle of death and rebirth, which suggests that the origin of the plays may be much older. Later versions of the mummers plays used the figure of St. George fighting a dragon, and they employed more dialogue to balance the action.

When Christianity spread through Europe, missionaries had great difficulty discouraging the wealth of local folk traditions that flourished in rural communities. Eventually, the reforming bishops decided that it was better to regulate than to prohibit them, so the Roman Catholic Church began incorporating pagan festivals into its own liturgical calendar and remythologizing local rituals. The spring cycle of festivities centring on fertility rituals and the rebirth of summer was adapted to the Christian version of death and resurrection, while Christmas absorbed celebrations around the winter solstice such as the Saturnalia and the Yule Fest, the Teutonic New Year celebration. Christian churches were built on the sites of pagan temples, and folk plays were even organized as part of the village church activities.

Typical of this tolerance was the Feast of Fools, first recorded in France at the end of the 12th century, in which the lower clergy took over the church building, wearing grotesque masks, dressing as women or minstrels, electing a mock bishop, censing with stinking smoke by burning the soles of old shoes, and generally burlesquing the mass. The inversion of status that took place in the Feast of Fools was characteristic of the folk festivals held at the time of carnival (just before the fasting of Lent) and the New Year's Saturnalia. Most of these centred on a mock king, or Lord of Misrule, who guided the follies.

Folk theatre was not a literary genre; its prime concern was to fulfill a communal function in the village. However, its significance in the development of theatre was that, being a style with which everyone was familiar, it could provide a rich stimulus for the more serious theatre that supplanted it. Many farcical scenes from folk dramas were included as interludes in the later religious plays, making them more vigorous and balancing entertainment with didacticism. Divorced from their validating mythology by the domination of Christian myths, the pagan celebrations soon began to lose their primary function, and eventually their true meaning was forgotten.

A consequence of the Roman Catholic Church's choice of Latin as the language of the liturgy was that classical texts continued to be read, and Terence, whose moral tone made him the least offensive of the Roman dramatists, acquired new popularity among a small scholarly elite. During the 10th century, at a convent in Gandersheim, Ger., a nun called Hrosvitha wrote six short plays modeled on Terence's style but in modified and Christianized form so as not to corrupt the sisters. Terence's bawds, slaves, and foolish old men were replaced by chaste Christian maids, honest men, and constant Christian martyrs. The plays were never publicly performed, though they may have been privately staged in the convent.

The plays of Hrosvitha of Gandersheim

LITURGICAL DRAMA

The tradition of medieval religious theatre stems directly from the mass itself, a complex ritual containing many theatrical elements in its function as a visible reflection of the invisible world. Because it was believed that harmony expressed religious values, an attempt was made from the 9th century to increase the musical effectiveness of the plainsong of the Roman Catholic Church by developing antiphonal singing in which the choir was divided into two parts. From this came the trope, a musical addition or embellishment to certain parts of the liturgy, as, for example, to the final syllable of the Alleluia.

It was in the trope of the Easter mass, recorded in a 10th-century manuscript from the Monastery of St. Gall in Switzerland, that the union of action, impersonation, and dialogue originated. Taken from various sources in the Bible, it dramatizes the visit of the three Marys to the tomb where Christ's body had been buried. They find the sepulchre empty and an angel guarding it. One section of the choir, representing the angel, asks, "Quem quaeritis?" ("Whom do you seek?"), to which the other half responds, and a short dialogue follows. In later versions the angel was represented by the priest in white robes and the Marys by three choirboys. Directions were added, dictating particular actions and precisely how the performers should move. In turn, a spice merchant (the first secular character, who was strikingly similar to the doctor figure of mummers plays and folk dramas) was added to haggle with the three Marys about the price of the ointment. The *Quem quaeritis?* soon spread throughout Europe (more than 400 versions survive), and by the end of the 10th century it had become a self-contained liturgical drama.

During the 11th and 12th centuries, the Nativity, along with other biblical themes, received similar treatment. To accommodate these dramas, the playing areas were extended from the altar to various locations throughout the church. Sometimes scenes were suggested by raised platforms, and machinery was developed to facilitate effects, such as angels descending. The clergy's intention of making the key episodes of the liturgy as vivid and accessible as possible to uneducated congregations was so successfully realized that by the end of the 12th century the plays incorporated spoken dialogue, partly in the vernacular, and were moved outside in front of the church to be performed independently of the liturgical service. One of the first such plays was *Adam,* performed before a French cathedral about 1170.

MYSTERY CYCLES

Use of the vernacular

Once the theatre had been moved outside the church, production of the plays was gradually taken over by the laity, and performances were given entirely in the vernacular. (Liturgical dramas, however, continued to be presented inside the church until the 16th century.) The number of short plays proliferated until they were organized into great cycles covering the whole biblical story from the creation to the Last Judgment, though centring on the Passion and designed to express the humanity as well as the divinity of Christ. In France they become known as *mystères* (from Latin *ministerium,* "service"), in Italy as *sacre rappresentazioni,* in Spain as *autos sacramentales,* in Germany as *Mysterienspielen,* and in England as mystery plays (later mystery cycles). Comprising up to 50 short plays, these cycles were sometimes performed over two or three days. In England the cycles of York, Wakefield, Coventry, and Chester survive, but on the Continent there are many more. As the presentation of these plays grew more elaborate, they became a civic affair, and special organizations took over their staging; *e.g.,* in France it was the *confréries,* while in England, the trade guilds.

Each guild would take responsibility for a particular play, usually related to its work: the building of Noah's ark, for example, would be staged by the shipwrights. Church vestments were replaced by appropriate contemporary costumes, and, because many of the plays called for complex and realistic effects—*e.g.*, scenes of torture and execution or appearances from Hell's mouth—sophisticated properties and machinery were devised to achieve them.

Initially, in the 12th century, the cycles were presented on a series of decorated platforms known as houses or mansions, following the type of layout established in the liturgical drama, with each representing a particular location. These mansions were usually arranged in a straight line or a semicircle with the audience in front. In Italy stages were placed around a city square with the spectators in the centre. An alternative presentation, used in England from the 14th century (and later in Spain), was processional staging on pageant wagons. This is thought to have grown out of the elaborate Corpus Christi processions (from 1311), in which decorated carts displaying religious tableaux were used. The tradition of tournaments and the pageantry set up for royal entries also had an influence. Each play was mounted on a "pageant," or cart, often built and decorated to suggest the scene depicted. These mobile stages were paraded around the town, stopping at various stations where the actors repeated their performance in front of a group of spectators, who then waited for the next cart to appear.

Although both audience and players were united by a common faith strong enough for the actors to rehearse months in advance and for the spectators to stand all day watching the plays, the factor of entertainment became increasingly important. This was, the religious theme notwithstanding, secular theatre. It was the comic characters, especially the devils, who were most popular, and it was here that there may have been an element of professionalism, with the minstrels and jongleurs adding their own skills and brand of humour. Furthermore, once the mystery cycles had abandoned the uniformity of Latin, national differences became accentuated when local customs, idioms, and folk traditions were incorporated into the plays. In England the juxtaposition of solemnity and humour helped to flavour the spirit of the great Elizabethan theatre that was to follow.

MORALITY PLAYS

After the earthy humour and simple devotion of the mystery cycles, the morality plays that appeared during the 15th century show theatre taking what at first seems to be a step backward. These plays, however, reflect the darker worldview of a people that had experienced recurrent plagues and had begun to regard human destiny as "worm's meat," where the skeleton figure of death was a potent emblem constantly alluded to in sermons. Morality plays were virtually sermons dramatized through allegory. They portrayed the span of human life in abstract terms, with Mankind or Humanum Genus setting out on a pilgrimage in which he encountered a whole range of vices and virtues such as Ignorance, Humility, and the Seven Deadly Sins who contended for possession of his soul. The principal themes were the choice between good and evil, the transitory nature of life, and the immediacy of death, all of which reflect a medieval preoccupation with the conflict between the spirit and the flesh. Such concerns were particularly relevant at a time when trade and finance were rapidly expanding, offering merchants the prospect of great personal wealth and a life of material luxury.

The use of allegory

Morality plays probably originated in England, the earliest known text being *The Castell of Perseverance* (*c.* 1405–25). However, one of the best of the genre, *Everyman,* began in the Netherlands, and moralities were frequently performed in France. Performances initially took place in churches, then on simple outdoor stages, though without the visual extravagance that the mystery cycles demanded. Although the plots were stereotyped and the abstract characters allowed little scope for development, morality plays achieved considerable sophistication—they were intended for an educated, middle-class audience—and moved a long way toward secularization, thus forming a significant link between the medieval and the modern theatres. Nevertheless, in the 16th century, at the height of their aesthetic achievement, morality plays were suppressed in England, primarily because religious drama was beginning to become an instrument of politico-religious propaganda under successive Roman Catholic and Protestant governments.

INTERLUDES

As a development of the morality play that drew on the legacy of the minstrel, interludes (from Latin *interludium*) were performed in Europe by small companies of professional actors during the 15th and 16th centuries. The term covers a wide range of entertainment, from simple farces performed on small stages in public places to dramatic sketches performed at banquets in the halls of the nobility. In both cases the plays were purely secular and more concerned with ideas than with morals. They were called *Fastnachtsspiele* in Germany and *kluchtspelen* in the Netherlands; they were also performed in Italy and Spain, but most interludes came from France, where they were known as *soties,* and from England. These pieces usually dealt with the antics of foolish or cunning peasants, exploring the relationship between master and servant or husband and wife. In England the move toward professionalism was accelerated by a law that subjected "all players of farces, minstrels and other entertainers" to be whipped if they did not belong to a member of the nobility.

Secular character of the interludes

The Renaissance

CLASSICAL REVIVAL

By the early 15th century, artists in Italy were becoming increasingly aware that, while Rome had once been the centre of the Western world, its power and prestige had steadily declined since the invading Germanic tribes broke up the empire. The belief that art, science, and scholarship had flourished during the classical period stimulated the desire for a revival of the values of that period. Both architecture and painting found new inspiration in Greek and Roman models, and the discovery of perspective added new possibilities, which in turn were to have a profound effect on stage scenery. At the same time classical literature was reexamined: new texts were found and old ones edited. The capture of Constantinople by the Turks in 1453 resulted in an exodus of Greek scholars to Italy, and they brought with them their knowledge of Greek literature.

The invention in Europe of the printing press made the new learning more widely accessible and revolutionized the whole educational system. Increased commerce encouraged exploration, and the discovery of the Americas by Columbus in 1492 brought about a new outlook on the world. Whereas learning had traditionally been sought in the seclusion of monasteries, the new learning of the Renaissance was more widespread and dynamic. Scholars were not satisfied with merely understanding the ideals of antiquity; they wanted to re-create them. This also gave man new dignity and confidence. The world was regarded not as something to be overcome in order to have a life in the next world, but as something to be enjoyed. The spirit of the Renaissance was epitomized in the words of the Greek philosopher Protagoras: "Man is the measure of all things." Even though this humanist view sometimes clashed with Christian doctrines, the papacy reached, if somewhat reluctantly, a modus vivendi with the new learning. Indeed, the Vatican Library amassed works of classical culture from all over the Christian world. The popes and the wealthy families of Italy became patrons of the arts, gathering scholars and artists in their courts.

THE RENAISSANCE STAGE

The printed Latin texts of Terence, Plautus, and Seneca were widely read. By the end of the 15th century attempts were made to stage their works, first in Rome, sponsored by Pomponius Laetus, and then in Ferrara. At first the stages resembled classicized versions of the mansions used for mystery plays, though compressed onto a single raised

stage with curtained entrances between pillars to represent various houses. Later efforts concentrated on re-creating the form of the classical stage inside large halls.

One of the greatest influences on the development of theatre buildings in the Renaissance was the discovery in 1414 of *De architectura* of Vitruvius, a Roman architect of the 1st century. This 10-volume treatise contained valuable information on the scenery used for classical tragedy, comedy, and satyr plays, along with detailed descriptions of the Roman theatre with its auditorium, orchestra, and stage backed by the *scaenae frons.* Vitruvius' work, translated and published all over Europe, was provided with woodcuts showing ground plans and front elevations of classical stages. Various reconstructions of the Roman theatre were built, culminating in the beautiful Teatro Olimpico at Vicenza, designed by the Venetian architect Andrea Palladio and completed in 1585 by Vincenzo Scamozzi. It is Europe's oldest surviving indoor theatre. Palladio had created a magnificent *scaenae frons,* but Scamozzi added three-dimensional perspective vistas of street scenes behind the archways. It was this preoccupation with perspective that characterized future developments of the Renaissance stage and indeed the modern theatre, though the effects were usually achieved through painted backdrops and wings. Sebastiano Serlio's influential *Second livre de la perspective* (1545; *The Second Book of Architecture*), generally referred to as "Architettura," outlined three basic stage settings, suggesting an impressive arrangement of palaces and temples for tragedy, complex street scenes for comedy, and idealized landscapes with trees and cottages for pastoral plays.

The impact of Vitruvius' work

MAJOR THEATRICAL STYLES, TENDENCIES, AND FORMS

Italian Neoclassicism. Ironically, while all the innovations seemed to originate in Italy and then spread through Europe, the plays that were first performed on the new stages were extremely dull. Far from liberating the creative mind, the classical ideals had only constricted it. Partly to blame was the adoption of the so-called Aristotelian unities of time, place, and action, which became, in the hands of theorists, a set of rules so rigid that they strangled drama by forcing it into a framework where the action had to take place in a single location in the space of a single day. At a time of expansion and change, such rules only created a disharmony between form and content and between the stage and the play. A further reason was that this theatre took place inside the palaces of isolated and parochial cities in the presence of a privileged elite. Cut off from the public, lifeless tragedies and limp comedies resorted to philosophical discourse as a substitute for the passion that was meanwhile animating the theatre in England and Spain.

Significantly, the bawdy comedies of Plautus provided inspiration for two of the most interesting dramatists of the Italian Renaissance in the early 16th century. Ludovico Ariosto, a poet at the court of Ferrara, was the first to break away from the strict imitation of classical models and produce a truly Italian flavour in his work. The second figure was Ruzzante (the stage name of Angelo Beolco), who acted in his own farces about rustic life written in the Paduan dialect. Through his use of everyday situations and distinctly Italian character types, Ruzzante introduced a more natural style of acting, drawn from life and observation of people.

The intermezzi

As a relief from the severity of classical plays, intermezzi were introduced between the acts as lighthearted and spectacular diversions, usually dealing with mythological subjects. These rapidly became more popular than the plays themselves and were often performed as independent entertainments at weddings and banquets in the courts of Italian princes. As the scenic aspects of the intermezzi grew more elaborate, changeable scenery was developed, as was complicated machinery with which to mobilize clouds, waves, and sea monsters. Five basic settings were established: heaven, hell, the countryside, the sea, and a city street or square.

Courtly entertainments. During the 15th and 16th centuries, some of Italy's finest painters and musicians were employed to organize entertainments at court. Leonardo da Vinci, who designed a revolving stage in 1490 (it was never built, however), arranged the settings, masks, and costumes of *Festa del Paradiso,* an entertainment given during the wedding celebrations for Lodovico Sforza, duke of Milan. Raphael also painted much admired stage settings. Equestrian ballets and triumphal processions were a spectacular feature requiring careful preparation, and they became the highlight of these displays of power and wealth. Princes, dukes, and monarchs were invited to such festivals and rode on horseback or in ornate carriages in processions of allegorical floats. Sometimes their entrances were choreographed as they passed under specially constructed triumphal arches or towers and open stages with *tableaux vivants.* In France the *entrées solennelles*—entrance processions of great pomposity—were developed to a peak of elaborate ceremonial display. Aquatic pageantry also became popular in the 17th century, with the monarch surrounded by a collection of ornate barges, sea monsters, scallop shells, and ships.

A popular new genre among the Italian nobility in the latter half of the 16th century was the pastoral. It was a sophisticated form of entertainment dramatizing classical themes in the romantic but highly artificial setting of an Arcadian landscape peopled with gentle nymphs, shepherds, magicians, and satyrs.

Opera. One of the most enduring products of the Renaissance theatre was the opera. It grew out of experiments by the Florentine Camerata at the end of the 16th century to revive Greek tragedy. The men who formed the Florentine Camerata believed that the Greeks had originally recited or chanted their plays to music, and in setting out to recreate these conditions, the Camerata used music to heighten the poetic qualities of the dialogue. Heavily influenced by the intermezzi that were currently in fashion, the first attempts were on mythological subjects (Daphne, Orpheus, etc.). The opera was an immediate success. The novelty impact of the music meant that the libretto diminished in importance. By 1607 Claudio Monteverdi had composed his masterpiece, *Orfeo,* which placed the emphasis squarely on music and established the basic form that European opera was to take for the next 300 years.

The Florentine Camerata

At first, opera was performed on special occasions intended to display the patron's status and wealth; thus it was politically important. Great care was lavished on the visual aspects of the opera, and the librettos gave ample opportunities for scene painters and stage engineers to exploit their new mastery of perspective. As the scenery became more opulent, so the shape of the theatre was altered to accommodate it. The proscenium arch was developed to frame the setting and facilitate changes of scenery, while the auditorium was extended to a horseshoe shape. The earliest example of this type of theatre was the Teatro Farnese in Parma (1618–28), the prototype of the modern opera house. From its exclusive beginnings, the appeal of opera broadened, and in 1637 the first opera house was opened to the general public in Venice. By this time, the form had also caught on in Vienna.

Commedia dell'arte. Around the mid-16th century, there emerged in Italy a lively tradition of popular theatre that fused many disparate elements into a vigorous style, which profoundly influenced the development of European theatre. This was the legendary commedia dell'arte ("theatre of the professionals"), a nonliterary tradition that centred on the actor, as distinguished from the commedia erudita, where the writer was preeminent. Although the precise origins of the commedia dell'arte are difficult to establish, its many similarities with the skills of the medieval jongleurs, who were themselves descendants of the Roman mimes, suggest that it may have been a reawakening of the *fabula Atellana,* stimulated and coloured by social conditions in Italy during the Renaissance.

In spite of its outwardly anarchic spirit, the commedia dell'arte was a highly disciplined art requiring both virtuosity and a strong sense of ensemble playing. Its special quality came from improvisation. Working from a scenario that outlined the plot, the actors would improvise their own dialogue, striving for a balance of words and actions. Acrobatics and singing were also used, as well as the *lazzi* (special rehearsed routines that could be inserted into

Importance of improvisation

the plays at convenient points to heighten the comedy). Because the actors stayed together in permanent companies and specialized in playing the same role for most of their professional lives, they achieved a degree of mastery that had been hitherto unknown on the Italian stage and that must have made the rest of the theatre seem all the more artificial. Another reason for the impact of the commedia dell'arte was that it heralded the first appearance in Italy of professional actresses (the best known being Isabella Andreini), though the female characters were never as sharply developed as their male counterparts. Most of the characters were defined by the leather half-masks they wore (another link with the theatre of antiquity), which made them instantly recognizable. They also spoke in the dialect of their different provinces. Characters such as Pantalone, the miserly Venetian merchant; Dottore Gratiano, the pedant from Bologna; or Arlecchino, the mischievous servant from Bergamo, began as satires on Italian "types" and became the archetypes of many of the favourite characters of 17th- and 18th-century European theatre.

From humble beginnings, setting up their stages in city squares, the better troupes—notably Gelosi, Confidenti, and Fedeli—performed in palaces and became internationally famous once they traveled abroad. The commedia dell'arte swept through Europe. It was particularly popular in France, where resident Italian troupes were established before the end of the 16th century. Local variations on the characters appeared in the 17th century. The cheeky servant Pedrolino became the melancholy Pierrot in France, while Pulcinella became Punch in England. By the 18th century the commedia dell'arte was a lost art, though its spirit lived on through the work of the dramatists it inspired, among whom were Molière (stage name of Jean-Baptiste Poquelin), Carlo Goldoni, and William Shakespeare.

Jesuit theatre and school drama. A reflection of the humanist tradition in Europe was the emergence of the school drama in the second half of the 16th century. This was an amateur movement in which Latin plays were performed as part of the curriculum. Soon after the Society of Jesus was founded in 1540 to combat the heresies of the Reformation, it was realized that theatre could be an excellent means of glorifying the Roman Catholic Church and showing the evils of free thought. Consequently, the school play became an important activity in the Jesuit colleges that were established all over the Continent. While retaining both the language and techniques of the classical writers, the Jesuit dramatists turned to biblical themes and the lives of the saints and martyrs for their subject matter. Since part of the educational purpose of this type of drama was to teach pupils how to behave and express themselves in accordance with the requirements of the upper classes, tragedies were preferred to comedies, because the latter were considered unsuitable in their levity and crudeness. In spite of its severity of tone, the Jesuit theatre flourished in the 16th and 17th centuries by adapting to local customs and turning the latest theatrical innovations to its own use. Thus music and singing were incorporated in the plays, which were eventually expanded to include some of the elaborate scenic effects used in contemporary opera. The Jesuit theatre produced no plays of lasting consequence, yet princes took part in its college performances and Roman Catholic emperors attended them. Also, some of the most important dramatists of the European theatre, including Pierre Corneille, Molière, and Goldoni, were educated in Jesuit schools and may have been influenced by their theatrical activities.

Subject matter of the school drama

Although the movement did not reach England for politico-religious reasons, school plays accounted for the first secular comedies in English during the first half of the 16th century—namely, *Ralph Roister Doister* and *Gammer Gurton's Needle.* And, in 1560, Elizabeth I decreed that the scholars of Westminster School should perform a Latin play every Christmas. This practice has endured until the present day, making it perhaps the longest continuous acting tradition in Europe.

Spain's Golden Age. Because the Reformation, which divided Europe in the early 16th century, had not affected Spain, the long tradition of religious drama continued there throughout the Renaissance in the form of *autos sacramentales.* Usually one-act allegories, these plays were performed as part of the Corpus Christi celebrations in which the king participated. As the prudent Spanish clergy had purged religious drama of those elements that laid it open to ridicule in other European countries, *autos* became a serious art form cultivated by some of the finest poets of the Spanish Golden Age.

Autos sacramentales

The vigour of the secular theatre was offset by a lack of permanent playhouses. In the early 16th century, the first professional companies, like that of Lope de Rueda, had to travel about as strolling players, carrying their own equipment with them. They were so poor that, in the words of Cervantes, "their whole baggage would go into a single sack." Lope de Rueda was noted for the lively use of colloquial speech in his short comic sketches known as *pasos.* These were performed between the acts of more serious dramas. Plays were sometimes presented in palace halls, but most often they were performed in *corrales,* where an improvised stage was set up at one end of the square formed by the walls of adjoining houses.

When the first permanent theatres were built, they were not patterned on the Italian model, but rather they incorporated features of the *corrale.* The audience stood in a rectangular courtyard (*patio*) or sat in galleries, with the women having to sit apart in a special gallery of their own. The stage stretched across one end of the square with an inner stage at the back. Very little scenery was used, though there were trapdoors in the floor and machinery above for "flying" people or objects. The theatre was open to the sky, but an awning could be drawn over the audience to provide protection against sunlight and rain. It was a stage well adapted for rhetoric and poetry, where the imagination of the audience could be stimulated. Furthermore, it was a theatre for all social classes. By the end of the 16th century, permanent theatres were established in Seville, Valencia, and Madrid, where two of the first were the Corral de la Cruz (1579) and the Corral del Príncipe (1582). In addition to the main play, programs included short comic sketches, musical interludes, ballads, and dances.

The strength of the Spanish theatre of the Golden Age was that, while embracing some of the Italian innovations in staging and acting (commedia dell'arte troupes exerted a strong influence in Spain from 1574), it was never restrained by the rules of Classicism. Instead, it developed a robust national style that was passionate, romantic, and lyrical and that could weave together comedy and tragedy in a way that was never possible in Italy or France. This style found rich expression in the work of Lope de Vega. His prodigious output of more than 1,000 plays, about 400 of which survive, gives an idea of the audience's insatiable demand for new works. Drawing on a wide variety of materials for tragedies, comedies, pastorals, histories, and the distinctly Spanish genre of *comedias de capa y espada* (cloak-and-dagger plays), Lope portrayed a rigid society divided into three estates: the king, the nobles, and the common people. Entertainment was his first concern, and his depiction of peasant characters, both comic and tragic, was particularly vivid.

The dramas of Lope de Vega and Calderón de la Barca

In the first half of the 17th century the Baroque style of theatre, with its elaborate scenery and stage machinery, was used to great advantage by Pedro Calderón de la Barca. Attached to the Spanish court, he was not under as much pressure as Lope to be prolifically inventive, yet he wrote nearly 200 plays. While lacking the sheer vigour of Lope's works, Calderón's plays are more refined and philosophical, even though many of his characters appear to be rigidly bound by the idea of the *pundonor* ("point of honour"). In later life, Calderón wrote many fine *autos sacramentales* and other plays on religious themes. The idea that "all the world is a stage" was expressed in *El gran teatro del mundo* (*c.* 1635; *The Great Theatre of the World*) through the hierarchical concept that every man plays his part before God. This theme was also reflected in Calderón's finest play, *La vida es sueño* (1635; *Life Is a Dream*).

Elizabethan and Jacobean theatre. In England the influence of the Italian Renaissance was weaker, but the

theatre of the Elizabethan Age was all the stronger for it. Apart from the rediscovery of classical culture, the 16th century in England was a time for developing a new sense of national identity, necessitated by the establishment of a national church. Furthermore, because the English were more suspicious of Rome and the Latin tradition, there was less imitation of classical dramatic forms and an almost complete disregard for the rules that bound the theatre in France and Italy. England built on its own foundations by adapting the strong native tradition of medieval religious drama to serve a more secular purpose. When some of the continental innovations were blended with this cruder indigenous strain, a rich synthesis was produced. Consequently, the theatre that emerged was resonant, varied, and in touch with all segments of society. It included the high seriousness of morality plays, the sweep of chronicle histories, the fantasy of romantic comedies, and the irreverent fun of the interludes.

Basic characteristics

At the same time, the theatre had to contend with severe restrictions. The suppression of the festival of Corpus Christi in 1548 as a means of reinforcing the Protestant Church marked the rapid decline of morality plays and mystery cycles. Their forced descent into satirical propaganda mocking the Catholic faith polarized the audience and led to riots. By 1590, playwrights were prohibited from dramatizing religious issues and had to resort to history, mythology, allegory, or allusion in order to say anything about contemporary society. Flouting these restrictions meant imprisonment. Nevertheless, playwrights managed to argue highly explosive political topics. In Shakespeare's histories, for instance, the subject of kingship is thoroughly examined in all its implications: both the rightful but incompetent sovereign and the usurping but strong monarch are scrutinized—a most daring undertaking during the reign of Elizabeth I (1558–1603). The situation for actors was not helped by the hostile attitude of the City of London authorities, who regarded theatre as an immoral pastime to be discouraged rather than tolerated. Professional companies, however, were invited to perform at court from the beginning of the 16th century (though on a smaller scale than on the Continent), and public performances took place wherever a suitable space could be found—in large rooms of inns, in halls, or in quiet innyards enclosed on all sides with a temporary platform stage around which spectators could gather while others looked out from the windows above. But such makeshift conditions only retarded the development of the drama and kept it on an amateurish level.

The Elizabethan theatre. These conditions were considerably improved during Elizabeth's reign by the legitimizing in 1574 of regular weekday performances and the building of the first playhouse in 1576 by James Burbage. Called simply the Theatre, it was erected in London immediately outside the City boundary. Others followed, including the Curtain, the Rose, the Swan, and the Globe, where most of Shakespeare's plays were first staged. Just as the Spanish playhouse reproduced the features of the *corrale* it had grown out of, so the Elizabethan playhouse followed the pattern of the improvised innyard theatre. It was an enclosed circular structure containing two or three galleries with benches or stools and had an unroofed space in the middle where spectators could stand on three sides of the raised platform stage. Behind the stage was a wall with curtained doors and, above this, an actors' and musicians' gallery. Large numbers of people could be accommodated, and the price was kept low at between one penny and sixpence. This type of stage allowed for fluid movement and considerable intimacy between actors and audience, while its lack of scenery placed the emphasis firmly on the actor interpreting the playwright's words. Such sheer simplicity presented a superb challenge for the writer: the quality of both language and acting had to be good enough to hold the attention of the spectators and make them use their imaginations.

This challenge was quickly taken up by a generation of playwrights who could carry forward the established dramatic forms and test the possibilities of the new stage. Christopher Marlowe was the major innovator, developing a vigorous style of tragedy that was refined by his contemporary, William Shakespeare, who began writing for the theatre about 1590. At this time, professional companies operated under the patronage of a member of the nobility. In Shakespeare's company, the Chamberlain's Men (later renamed the King's Men), the actors owned their playhouse, prompt books, costumes, and properties, and they shared in the profits. Other companies paid rent to the patron and received salaries from him. There were very few rehearsals for a new play, and because the texts were not immediately printed (to avoid pirating by rival companies) each actor was usually given only his own lines, with the relevant cues, in manuscript form. No women appeared on the Elizabethan stage; female roles were taken either by boy actors or, in the case of older women, by adult male comedians. As in Italy, all the actors had to be able to sing and dance and often to make their own music. The great actors of the day were Richard Burbage, who worked in Shakespeare's company, and Edward Alleyn, who was mainly associated with Ben Jonson. In spite of the fact that theatres such as the Globe played to a cross section of London's populace, audiences seem to have been attentive and well behaved.

Professional companies

An alternative to the outdoor public playhouse was the private indoor theatre. The first of these was an abandoned monastery near St. Paul's Cathedral, converted in 1576 by Richard Farrant and renamed the Blackfriars Theatre. Others included the Cockpit, the Salisbury Court, and the Whitefriars. Initially these theatres were closer to the Spanish model, with the bare stage across one end, an inner stage at the back, benches in front for the audience, and galleries all around. Later, they made use of more elaborate scenery and featured the Italian-style proscenium arch. Because of the reduced size of the audience, higher prices had to be charged, which excluded all but the more wealthy and learned segment of the public. This in turn affected the style of writing; these private theatres were mostly used by boy companies that presented a more refined and artificial type of drama. One of their chief dramatists was John Lyly, though Ben Jonson wrote many of his plays for them. Growing rivalry between the boy and adult companies, exacerbated by hostility from the increasingly powerful Puritan movement, resulted in James I imposing even tighter controls and exercising heavy censorship on the theatre when he came to the throne in 1603.

Jacobean theatre. Although the Italian influence gradually became stronger in the early part of the 17th century, the English theatre was by then established and confident enough to take over foreign ideas without losing any of its individuality. Jonson became increasingly preoccupied with the dramatic unities, while other writers of the Jacobean period such as John Webster, Thomas Middleton, and John Ford favoured a more definite separation of comedy and tragedy than had been the case in Elizabethan drama. They were given to sensationalism in their revenge plays, finding inspiration in the darker moods of Seneca and often setting them in Italy.

New trends

Meanwhile, at court the pastoral was finding new popularity, partly because it provided opportunities for spectacular scenery, and with it came the revival of the masque—a sumptuous allegorical entertainment combining poetry, music, dance, scenery, and extravagant costumes. As court poet, Ben Jonson collaborated with the architect and designer Inigo Jones to produce some of the finest examples of the masque. Having spent a few years in Italy, Jones was greatly influenced by the Italian painted scenery and its use of machinery. On his return to England he did much to bring scenic design up to date, introducing many innovations. Members of the court had thorough training in dancing, fencing, singing, instrumental music, and courtly ceremonial. They were therefore well prepared to perform in the masques, even to take solo parts and to appear in the chorus. Masques became even more elaborate under Charles I, but in 1634 Jonson angrily withdrew his contribution when he saw that the visual elements were completely overtaking the dramatic content. When the Civil War broke out in 1642, the Puritans closed all the theatres and forbade dramatic performances of any kind. This created an almost complete break in the acting

tradition for 18 years until the Restoration of Charles II, after which the theatre flourished once more, though on quite different lines.

German theatre. While England and Spain were developing their own national styles of theatre, the German-speaking countries lagged well behind, embroiled in constant warfare and religious upheaval and lacking a unifying capital city as a cultural focal point. Classical plays had little more than academic interest, and the tradition remained indigenous albeit crudely medieval. The most notable writer was the Meistersinger Hans Sachs, who transformed the bawdy *Fastnachtsspiele* into more acceptable farces with which to entertain Shrovetide carnival crowds. He also established Germany's first theatre building inside a church in Nürnberg in 1550, though there were no truly professional companies to fill it.

Traveling troupes in Germany

An unexpected stimulus came from touring English troupes that had firmly established themselves in Germany by the end of the 16th century. Although there was a good deal of cross-fertilization between England and the Continent, many English actors chose exile as an escape from monopolies, suppression, and the withdrawal of playing licenses at home. They gave public performances in towns or at rural fairs and private ones in the halls of nobles. Robert Browne's company was the first, arriving in Frankfurt in 1592. In a country where local theatre was weighed down by excessive moralizing, these actors made an immediate impact through their robustness and vivid professionalism. Their repertoire consisted mainly of pirated versions of Elizabethan tragedies and comedies, performed in English, though heavily cut and padded with enough music, dancing, acrobatics, and dumb show to overcome the language barrier. In between the acts a clown figure, combining the English fool and the German *Narr* (from the *Fastnachtsspiel*), took over with improvised antics in pidgin English sprinkled with Dutch and German phrases. Thomas Sackville created one of the first of such clown figures in the character Jan Bouschet. Similar English creations were Hans Stockfisch and Pickelherring—prototypes of the totally German character Hanswurst, who found his way into all the improvised comedies of the day. As the proportion of German actors in the English companies increased, a more indigenous drama developed known as *Haupt-und-Staatsaktionen.* As this term implies, such plays dealt with the intrigues of high characters in high places and abounded with blustering rhetoric and gory sensationalism. The last English troupes left Germany in 1659, by which time the Italian style of staging, with its perspective scenery, had become the fashion in spectacular court operas and the elaborate productions of Jesuit school plays (see above).

Dutch strolling players also visited Germany, performing *vertoonige* ("living tableaux") and contemporary plays, Spanish drama being much favoured. Italian traveling players presented puppet theatre in Austria and southern Germany as an offshoot of the commedia dell'arte, which itself was widely imitated, particularly in Austria. While the strolling players did little to elevate German theatre to the level of the highest art, they did at least establish vital links with neighbouring European cultures, helping to inject new ideas into backward traditions and precipitating the emergence of the professional actor.

French Neoclassicism. Theatre companies in France in the early 16th century were playing a mixed fare of moralities, miracle plays, farces, and soties. The most important company was an amateur guild called the Confrérie de la Passion, which held a monopoly on acting in Paris. In 1548 it opened its own theatre, the Hôtel de Bourgogne, a long narrow room with the stage filling one end, a pit for standing spectators, and two galleries around the walls. Both auditorium and stage were lit by candles. Soon after the theatre opened, the Confrérie was forbidden by decree to perform religious plays for fear that they could be used to debase Roman Catholicism. The feeble traditions of indigenous secular drama in its repertoire were soon overpowered by the Renaissance influence, and dramatists began looking to classical antiquity for inspiration. Civil war, however, halted the appearance of any truly great drama until well into the 17th century. The new plays that appeared in Paris—mainly pastorals and tragicomedies—were written by classical scholars as imitations of the Italian commedia erudita, but the French love of order resulted in the intensification of the dramatic unities of time, place, and action. The first fully professional company, which included women, was that of Valleran-Lecomte; it took over the Hôtel de Bourgogne toward the end of the century, performing its plays on the medieval-style multiple setting stage. The acting in these Neoclassical plays was not given to realism: each actor stood at the front of the stage to declaim his lines and then stepped back to allow the next actor to speak.

National unity came in the early 17th century under Louis XIII and his brilliant adviser, the cardinal de Richelieu, and with unity came the desire (similar to that in Tudor England) to create a strong national culture. Theatre companies were active in the provinces, but Paris, the centre of cultural life, was the goal for which they all aimed. In 1634 the Théâtre du Marais was opened in an indoor tennis court, and in 1641 Richelieu built his own Italian-style theatre (complete with all the latest machinery), which after his death became the Théâtre du Palais-Royal. Richelieu, who took an active interest in theatre, had also tried to purify comedy and tragedy by discouraging what he considered the formless tragicomedy. His efforts, however, were thrown into confusion by the arrival of the first French play of any real worth, Pierre Corneille's *Le Cid* (1637), a tragicomedy that ignored the revered unities. Working smoothly within the rules, Corneille's rival, Jean Racine, took French Neoclassical drama to its greatest heights with his nine tragedies, of which *Phèdre* (1677) is regarded as the pinnacle.

The art of Molière

Both Racine and Corneille were overshadowed by Molière, who is considered the world's greatest comic dramatist. After 13 years of touring France with his company, the Illustre-Théâtre, Molière was accepted at the court of Louis XIV in 1658 and began to elevate the crude farce to the level of sophisticated social comedy, placing it on a par with tragedy. For several years he shared the Petit-Bourbon theatre with a troupe of commedia dell'arte actors led by Tiberio Fiorillo and was much influenced by their realistic style of playing. Later he moved to the Palais-Royal. Far from imitating foreign plays, Molière created distinctly French characters based on an acute observation of social manners. After Molière's death, Louis XIV amalgamated the Illustre-Théâtre with two other companies in 1680 to form Europe's first national theatre, the Comédie-Française, which continues to further the cultural aims of France to the present day.

Spread of national theatres. In the course of the succeeding centuries, national theatres were established in many other European countries but not necessarily for the same reasons. German national theatres fought to shake off the infiltration of French culture and to develop native traditions. It was the aim of the Austrian emperor Joseph II to institute national theatres for all the peoples of his empire so that they might become acquainted with the works of world literature in their own tongue. After establishing a national theatre for the German-speaking population of Austria, Joseph II then supported the Czechs and Slovaks in their efforts toward their own national theatre. Later, one was founded in Budapest for the Hungarians. Gustav II created the Swedish national theatre. Catherine the Great of Russia also set out to introduce her people to the dramatic works of world literature performed in the Russian language.

There was no court theatre in the Netherlands. The performances of plays and the organization of theatre festivals had, since the 15th century, been in the hands of the *Rederijkerskamers*—societies of amateur enthusiasts similar to the French *confréries.* The plays—both serious religious pieces and farces—were usually presented outdoors on a raised platform with a curtained facade. The curtain could be closed for scene changes, though the settings themselves were very simple. In 1617 the first Dutch Academy was opened, and one of its priorities was to foster a higher standard of theatre developing at the time under a strong French influence. This eventually led to the construction of the first indoor theatre in Amsterdam, the Schouwburg.

It opened with *Gysbrecht van Aemstel* (1638), a patriotic play in the classical tradition by the Netherlands' major dramatist, Joost van den Vondel. The Schouwburg, which had a semipermanent setting, was remodeled in 1665 along Italian lines, though this did nothing to stem the general decline in Dutch drama.

Ballet and opera-ballet. If there was a lack of great theatre in France before Corneille, it was well compensated for by extravagant court ceremonials in which dance featured prominently. These reached a high level of sophistication in the later 16th century, stimulated by the presence of Italian dancing masters invited to the French court by Catherine de Médicis. A product of this collaboration was the *ballet comique,* a courtly dance entertainment with words. Another Italian import was changeable-perspective scenery, which was brought to Paris in 1645 by the designer Giacomo Torelli, who completely refurbished the Petit-Bourbon. The staging of court ballets was accordingly adapted to show off the possibilities of the new machinery. Louis XIV often took part in these and earned the title Le Roi Soleil (The Sun King) when he performed as the Sun in *Le Ballet de la nuit* in 1653. Molière was called upon to provide texts for elaborate court festivities at Versailles involving ballets, plays, fireworks displays, and theatrical banquets.

Louis XIV also organized the teaching and presentation of music and dance by setting up academies. The Académie Royal de Musique (1669) was officially given the exclusive right to present operas, which led to a new genre, the opera-ballet, initiated by the composer Jean-Baptiste Lully, which combined vocal scenes with danced interludes. Following the developments in Italian opera, composers made new demands on singers, who had to study for years in order to be able to meet them successfully. After the mid-17th century, singers exerted considerable influence on the structure of new works because they demanded showpiece arias at certain places in the text. The dramatic technique of Baroque opera followed set rules: arias were to be sung at the front of the stage, facing the audience; the chorus was directed as a static body; and the ornate setting was an elaborate decoration with which to please the eye rather than a functional definition of the acting area. One effect of the academies was to transfer dance activities from the court to the professional stage, and in 1681 the first professional dancers appeared in *Le Triomphe de l'amour* (*The Triumph of Love*), choreographed by Charles-Louis Beauchamp to Lully's music.

The opera-ballet of Jean-Baptiste Lully

Restoration theatre. One of the first gestures of Charles II upon his Restoration in 1660 was to reverse Puritan sobriety by encouraging the kind of entertainment and theatrical activities that he had seen during his years of exile at the French court. Within months of his return to London he granted royal patents to Thomas Killigrew and Sir William Davenant to establish two theatre companies, the King's Players and the Duke's Players, respectively. Significantly, they chose to follow the French example and convert two indoor tennis courts as temporary premises rather than take over one of the surviving Elizabethan playhouses. In 1671 Sir Christopher Wren built the Duke's Theatre, Dorset Garden, for Davenant, and three years later he built the first Theatre Royal, Drury Lane, for Killigrew. These theatres combined continental innovations with some of the features of the Elizabethan stage. A curved "apron" stage extended beyond the proscenium arch from which entrance doors opened, indicating that most of the action was played toward the front of the stage with the scenery as a mere background. Stock sets of changeable flats were used, and lighting was provided by candles. The greatest impact, however, came from the introduction of actresses to the English stage, the most famous being Nell Gwyn.

The first productions were reworkings of Elizabethan and Jacobean plays, tailored to suit the tastes of the new aristocratic audience composed almost exclusively of courtiers and their attendants. (The majority of the populace, still under the influence of Puritanism, stayed away and probably could not have afforded it anyway.) Values had changed since Shakespeare's day: the new audience consisted of fashionable young cynics and dilettantes, self-indulgent rakes and wits who prized glittering conversation and were interested only in seeing themselves on stage, however satirical the portrait. Thus came about the bawdy comedy of manners, heavily influenced by Molière but chilled with the dry wit of the London aristocracy. Romance and feeling gave way to intellect in sophisticated plays about cuckoldry, gossip, intrigue, and sexual license, yet tempered with a strong sense of decorum. Although most dramatists of the time did not consider themselves professional writers, George Etherege and William Wycherley developed an elegant style of prose drama that was refined by Sir John Vanbrugh and later William Congreve, whose *Way of the World* (1700) is the finest example of Restoration comedy. At the beginning of the 18th century there was a softening of cynicism in the comedies of George Farquhar, which brought the period to a close.

Comedy of manners

As the late 17th century was not a heroic age, tragedy fared less well in England. The poet John Dryden tried unsuccessfully to combine the merits of Racine and Shakespeare in a genre of rhymed heroic tragedy. His blank-verse tragedy *All for Love* (1677) was more lasting. The weakness of Restoration theatre was that, by concentrating on its aristocratic audience, it excluded most of the populace and was therefore not representative of the various levels of English society. Not surprisingly, the theatre was always struggling to survive, and after the 1670s audiences dwindled. In 1682 the King's Players and the Duke's Players merged to form the United Company, and for 13 years London supported only one theatre.

The rise of a middle-class theatre

THE 18TH CENTURY

A general decline in the level of playwriting during the 18th century was offset in large part by the emergence of some excellent actors and the building of hundreds of theatres throughout Europe. A new audience also emerged at this time. Inflation and the studied carelessness of the aristocracy had left many noble families impoverished, while middle-class merchants and financiers prospered. Intermarriage became a necessity for the nobility and a means of increasing social status for the middle class, whose members constituted the greater part of the new theatregoing public. Eager to enjoy its hard-won privileges but at the same time unable to cultivate the same tastes as the nobility, the middle class demanded something less artificial and formal than the theatre of the late 17th century—something more realistic and genteel. This audience was not prepared to labour over aesthetic subtleties; it wanted sensation.

Middle-class drama. In France, there was no one to carry forward the genius of Racine, and Neoclassical tragedy gave way to the *drame bourgeois* of Denis Diderot, whose moralizing domestic plays made a heavy appeal to the emotions. Voltaire, however, managed to sustain the form of Racine while widening the content to include historical subjects, sometimes exploiting the exoticism of Eastern settings in plays such as *Zaïre* (1732). Voltaire was fortunate to have some of the greatest actors of the period appear in his plays, among them Henri-Louis Lekain. In England George Lillo made tragedy more domestic by using middle-class characters in *The London Merchant* (1731). His example was followed in Germany by Gotthold Ephraim Lessing in *Miss Sara Sampson* (1755), an attempt to shake off French Neoclassical influence and produce a truly German genre—the *bürgerliches Trauerspiel* ("middle-class tragedy"). A similar attempt to be rid of the delicacy of Racine came from the Italian dramatist Count Vittorio Alfieri. In plays such as *Oreste* (1778), he went back to the Greeks for inspiration, filling the old stories with strong passions.

The domestic tragedies of Lillo and Lessing

A more accessible genre for conveying high tragic sentiment was the opera. Kings and princes in nearly every European country built court theatres to house it, and when the composition of the audience widened, huge opera houses were constructed. Milan's Teatro alla Scala (1778), for example, seated more than 2,000 people. Notwithstanding national variations—Henry Purcell and George Frideric Handel in England, Christoph Gluck and

Wolfgang Amadeus Mozart in the Germanic countries—opera remained essentially Italian. The Bibiena family of Bologna reigned as the supreme masters of scenic design, exerting influence throughout Europe. The family's most famous innovation was the *scena per angola,* in which the lines of perspective seem to move to vanishing points on either side of the scene rather than in the centre of the scene. The comic side of opera was expressed in the French *opéra-comique* and the Italian *opera buffa,* in which there was more balance between the music and the libretto. This was particularly the case in the popular English ballad opera, which was more like a play with songs. The best known example of English ballad opera is John Gay's *Beggar's Opera* (1728).

Smaller playhouses also abounded to accommodate the growing number of plays. At the beginning of the century, Paris had three theatres, but by 1791 there were 51. The growth of playhouses in London was discouraged by the Licensing Act of 1737, which gave the lord chamberlain extensive powers to censor all plays and to uphold the monopoly of the two patent theatres in London. Theatre managers, however, found a way around this by filling out their programs with musical items. (Similar laws in Paris were evaded by unlicensed actors who played in *forains,* the illegal theatres of the fairgrounds.) Outside London, the spread of theatres royal in provincial towns gave new importance to the touring circuits, which became valuable training grounds for young actors. It was in this way that the century's greatest actor, David Garrick, gained his early experience. In both tragedy and comedy, Garrick developed a more natural style of acting that became widely influential. As manager of the Drury Lane Theatre, he introduced concealed stage lighting and stopped the practice of spectators sitting on the stage. (Voltaire did the same in France.) It is interesting to note that at a time when Garrick was buried in Westminster Abbey, French actors, under penalty of excommunication, still had to be buried in unconsecrated ground.

Some of the most important dramatic contributions in the 18th century were in the field of comedy. Dominated at first by the tearful comedies of Colley Cibber and Sir Richard Steele in England and the *comédie larmoyante* of Nivelle de La Chaussée in France, the form spluttered to life as a reaction against sentimental drama. Oliver Goldsmith evoked the Elizabethan mood and signaled a return to hearty laughter in *She Stoops to Conquer* (1773); Richard Brinsley Sheridan tried to revive the comedy of manners in *The School for Scandal* (1777).

In France and Italy, the most interesting developments were literary applications of the commedia dell'arte. Banished by Louis XIV, the Italian actors were back in 1716 under the name Comédie-Italienne. This time they softened their style to suit prevailing taste and found a sympathetic writer in Pierre Marivaux, who developed a more refined expression of the commedia dell'arte spirit.

Goldoni and Gozzi

In Italy, where the commedia dell'arte was already becoming lifeless, two rival playwrights, Carlo Goldoni and Carlo Gozzi, tried to reform it in different ways. Goldoni replaced the improvised dialogue with fully written texts, and, although he achieved popularity with *Il servitore di due padrone* (*c.* 1745; *The Servant of Two Masters*), he faced bitter opposition from the profession. Gozzi, on the other hand, allowed his actors plenty of opportunity for improvisation. He mixed fairy-tale fantasy and realism in a type of play he called *fiabe,* the best known example being *L'amore delle tre melarance* (1761; *The Love for Three Oranges*). Comedy reached an exuberant peak in two plays by the French dramatist Pierre-Augustin Caron de Beaumarchais: *Le Barbier de Séville* (1775; *The Barber of Seville*) and *Le Mariage de Figaro* (1784; *The Marriage of Figaro*).

A curious offshoot of the commedia dell'arte in England was introduced in 1717 by the actor John Rich. Under the stage name of Lun, he played Harlequin in a new form he called pantomime. The entertainment began with a familiar story or classical legend in verse, then the characters were transformed into commedia dell'arte figures for the harlequinade in which their tricks and adventures were mimed to music. Rich produced a pantomime annually until 1760. The form continued after him and became even more popular in the 19th century.

Beginnings of American theatre. The strongly Puritan sentiments of settlers in North America prohibited the development of theatre until the early 18th century when a number of English actors arrived in the South and began staging plays in temporary venues. The first theatres were built in Williamsburg, Va. (*c.* 1716), and Charleston, S.C. (1730). By the mid-1730s a number of theatres had opened in New York, and the first visiting company from London performed in Williamsburg in 1752. In the absence of any local dramatists, the repertoire in America consisted mainly of successes from the London stage. After independence (1782), several of the new states tried to prohibit theatrical performances on moral grounds. To combat this, one touring company announced its presentation of Shakespeare's *Othello* as "a moral dialogue in five acts." By the end of the century, however, professional theatre was well established and such groups as the American Company were giving regular seasons.

First theatres in British colonial America

THE ROMANTIC THEATRE

The last decades of the 18th century were characterized by a breakaway from the cool reason of Neoclassicism and an urge to reassert freedom and national consciousness. The French and American revolutions were the most notable consequences of this, but there were stirrings throughout Europe. The theatre became an important means of arousing patriotic fervour, a function that was to continue well into the 19th century. At the same time, the doors were opened to the lower classes, who swelled the audience and imposed their own tastes on the theatre. More and more playhouses were built to accommodate the demand.

A spirit of Romanticism swept through all the arts. In the theatre, formalized rules were cast aside to allow for much more individualistic and passionate expression. The emphasis on detail, as opposed to the Neoclassical preoccupation with the general and representative, led toward naturalism on the one hand and a drama of the subjective imagination on the other. Almost every major poet turned his hand to writing plays. The source of inspiration for them all was Shakespeare, who enjoyed a new wave of appreciation in numerous translations and productions all over Europe.

The English poets, among them Lord Byron, John Keats and Percy Bysshe Shelley, failed in their attempts to create a drama that suited prevailing tastes, partly because they were not prepared to descend to a level that they considered vulgar and partly because they were overshadowed by the weight of their own dramatic heritage, having very little to add to it. By contrast, the influence of Shakespeare in Germany proved liberating. The breakaway from French Neoclassical drama, which had been heralded by Lessing in the 1760s, found full expression in the Sturm und Drang (Storm and Stress) movement that began with Johann Wolfgang von Goethe's tempestuous first play, *Götz von Berlichingen* (1773; Eng. trans., *Götz von Berlichingen*). Its medieval theme led to a wave of historical writing and "gothicism" (a preoccupation with an idealized and melodramatic past that later became especially popular in England) and with it a new interest in the visual aspects of theatre production. The greatest exponent of the genre was Friedrich von Schiller, whose first play, *Die Räuber* (1781; *The Robbers*), left audiences stunned. Goethe and Schiller were both involved with the court theatre at Weimar. When Goethe, as director of the theatre, saw that the Sturm und Drang movement was leading to excess and absurdity, he reverted to a more Classical style of theatre. Heinrich von Kleist, best known for his play *Prinz Friedrich von Homburg* (1821; *The Prince of Homburg*), is considered by some the only dramatist of real merit at the time.

The Sturm und Drang

Melodrama. The reduction of Schiller's poetic style of Romanticism to a level of popular entertainment for unsophisticated audiences resulted in the melodrama that, in spite of its lack of literary merit, became one of the most popular forms of the 19th century. For example, August von Kotzebue, whose work Goethe was reluctantly forced to stage at Weimar, wrote more than 200 melo-

Influence of Kotzebue and Pixérécourt

dramas and exerted an enormous influence in England and France. The French dramatist Guilbert de Pixérécourt also enjoyed wide popularity. His play *Coelina, ou l'enfant du mystère* (1800) was translated into English (without acknowledgement) by Thomas Holcroft as *A Tale of Mystery* and became in 1802 the very first melodrama to be seen in England.

Both Kotzebue and Pixérécourt used a great variety of subjects with historical and exotic locations. They took every opportunity to incorporate sensational or terrifying effects, such as floods, fires, and earthquakes, and made use of live animals on stage. In their works, characters tended to be stock types and words became secondary to lively action. Much of the dialogue was accompanied by incidental music in an effort to heighten emotional impact. Even the best actors of the day, including John Philip Kemble and his sister Sarah Siddons, were compelled to appear in melodramas as an alternative to Shakespeare.

The early 19th century. While Shakespearean tragedy remained the main inspiration for serious Romantic drama in Russia, Poland, Hungary, and the Scandinavian countries during the early 19th century, little of true merit was produced. After the French Revolution had settled, Napoleon reconstituted the Comédie-Française in 1799 under the actor François-Joseph Talma, who introduced many reforms and encouraged a less declamatory style of speech. In England, after a triumphant debut at Drury Lane in 1814 as Shylock in Shakespeare's *Merchant of Venice,* Edmund Kean went on to become the greatest actor of the age, specializing in classic villain roles.

The most influential contributions, however, were in the field of popular theatre. Joseph Grimaldi created the much loved clown character in the harlequinade section of the English pantomime, appearing annually at Covent Garden until his retirement in 1823. At about this time, Jean-Gaspard Deburau rekindled interest in the art of mime through his portrayals of the white-faced Pierrot at the Théâtre des Funambules in Paris. Both men became living legends.

A strain of fantastic comedy, influenced by Gozzi in its juxtaposition of the fairy-tale world and reality, was developed in Germany and Austria in the plays of Johann Nestroy and Ferdinand Raimund. In England this found expression in the extravaganza (similar in spirit to the pantomime) mainly through the fairy plays of J.R. Planché. His example was followed later in the century by Sir W.S. Gilbert, who became famous for the satirical operettas he wrote with Sir Arthur Sullivan, notable among which was *Iolanthe* (1882). The English burlesque (a more satirical version of the extravaganza) and the *burletta* (a farce with songs) were also popular forms of the time, as was their French counterpart, the vaudeville, which paved the way for the operetta.

Rise in the number of theatres. A sharp increase in the number of theatre buildings matched the rapid growth in urban development. During the London winter season of 1807, for example, only 10 theatres were operating; by 1870 there were 30. Drury Lane was rebuilt on a huge scale in 1794, designed to seat 3,600 people. This made audiences difficult for actors to control, and naturalistic acting became almost impossible. Most of the new theatres, however, were much smaller.

In 1803 London's Lyceum Theatre substituted gas for candles and oil lamps as a source of illumination, and other theatres were quick to follow suit. This meant that the brightness of light on stage could be controlled to a degree never before known. The disadvantages, however, were an appalling smell and a greatly increased danger of fire from the naked jets of flame. Faced with the prospect of a much wider theatregoing public, theatres became more specialized, catering to particular classes and their corresponding tastes. For middle-class audiences, changes in the auditoriums of European public theatres brought about greater comfort and respectability, with the result that spectators became quieter during the performance. In England, for example, soft seats were installed in the pit by the late 1820s. Galleries with their open boxes were divided into closed boxes near the proscenium arch, allowing for privacy, with the rest of the gallery open and known as the "dress circle." For the poorer sections of the English populace, there were the small "penny theatres" (of which more than 80 existed in London during the 1830s), where patrons paid a penny to see short, crudely mounted productions. Some individuals began to exploit their special talents as singers, dancers, mimics, and jugglers, giving solo performances in ale houses and taverns. These forms of entertainment became so popular that a great chain of provincial and metropolitan theatres sprang up from the music room annex of the public saloon during the second half of the 19th century. In England these forms came to be known as music hall and in the United States as vaudeville.

Romantic realism. The visit to Paris of an English Shakespearean company in 1827 had an immediate effect on French drama and acting techniques, inspiring Victor Hugo to write *Hernani* (1830), which signaled the beginning of a more distinctly literary Romanticism in France. Although this play eventually put an end to Neoclassicism, its first performance caused riots in the Comédie-Française. Historical dramas with a strong nationalist spirit began appearing in nearly every country, finding particularly stirring expression in the opera. In Germany Richard Wagner worked to create a more unified presentation of poetry, music, dance, and scenery in historical and mythic operas such as *Die Meistersinger von Nürnberg* (1868; *The Mastersingers of Nuremburg*), culminating in the first full production of the mighty *Ring des Nibelungen* (1869–76; *The Ring of the Nibelungen*) in the specially constructed Bayreuth Festspielhaus. This theatre, which departed from the Baroque opera house, set a pattern of theatre production that is still followed today: its fan-shaped auditorium was the first to be darkened during the performance to encourage the sharpest concentration on what was happening on stage. Opera of a different style reached a peak in Italy through the works of Guiseppe Verdi.

Popularity of historical dramas and historical operas

The main trend in Europe around the middle of the century was toward Romantic realism and the development of a theatre of ideas. It was at this time that the Russian theatre began to take on new life in Nikolay Gogol's biting satire *Revizor* (1836; *The Inspector General*) and with more delicate comic realism in the plays of Aleksandr Nikolayevich Ostrovsky and Ivan Turgenev. Edward George Bulwer-Lytton wrote one of the first English plays on a contemporary theme (*Money* [1840]), and the Irish writer and actor Dion Boucicault, best known for *London Assurance* (1841), had great success in both London and New York City with his melodramas. It was Boucicault who helped to establish author's copyright in the United States (1856) after he became the first dramatist in Britain to receive a royalty payment for his plays. Lord Lytton gave his name to the Act of 1833, which established author's performance copyright in England.

Eugène Scribe dominated the French stage with his 400 "well-made plays" through which he developed a formula for creating highly commercial theatre wherein plot rather than character was the main concern. Eugène Labiche carried such techniques into farce, and another Scribe disciple, Victorien Sardou, became the leading French dramatist of the second half of the century. In spite of the shallowness of his plays, Sardou provided some memorable roles for the great French actress Sarah Bernhardt. A more serious type of drama, developed by Alexandre Dumas *fils,* was the thesis play (also called problem play), in which social problems were debated.

The French "well-made play"

The actor-manager. If contemporary plays were of a poor standard, the deficiency was partly hidden by flamboyant productions and bravura performances by star actors, many of whom managed their own companies. The 19th century was the heyday of the actor-manager. Star, licensee of the theatre, and arranger of the performance, he dominated the forestage while his fellow actors were relegated to the background as a sort of mobile dressing.

Although the actor-managers chose plays for good acting parts rather than for their dramatic value, they introduced many reforms. In England William Charles Macready, one of the great tragedians of the century, was among the first to introduce full rehearsals for his company. After the monopoly of the patent theatres was removed in 1843,

Samuel Phelps staged nearly all of Shakespeare's plays at Sadler's Wells, including many of the lesser known ones. The greatest actor-manager was Henry Irving, who first made his name in a melodrama by Leopold Lewis called *The Bells* (1871). Although he devoted much time to touring, the Lyceum became London's principal theatre under his management. Irving also helped to raise the status of actors, becoming in 1895 the first English actor to be knighted.

Because of the technical difficulties of manipulating complicated scenic effects (*e.g.,* storms, forest fires, and earthquakes), the star actor was eventually obliged to hand over artistic control to a neutral observer, the stage manager, who could coordinate all aspects of the production. Thus the stage manager's function became increasingly important until he was eventually elevated to the status of *régisseur,* or director.

Movement toward realism. The Romantic movement at the beginning of the 19th century had stimulated an interest in historical plays, which in turn gave rise to an almost obsessive preoccupation with authentic settings and costumes. In England Charles Kean's productions of Shakespeare crowded so much archaeological detail onto the stage that new scenes were often invented to make full use of the designer's research. In Kean's production of *Hamlet* in 1858, for instance, the recurring stage direction "a room in the castle" was represented by at least four different settings. Needless to say, this did incalculable damage to both the pace and fluidity of the play. In such impressive surroundings crowd scenes reached new peaks of popularity and spectacle. Large numbers of exotic animals were also used whenever an excuse could be found. One of the most sensational effects, however, was the "racing drama" in which live horses galloped on moving belts set into the stage floor. In this way, the chariot race of William Young's *Ben Hur* could be staged in New York City in 1899. Realism found its way into domestic dramas, too, one of the earliest innovations being the box set that replaced the perspective backcloth and wings depiction of a room with three solid walls and a ceiling. This feature was introduced to the English stage in 1832 by the actress and singer Madame Vestris at the Olympic Theatre.

Emphasis on scenic realism

A move toward ensemble acting was perhaps the logical continuation of efforts to achieve scenic realism. Madame Vestris demanded a more natural style of playing from her actors, and her example was followed by Charles Kean in his handling of crowd scenes: the extras were divided into small groups, each led by an experienced actor. But the most decisive move toward ensemble playing under the guidance of a modern theatre director was made by George II, duke of Saxe-Meiningen. The Duke was influenced by the stagings of Kean, which he had seen on visits to London. Assisted by the actor Ludwig Chronegk, he assumed control of his state theatre company as director and designer in 1866 and achieved an unrivaled harmony and discipline of playing. The company's extensive European tours between 1874 and 1890 had a considerable impact on actors and actor-managers. On the level of domestic drama, an attempt at contemporary realism was made by the English dramatist T.W. Robertson in the 1860s in both the writing and production of his plays. The style came to be known as "cup-and-saucer" drama because of the meals that were eaten on stage.

The introduction of electricity in theatres allowed for much brighter lighting on stage, providing yet another reason for eliminating exaggerated acting. The first experiments with electric stage lighting were at the Paris Opéra in 1846, but full systems were not installed until about 1880. In England the first use of electric stage lighting was in 1881 at the Savoy Theatre.

The advances in stage production eventually helped to stimulate a higher level of drama. The tradition of the French "well-made play" was carried forward in England on a more serious note in Arthur Wing Pinero's *Second Mrs. Tanqueray* (1893) and with a brilliance of wit that evoked the Restoration comedy of manners in Oscar Wilde's *Importance of Being Earnest* (1895).

The full impact of realist drama in the final decades of the 19th century came from northern Europe, first in the plays of the Norwegian dramatist Henrik Ibsen and later in the work of the Russian playwright Anton Chekhov. Together, though in different ways, they exerted a strong influence on the course of acting and writing that has lasted to the present day. Ibsen achieved international recognition through his verse dramas, *Brand* (1865; Eng. trans., *Brand*) and *Peer Gynt* (1867; Eng. trans., *Peer Gynt*), though his reputation rests mainly on the realistic contemporary plays that set out to expose social evils. *Samfundets støtter* (1877; *Pillars of Society*), *Et dukkehjem* (1879; *A Doll's House*), and *Hedda Gabler* (1890; Eng. trans., *Hedda Gabler*) are among the best known of such works.

Naturalism. As early as 1867, the French novelist Émile Zola had called for a rejection of all artifice in the theatrical arts, as in the novel, demanding that plays be faithful records of behaviour—namely, scientific analyses of life. *Thérèse Raquin,* an 1873 dramatization of his own novel (written in 1867), represents the first consciously Naturalistic drama.

Zola's "slice-of-life" technique found fuller expression in Sweden in August Strindberg's *Fröken Julie* (1888; *Miss Julie*), which heralded a new generation of writers whose plays dealt with themes centring on real contemporary society, treated in action and dialogue that looked and sounded like everyday behaviour and speech. These writers included Gerhart Hauptmann in Germany, Henry Becque in France, and Maxim Gorky in Russia. Partly because their plays often dealt with the gloomier side of life, audiences were at first small. In spite of the lack of commercial success, sympathetic productions were made possible by a number of independent "free" theatres that appeared throughout Europe.

The "slice-of-life" technique in drama

Théâtre-Libre. In 1887 André Antoine, an enthusiastic amateur actor, formed a small company in Paris, which he called Théâtre-Libre. His intention was to provide a showcase theatre for young playwrights of the new Naturalistic drama, from both France and abroad, who could find no other opportunity of bringing their work before the public. Antoine's first production was a group of one-act plays that attracted the attention of leading avant-garde theatre intellectuals such as Zola and Becque. The following year, Leo Tolstoy's *Vlast tmy* (1888; *The Power of Darkness*) was presented, and Théâtre-Libre took on an international significance. Apart from the work of such French writers as Becque and Eugène Brieux, Théâtre-Libre also introduced the plays of Ibsen, Strindberg, Hauptmann, and the Norwegian Bjørnstjerne Bjørnson. Because of financial difficulties the theatre closed in 1896, but by then it had already exerted an enormous influence on playwriting, direction, and acting and had helped to liberate French theatre from the artificiality in which it had been steeped. Antoine encouraged his actors to behave as if they were unaware of the presence of the audience, while his settings aimed to achieve in meticulous detail the impression of real life. He became famous for hanging real carcasses of meat in the stage setting of a butcher's shop.

Major contributions

Freie Bühne. Disturbed by the stagnation of theatre in Germany during the 1880s, young intellectuals tried to promote the revolutionary Naturalistic drama by opening the Deutsches Theater in Berlin, but they soon ran into trouble with the censors. In 1889, a group of writers headed by the theatre critic Otto Brahm formed a private theatre club called the Freie Bühne after Antoine's Théâtre-Libre. Its earliest productions were of Ibsen's *Gengangere* (1885; *Ghosts*) and Hauptmann's first play, *Vor Sonnenaufgang* (1889; *Before Dawn*), and it also staged the latter's better-known *Weber* (1892; *The Weavers*). When Brahm became director of the Deutsches Theater in 1894, the Freie Bühne was attached to it as an experimental division, though by this time the new drama was being accepted throughout Germany in similar theatres dedicated to bringing serious plays to the working class at reasonable prices. Other so-called free theatres in Berlin were the Freie Volksbühne ("Free People's Theatre") and the Schiller Theater.

The independent theatre. Dissatisfaction with established systems of theatre, including the all-powerful actor-manager and the indulgence in scenic spectacle, also existed in England. Critics had long deplored the lack of

worthwhile modern English drama, and toward the end of the century William Archer was one of many writers who called for an equivalent of the Théâtre-Libre that would bring the "theatre of ideas" to England. Inspired by Antoine's example, Jacob Grein, a Dutchman living in England, organized the Independent Theatre Club. The theatre opened in 1891 with Archer's translation of Ibsen's *Gengangere,* provoking a storm of moral fury. One champion of the new group and its policies was the theatre critic George Bernard Shaw; his first play, *Widower's House* (1892), which dealt with the subject of slum landlordism, was produced there the following year. The theatre was supported by a small group of subscribers, many of them distinguished writers. Although it ceased activity in 1897, the Independent Theatre Club prepared the way for the Stage Society, founded in 1899. For the next 40 years the society arranged private Sunday performances of experimental plays at the Royal Court Theatre in London.

Moscow Art Theatre. The movement toward Naturalism that was sweeping Europe reached its highest artistic peak in Russia in 1898 with the formation of the Moscow Art Theatre (later called the Moscow Academy Art Theatre). Its name became synonymous with that of Anton Chekhov, whose plays about the day-to-day life of the landed gentry achieved a delicate poetic realism that was years ahead of its time. Konstantin Stanislavsky, its director, became the 20th century's most influential theorist on acting. In the early 19th century Russian theatre had been one of the most backward in Europe, content to play a repertoire of stock theatrical pieces, mainly French comedies and farces, or Russian imitations of them. Little time was spent on rehearsal; the plays were so similar that the same performances and sets could be used time and again. However, the Meiningen Company, which had visited Russia during the late 1880s, had pointed the way to reform with its exemplary discipline.

During a 17-hour conversation in a Moscow restaurant, Stanislavsky, an amateur actor of considerable experience, and Vladimir Nemirovich-Danchenko, a playwright, teacher, and drama critic, talked over their vision of an ideal theatre company, its artistic policy, and its production methods. On the basis of their discussion, they formed a group they called the Moscow Art Theatre Company. No great stir was made until, later that year, they revived Chekhov's *Chayka* (1896; *The Seagull*), which had failed badly in its incompetent first production in St. Petersburg. An instant success, the new production established the reputation of both Chekhov and Stanislavsky. The intimacy and truthfulness of the acting were something entirely new. Through his stagings of several of Chekhov's other plays, *Dyadya Vanya* (1897; *Uncle Vanya*), *Tri sestry* (1901; *Three Sisters*), and *Vishnyovy sad* (1904; *The Cherry Orchard*), Stanislavsky developed a style of infinitely detailed production, the result of long and methodical rehearsals, to achieve an almost perfect surface naturalism.

Stanislavsky's innovations

The American theatre. Although there was no lack of enthusiasm in developing an indigenous American theatre at the end of the 18th century, the plays that appeared proved lifeless and derivative, often little more than adaptations of English successes. It was not until the early 20th century that actors had a chance to portray American characters in well-written roles that were comparable to those of the European theatre. The first play by a native American was Thomas Godfrey's Neoclassical tragedy *The Prince of Parthia* (1767), but recognizable American characters did not appear on stage until Royall Tyler's comedy *The Contrast* (1787). This work introduced a favourite theme of early American drama: the triumph of native honesty and worth over foreign sham and affectation.

The growth of American theatre owed more to its actors than to its dramatists. In the early decades of the 19th century, the finest English actors, notably Edmund Kean, William Charles Macready, and Charles Kemble, visited the United States and provided a stimulus for the local actors they worked with. Before long, the gesture was returned when such American actors as Edwin Booth, Edwin Forrest, and Charlotte Cushman appeared with some success on the London stage. Forrest, whose acting was characterized by muscular strength and great vocal power, was perhaps the first to popularize the virile outdoor image cultivated by many American actors ever since. His most famous role, Spartacus in Robert Bird's *Gladiator* (1831), was specially written for him. The Booths were an eminent acting family: Junius Brutus Booth had acted with Edmund Kean, and his son Edwin with Irving, but they achieved notoriety when another son, John Wilkes Booth, assassinated Abraham Lincoln in 1865.

Eminent American actors

By the middle of the 19th century, the number of theatres in the United States had multiplied. Many of them were based on English models and offered a high standard of comfort and luxury. Detailed historical accuracy in setting and costume first attracted attention in Charles Kean's visiting production of Shakespeare's *King John* (1846), and the new box settings (three solid walls to suggest a room instead of the traditional side wings and backcloth arrangement) began to be used in Edwin Booth's theatre from 1869, after which realistic staging became increasingly popular. This trend was stimulated by the introduction of gas lighting about 1825 and of electric lighting about 1885.

Styles of acting also leaned increasingly toward realism as the century advanced. Joseph Jefferson, whose career spanned 71 years, was the leading comic actor of his day, best remembered in the title role of Dion Boucicault's version of *Rip Van Winkle* in the 1860s. One of the great actress-managers was Mrs. John Drew, who was famed for her frequently revived portrayal of Mrs. Malaprop in Sheridan's *Rivals.* Black American actors were rarely seen on the 19th-century stage; Negro roles were usually played by white actors with black makeup, giving rise to shallow and stereotyped portrayals. One of the first playwrights to treat the American Negro seriously was Boucicault in *The Octoroon* (1859). After a surfeit of melodrama, a more distinctly American style of drama began to evolve through the work of Bronson Howard, whose first play, *Saratoga* (1870), helped to make him the first to earn his living solely by playwriting.

As the population spread westward and southward, spurred by the gold rush and the expansion of the railways, so the demand for theatre became more widespread. In the South showboats on the Mississippi and Ohio rivers provided floating entertainment, mostly melodramas. Most of the leading actors of the time made visits to California, where the first theatres were built in the 1850s. Initially, star actors would work with local resident companies, but the majority of these were eventually overtaken by full touring productions that originated in New York City. By the 1870s, these companies were providing entertainment throughout the country. Booking agencies were formed to liaise between companies and theatres, and from this activity a group of theatre owners, producers, and agents formed the first Theatrical Syndicate in 1896. Although its original aim was to streamline the organization of entertainment and prevent exploitation, it soon gained a monopoly on theatre by controlling bookings in New York City and in key cities on the touring circuits. Because its blatant commercialism discouraged high artistic standards, the monopoly was fiercely resisted by the more innovative producer-directors such as David Belasco, who helped to introduce to the American stage the European fashion for scenic naturalism. Making use of the latest stage machinery, he devised many spectacular effects and used a real flock of sheep on stage in one production of a Passion play.

Popular entertainment. Alongside the developments in "legitimate" theatre, the last decades of the 19th century saw the rise of several forms of popular entertainment that often reached much larger audiences and created a new range of star performers. In these traditions lay the seeds of the 20th century's most popular theatrical genre, the musical comedy.

One of the greatest showmen of the time was P.T. Barnum. Founder of the American legend of "show business," he promoted melodrama, exhibited the midget Tom Thumb in the United States and England, and finally merged with James A. Bailey in 1881 to form "The Greatest Show on Earth," a three-ring circus, which was taken over in England by the Ringling Brothers after Barnum's

death. The American brand of spectacular entertainment achieved international fame through Buffalo Bill Cody's Wild West shows, which featured a large cast of cowboys, Indians, and animals, as well as the famous sharp-shooter Annie Oakley. Another form that enjoyed enormous popularity in the United States and England throughout most of the century was the minstrel show, inspired by Thomas Darthmouth Rice. The performers were at first white men with black makeup, though later Negroes appeared in the shows. Sitting in a semicircle and playing banjos, tambourines, bones, and fiddles, they sang comic songs and sentimental ballads interspersed with soft-shoe dances and snatches of cross-fire dialogue.

By the 1880s, the music hall was at the height of its popularity in England, with a proliferation of newly constructed halls all over London and in the main cities. As the audience widened from predominantly male working-class spectators to include middle-class men and women, the layout of the auditoriums changed. The old-style intimate halls with their drinking facilities and tables gave way to larger, more theatrelike buildings, one of the most luxurious of which was the London Pavilion. An evening's bill could feature more than 20 different acts, including jugglers, acrobats, conjurers, ventriloquists, dancers, slapstick comedians, and singers ranging from vulgar to light classical. Two of the most famous performers of the 1880s were Marie Lloyd, who specialized in risqué songs, and the comedian Dan Leno, who, like many music-hall stars, made annual appearances in pantomime as well. Vesta Tilley, the male impersonator, created the character Burlington Bertie; Sir Harry Lauder was the finest Scottish comedian; Little Tich was famed for his short stature and elongated boots; Jules Léotard and Charles Blondin achieved international fame as acrobats; and Grock (original name Charles Adrian Wettach), the greatest clown after Grimaldi, played 20 instruments and delighted London audiences from 1903 until 1924. By then, the music hall was in decline, unable to compete with the new forms of mass entertainment into which many of its performers were drifting—revue, musical comedy, cinema, radio, and, later, television. There was a similar form of entertainment in France, while in the United States vaudeville retained many of the features and acts of the English music hall. It was first presented in New York City in 1881 as an attempt to provide "clean" entertainment for respectable family audiences.

On a more sophisticated level, light opera was developing in Europe out of the German *Singspiel* and the French *opéra-comique*. Early examples were Jacques Offenbach's classical burlesque, *Orphée aux enfers* (1858; *Orpheus in the Underworld*), Johann Strauss's *Fledermaus* (1874; *The Bat*), and the satirical operas of Gilbert and Sullivan. These led to the romantic operettas of Victor Herbert in the United States and Franz Lehár in Austria. But it was Jerome Kern who in the early 20th century first developed a genuinely American sound from ballad and ragtime musical forms that helped to forge the particular identity of the American musical comedy.

Jerome Kern and the American musical comedy

20th-century theatre

The achievements of Realism at the end of the 19th century have continued to the present day, but the most influential innovations in early 20th-century theatre came from a vigorous reaction against Realism. Just as the visual arts exploded into a chaos of experiment and revolt, generating numerous styles and "isms," so the theatre seized upon anything that came to hand in an effort to express the contradictions of the new age. Inspiration was sought in machines and technology, in Oriental theatre, Cubism, Dada, the psychoanalysis of Freud, and the shock of a world war that spawned widespread disillusionment and alienation. The results of this eclecticism were often anarchic and exhilarating: designers and directors were as influential as playwrights, though relatively little theatre of lasting value was produced. Nevertheless, such early experiments set the tone and widened the theatrical vocabulary for all the innovations that have followed.

The beginnings of the revolt against Realism were already hinted at before the 19th century was over, sometimes in the works of the Realist writers themselves. Ibsen, for example, turned increasingly toward Symbolism in his later plays such as *Bygmester Solness* (1892; *The Master Builder*) and *Naar vi døde vaagner* (1899; *When We Dead Awaken*), though still in the Realist mold. Frank Wedekind's *Frühlings Erwachen* (1891; *Spring Awakening*) began its study of adolescent love in the slice-of-life Naturalistic mode and ended in the realm of ghosts and dreams, foreshadowing Expressionism, which was to preoccupy other German dramatists during the 1920s. Strindberg also is regarded as one of the fathers of Expressionism by virtue of his later works such as *Ett Drömspel* (1902; *A Dream Play*) and *Spöksonaten* (1907; *The Spook [Ghost] Sonata*). In France the marionette play *Ubu roi* ("King Ubu"), written in 1888 by Alfred Jarry at the age of 15, created a scandal when it was later performed with live actors in 1896. Its use of puppet techniques, masks, placards, and stylized scenery was to be taken up decades later in French avant-garde theatre.

Wedekind and Strindberg as pioneers of Expressionism

BEYOND REALISM

The new stagecraft. Since Naturalistic scenery had led to an excessive clutter of archaeologically authentic detail on stage, the reaction against it favoured simplicity, even austerity, but with a heightened expressiveness that could convey the true spirit of a play rather than provide merely superficial dressing. One of the first advocates of this view was the Swiss designer Adolphe Appia, who used the latest technology and exploited the possibilities of electric lighting to suggest a completely new direction in stage design. Appia believed that the setting should serve to focus attention on the actor, not drown him in two-dimensional pictorial detail. The imaginative use of light on a few well-chosen forms—simple platforms, flights of steps, and the like—was sufficient to convey the changing mood of a play.

Because his views were so radical, Appia had few opportunities to realize his theories. They were, however, carried forward at the beginning of the century by the English designer and director Edward Gordon Craig, who used strong lighting effects on more abstract forms. He felt that a suggestion of reality could create in the imagination of the audience a physical reality: a single Gothic pillar, for instance, designed to stand alone and carefully lit, can suggest a church more effectively than a cardboard and canvas replica faithful to the last detail. But, like Appia, Craig became better known as a theorist than a practitioner. In his book *The Art of the Theatre* (1905) he outlined his concept of a "total theatre" in which the stage director alone would be responsible for harmonizing every aspect of the production—acting, music, colour, movement, design, makeup, and lighting—so that it might achieve its most unified effect. More controversial were Craig's ideas on the depersonalization of the actor into what he called the *Übermarionette* ("super-marionette"), based on a new symbolic form of movement and gesture (not unlike that of the Oriental actor) in which the actor's ego would not obtrude on the symbolic design. While they may not have found a practical way of achieving their visions, both Appia and Craig exerted an enormous influence on the next generation of directors and stage designers, particularly in their principle of painting with light.

The work of Max Reinhardt

The Austrian director Max Reinhardt came close to achieving many of Craig's ideals, especially in the power he exerted over every aspect of theatrical production. Beginning as an actor in Otto Brahm's company at the Deutsches Theater in Berlin, Reinhardt won acclaim for his inventive staging of Shakespeare's *Midsummer Night's Dream* in 1905 and thereafter devoted himself entirely to directing: he dominated the theatre of central Europe for 25 years. His flair for bold theatricality made him many enemies among the Realists, but it also returned a sense of colour and richness to the theatre of the time. Reinhardt was pragmatic in his approach to acting: rejecting the idea of "one style," he demanded for modern plays a style realistic in feeling but avoiding the drab exactness of Realism. In productions of the classics, he demanded lively, supple speaking in place of the slow, ponderous

delivery of the traditionalists. He always made his actors think afresh about their characters instead of assuming ready-made characterizations.

In his endeavours to break down the separation of stage and auditorium, Reinhardt often took his actors out of the theatre to play in unconventional settings. He produced Sophocles' *Oedipus Rex* in a circus arena in Berlin, and for his production of Karl Gustav Vollmöller's *Mirakel* (performed in 1911 and published in 1912; *The Miracle*), he transformed the huge Olympia exhibition hall in London into a cathedral with the audience as part of the congregation. In 1920 he helped to found the Salzburg Festival and directed Hugo von Hofmannsthal's morality play *Jedermann* (1911; *Everyman*) in the cathedral square. Although he was a master of spectacle, his versatility was such that he directed subtle and intimate plays in small theatres with equal skill.

Russia. At the beginning of the century, Russia was surging toward revolution, which makes it less surprising that some of the first attacks on Naturalistic theatre should have originated there. While continuing in the Realistic vein of his productions of Chekhov's plays and Gorky's *Na dne* (1902; *The Lower Depths*) at the Moscow Art Theatre, Stanislavsky also recognized the need to find new artistic paths. In 1905 he set up a studio for experimental theatre and appointed one of his former actors, Vsevolod Meyerhold, as its director. Influenced by Craig, Meyerhold immediately began to implement his own ideas involving the total supremacy of the director, so that his actors became little more than puppets. So much did this contradict everything the Moscow Art Theatre stood for that Stanislavsky closed the studio and thought further about the function of the actor. Determined that the actor should not in future be subordinated to the director's will, he began to train his company in an approach based on "emotional memory." This emphasized the self-expression of the actor who, in collaboration with the director, should achieve a unified interpretation of the play. After the Revolution in 1917, Stanislavsky allowed himself to become involved in the new plans for the arts that the revolutionary government had conceived, but he refused to allow his theatre to become a platform for spreading propaganda. He believed that his mission was to maintain a high standard of acting that other theatres might emulate when the initial excesses of the Revolution abated. He did, however, achieve a much bolder style in nonrealistic plays such as Maurice Maeterlinck's *Oiseau bleu* (1908; *The Blue Bird*) and in some of the productions toward the end of his career.

Curiously, it was the avant-garde that Lenin's government entrusted to guide the Russian theatre into the new revolutionary era. Meyerhold was back in vogue, declaring that the principles of propagandist theatre conformed with those of Marxism because they attempted to underline the "unindividuality" of man. In 1918 he stage the first Soviet play, *Misteriya-buff* (1921; *Mystery-Bouffe*) by Vladimir Vladimirovich Mayakovsky. With Aleksandr Tairov, director of the Kamerny Theatre, Meyerhold developed the Formalist style, in which representative types replaced individual characters amid Constructivist settings of gaunt scaffolding supporting bare platforms, with every strut and bolt exposed to view. The aggressive functionalism of this type of setting was regarded as having considerable propaganda value when the Soviets were being taught to revere the machine as part of their training to become a great industrial nation. Meyerhold sought to eliminate the actor's personality even further through a system he called "bio-mechanics." Placing emphasis on the physical and athletic aspects of the actor's body, Meyerhold's system drew on a variety of influences, including commedia dell'arte, Kabuki theatre, and the ideas of Craig and the physiologist Ivan Petrovich Pavlov.

Meyerhold's Formalist style

As director of one of the studios of the Moscow Art Theatre from 1920, the more moderate Yevgeny Vakhtangov tried to bridge the gap between Realism and the avant-garde. In place of Stanislavsky's inner realism, he wanted what he called "outer technique." While preserving a deep respect for the actor's art—something he learned from Stanislavsky—he brought bold gesture and vivid colour to his productions, the best of which were a Yiddish performance of *Der Dybbuk* (1920; *The Dybbuk*) by S. Ansky (pseudonym of Solomon Zanvel Rappoport) and *Turandot* (1762; Eng. trans., *Turandot*) by Carlo Gozzi, both staged just before his death in 1922.

The experimentation of the 1920s came to an abrupt halt under Stalinist rule with the imposition of Socialist Realism on the arts in 1932. It was decreed that all theatre should be adjusted to the level of the worker-audience with the aim of educating the public in the ideals of the Communist revolution. In practice, this resulted in a wave of simplistic and old-fashioned propaganda plays in which theatrical artistry was sacrificed to party dogma. Theatre virtually ceased to progress, since any originality was condemned as decadent. Scenery became more and more laboriously realistic, for a setting that was in any way impressionistic was condemned as belonging to "abstract art." One of the most successful directors of the time was Nikolay Pavlovich Okhlopov, who was put in charge of the Realistic Theatre (formerly one of the Moscow Art Theatre studios) in 1932. There, he tried to find new ways of presenting plays by using multiple stages and generally breaking away from the constrictions of the proscenium-arch format. In 1938, however, the Realistic Theatre was closed on grounds that its work appealed too exclusively to intellectuals. As part of the reaction against Formalism, Meyerhold was dismissed in 1934, and Tairov, rebuked for being out of touch with his audience, was relieved of his directorship of the Kamerny Theatre and forced to work under a committee.

Socialist Realism

Italy. As in Russia, the new technology provided a stimulus for the revolt against *verismo* ("realism") in the Italian theatre at the beginning of the century. The most important movement was Futurism. Initiated by Filippo Tommaso Marinetti in 1909, it embraced painting, sculpture, and poetry, as well as theatre, and it prefigured most of the non-Realistic approaches to the theatre that were to follow: Dada, Surrealism, Constructivism, the Theatre of the Absurd, and even the "happenings" of the 1960s. In theatres and art galleries the Futurists devised performances that celebrated the ecstasy of speed, explored states of madness, depicted man as a machine, and had performers moving among the spectators to provoke the audience in a general smashing down of the "fourth wall" and, with it, the illusionary power of theatre.

The Futurist movement

In 1921 Anton Giulio Bragaglia founded the Teatro Sperimentale degli Indipendenti, which borrowed from the Futurists but subordinated mechanics and technology to the play itself. He aimed to restore theatricality to the drama, using light, multidimensional space, masks, and costumes to Surrealistic effect. He also wished his actors to master the acrobatic aspects of the commedia dell'arte as an antidote to cerebral acting. Another movement was the Teatro Grottesco, which explored the contradictions between outward appearance and inner reality. This became a central theme in the work of the dramatist Luigi Pirandello, whose plays questioned the very basis of realism on a stage that was itself artifice. After his best known play, *Sei personaggi in cerca d'autore* (1921; *Six Characters in Search of an Author*) brought him international fame, he founded in 1925 his own company, the Teatro Odeschalchi, in Rome. After the rise of Mussolini, much of the avant-garde theatre of the late 1920s became aligned with Fascism. Until the 1930s, there was no state support for the theatre, and even then those writers and directors opposed to Fascism were excluded.

Expressionism in Germany. The term Expressionism was coined at the beginning of the 20th century to describe a style of painting that reacted violently against late 19th-century Naturalism and Impressionism. Applied to the theatre, it represented a protest against the existing social order. Initially it was concerned with spirit rather than with matter, and typically sought to get to the essence of the subject by grossly distorting outward appearance or external reality. This "subjective" first phase of Expressionism began in Germany about 1910, though its forerunners had appeared earlier in the plays of Wedekind and in Strindberg's *Ett Drömspel,* which put Realistic drama onto a supernatural plane. The leading exponent

of early Expressionism in Germany was Georg Kaiser, whose themes centred on the struggle of the individual to fulfill himself in a hostile civilization. After World War I, the movement gained momentum from the social and political upheaval into which Germany was plunged. This later "activist" phase became more directly political and was represented by the plays of Ernst Toller, which called for a socialist revolution. *Die Maschinenstürmer* (1922; *The Machine Wreckers*) is Toller's best known play.

Characteristics of Expressionist drama

The language of Expressionist drama was stark and exclamatory, often overthrowing the conventions of grammar. Short scenes took the place of longer acts. Shafts of light picked out figures on a darkened stage, and scenery was limited to one or two symbolic forms. Characters were symbols instead of people. All this called for highly stylized acting, and directors looked for inspiration to the world of dance: German cabaret dancers, the eurythmy of Rudolf Steiner, and Rudolf von Laban's system of eukinetics were all important influences. The most notable director of the German Expressionist theatre was Erwin Piscator. Later in the 1920s, when steel, timber, and other materials once again became plentiful, Piscator directed a series of productions using elaborate and expensive machinery. The front of his stage was constructed on a conveyer-belt principle so that the actors appeared to walk from one location to the next. In the centre, a cantilever bridge moved up and down, while slides and films were projected onto different surfaces. Above the proscenium, slogans blazed in lights, and the gigantic shadows of pulsating machines were thrown onto gauzes.

Another director, Leopold Jessner, also made full use of building materials once postwar restrictions on their use had been lifted. His favourite setting was a vast flight of steps extending the entire width of the stage, rising steeply to a platform at the back. Like so many directors of the time, Jessner was greatly influenced by the new stagecraft of Craig and by the work of the Soviet directors of the postrevolutionary Constructivist theatre. Partly because of its abstract nature, Expressionist theatre was exciting but rarely artistically successful. By 1925 the movement was over, giving way to the epic theatre developed and cultivated by Piscator and Bertolt Brecht (see below). Further experiment in the German theatre was cut short by the accession to power by the Nazis in 1933.

Avant-garde in France. At the beginning of the 20th century, France was the international centre for innovation in the visual arts, but such was not the case with the theatre. In Paris theatres were dominated by wealthy patrons eager for the farces of Georges Feydeau and the boulevard tradition of well-made plays about sexual adventure and adultery. However, when the reaction against Realism did come, it had more lasting results than Constructivism, Futurism, or Expressionism, possibly because in France it centred on efforts to dignify the art of the actor rather than to exploit or devalue it. The reaction was initiated by the literary critic Jacques Copeau, who in 1913 set up his own company, the Théâtre du Vieux-Colombier. Although Copeau was influenced by the Naturalistic acting style that Antoine had demanded, he disliked Realistic theatre; yet, he also had an aversion to artificiality. Like Reinhardt, he sought to break down the barrier between the actor and the audience. His stage did away with the front curtain (for the first time on the modern French stage), and it extended out from the proscenium arch to surround the audience on three sides. Decor was used sparingly; the atmosphere for each play was created almost entirely by lighting. The intimate scale (Copeau's theatre seated only 200) allowed for natural delivery and movement, though even in contemporary plays gesture was used selectively to give every action particular significance. Copeau staged plays by a few new authors, but the main thrust of his work was in classics. His productions of Shakespeare and Molière were notable for their lightness, grace, and gaiety, as well as for their strong sense of ensemble playing. In 1921 Copeau opened a theatre school at the Vieux-Colombier that recognized the importance of body movement and vocal expression. One of his pupils, Étienne Decroux, continued this work to become the father of modern mime. Both company and school closed in 1924.

The work of Jacques Copeau

In 1927 the "Cartel" was formed to revitalize French avant-garde theatre and offer a viable alternative to boulevard plays. It comprised four directors, each with his own style: Louis Jouvet and Charles Dullin (both former actors with the Vieux-Colombier) and Georges Pitoëff and Gaston Baty. Jouvet's productions of Molière were his most important contribution; he freed the plays from the weight of tradition that was stifling them. Dullin's productions, which were less subjugated to the text, revealed a flair for movement, music, and bright colours. They stood in sharp contrast to the ascetic productions of Pitoëff, who believed that the director's primary aim should be to focus attention on a play's central idea, eliminating all details of decor and acting that might obscure it. Pitoëff's great contribution was the number of foreign dramatists he introduced to Parisian audiences. Baty, who had served his apprenticeship under Reinhardt, possessed a strong pictorial sense: his groupings and movement were beautifully composed, but they often existed for themselves rather than for the play.

Copeau's nephew, Michel Saint-Denis, formed the Compagnie des Quinze in 1930 with members of the defunct Vieux-Colombier and produced several of André Obey's plays, including *Noé* (1931; *Noah*). By the time the Compagnie des Quinze disbanded in 1934, it had become internationally famous for its lively productions. In the same year, Jouvet, Dullin, Baty, and Copeau were appointed as directors of the Comédie-Française in an effort to revive its flagging morale and declining artistic standards. In place of indulgent star performances, they introduced a more unified approach to production that clarified the text; thus they restored the theatre's high reputation.

Ireland. The establishment of an Irish national theatre during the early years of the 20th century was not a reaction against existing forms of theatre. Rather, it was a nationalist movement to establish an indigenous theatre, independent of European fashion, which could displace the sentimental and imitative plays that dominated the Irish stage. The first step was taken in 1898, when the poet William Butler Yeats and the playwright Augusta, Lady Gregory, founded the Irish Literary Theatre to encourage poetic drama. They soon developed a recognizable company style, and after performances in London Annie Horniman (pioneer of the British repertory movement) provided them with a permanent home in 1904 at the rebuilt Abbey Theatre in Dublin. The brilliant work of the group became world famous; it included the performances of many fine native actors as well as the contributions of outstanding dramatists, most notably J.M. Synge and Sean O'Casey. Several of these writers became interested in innovative techniques and forms. O'Casey, for one, was attracted to the Expressionist theatre and incorporated some of its techniques in *The Silver Tassie* (1929). During the 1920s, Yeats too tried his hand at experimentation, composing poetic dance plays based on the Japanese Nō theatre.

The Irish Literary Theatre

Great Britain. British theatre paid very little attention to the anti-Realistic movements that characterized experimental theatre in the rest of Europe. The domination of the actor-manager was effectively challenged by Harley Granville-Barker and John E. Vedrenne at London's Royal Court Theatre; between 1904 and 1907 they staged numerous new plays by British and continental writers. The major dramatist at the Royal Court—indeed the most important British dramatist of the century—was George Bernard Shaw. With plays such as *Man and Superman* (1903), he made theatre a lively platform for the discussion of social and philosophical issues, usually through the medium of laughter. Shaw availed himself of a wide variety of styles and models, including mythology in *Pygmalion* (1916) and history in *Saint Joan* (1924), but he always transformed his models to make them relevant to his own age.

George Bernard Shaw

The staging of Shakespeare's plays was revolutionized by Granville-Barker's productions at the Savoy Theatre, which were admired for their simplicity, fluidity, and speed. Equally significant for the British theatre was the founding of the first provincial repertory theatre in 1908 by Horniman at the Gaiety, Manchester. It not only pro-

vided opportunities for promising British playwrights but also presented works by important continental dramatists. Other repertory theatres followed: Liverpool in 1911 and Birmingham in 1913. For years the repertory movement continued with distinction, but after World War II it was regarded largely as a training ground where actors gained experience before making an assault on London—an attitude that was not rectified until the 1960s.

In London a repertory-style theatre was established by Lilian Baylis at the Old Vic in 1914, but it became most famous as a home for Shakespeare's plays, all of which were staged there over the following nine years. In 1931 Baylis reopened Sadler's Wells Theatre as a centre for opera and ballet. This theatre eventually became the base for the Royal Ballet and the English National Opera. After World War I, production costs and theatre rents rose so sharply that many West End theatres could not afford to remain open. They were taken over by commercially minded impressarios who favoured musical comedy, farce, and melodrama. Because of this situation, serious plays were left to the small theatre clubs.

During the 1930s, experimentation that went beyond straightforward Naturalism increased. Noël Coward revived the comedy of manners in *Private Lives* (1930); J.B. Priestley explored the cyclic concept of time in *Time and the Conways* (1937); and T.S. Eliot found a modern idiom for the poetic drama in his verse play *Murder in the Cathedral* (1935), originally performed in Canterbury cathedral. British acting and directing were stimulated by Theodore Komisarjevsky, who in 1919 emigrated to Britain from the Soviet Union, where he had been director of the Russian imperial and state theatres. His direction of plays by Chekhov and other Russian writers set new standards in English theatre, but his Shakespearean productions at Stratford-upon-Avon in the 1930s often infuriated audiences accustomed to conventional productions. His renderings were full of invention, sometimes brilliant, amusing, and illuminating, sometimes merely wayward. Equally influential was the French director Michel Saint-Denis. After his Compagnie des Quinze disbanded, he settled in England, where he directed several classical productions. Moreover, in 1935, he opened the London Theatre Studio to train young actors in the tradition that Copeau had begun in Paris.

United States. American theatre at the beginning of the 20th century was so heavily dominated by commercialism that some kind of revolt was to be expected. An attempt to establish a European-style art theatre in New York City was made in 1909 with the opening of the New Theatre, but the building was so cavernous and unsuited for experimental work that the venture collapsed after two seasons. Visits by the Abbey Theatre group in 1911, Reinhardt's *Sumurūm* in 1912, Granville-Barker's company in 1915, and Copeau's Vieux-Colombier in 1917 provided exciting glimpses of the work of Europe's art theatres and stimulated a large number of "little theatres" in provincial cities. Dedicated to producing the best of European and classical drama and to fostering new American plays, these groups were staunchly amateur, with their memberships organized by subscription, so that true experiment could be conducted without commercial pressure. One of the first such companies in New York City was the Washington Square Players. From a similar group, the Provincetown Players, emerged the first American dramatist of international stature: Eugene O'Neill. His first full-length play, *Beyond the Horizon,* was successfully produced in 1920. Most of O'Neill's subsequent work represented a restless search for theatrical style: he tried Expressionism in *The Emperor Jones* (1920) and *The Hairy Ape* (1922), masks in *The Great God Brown* (1926), and allegory in his updating of Aeschylus' *Oresteia* trilogy, *Mourning Becomes Electra* (1931), before he found a suitable idiom for modern tragedy in his autobiographical play *Long Day's Journey into Night* (1941; produced 1956).

O'Neill's experimentation with theatrical style

Art theatre was established on a commercially successful basis by New York City's Theatre Guild in 1918. During the next two decades it became the most important platform for American drama, encouraging such playwrights as Robert Sherwood, Maxwell Anderson, and Elmer Rice, in addition to O'Neill and European writers. The Theatre Guild's success quickly spurred independent Broadway producers to follow its example. The artistic challenge was also taken up by various designers, including Lee Simonson, Norman Bel Geddes, and Jo Mielziner, who provided distinguished settings that were realistic, symbolic, or expressionistic as required. The psychological depth of the new drama called for refinements in acting styles: Alfred Lunt, Lynn Fontanne, Helen Hayes, John Barrymore, Katherine Cornell, and Tallulah Bankhead were among the finest actors of the period, combining virtuosity with truthfulness. When the Moscow Art Theatre company visited New York City in 1923, two of its members were so impressed as to stay on and form the American Laboratory Theatre through which to teach the techniques of Stanislavsky. In 1927 *Show Boat* by Oscar Hammerstein II and Jerome Kern set new standards in the musical theatre, and in spite of competition from the expanding motion-picture industry, the number of productions on Broadway grew from 150 in the 1920–21 season to 280 in 1927–28.

The stock market crash of 1929 heralded the end of the unparalleled prosperity of both the theatre and the nation. The nation recovered from the ensuing economic depression, but the theatre, under increasing competition from motion pictures, radio, and television, did not. During the next 30 years, traveling companies all but disappeared, and productions on Broadway shrank to 60 in 1949–50, thereafter averaging between 50 and 60 a year. No new theatres were constructed. Nevertheless, live theatre continued to attract talented writers. From the social protest movement of the 1930s came Clifford Odets, Sidney Kingsley, Lillian Hellman, Thornton Wilder, and William Saroyan. So far, little attention had been paid to actor training, but in 1931 Harold Clurman, Cheryl Crawford, and Lee Strasberg formed the Group Theatre (an offshoot of the Theatre Guild) to develop new writers and evolve a style of acting, influenced by Stanislavsky's system, that sprang from a fresh observation of life rather than from the repetition of familiar clichés. From 1935 to 1939 the WPA Federal Theatre Project, established and funded by the Works Project Administration of the U.S. government to provide employment for out-of-work actors, presented hundreds of productions of all sorts throughout the country and showed that a large untapped audience existed for live theatre at low prices.

The Group Theatre

THEATRE SINCE WORLD WAR II

Efforts to rebuild the cultural fabric of civilization after the devastation of World War II led to a rethinking of the role of theatre in the new society. Competing with the technical refinements of motion pictures, radio, and television (all of which were offering drama), the live theatre had to rediscover what it could give to the community that the mass media could not. In one direction, this led to a search for a "popular" theatre that would embrace the whole community, just as the Greek theatre and the Elizabethan theatre had done. In another, it brought to fruition a new wave of experiments that had started before the war and was not to subside until the early 1970s—experiments that sought more radically than ever to challenge the audience, breaking down the barriers between spectators and performers.

Epic theatre of Brecht. Although Bertolt Brecht's first plays were written in Germany during the 1920s, he was not widely known until much later. Eventually his theories of stage presentation exerted more influence on the course of mid-century theatre in the West than did those of any other individual. This was largely because he proposed the major alternative to the Stanislavsky-oriented realism that dominated acting and the "well-made play" construction that dominated playwriting.

Brecht's earliest work was heavily influenced by German Expressionism, but it was his preoccupation with Marxism and the idea that man and society could be intellectually analyzed that led him to develop his theory of "epic theatre." Brecht believed that theatre should appeal not to the spectator's feelings but to his reason. While still providing entertainment, it should be strongly didactic and capable

of provoking social change. In the Realistic theatre of illusion, he argued, the spectator tended to identify with the characters on stage and become emotionally involved with them rather than being stirred to think about his own life. To encourage the audience to adopt a more critical attitude to what was happening on stage, Brecht developed his *Verfremdungs-effekt* ("alienation effect")—*i.e.*, the use of anti-illusive techniques to remind the spectators that they are in a theatre watching an enactment of reality instead of reality itself. Such techniques included flooding the stage with harsh white light, regardless of where the action was taking place, and leaving the stage lamps in full view of the audience; making use of minimal props and "indicative" scenery; intentionally interrupting the action at key junctures with songs in order to drive home an important point or message; and projecting explanatory captions onto a screen or employing placards. From his actors Brecht demanded not realism and identification with the role but an objective style of playing, to become in a sense detached observers.

Brecht's *Verfremdungs-effekt*

Brecht's most important plays, which included *Leben des Galilei* (*The Life of Galileo*), *Mutter Courage und ihre Kinder* (*Mother Courage and Her Children*), and *Der gute Mensch von Sezuan* (*The Good Person of Szechwan*, or *The Good Woman of Setzwan*), were written between 1937 and 1945 when he was in exile from the Nazi regime, first in Scandinavia and then in the United States. At the invitation of the newly formed East German government, he returned to found the Berliner Ensemble in 1949 with his wife, Helene Weigel, as leading actress. It was only at this point, through his own productions of his plays, that Brecht earned his reputation as one of the most important figures of 20th-century theatre.

Certainly Brecht's attack on the illusive theatre influenced, directly or indirectly, the theatre of every Western country. In Britain the effect became evident in the work of such playwrights as John Arden and Edward Bond and in some of the bare-stage productions by the Royal Shakespeare Company. Western theatre in the 20th century, however, has proved to be a cross-fertilization of many styles (Brecht himself acknowledged a debt to traditional Oriental theatre), and by the 1950s other approaches were gaining influence.

Theatre of Fact. A more uncompromising method of bringing social issues to the stage has been Documentary Theatre, or the Theatre of Fact. In this case, the presentation of factual information usually takes precedence over aesthetic considerations. Out of the social protest movement that arose during the years of depression in the 1930s, a unit of the WPA Federal Theatre Project in the United States (see above) adopted what it called a Living Newspaper technique, taking inspiration from motion pictures (especially in the use of short scenes) to present highlighted versions of contemporary problems. The technique has since had varying degrees of success on stage. Real events are reconstructed and interpreted, either through fictional revisions or through the use of authentic documentary materials (*e.g.*, transcripts of trials, official reports, and lists of statistics). The form became popular in the 1960s through works such as Rolf Hochhuth's *Stellvertreter* (1963; *The Representative*), Peter Weiss's *Ermittlung* (1965; *The Investigation*), Heinar Kipphardt's *In der Sache J.R. Oppenheimer* (1964; *In the Matter of J. Robert Oppenheimer*), and in the Royal Shakespeare Company's *US* (1967). It has been used in Scotland in the 1980s by John McGrath's group called 7:84.

The Living Newspaper technique

Theatre of the Absurd. The postwar mood of disillusionment and skepticism was expressed in bizarre terms by a number of foreign playwrights living in Paris. Although they did not consider themselves as belonging to a formal movement, they shared a belief that human life was essentially without meaning or purpose and that valid communication was no longer possible. The human condition, they felt, had sunk to a state of absurdity (the term was coined by the French Existentialist novelist and philosopher Albert Camus). Some of the first plays of the Theatre of the Absurd, as the school came to be called, were concerned with the devaluation of language: Eugène Ionesco's *Cantatrice chauve* (*The Bald Soprano*, or *The Bald Prima Donna*) and Arthur Adamov's *Invasion* (*The Invasion*), both produced in 1950, and Samuel Beckett's *Waiting for Godot*, first produced in French as *En attendant Godot* in 1953. The spirit of Absurdism, however, can be traced back to Alfred Jarry's anarchic *Ubu roi*, produced in 1896. Logical construction and rationalism were abandoned in the Absurd school to create a world of uncertainty, where chairs could multiply for no apparent reason or humans turn inexplicably into rhinoceroses. Later Absurdist writers included Harold Pinter of Great Britain and Edward Albee of the United States, though by the 1960s the movement had nearly burned itself out.

Theatre of Cruelty. During the early 1930s, the French dramatist and actor Antonin Artaud put forth a theory for a Surrealist theatre called the Theatre of Cruelty. Based on ritual and fantasy, this form of theatre launches an attack on the spectators' subconscious in an attempt to release deep-rooted fears and anxieties that are normally suppressed, forcing people to view themselves and their natures without the shield of civilization. In order to shock the audience and thus evoke the necessary response, the extremes of human nature (often madness and perversion) are graphically portrayed on stage. Essentially an anti-literary revolt, the Theatre of Cruelty usually minimizes the text by emphasizing screams, inarticulate cries, and symbolic gestures. Artaud tried to achieve these ideals in his production of *Les Cenci* (1935), but his real influence lay in his theoretical writings, notably *Le Théâtre et son double* (1938; *The Theatre and Its Double*). Only after World War II did the Theatre of Cruelty achieve a more tangible form, first in the French director Jean-Louis Barrault's adaptation of Franz Kafka's *Prozess* (*The Trial*), produced in 1947, and later through the plays of Jean Genet and Fernando Arrabal. The movement was particularly popular during the 1960s, in part due to the success of Peter Brook's 1964 production of Peter Weiss's *Marat/Sade* for the Royal Shakespeare Company.

Surrealist theatre

Poor theatre. In terms of furthering the actor's technique, the Polish director Jerzy Grotowski, together with Stanislavsky and Brecht (see above), are the key figures of the 20th century. Grotowski first became internationally known when his Laboratory Theatre, established in Opole, Pol., in 1959, triumphantly toured Europe and the United States during the mid-1960s. His influence was further enhanced by the publication of his theoretical pronouncements in *Towards a Poor Theatre* (1968). Grotowski shared many ideas with Artaud (though the connection was initially coincidental), especially in the conception of the performer as a "holy actor" and the theatre as a "secular religion." Theatre was to go beyond mere entertainment or illustration; it was to be an intense confrontation with the audience (usually limited to fewer than 60). The actors sought spontaneity within a rigid discipline achieved through the most rigorous physical training. Rejecting the paraphernalia of the "rich theatre," Grotowski stripped away all nonessential scenery, costumes, and props to create the so-called poor theatre, where the only focus was the unadorned actor. His productions included adaptations of Calderón's *Príncipe constante* (1629; *The Constant Prince*) and the Polish writer Stanisław Wyspiański's *Akropolis* (1904; *Acropolis*).

Jerzy Grotowski's influence on acting

The poor theatre became a worldwide fashion during the late 1960s and early 1970s, even though most groups who attempted it produced only self-indulgent imitations that tended to exclude the audience. Significantly, this sense of reduction was evident in Grotowski's own work: from 1976 he excluded the audience altogether, preferring to work behind closed doors. The spirit of poor theatre has been more theatrically conveyed by Peter Brook. After leaving England in 1968 to establish the International Centre of Theatre Research in Paris, Brook created a series of vivid productions that included *Ubu roi* (1977), a scaled-down version of Georges Bizet's opera *Carmen* (1982), and *Le Mahabharata* (1985), a nine-hour version of the Hindu epic *Mahābhārata*.

United States. By the beginning of the 1950s the vitality of American theatre was acknowledged around the world. The international reputation of Eugene O'Neill was complemented by two potent young dramatists: Arthur

Miller, who turned the ordinary man into a figure of tragic stature in *Death of a Salesman* (1949) and *The Crucible* (1953), and Tennessee Williams, who created a world festering with passion and sensuality in plays such as *A Streetcar Named Desire* (1947). At the same time, the director Lee Strasberg, together with Elia Kazan, was codifying the teachings of Stanislavsky into "the Method," which generated both controversy and misunderstanding. Although the Actors Studio, founded by Kazan in 1947, produced many fine actors, including Marlon Brando, Geraldine Page, and Paul Newman, the Method proved inadequate as an approach to acting in classical plays; it was best suited to the realism of the new American plays and films.

Off-Broadway. This phenomenon developed as a reaction to the commercialism of New York theatre. More experimental plays could be presented in smaller buildings outside the main theatre district. The artistic success of many of these productions meant that some writers (Edward Albee, for example), could graduate to Broadway. Off-Broadway also enabled black playwrights such as James Baldwin and Leroi Jones (Imamu Amiri Baraka) to dramatize racial issues with a frankness that had not previously been seen on the American stage.

"Off-Off-Broadway"

During the 1960s, a strong avant-garde theatre movement known as "Off-Off-Broadway" emerged. Among the most influential groups were Joseph Chaikin's Open Theatre, Richard Schechner's Performance Group, Julian Beck's and Judith Malina's Living Theatre, and Peter Schumann's Bread and Puppet Theatre. These groups sought to smash the barriers between the actor and the audience, exploring ritual, sexuality, nudity, and primitivism. They also signaled, however, a movement away from literary values: coherent speech and concise dialogue were in most cases replaced by improvisations, grunts, and shrieks. As with the British "fringe theatre," this movement generated great excitement and vitality, but at its worst it produced gratuitous violence, self-indulgence, and ultimately the alienation of the very audience that it set out to embrace. The political wing of the avant-garde was street theatre, or "guerrilla theatre," where short agitprop ("agitational propaganda") plays were performed on city streets or in parks. In this manner, the San Francisco Mime Troupe combined political protest with the techniques of the commedia dell'arte to reach a non-theatregoing public. By the late 1970s, the wild experiments had dissolved into conventional playwriting, mostly of mediocre quality; Sam Shepard and David Rabe were exceptions. Even by the mid-1980s, very little had emerged to replace the exuberance of that period when theatre seemed to have found a new immediacy and a fresh way of involving all segments of the community.

Government subsidy. In spite of state aid from organizations such as the New York State Council on the Arts, created in 1960, and the National Endowment for the Arts (1965), the running of American theatre has remained strongly commercial. The most consistently successful American playwright from the 1960s to the 1980s has been Neil Simon, whose comedies such as *The Odd Couple* (1965) and *Plaza Suite* (1968) have fared very well. On Broadway theatre management, because of economic factors, has been reluctant to stage serious new plays unless they have been proven successes in London. A notable exception to this situation has been the New York Shakespeare Festival, founded by Joseph Papp in 1954 under the name Shakespeare Workshop. From 1962 it has occupied a permanent site—the outdoor Delacorte Theatre in Central Park—where it offers free entertainment. Since 1981, it has received a regular subsidy from New York City. Outside New York City, regional theatre has continued to expand with resident professional companies being established in many cities—the Guthrie Theatre in Minneapolis, Minn., for example. Such companies offer both commercial and experimental theatre as an alternative to touring Broadway hits.

The musical comedy. After Rodgers and Hammerstein breathed new life into the musical comedy with *Oklahoma!* (1943), the form acquired more sophistication with such Broadway successes as *Guys and Dolls* (1950) and *My Fair Lady* (1956), and it broke new ground in *West Side Story* (1957), which conveyed much of the plot through dance. The range of subjects widened: hippie culture was introduced in *Hair* (1967); religion was popularized in *Godspell* (1971) and *Jesus Christ Superstar* (1971); and dance became the central element in shows such as *A Chorus Line* (1975) and *Dancin'* (1978). By the 1980s, Stephen Sondheim had become the most innovative force in the musical theatre, combining the roles of lyricist and composer in such works of immense technical sophistication as *Company* (1970), *A Little Night Music* (1973), and *Sunday in the Park with George* (1984).

Revitalization of the musical comedy

University theatre. Another major source of theatre in the United States is supplied by the drama departments of colleges and universities. The American Educational Theatre Association (AETA) was established in 1936 with 80 members, but by the 1980s, as the American Theatre Association (ATA), it included about 1,600 U.S. college and university drama departments. All of these have their own theatre; some are as well equipped as Broadway and regional theatres. In addition to promoting work by local student groups, many university theatres from time to time employ professional actors and directors for summer stock productions.

Great Britain. World War II had left British theatre in a precarious state. In London's West End, about a fifth of the theatres were destroyed or damaged by bombing. Furthermore, production costs multiplied, an entertainment tax of 10 percent of gross receipts was imposed by the government, and theatre managements—many of them controlled by a monopoly known as The Group—tended to choose thrillers, light comedies, revues, and Broadway musicals over more demanding plays. In the early 1950s the star system dominated the theatre, and one of the most prominent dramatists was Terence Rattigan. The classics, however, were kept robustly alive by the last of the actor-managers: Sir Donald Wolfit, Sir Laurence Olivier (later Lord Olivier), and Sir John Gielgud. Olivier and Gielgud were supported by a generation of outstanding actors, many of whom had begun their careers in the 1930s and were able to adapt to changes in the theatrical climate (as well as to the growth of motion pictures and television) through to the 1980s. These actors included Sir Ralph Richardson, Sir Michael Redgrave, and Dame Peggy Ashcroft.

By the mid-1950s, the influence of Brecht was becoming apparent. The director Joan Littlewood was one of the first to use his techniques; in 1953 she moved her company, the Theatre Workshop (formed in 1945 in Manchester for working-class audiences), to the Theatre Royal, Stratford, in the East End of London. There she encouraged young writers and evolved a series of highly successful collective productions, many of them (*e.g., Oh, What a Lovely War!* [1963]) developed through improvisation. After observing the Berliner Ensemble at work in Germany, George Devine set up the English Stage Company at the Royal Court Theatre in 1956 to encourage new playwrights and promote foreign drama. That year marked a turning point in British theatre, with Samuel Beckett's *Waiting for Godot* (in his own translation) introducing the Theatre of the Absurd and John Osborne's *Look Back in Anger* initiating a new wave of antiheroic, "kitchen-sink" dramas. Other young writers at the Royal Court were Arnold Wesker and John Arden. The wider distribution of higher education grants after World War II meant that by the mid-1950s a new breed of actors was coming out of drama schools to perform these new plays. The rise of actors such as Peter O'Toole, Albert Finney, Tom Courtenay, Joan Plowright, and Alan Bates brought fresh energy to the theatre and marked a transition away from the elegant actors of the late 1940s who exuded upper-class sophistication.

Alternative theatre. A vigorous reaction against the mainstream of theatre erupted in the late 1960s, stimulated by a wave of political protest around the world, visits by French and American avant-garde companies, an upsurge of "alternative culture," and an abolition of the lord chamberlain's powers of censorship (1968). Following the example of the Traverse Theatre in Edinburgh, a profusion of "fringe" theatres sprang up in converted

Proliferation of "fringe" theatres

cellars, warehouses, and the back rooms of pubs. Rock music, Dada, and Artaud were inspiration for groups such as The People Show, Pip Simmons Theatre Group, and Ken Campbell's Road Show. Other companies—Foco Novo, Portable Theatre, 7:84, Belt & Braces, and CAST—were more politically motivated. From these came several major dramatists, including Howard Brenton, David Hare, Trevor Griffiths, and David Edgar, all of whom had been assimilated into mainstream theatre by the end of the 1970s. Although most fringe plays quickly disappear without a trace, several have successfully transferred to the West End. Indeed, the fringe continues to provide an important stimulus for the British theatre.

National theatres. Since the early 1960s, Britain's theatrical reputation had rested mainly on the work produced by its two national companies. Peter Hall formed the Royal Shakespeare Company in 1961 as a reorganization of the Shakespeare Memorial Theatre at Stratford-upon-Avon. The following year, he was supported by two codirectors, Peter Brook and Michel Saint-Denis, and the company opened a permanent London base at the Aldwych Theatre to explore modern and classical plays while concentrating on Shakespeare at Stratford. During this period, Brook established himself as one of the finest directors of the century, two of his most memorable productions being *King Lear* (1962) and *A Midsummer Night's Dream* (1970). In 1982, under the artistic directorship of Trevor Nunn and Terry Hands, the company left the Aldwych and moved into the newly built Barbican arts complex in the City of London, while retaining the Stratford theatre.

The first attempts to set up a permanent national theatre in London were made in the 19th century, though it was not until 1962 that Sir Laurence Olivier formed the National Theatre company, which was temporarily housed in the Old Vic. After delays by successive governments, work began in 1969 on the National Theatre building (housing three separate theatres), situated on the south bank of the Thames not far from the site of Shakespeare's Globe Theatre. It finally opened in 1976 under the directorship of Peter Hall (later knighted).

The importance of these two companies is that, apart from providing lavish reassessments of classical plays featuring the best actors of the day, they have been able to commission large-scale works that no one else could have afforded: John Whiting's *Devils* (1961) and Peter Shaffer's *Royal Hunt of the Sun* (1964) both broke away from the "well-made play" construction, leaning toward the Epic Theatre of Brecht; and David Edgar's 8½-hour dramatization of Dickens' *Nicholas Nickleby* (1980) proved a huge success in London and in New York City. Notwithstanding the emphasis on classical work, both companies have retained a strong commitment to contemporary drama and have nurtured Britain's leading dramatists of the 1970s and 1980s, including Harold Pinter, Edward Bond, Tom Stoppard, Alan Ayckbourn, David Hare, and Howard Brenton.

Government subsidy. One of the major changes in British theatre since World War II has been that state subsidy plays an increasingly vital role in its development and survival. While the subsidy has helped to shield the theatre from commercial pressures, it has left the theatre vulnerable and overdependent on continuing grants.

State aid began with the formation of the Council for the Encouragement of Music and the Arts (CEMA) in 1940. From this developed the Arts Council of Great Britain in 1946 with the aim of providing "State support for the arts, without State control." It has encouraged new writing and supported fringe, touring, community, and repertory theatres, including the two national companies, besides subsidizing Regional Arts Associations and other artistic ventures. By keeping ticket prices artificially low, the Arts Council has helped to make serious drama accessible to most of the population and thereby provides a widespread alternative to commercial theatre.

From the early 1960s, the sums given to the Arts Council by the government increased substantially. By the end of the 1970s, however, the rate of expansion had outstripped the supply of money, and most subsidized theatre companies were facing serious cutbacks, some actually closing. As a consequence, in the 1980s the government and the Arts Council adopted a policy of encouraging theatres to seek additional sponsorship from industry.

Regional theatre. In the provinces theatre is divided into touring, repertory, and amateur companies. Large theatres in the main cities are visited by touring companies, and at Christmastime most of them stage an elaborate pantomime that often runs for three or four months. After a lean period in the 1950s when it competed with television, repertory theatre (now also known as regional theatre) found new life in the 1960s with the building of many fine civic playhouses, some even equipped with additional studio theatres for experimental work. Improved conditions, longer runs, and increased subsidies resulted in higher artistic standards. The repertory theatres remain a valuable testing ground for actors, directors, and dramatists, often supplying new plays and productions for the West End. The vast amateur-theatre movement in Britain (there were about 17,000 groups by the mid-1980s) is coordinated by the British Theatre Association, formerly called the British Drama League. The association also runs many training courses throughout the country. Although there is little movement from amateur to professional status, the National Youth Theatre has given many prominent actors their first experience in theatre. Most professionals graduate from drama schools, some of the most reputable being the Royal Academy of Dramatic Art (RADA), the Central School of Speech and Drama, and the Guildhall School of Music and Drama.

Importance of repertory theatres

Australia, New Zealand, and Canada. From the early 1970s, a characteristic style of theatre emerged in Australia, spawned mainly by smaller companies. Typical examples of such companies are the Australian Performing Group in Melbourne and the Nimrod Theatre in Sydney, both of which are dedicated to promoting the work of new writers. New Zealand has witnessed similar efforts. Most of the plays have been produced in Auckland's Mercury Theatre and Wellington's Downstage, with very few being performed outside New Zealand. Canadian drama has been equally slow to reach the international stage in spite of vigorous efforts to encourage new plays. More prestigious is the annual Shakespeare Festival at Stratford, Ont. Founded in 1953 by Tyrone Guthrie, it has produced a consistently high standard of work and has attracted some of the finest Canadian and British actors.

France. Although France has produced a number of outstanding dramatists since World War II, including Jean Anouilh, Jean-Paul Sartre, Samuel Beckett, Jean Genet, and Marguerite Duras, the development of the theatre has been dominated by directors. A leading force, and one of the greatest actors of the century, has been Jean-Louis Barrault, who excelled in both classical and modern plays. As a mime (trained by Decroux), he achieved international fame for his re-creation of the pantomimes of Deburau in the film *Les Enfants du paradis* (1945; "The Children of the Gods"), and as a director he became the foremost exponent of the poetic dramas of Paul Claudel. In 1946 he left the Comédie-Française with his wife, the actress Madeleine Renaud, to form the Compagnie Renaud-Barrault, which has remained one of France's finest and most innovative companies.

The achievements of Jean-Louis Barrault

Mime found another champion in Marcel Marceau. He developed the character Bip in 1946 and has since toured the world many times with his solo performances.

An attempt to widen the appeal of theatre was made in 1951, when Jean Vilar was appointed director of the Théâtre National Populaire (TNP). At the huge Palais de Chaillot in Paris (seating nearly 3,000), Vilar brought together new audiences by presenting a repertoire of mainly classical plays at ticket prices that students and workers could afford. As part of a policy to decentralize French theatre by setting up provincial companies, the TNP was moved to Villeurbanne in 1972 under the directorship of Roger Planchon. A move toward collective creation in the late 1960s precipitated a wave of vigorous avant-garde companies such as Ariane Mnouchkine's Théâtre du Soleil and Jérôme Savary's Grand Magic Circus. By the mid-1980s, however, the absence of gifted new writers shifted the emphasis in French theatre to reassessments of

classical plays, particularly those of Molière. Two of the most prominent directors have been Antoine Vitez at the Théâtre National de Chaillot and Patrice Chéreau at the Théâtre des Amandiers at Nanterre.

Germany. Few dramatists of distinction appeared in Germany after World War II in spite of the stimulus created by the return of Brecht, the rebuilding of theatres, and the large amounts of money poured into the theatrical arts by both the East and West German governments. Consequently, German classics and foreign plays dominated the stage. The two notable German-speaking dramatists of the 1950s, Max Frisch and Friedrich Dürrenmatt, were both Swiss. Outstanding work, however, was achieved by the Austrian-born actor, Fritz Kortner, who returned to West Germany from the United States in 1947 to direct a series of productions imbued with meticulous realism. Throughout the 1960s, there was more sense of experiment in plays by Peter Weiss (living in Sweden), Peter Handke, and Günter Grass. Peter Stein, director of the Schaubühne in Berlin from 1970 to 1985, earned international acclaim through his innovative interpretations of foreign plays, especially Gorky's *Dachniki* (1905; *Summerfolk*) in 1974 and Aeschylus' *Oresteia* in 1981. In East Germany, where the theatre has been heavily controlled by the state and geared toward educating the workers on farms and in factories, Socialist Realism has proved a deadening influence.

Soviet Union. After Stalin's death in 1953, the heavy restrictions on Soviet theatre began to loosen, signaling a slow and cautious return to experiment. The influence of Meyerhold (rehabilitated in 1955) was discernible in productions by the veteran Nicolay Okhlopkov, who remained the most original and stimulating director of his day. The scale of the Soviet theatre was gigantic: companies played in more than 50 languages; there were vast numbers of theatres, many with huge and superbly equipped stages; companies of 100 actors or more were not unusual, and they maintained extensive repertoires. Yet, the security derived from enormous state subsidies, combined with the vast output of work, tended to give rise to mediocre standards.

So large was the theatregoing public that the professional theatre could not satisfy the demand for dramatic entertainment, and every encouragement was given to the amateur movement. Most companies accepted responsibility for at least one amateur group, the members of the company giving much time to advising and training it. Amateur companies of outstanding merit were given the title "people's theatre." The close relations between amateurs and professionals were mutually beneficial, for professionals found that the contact infused freshness and reality into their work.

Shift in emphasis

In the 1960s, the theatre gradually began to free itself from ideology, placing more emphasis on entertainment value. Socialist heroes gave way to ordinary citizens on the stage; farce and vaudeville were revived; and absurd, grotesque, and fantastic elements reappeared in new plays. By the late 1970s, one or two of the experimental companies could once more take their place alongside the best in Europe. The Rustavelli Company from Georgia was acclaimed during its visits to Britain in 1979 and 1980. Yury Lyubimov, director of the prestigious Taganka Theatre, successfully reproduced his adaptation of Dostoyevsky's *Prestupleniye i nakazaniye* (1866; *Crime and Punishment*) in London in 1983 with English actors. In search of even more artistic freedom, he defected to the West the following year.

Other European countries. Of all the eastern European countries, Poland has produced the most exciting theatre, but because of heavy censorship this has come from directors rather than from writers. Experiment has long been encouraged within the state-subsidized system, and in the 1960s several Polish dramatists of the pre-World War II period, including Stanisław Wyspiański, Stanisław Ignacy Witkiewicz, and Witold Gombrowicz, were rediscovered in powerful productions that commented on contemporary issues. Apart from Jerzy Grotowski, prominent directors included Andrzej Wajda, Józef Szajna, and Tadeusz Kantor. The latter was the founder of the Cricot 2 theatre group, and his production in 1975 of *Umarla klasa* (*The Dead Class*), mixing puppets and actors, recalled Gordon Craig's concept of the *Übermarionette.* A strong mime company was led by Henryk Tomaszewski. In Czechoslovakia mime had another gifted exponent in Ladislav Fialka, and at the National Theatre in Prague during the 1950s Josef Svoboda was widely regarded as the world's leading stage designer.

In Italy theatre was stimulated by the establishment of permanent regional companies (*teatri stabili*) immediately after World War II. The first of these, the Piccolo Teatro di Milano, was controlled by Giorgio Strehler, Italy's finest director. His production of Carlo Goldoni's aforementioned play *Servitore di due padrone,* frequently revived since 1947, became world famous. The abolition of censorship in 1962 opened the way for more adventurous experimental theatre, though once again directors overshadowed playwrights. The exception has been Dario Fo, a brilliant actor, mime, director, and dramatist, whose political farces evoked the spirit of the commedia dell'arte. One of his most widely translated plays is *Morte accidentale di un anarchico* (1970; *Accidental Death of an Anarchist*).

Theatrical Production

Theatrical production comprises all aspects of planning, rehearsing, and presenting a work to an audience at a particular time and place by living performers using either themselves or inanimate figures such as puppets as the medium of presentation. A theatrical production can be either dramatic or nondramatic, depending upon the activity presented. While dramatic productions frequently conform to a written text, it is not the use of such a text but rather the fictional mimetic (from Greek *mimēsis,* "imitation," "representation") nature of the performer's behaviour that makes a work dramatic. A person walking a tightrope is performing an acrobatic act, whereas a person who pretends to be an acrobat walking a tightrope is performing a dramatic act. Both performers are engaged in theatrical presentation, but only the latter is involved in the creation of dramatic illusion. Though a dramatic performance may include dancing, singing, juggling, acrobatics, or other nondramatic elements, it is concerned mainly with the representation of actual or imagined life.

In nondramatic theatrical productions there is no imitation of "another existence" but simply the entertainment or excitation of the audience by the performer. Whether acrobatic or musical, gestural or vocal, such activity is theatrical because it is presented by a living performer to an audience, but it remains nondramatic so long as it has a purely presentational quality rather than a representational one.

In any single theatrical production, one or another type of activity may so prevail that there is little difficulty in determining the aesthetic nature of the final work. A play by the 19th-century Norwegian dramatist Henrik Ibsen, with its depiction of middle-class behaviour, minimizes nondramatic activity; the recital of a song by the 19th-century Romantic composer Franz Schubert, by contrast, with its emphasis upon musical values, may ignore dramatic elements and, to a great extent, even the act of presentation itself. Between these extremes, however, there are many types of theatrical production in which the aesthetic nature of the form is less simple. Opera, for example, employs both drama and music, in shifting patterns of emphasis.

In the 20th century in Europe and the United States several forms arose that combine dramatic and nondramatic material. Vaudeville, or music hall, for instance, employs a succession of fictional sketches, musical and dance numbers, feats of dexterity, and other acts, some of which are representational, others not. In the musical theatre, song and dance serve both to further the narrative and to provide a break from purely dramatic presentation. This variety also characterizes much of Oriental theatre, in which dramatic moments are elaborated in dancelike exhibitions. In light of these examples, the definition of what constitutes theatrical production must remain elastic.

The present article examines the chief elements of theatrical production and the development of theatres and staging and concludes with a survey of scenic design, stage lighting, stage machinery, costumes, and makeup. For a general discussion of theatre as an art form, with specific treatment of the crafts of acting and directing, see THEATRE, THE ART OF THE. Drama as a literary genre is treated in LITERATURE, THE ART OF. The history of dramatic literature is covered in THEATRE, THE HISTORY OF WESTERN; and with that of the other genres according to language—*e.g.,* AMERICAN LITERATURE; FRENCH LITERATURE. For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* Part Six, Division II, especially Section 622.

The article is divided into the following sections:

Elements of theatrical production

According to the British director Peter Brook, theatre occurs whenever someone crosses neutral space and is watched by another person. This definition raises some problems, such as the difficulty of determining neutral space, but it is useful in its firm commitment to demystifying theatrical production. In former times the idea of the actor as motivated by a desire to create astonishment and wonder was sometimes seen as the basis of all theatre. Certainly there are types of performance that entail ritual and magic, but theatre is far more frequently rooted in attempts to structure emotion and experience.

Generally speaking, all theatrical productions have certain elements in common: the performer or performers, their acting in space (usually some sort of stage) and time (some limited duration of performance), and a producing process and organization.

THE PERFORMER

Skills and attributes. The work of the actor falls into five main areas: (1) the exhibition of particular physical, including vocal, skills; (2) the exhibition of mimetic skills, in which physical states and activities are simulated; (3) the imaginative exploration of fictitious situations; (4) the exhibition of patterns of human behaviour that are not natural to the actor; and (5) interaction, while engaging in these activities, with other actor-characters and with members of the audience.

At certain times in the history of Western theatre, the highest degree of physical skill has been associated with nondramatic performance. In Oriental theatre, however, such distinctions do not apply. Chinese opera and Japanese drama require the actor to play one type of role for his entire professional life. The actor must play this role in a manner strictly determined by tradition, reproducing specific patterns of movement and speech that can only be mastered by first gaining control of complex physical skills. Later, if especially gifted, an actor may bring to a role certain refinements of the tradition, which may be handed down to a succeeding generation.

Western drama, however, does not usually provide the actor with quite so defined a repertoire of movements and utterances. It is true that actors in the Italian commedia dell'arte of the 16th to the 18th century specialized in one role and transmitted to their successors a body of situations, speeches, and *lazzi* (stage sketches, or routines). Nevertheless, they seem to have had more leeway than their Oriental counterparts in exercising invention and personal expression. Great rhetorical skill has been demanded of the Western actor, however, for the intricate metrical patterns of Greek, Latin, French, English, and Spanish drama have been part of the glory of their respective theatres.

Naturalistic theatre, which flowered in the late 19th century, made rhetoric obsolete, requiring the actor to hide virtuoso performing skills by creating the illusion of everyday behaviour. This meant that more weight was given to the actor's personal attributes. The magnetism of a performance derived no longer from stylized behaviour but from intense personal revelation. This requires a marked ability to focus energies, to concentrate intently either upon the audience directly or upon a fellow actor and, thereby, indirectly upon the audience. All good actors can project a concentrated force, or "presence," which has become increasingly important to the actor in performance as set patterns of playing have disappeared. Presence is not a fixed, definable quality but rather a process of continuous growth and change that takes place before the eyes of the audience.

Relation to the audience. In nondramatic theatre the performer generally acknowledges the presence of the audience and may play directly to it. In dramatic theatre the actor may or may not do so. In Greek Old Comedy, an actor speaking for the author might cajole, advise, or challenge the spectators. By contrast, the naturalistic actor plays as though a "fourth wall" closes off the room of the stage. Between these two extremes fall a variety of relationships. In some instances, although direct contact is made, the audience is itself assumed to be playing a role, as in trial plays in which the audience is treated as a jury or as spectators in the court of justice. In other instances, the actor may address the audience one moment and play as though there were a fourth wall the next.

The quality of the contact between performer and audience is subtly modified by the nature of the performer's place and role in society. In the broadest terms, the performer may be seen as a celebrant, servant, or critic of society. As a celebrant, the actor performs an almost priestly function, and in certain types of production the actor may in fact be a priest. In such instances, the actor mediates between the audience and the divine or spiritual dimension. In Greek tragedy, Japanese Nō theatre, and medieval mystery plays the actions of the performers have a religious as well as dramatic significance, but this is by no means always the case.

More often the actor has been a servant, akin to the household retainer or court jester. In classical Rome actors were slaves or lowly freedmen. In Elizabethan England the actor was nominally the protégé of a powerful courtly patron or, if he lacked patronage, was considered a rogue and vagabond. Such performers, as servants or inferiors, necessarily approached their audiences in supplicatory terms. With the growth of the commedia dell'arte companies, which were established on a commercial basis, the relationship between actor and audience changed into one of producer and consumer.

In the 19th century, with the flourishing of the Romantic movement and the rise of nationalist consciousness throughout Europe, the actor as rebel began to appear.

The role of the theatre was then a powerful one; actors learned to utilize the material of the play, even of classic works, to make political statements. Later, in the 20th century, the traditional boundaries between actors and spectators were broken down, and the performer became in some cases a virtual assailant of the audience. The Living Theatre, formed in 1947 in New York City by Julian Beck and Judith Malina, engaged the audience in direct personal and physical contact. In the 1970s, Augusto Boal of Brazil developed the theatre of the oppressed, in which performance was intended to serve the triple function of entertainment, education, and consciousness-raising. Similar techniques found wide use in the 1970s and '80s in such special-interest movements as feminist theatre, homosexual theatre, black theatre, prison theatre, theatre of the deaf, theatre of the handicapped, and theatre of the aged.

The actor as character. Another aspect of the dramatic performer's work has to do with the portrayal of characters, both as individuals and as types. In portraying an individual character, the performer adopts a fictional framework and acts according to the text's demands. When playing Macbeth, for instance, he behaves "as if" he sees the phantom dagger referred to in the text. In many roles, however, the actor must work within established categories of stock types. Roman comedy, for instance, utilized a limited number of stock characters, such as the cunning slave, the passionate young lover, and the suspicious old father. The king, the wise counselor, the raging tyrant are examples derived from historical and biblical sources; the leading man, the juvenile, the ingenue, and the villain are examples from theatrical tradition itself.

Stock characters

While stock types stress those features of personality common to all human beings, naturalistic, or "slice-of-life," drama seeks to individualize each role. This requires that the actor as well as the author draw from personal observation and experience. With the rise of dramatic Naturalism in the late 19th and early 20th centuries, there arose corresponding theories of acting, notably those of Konstantin Stanislavsky, director of the Moscow Art Theatre. While an actor of this period might start with a generalized "type" (a country doctor, for example), efforts during rehearsal were bent on differentiating this doctor from any other. This style of acting demanded extensive preparation, with rehearsal periods of up to a year.

Naturalistic acting raises questions about the relation between the actor and the role performed: Does the actor merely simulate behaviour, or does he in some sense actually experience the passions and thoughts of the character? Central to the actor's art though this question is, it has never been satisfactorily answered.

SPACE AND TIME

The distinction between actor as performer and actor as character is matched by a distinction between the presentational and representational nature of space and time in theatrical production.

The playhouse area. Performer and audience exist together in a common area, within which there is a clearly delineated performing space (ring, stage platform, pit) and an audience space, the two structurally related. Some of the more common patterns of relationship are (1) an amphitheatre, with a bank of spectators half surrounding a playing area; (2) a circle of spectators standing or sitting around a ring in which the performance takes place; and (3) rows of seated spectators facing a raised platform. Theatre space is often associated with a special building, but this has not always been the case, nor is it always the case in modern times. Often theatre space has embraced a town square or even an entire town so that performers and audience are able to mingle. Modern attempts to create a space within which the distinction between performer and audience is blurred (called environmental theatre) echo earlier examples from the popular theatre.

Performance space and audience space

Isolation of the performer. Almost all productions (the so-called happenings of the 1960s are notable exceptions) endeavour to achieve two basic aims. First, every production seeks to impart a special quality to the theatrical area. Use of a theatrical building may in itself provide a heightened sense of locale. Otherwise, special decoration of familiar locales (town, market square) may transform them into ceremonial or festive spaces. Next, every production tries to make the performer visible and audible to the audience. On flat ground the circle or ring has often proved best. In hilly country the amphitheatre is the readiest solution. When a playing area is to be permanent, some means of raising the performer above the level of the crowd is often introduced, such as boards laid over trestles. The degree to which the performer is to be isolated depends partly on how complete and detailed a view of the presentation the audience expects.

The isolation of the performer has, however, another property. Marking out a playing area was in early antiquity an activity connected with religion. In classical Greece, for instance, the altar of the god Dionysus was surrounded by a circle for dancing. This was the origin of the performance space. Even when the direct religious tie was broken, stepping into the ring or onto the stage was still regarded as a passage into another world. This is equally true of the sawdust ring of the circus and the bare boards of the trestle stage. Some traditional theatres, especially those of the Orient, still regard the act of preparing to go on stage (putting on makeup, for instance) as sacred. Because of this, the isolation of the actor is spiritual almost as much as physical.

Symbolic aspects

Illusion of place. In dramatic production the magical property with which a performing area is invested is augmented by the fictional action of the drama. The stage becomes another locale by an act of imagination undertaken by both actors and audience. The illusion of place may be created simply by speech: at the opening of a scene in Shakespeare's *Twelfth Night,* for instance, one of the characters asks, "What country, friends, is this?" and is told, "This is Illyria, lady." It may be created visually, by the designer's ingenuity; the audience sees a room or a garden, and its attention is fixed on this imaginary setting, while its consciousness of the stage as a performing space becomes secondary.

In some productions, especially those inspired by the antinaturalistic theories of the Russian director Vsevolod Meyerhold, the audience is constantly reminded that it is in a theatre. Naturalistic productions, in contrast, following the principles of Stanislavsky, encourage a clear distinction between performing area and viewing area. On the other hand, the theatre has often reconciled the contradictory elements of dramatic space. The ancient Greek theatre combined the actor's platform with a more public dancing circle, to which there was ready access from the seats. The 18th-century English stage moved out from a recessed picture of a representational locale to a projecting apron that merged with the auditorium. In both examples, the theatre found a physical convention for mediating between actor and audience.

Real versus illusory time. Time likewise has a dual character in drama. The performer and audience exist together in chronological time. But the actor as character exists in dramatic time. Neoclassical drama of the 17th century, especially in France, endeavoured to make the duration of the performance coincide with that of the play's action. But, as a rule, drama has achieved its effects by accentuating the discrepancy between "real" and "illusory" time.

On one hand, the performer projects a sequence of activity upon which the audience concentrates intensely. Because it is difficult to maintain full attention over very long periods, it must be modulated; that is, stimulated, relaxed, and stimulated again. These contrasts and suspense make the real time spent at a performance absorbing and deeply felt. This experience is heightened by the illusion that another time scheme is also operating, that of the fictional event. Some drama gains its effects by suggesting that chronological and dramatic time differ between, but not within, scenes; that is, months may pass between Act I and Act II of *Three Sisters* by the Russian playwright Anton Chekhov, but within any act the dramatic time scale is the same as the chronological one. Shakespeare, however, presents a scene in *Othello* (Act II, scene 2) that takes about 25 minutes to play, yet during this scene an

Modulation of attention

entire night supposedly passes. One of the most extensive temporal schemes in drama is to be found in the medieval cycles of miracle plays, which unfolded over a period of two to four days and which covered the history of the universe from a time before Genesis to the Day of Judgment yet to come.

In contrast to this ambitious inclusion of all time is the handling of time in Japanese Nō theatre, in which real time, with its inevitable passage, is retarded to create a sensation of timelessness. The deliberate pace of the performer, the reiteration of the drum, and the unchanging facade of the stage add to this impression. The American Robert Wilson has devised performances that may last through the night. In these circumstances, the tension that results from expectation and that directs the mind to anticipate events and outcomes is dissipated, the spectator tires, and the mind fluctuates between waking and half-sleeping states in which the events on the stage mingle with mental fantasies to produce a new mode of consciousness.

THE PIECE AND ITS PERFORMANCE

Planning and rehearsal

Preparation of content. Traditionally the dramatic piece has been planned in advance and rehearsed, although there are degrees of advance planning and rehearsal. Even the supposedly impromptu performances of the commedia dell'arte players could not take place without detailed preparation beforehand. In much dramatic theatre advance planning involves the preparation of a written script, sometimes prepared by a dramatist and sometimes created by the actors themselves in collaboration with each other or with a writer. The script thus may be either a tentative scenario or a finished blueprint of the final presentation (a playtext).

Whether scenario or playtext, a piece consists of segments of activity arranged in a meaningful sequence. More often than not this is a narrative sequence, and thus each segment of activity presents a step in the unfolding of a story. But the sequence may also be based on a common motif or recurrent characters. The segments of activity, usually termed episodes or scenes, can include many kinds of behaviour—*e.g.*, persuasion of one person by another, delivery of a speech, singing of a song, hand-to-hand combat.

Theatrical tradition and social practice largely determine the scope of the material to be presented. In ancient Greece, for example, myths often provided the material for tragedy, with debate, lamentation, prophecy, and choral comment constituting the main activities. In other traditions, storytelling, singing, acrobatics, and speeches are the ingredients. The dramatist, manager, and actor all operate within the context of performing routines and production conditions. Material drawn from other arts and from personal experiences may also be used.

Performing the piece. The occasion affects the manner in which the actor addresses the audience or represents a character; it also influences his physical appearance. In Japanese Nō theatre and ancient Greek drama, the actor is often transformed by costume into a superhuman figure. Raised headdresses, painted or masked faces, enveloping robes all contribute to the creation of a figure endowed with symbolic significance. In some societies, the actor is viewed not as a hero or demigod but as the epitome of contemporary society.

Although the actor is the focus of attention while performing, the preparatory and rehearsal phases tend to be organized by others. While in the Renaissance the actors themselves were in control of all phases of production, at other times they have been under the control of theatre managers and stage directors. A significant part of the alternative theatre movement in the mid-20th century was an attempt on the part of actors to establish a collective organization and to reclaim a share of power in the process of making theatre.

The importance of stage scenery is determined by the degree to which either the auditorium or playing area needs to be transformed for a performance. Four possibilities exist: little or no change is introduced into either area (as in the Elizabethan public theatre); the playing area remains unaltered while the audience area is changed (as in erecting banks of seating in a town square); the playing area is changed while the audience area remains fixed (as in proscenium theatre, in which a frame or arch separates the stage from the auditorium); or both areas are transformed (as in Renaissance court theatre or some contemporary theatrical productions).

The fixed playing space often has emblematic significance. In Japan, the Nō stage has three pine trees symbolizing heaven, Earth, and man, and on the Kabuki stage the right-hand side is more eminent than the left. The Elizabethan playhouse used trap doors to signify transit from Earth to heaven or hell. The practice of changing the visual and physical arrangement of the playing area became widespread in Europe during the Renaissance. At first, designers devised generalized scenery to be used for tragic, comic, and pastoral dramas. Later they created a setting unique to a particular play. With the emergence of designed space and changeable scenery, there arose an entire profession of scenic architects and mechanics whose work at times overshadowed that of the actors in importance. By the 20th century the designer's task had become so complex that it was usually divided among scenic, costume, and lighting personnel and involved technicians, electricians, stagehands, prop masters, wardrobe mistresses, and many others working together.

The emergence of set design

No single pattern for production exists, since there are too many social and personal variables at work. Certain broad observations can be made, however. First, any production is normally part of a more continuous enterprise. The continuity may be provided by the civic or religious life of the community, the stable associations of an acting troupe, or the permanence of a producer's office.

Patterns of theatrical production

Next, the production process tends to be either cooperative or hierarchical. The company for which Shakespeare wrote and to which he belonged seems to have been a collective. It remained for more than 25 years a community of professional associates and friends. More usual is the hierarchical organization, in which a single individual controls a production. In most instances, the professional specialty of that leader is dictated by the conditions of the particular theatre in which he works. In 17th-century France, for instance, the leader virtually had to be an actor (Molière was an actor turned actor-manager-dramatist). In the commercial theatre of the 20th-century United States he virtually has to be an impresario.

Finally, the mode of planning and rehearsing a production may be influenced by the artistic concept of an individual or a group. As long as theatre was part of a continuing tradition, its mode of production varied little, being conditioned partly by the social role of theatre and partly by the type of material the actor performed. Thus, the actor who played one type of role for an entire professional life concentrated on perfecting recurrent stage routines, while the actor who handled many different roles within a brief season had to be more adaptable.

During the 19th century there evolved new theories of production that affected both styles of performance and methods of rehearsal. Gradually, the idea of ensemble arose, stressing harmony of ideal and craft among what was usually a small group of actors in order to achieve a unity of effect. These ideas necessitated the careful orchestration of all elements of production. In the 18th and early 19th centuries, the dominant element was the star actor; it then became the star ensemble (the Moscow Art Theatre, for instance) and, through the ensemble, the director.

Aspects of theatrical production

The development of international communications has had its effect on the theatre. The advent of railway and steamship travel in the 19th century led to an increase in international touring by theatre companies, and performers such as the French actress Sarah Bernhardt and the Italian operatic tenor Enrico Caruso became as well known in North and South America as in Europe. In the 20th century the cinema, radio, and television and video recording extended even further the range of potential audiences for theatrical performances. In the 1960s The Living Theatre inspired a whole generation of performers throughout the world, and Jerzy Grotowski's Polish

Laboratory Theatre influenced performers who had never been to Europe or seen him work firsthand. International theatre festivals that bring together performers from many varied traditions have become regular occurrences.

TYPES OF PRODUCTION

Numerous forms of spectacle, such as dramatic and nondramatic pageants, the circus, son et lumière, and gymnastic presentations, are closely allied with theatre and indeed are considered by some classifications to be theatrical. Some of these types of production are treated more fully in the article PAGEANTRY AND SPECTACLE.

Pageantry. Nondramatic pageantry includes civic processions, such as parades, as well as static displays, such as gymnastic demonstrations. The appeal of nondramatic pageantry lies in overwhelming visual spectacle. The performer is presented as a member of the collective, and, even where one individual may stand out, such as the parade "royalty," he is essentially passive and wins attention merely as the focal point of a number of performers. In certain religious pageants the focal figure is not a living person at all but the icon or statue of a god or saint.

Dramatic pageantry has much in common with the nondramatic: both have communal involvement, stress on visual display, processional or static masses, and a fictional character. Segments of the pageant may illustrate a historical or legendary incident, or the pageant as a whole may have a historical, mythical, or allegorical theme. Performers in the United States reenacting the dumping of tea into Boston Harbor exemplify historical pageantry; in England the assault on the Castle of Beauty by Knights of the Mount of Love, a pageant celebrating the marriage of Prince Arthur to Catherine of Aragon in 1501, exemplifies the allegorical type common at Renaissance courts. Pageantry of both the dramatic and nondramatic sort continues to play a significant role in the legitimization of political actions and the assertion of social prestige.

Nondramatic theatre. Nondramatic productions include diverse oral and musical presentations, circus and vaudeville acts, gymnastic displays, and ceremonial occasions such as the coronation of a monarch. There is no narrative line in such productions, but the technical virtuosity of the performers or the ritual significance of the event becomes the focus of audience attention. As a form of presentation, the circus encompasses a wide range of different types of performance, including feats of daring, illusion, and skill. The type of circus performance that comes closest to dramatic theatre is that of clowns. The clown engages in simplified and circumscribed dramatic activity, sometimes a ludicrous parody of other forms of performance, but one that follows established conventions of dress, gesture, and behaviour.

The clown

In the latter part of the 20th century, boundaries between types of theatrical production have been increasingly eroded. As circuses have declined in popularity, circus techniques have been incorporated into other forms of theatre. So-called third theatre companies often use circus training techniques, and actors employ juggling and acrobatic skills in their dramatic performances. The British Footsbarn company, which travels the world in a manner reminiscent of the medieval and Renaissance players, uses circus imagery and techniques in its productions of Shakespeare. Samuel Beckett used the image of the clown in *Waiting for Godot* to create a parable on the absurdity of the human predicament.

Cabaret and vaudeville shows also bring together different types of performance, such as music and dancing, dramatic sketches, feats of daring, and illusion. These productions can take place in any kind of theatre or in nightclubs and restaurants, since staging requirements are usually minimal. It is possible to see this kind of performance as deriving directly from the street entertainers of folk culture and from the entertainments that took place between courses during medieval court banquets.

Cabaret and vaudeville

Dramatic theatre. The most common form of dramatic theatre is the presentation of a scripted play in which the actions of the performers depict a narrative. Typically, performers of such works consist of actors portraying characters, although Sicilian Paladin puppets, Javanese *wayang* shadow puppets, and Japanese *bunraku* puppets are examples of nonliving representations of characters, manipulated by living performers.

In some forms of dramatic production, music and dance may provide or supplement the narrative content. Opera inhabits a special region between drama and music and has prompted much discussion as to the relative importance of literary and musical elements in advancing opera's dramatic aspects. The musical development of opera predominated in the 17th and 18th centuries, whereas new works and productions since Richard Wagner in the late 19th century have increasingly emphasized dramatic features. Operetta and musical comedy are often seen as more closely allied to the theatre than to opera (see MUSICAL FORMS AND GENRES).

The musical, which has developed out of the operetta and musical comedy as an indigenous American theatrical genre, has become a powerful art form in its own right. Beginning with Oscar Hammerstein and Jerome Kern's *Show Boat* in 1927 and proceeding by way of the Rogers and Hammerstein musicals to the work of Leonard Bernstein and Stephen Sondheim, the musical has exhibited a growing sophistication and maturity in both themes and techniques. The modern musical integrates singing, dancing, and acting to a degree that no other Western theatre form attempts.

Dance theatre. While dance usually is recognized as an art in its own right, it sometimes shares so many features with the theatre that it is difficult to distinguish the two. Dance figured strongly in the early development of drama in the West and remains an essential feature of Asian drama.

Dance theatre, combining elements of dramatic presentation and dance, may be considered a separate art form. Originally this type of performance was predominantly American, though the term Dance Theatre was adopted by an independent theatre founded in Wuppertal, W.Ger., in the mid-1970s by Pina Bausch. Bausch, who sought to break down the traditional boundaries between theatrical forms, was one of the most innovative performers in European theatre in the 1980s.

Mime. Mime remains closely connected to drama, being merely a highly specialized form of enactment. Relying on movement without words, it enjoyed an immense vogue in imperial Rome, contributed to the style of commedia dell'arte, and underwent a revival in the latter half of the 20th century at the hands of such French performers as Jean-Louis Barrault and Marcel Marceau (see DANCE, THE ART OF).

SYSTEMS OF PRODUCTION

Since planning, rehearsal, and performance are common to all theatrical productions, the various systems of organizing and conducting these activities provide a useful set of production classifications.

The single performance. Single or limited performance of a presentation, as part of institutional or communal life, has been fairly common throughout the history of the theatre. The Greek city-state (polis), the medieval town, the Japanese temple, and the American high school are but a few of the bodies that have typically sponsored such dramatic performances. The Greek city-state and the medieval town organized their productions in a strikingly similar way, with the municipality exercising control. Until at least the 4th century BC, however, the Athenians presented new plays every year, whereas the medieval townspeople annually reenacted the same plays or variations of them. Yet in both systems many aspects of production were the same from year to year so that, single performance notwithstanding, each individual offering relied upon an established tradition.

This was less true of the Renaissance court masque (an allegorical dramatic performance featuring music and especially dancing), which was also presented only once. Although each production belonged to a tradition of courtly entertainment, masques of the 16th and 17th centuries became increasingly lavish and novel. A court official was responsible for the overall piece, much in the manner of the later theatre manager or entrepreneur. It was he

The Renaissance court masque

who recommended a dramatic poet to provide the text, hired the actors, made arrangements for stage scenery, and approved the results before offering them to the sovereign. The most fundamental distinction between this kind of production and earlier institutional types is that the masque was devised to the taste and at the will of one person, the monarch.

The permanent company. The development of a production system depending on a permanent company introduced a new element into theatre—professional virtuosity. The emergence of professional theatre companies was a feature of Renaissance urbanization. Various courts had maintained performers throughout the medieval period, but these were usually musicians or single performers. With the emergence of the town, the theatre company began to appear throughout Italy, France, Germany, England, and Spain, usually consisting of between five and 16 actors who devoted their lives to their craft.

The repertory troupe. Initially, the company was obliged to tour, since neither court nor city could employ full-time professionals. As a result, the actors became accustomed to performing in all kinds of places: halls, outdoor platforms, chapels, and village greens. To compensate for the lack of scenery, the actors used a rich array of costumes—some traditional for recurrent characters or situations, some opulent for their own sake. At all times the actors kept a number of plays in their repertoire so that they could either mount a new play at each performance during an extended stay in one place or repeat plays on request. When a troupe finally settled in one city, it continued this mode of presentation, and thus the modern repertory system was born.

Some permanent troupes performed pieces in which each actor portrayed a stock figure. Italian commedia dell'arte and Japanese Kabuki theatre both utilized such types. Molière, though as a dramatist far less rigid in portraying stock types, led a company each of whose members specialized. English and Spanish troupes, however, because of the demands of the plays, used actors who were much more flexible. The English and Spanish playwrights used a much wider range of characters in their episodic plays, and actors were required to play more than one role in productions. Otherwise, the companies had a great deal in common. Actors bought plays from writers, hired any supporting personnel they needed, and took the profits. Usually, the performers worked on a share system, dividing the proceeds among themselves.

Commercial management. The repertory troupe eventually came to be managed by an individual; the actor-manager was in his heyday from the late 18th to the early 20th century. As an employer, he was concerned less with the welfare of the actor and more with the profit he could extract from the public. Gradually, out of this change emerged the stock company and the single-show association. The stock company was an acting troupe usually managed and organized for a limited season to give a number of plays. Sometimes the manager would take the leading roles and engage others in support; otherwise, he would hire all the performers. The major shift in mode of production came when the stock companies stopped presenting plays in repertory and extended the run of a single play. This happened when city populations grew large enough to keep one play running for an indefinite time. At the end of the 17th century, a London play that ran for eight performances was deemed a success. In 1728, however, a production of John Gay's *Beggar's Opera* made theatrical history by running for 62 performances. By the mid-20th century, successful productions might run for several years. In London *The Mousetrap,* a dramatization of a thriller by Agatha Christie, has run for more than 30 years.

The stock company

With the extended run there was little need to maintain a company of actors, even for a season. Instead, single-show contracts were negotiated for actors, stage managers, scenic artists, a host of associates, and a theatre. Since a play was to be repeated indefinitely, it was feasible to invest more money in the accoutrements. Out of this system developed the need for an overall supervisor. At first, the manager or actor-manager undertook this task. Later, individuals specializing in this work appeared. As the play acquired commercial importance, the role of the dramatist changed so that by the 20th century the name of the dramatist had become a significant factor in selling a production.

The modern repertory company. During the rise of the stock company and single-show system, there continued to exist highly refined examples of the repertory ensemble. The Comédie Française, originally an amalgamation of two Parisian troupes, has existed since 1680. In opera the repertory system remains fundamentally unchanged. Toward the end of the 19th century, however, a widespread transformation of the acting ensemble and the repertory system it supported occurred throughout Europe. New theatres, devoted to naturalistic staging, were successfully established, and these, in time, became national theatres supported by the state.

Particularly famous among repertory companies are the Moscow Art Theatre and the Berliner Ensemble; others include the Abbey Theatre of Ireland, the Royal Shakespeare Company of the United Kingdom, and the Théâtre National Populaire of France. In Japan, the traditional Kabuki and Nō theatres have been declared national treasures. All of these theatres, because of government subsidy, maintain large staffs of actors, directors, designers, and other artists and craftsmen. Production is continuous. New plays or, more often, revivals of old plays enter the repertoire, while former productions are dropped. The works of major national authors receive regular performance, thus establishing the main lines of tradition for the company. Sometimes these repertory troupes conduct schools for training young people who might then enter the company.

Other systems. Besides these systems of production there are several forms known collectively as alternative theatre and later as third theatre. The impulses for the alternative theatre arose in the mid-1960s from a sense of dissatisfaction with traditional theatre, in terms of both its repertoire and its production methods and hierarchical structures. Known variously as underground, experimental, guerrilla, Off-Broadway, or fringe theatre, these nontraditional forms became widespread in the general climate of youthful political involvement throughout the Western world. In the United States, the Civil Rights Movement of the early 1960s and the peace campaigns of the Vietnam War era resulted in the formation of a large number of innovative companies. Notable among these groups were the San Francisco Mime Troupe, Bread and Puppet Theatre, and El Teatro Campesino. The San Francisco Mime Troupe revived commedia dell'arte techniques in their politically motivated street performances. El Teatro Campesino invented the *acto* in an attempt to create a specifically Chicano (Mexican-American) theatre. Many of their early performances took place on the picket lines during the California agricultural workers' strikes in the 1960s. Later, El Teatro Campesino explored Chicano mythology and history, inventing the *mito,* a form of ritualized exchange between performers. The debt of the alternative theatre groups to the earlier agitprop groups is immense (see below, *Developments in Russia and the Soviet Union: The propagandist theatre*).

As political ferment diminished in the early 1970s, many of the groups began to explore new directions. Members of The Living Theatre in the United States and the Polish Laboratory Theatre, as well as the Nordisk Theaterlaboratorium in Holstebro, Den., and other groups in North America and Europe, live cooperatively, share a common view of life, and seek to reflect that view in their productions. This shared life is superficially reminiscent of the touring troupe, but the endeavour to achieve a company ethos is closer to the religious motive of an earlier day.

MEANS OF ARTISTIC CONTROL

While communal theatres exercise collective control of production, artistic control has traditionally rested with a single member of the production company.

Actor domination. Perhaps the supreme example of the actor-dominated production can be found in the commedia dell'arte tradition. Not only did the actor have

financial and administrative control over production, but the very quality of performance was woven almost wholly out of the actor's art. At first, in the 16th century, the commedia troupe consisted of traveling actors; by the 17th century many of them had found permanent residence at the courts of Italy and elsewhere in Europe. Each actor had a special role (Arlecchino, Pantalone, Brighella, and the inamorato, or lover, among others) with its attendant set speeches and traditional business. The young would learn the tradition appropriate to a role and, if talented, embroider upon that tradition. Thus prepared, the actors would improvise a presentation on the thread of a story selected by the troupe leader. Scenarios of commedia dell'arte plays did exist, but they were only pale shadows of the production itself, which came to life only in performance.

Other actor-dominated theatres include the Elizabethan theatre, Chinese opera, and Kabuki. In these instances, however, the blending of administrative control and artistic preeminence did not go so far as in the commedia dell'arte. The Elizabethan professional company, for example, had a production system that was based upon actor control of the repertory, but the artistic character of the work was determined by the plays that were presented. However fine the actor's art, the dramatist's contribution was paramount.

Dramatist and director domination. During certain periods the work of the dramatist, regardless of his subsequent involvement, determined the creative process in production. In ancient Greece the selection of a play was the first step in production. In the 19th and 20th centuries the acquisition of a script was also the preliminary step in establishing the single-show association. Only occasionally, as in the court theatre at Weimar, of which Johann Wolfgang von Goethe took charge during the late 18th century, did the dramatist take responsibility for establishing and conducting the theatrical enterprise. Rarely has the dramatist dominated a production system, unless, as occurred with Molière, he was also an actor. A notable exception was the German playwright Bertolt Brecht.

In imperial Rome, the *dominus gregis* (manager of the festivals at which theatrical performances were given) controlled the lives and probably the art of the Roman comedians. During the 18th century the theatrical actor-manager came into prominence. But it was in the 19th century, with the rise of the stage director, that artistic and, in large measure, administrative control passed into the hands of a nonperformer.

The stage director was responsible for modulating the acting, correlating the animate and inanimate aspects of production, and creating a single effect that inevitably became the expression of his own genius. At the beginning of the 20th century, the British actor and director Edward Gordon Craig carried the ideal of unity even further by recommending the merger of director and scenic designer and advocating the reduction of actors to automatons completely responsive to the director-designer's vision.

The designer's rise to special importance had begun during the Renaissance. In the first half of the 17th century, the architect and designer Inigo Jones was the driving force behind the elaborate productions of the English court masque, while the stage machinery of Nicola Sabbatini and the designs of Giacomo Torelli exerted considerable influence in Italy and France.

Puppetry

A special theatrical form in which one person typically functions as manager, designer, and director is the puppet show. A puppet is any inanimate figure manipulated by a human being. The figure may be a three-dimensional hand-operated or body-operated puppet, either miniature or approaching life size; a two-dimensional shadow puppet manipulated by means of sticks; or a string-operated three-dimensional puppet, called a marionette. All types share a common aesthetic principle whereby their movement in a highly restricted space creates the illusion of lifelikeness. In some cultures, such as the Javanese and the Turkish, the puppet show has been a major theatrical form. In Japan the *bunraku* doll theatre commands a respect and a following comparable to those accorded the traditional live-actor theatres. In fact, many plays of the prominent writer Chikamatsu Monzaemon were written originally for the puppet theatre (see POPULAR ARTS: *Puppetry*).

AIMS AND FUNCTIONS

Religious. Most historians agree that drama emerged from religious ritual. At what precise point ritual became drama is uncertain, but formal drama is first known from ancient Greece.

Certainly, religious festivals gave rise to dramatic expression by reenacting the passion and trials of the god or man-god on whom the religion centred. In Christian Europe, biblical plays became attached to particular festivities, notably the Feast of Corpus Christi. Similarly, the story of the assassination of the 7th-century Shīʿite hero al-Ḥusayn ibn ʿAlī, grandson of the Prophet Muḥammad, was enacted at the Muslim festival of *taʿziyah*. As in ancient Greece, these festivals extended over many days and involved the whole community. In the 20th century, as popes and other religious leaders have traveled around the world to address the faithful, huge outdoor ceremonies have been conducted, often with the use of staging and lighting effects borrowed from the commercial theatre.

Educational and developmental. Initially, any educational aims of theatre were subsumed under its religious aims. But with the growth of educational institutions came student performances. A play might be enacted to cultivate appreciation of its literary qualities, to celebrate a graduation, or to commemorate a national holiday. At first these productions were communal in character and occasional in presentation. Then, for brief periods in Elizabethan and Jacobean England, school and choral masters endeavoured to turn this communal activity into a commercial operation by utilizing boys as professional actors.

Early in the 20th century, the educational philosophy of the dancer Isadora Duncan inspired a new emphasis on education in the theatre. Duncan, drawing inspiration from ancient Greece, sought to free dance from the strictures of classical ballet. Her work in teaching, along with that of Émile Jaques-Dalcroze, the Swiss founder of eurythmics, provided the cornerstone for educational dance. Children were given dance classes to develop both physical ability and self-expression.

The practice of producing school plays goes back at least to the Elizabethan period in England, when it was used to train pupils in rhetorical skills. In the 20th century a range of alternative activities have been explored under the heading of "drama in education." These classes have no direct performance aim and do not make a distinction between performer and audience. Classes can pursue a variety of aims: physical development, self-dramatization and self-expression, the dynamics of group relationships, role-playing, decision-making, and fantasy-exploration to develop the imagination. Some work has been done to bring drama into the centre of the school curriculum and to use its flexible methods as a medium for teaching other subjects, such as language skills.

Drama has also been used to enable psychiatric patients to reveal and objectify their mental traumas. Drama therapy, or psychodrama, employs theatre to promote healing rather than to analyze.

Theatre for development

Since 1950 many dramatic techniques have been utilized in an entirely new area called theatre for development. Theatre has been used, primarily in what is called the Third World, to foster literacy programs, population planning campaigns, and agricultural development programs. In Indonesia, for example, *wayang* shadow puppets have been used, with the content of traditional plays altered to include family planning messages. In some projects, theatre programs are prepared using villagers as consultants regarding content effectiveness.

Commercial. Theatre as a purely economic enterprise can be traced to the Renaissance, when there developed a professional theatre of the marketplace. Productions were offered in large population centres or were taken to villages and towns where a potential audience already existed. With a shift from theatre devised for an independently existing occasion to speculative theatre, seeking to create its own occasion, there is a shift from a communal to a cosmopolitan audience. Instead of presenting plays at

times that inherently hold sacred or civic meaning and, therefore, draw together the entire populace, commercial companies present plays with some frequency in order to attract a public large enough to support them. Instead of fulfilling a preordained social purpose, the commercial theatre has to justify itself and persuade people to attend by providing novelty and entertainment. (See above, *Commercial management.*) (B.Be./C.Ba.)

History of theatres and staging

ORIGINS OF THEATRE SPACE

The English word theatre derives from the Greek *theatron,* literally, "a place for seeing"; in its most common usage, it has come to signify a building or place so arranged that people can see and hear a performance given by others.

Forerunners of formal theatre

The civilizations of the Mediterranean basin in general, the Far East, northern Europe, and the Western Hemisphere before the voyages of Christopher Columbus in the second half of the 15th century have all left evidence of constructions whose association with religious ritual activity relates them to the theatre. Studies in anthropology suggest that their forerunners were the campfire circles around which members of a primitive community would gather to participate in tribal rites. Karnak in ancient Egypt, Persepolis in Persia, and Knossos in Crete all offer examples of architectural structures, purposely ceremonial in design, of a size and configuration suitable for large audiences. They were used as places of assembly at which a priestly caste would attempt to communicate with supernatural forces. The transition from ritual involving mass participation to something approaching drama, in which a clear distinction is made between active participants and passive onlookers, is incompletely understood. Eventually, however, the priestly caste and the performer became physically set apart from the spectators. Thus, theatre as place emerged.

DEVELOPMENTS IN ANCIENT GREECE

Visual and spatial aspects. During the earliest period of theatre in ancient Greece, when the poet Thespis—who is credited both with inventing tragedy and with being the first actor—came to Athens in 534 BC with his troupe on wagons, the performances were given in the agora (*i.e.,* the marketplace), with wooden stands for audience seating; in 498, the stands collapsed and killed several spectators. Detailed literary accounts of theatre and scenery in ancient Greece can be found in *De architectura libri decem,* by the 1st-century-BC Roman writer Vitruvius, and in the *Onomasticon,* of the 2nd century AD, by the Greek scholar Julius Pollux. As these treatises appeared several hundred years after classical theatre, however, the accuracy of their descriptions is questionable.

Theatre of Dionysus

Little survives of the theatres in which the earliest plays were performed, but essential details have been reconstructed from the architectural evidence of the Theatre of Dionysus in Athens, which has been remodeled several times since its construction in stone by the politician Lycurgus on the south slope of the Acropolis in about 330 BC. The centre of the theatre was the original dancing place, a flat, circular space containing the altar of Dionysus, called the orchestra. In the centre stood a platform with steps (*bemata*) leading to the altar (thymele). Nearby was the temple out of which the holy image would be carried on festival days so that the god could be present at the plays.

Theatrical representations, not yet wholly free of a religious element, directed their appeal toward the whole community, and attendance was virtually compulsory. Thus the first concern of theatre builders of the day was to provide sufficient space for large audiences. In the beginning, admission was free; later, when a charge was levied, poor citizens were given entrance money. It seems reasonable to assume, from the size of the theatres, that the actors performed on a raised platform (probably called the *logeion,* or "speaking place") in order to be more visible and audible, while the chorus remained in the orchestra. In later times there was a high stage, with a marble frieze below and a short flight of steps up from the orchestra. The great Hellenistic theatre at Epidaurus (Figure 2) had what is believed to have been a high, two-level stagehouse.

The earliest productions did not have a background building. The actors dressed in the *skēnē* (from which the word "scene" is derived), which was then a small tent, and the chorus and actors entered together from the main approach, the *parodos.* The earliest properties, such as altars and rocks, could be set up at the edge of the terrace. The first extant drama for which a large building was necessary was Aeschylus' trilogy the *Oresteia,* first produced in 458 BC. There has been controversy among historians as to whether the *skēnē* was set up inside a segment of the orchestra or outside the edge of the orchestra. The *skēnē* in its later development was probably a long, simple building at the left of the orchestra terrace.

The chorus

In the first period of Greek drama, the principal element of the production was the chorus, the size of which appears to have varied considerably. In Aeschylus' *Suppliants,* there were 50 members of the chorus, but in his other plays there were only 12, and Sophocles called for 15. The size of the chorus became smaller in the 5th century, as the ritual element of drama diminished. Since the number of actors increased as the chorus shrank, and the plots of the dramas became more complex, doubling of roles became necessary. On a completely open stage such substitutions were delayed, and the suspense of the drama was dissipated. Dramatic plausibility was also vitiated by the fact that gods and mortals, enemies and friends, always entered from the same direction. The addition of a scenic facade, with three doors, more than doubled the number of entrances and gave the playwright more freedom to develop dramatic tension. About 425 BC a firm stone basis was laid for an elaborate building, called a stoa, consisting of a long front wall interrupted at the sides by projecting wings, or *paraskēnia.* The spectators sat on wooden benches arranged in a fan shape divided by radiating aisles. The upper rows were benches of movable planks supported by separate stones planted in the ground. The seats of honour were stone slabs with inscriptions assigning them to the priests.

The background decoration consisted originally of a temporary wooden framework leaning against the front wall of the stoa and covered with movable screens. These screens were made of dried animal skins tinted red; it was not until Aeschylus that canvases in wooden frames were decorated according to the needs of a particular play. Aristotle credits Sophocles with the invention of scene painting, an innovation ascribed by others to Aeschylus. It is notable that Aeschylus took an interest in staging and is credited with the classic costume design. Simple Greek scenery was comparable with that of the 20th century; the impulse to visualize and particularize the background of the action became strong. Painted scenery was probably first used in production of the *Oresteia;* some 50 years afterward a second story was added to the wooden scene structure. A wooden colonnade, or portico, the *proskēnion,* was placed in front of the lower story of the building. This colonnade, which was long and low, suggested the exterior of either a house, a palace, or a temple. Painted screens set between the columns of the *proskēnion* suggested the locale.

The invention of scene painting

In the beginning, scenery was probably altered slightly during the intermissions that separated the plays of a trilogy or a tetralogy or during the night between two festival days. By the latter part of the 5th century, scene changes were accomplished by means of movable painted screens. Several of these screens could be put up behind one another so that, when the first one was removed, the one immediately behind appeared.

Soon after the introduction of the facade, plays were uniformly set before a temple or a palace. To indicate a change of scene, the *periaktoi* were introduced. These were upright three-sided prisms—each side painted to represent a different locality—set flush with the palace or temple wall on either side of the stage. Several conventions were observed with regard to scenery; one was that if only the right *periaktos* was turned, it indicated a different locality in the same town. According to another convention, actors entering from the right were understood to be coming from the city or harbour and those from the left to be coming from the country.

The permanent facade was also used to hide the stage properties and the machinery. Evidence for the use of the so-called flying machine, the *mēchanē* (Latin *machina*), in the 5th century is given in the comedies of Aristophanes; a character in his play *Peace* ascends to heaven on a dung beetle and appeals to the scene shifter not to let him fall. The *mēchanē* consisted of a derrick and a crane. In the time of Euripides it was used conventionally for the epilogue, at which point a god descended from heaven to sort out the complications in the plot, a convention that became known as deus ex machina ("god from a machine"). The lavish use of flying machines is attested by the poet Antiphanes, who wrote that tragic playwrights lifted up a machine as readily as they lifted a finger when they had nothing else to say.

The "flying machine"

A wheeled platform or wagon, called *ekkyklēma,* was used to display the results of offstage actions, such as the bodies of murder victims. The *ekkyklēma,* like the *periaktoi,* was an expedient for open-air theatre, in which the possibilities for creating realistic illusions were severely limited. A realistic picture of an interior scene under a roof could not be shown, because the roof would block the view of those in the higher tiered seats of the auditorium. So the Greeks, to represent the interior of a palace, for example, wheeled out a throne on a round or square podium. New machines were added in the Hellenistic period, by which time the theatre had almost completely lost its religious basis. Among these new machines was the *hemikyklion,* a semicircle of canvas depicting a distant city, and a *stropheion,* a revolving machine, used to show heroes in heaven or battles at sea.

(Ho.B./C.Ba./G.C.I.)

Acoustics. Much recent study has centred on the problem of acoustics in the ancient theatre. The difficulty in achieving audibility to an audience of thousands, disposed around three-fifths to two-thirds of a full circular orchestra in the open air, seems to have been insoluble so long as the performer remained in the orchestra. A more direct path between speaker and audience was therefore essential if the unaided voice was to reach a majority of spectators in the auditorium. Some contend that the acoustical

problems were to a degree alleviated when the actor was moved behind and above the orchestra onto the raised platform, with more of the audience thus being placed in direct line of sight and sound with him. By this time, the actors' masks had reached considerable dimensions, and there are grounds for believing that their mouth orifices were of help in concentrating vocal power—much as cupped hands or a rudimentary megaphone would be.

Increased architectural and engineering sophistication in the Hellenistic Age encouraged further innovations. The theatres of mainland Greece, the Aegean islands, and southern Italy had been constructed in hillsides whenever possible, so that excavation and filling were kept to a minimum; or, lacking a suitable slope, earth was dug out and piled up to form an embankment upon which stone seats were placed. By contrast, the cities of Asia Minor, which flourished during the Hellenistic Age, did not rely on a convenient slope on which to locate their theatres. The principles of arch construction were understood by this time, and theatres were built using vaulting as the structural support for banked seating. Archaeological remains and restoration of theatres at Perga, Side, Miletus, and other sites in what is now Turkey exhibit this type of construction. By a third method, auditoriums were hewed out of rock. Of some six such Greek theatres extant, two excellent examples (both extensively remodeled in Roman times) are the great theatre at Syracuse in Sicily and that at Argos in the Peloponnese. The best preserved of all Greek theatres, also in the Peloponnese and now partially restored, is the magnificent theatre at Epidaurus. This theatre provided seats for some 12,000 people, and its circular orchestra is backed by a stagehouse and surrounded on three sides by a stone, hillside-supported bank of seats. Both chorus and actors performed in the orchestra, but only the actors used the two levels of the stagehouse as well. Theatre construction flourished during the Hellenistic Age as never before in classical times, and no city of any size or reputation was without its theatre. (G.C.I.)

Vaulted seating construction

DEVELOPMENTS IN ANCIENT ROME

The development of the theatre, following that of dramatic literature, was slower in Rome than in Athens. The essential distinction between Roman and Greek stage performances was that the Roman theatre expressed no deep religious convictions. Despite the fact that the spectacles were technically connected with the festivals in honour of the gods, the Roman audience went to the theatre for entertainment. The circus was the first permanent public building for spectacles, which included chariot races and gladiatorial fights. When Etruscan dancers and musicians were introduced in 364 BC, they performed in either the circus, the forum, or the sanctuaries in front of the temples. The players brought temporary wooden stands for the spectators. These stands developed into the Roman auditorium, built up entirely from the level ground.

Theatre as entertainment

Stage design. The most important feature of the Roman theatre as distinct from the Greek theatre was the raised stage. As every seat had to have a view of the stage, the area occupied by the seating (*cavea*) was limited to a semicircle. As in Greek theatre, the scene building behind the stage, the *scaenae frons,* was used both as the back scene and as the actors' dressing room. It was no longer painted in the Greek manner but tended to have architectural decorations combined with luxurious ornamentation (Figure 3). The audience sat on tiers of wooden benches, *spectacula,* supported by scaffolding. There was no curtain; the back scene, with its three doors, faced the audience.

When the popular comedies or farces of southern Italy were introduced to Rome, they came with their own distinctive type of stage—the *phlyakes* stage. Comedies in Italy were mimes, usually parodies of well-known tragedies, and the actors were called *phlyakes,* or jesters. They used temporary stage buildings of three main forms. One was the primitive low stage, a rough platform with a wooden floor on three or four rectangular posts. The second was a stage supported by low posts, covered with drapery or tablets; sometimes steps led up to a platform and a door was indicated. The third type was a higher stage supported by columns, without steps but usually with a back wall. The stages often had a short flight of five to seven steps in the centre, leading to the podium. The forewall, covered with drapery, was often decorated, and the background wall usually had objects hanging from it. The rear wall sometimes had other columns, besides the ones set at the corners, as well as doors and, in several cases, windows to indicate an upper floor. The door was usually behind a heavily decorated porch, with a sloping or gabled roof supported by beams and cross struts. Among the furnishings there were usually trees, altars, chairs, thrones, a dining table, a money chest, and a tripod of Apollo (*i.e.,* an oracular seat). The stage was set up in the marketplace in the smaller towns and in the orchestras of Greek theatres in the larger cities.

Roman stone theatres

and under the inspiration of Hellenistic colonists, the Romans began to build stone theatre buildings. Beginning by remodeling Greek and Hellenistic theatres, they eventually succeeded in uniting architecturally their own concept of the auditorium with a single-level, raised stage. This they did by limiting the orchestra to a half circle and joining it to the auditorium, thereby improving on the acoustics of Greek and Hellenistic theatres. They also brought to perfection the principles of barrel and cross vaulting, penetrating the seat bank at regular intervals with *vomitoria* (exit corridors). The raised stage was at a single, much lower level than in the Hellenistic theatre. It was roofed, and entrances to it were increased to five: three, as before, in the wall at the rear of the stage and one at each side (Figure 4). The Romans' love of ostentatious architecture led them to adorn the permanent background with profuse sculptures. In some theatres a drop curtain was used to signal the beginning and end of performance. In some cases, a canvas roof was hoisted onto rope rigging in order to shade the audience from the sunlight. (Ho.B./C.Ba.)

The Roman stage

In Roman theatres the stage alone was used by the actors, who entered the playing space from one of the house doors or the side entrances in the wings. The side entrance on the audience's right signified the near distance and the one on the audience's left the farther distance. If a scene took place in a town, for instance, an actor exiting audience right was understood to be going to the forum; if he exited audience left, he might be going to the country or the harbour. *Periaktoi* at the side entrances indicated the scenery in the immediate neighbourhood. If the play required a character to move from one house to another without bringing him on the stage, which represented the street, the actor was supposed to use the back door and the *angiportum* (*i.e.,* an imaginary street running behind the houses). Since interior scenes could not be represented easily, all action took place in front of the houses shown in the background. If a banquet was to be depicted, the table and chairs would be brought on stage and removed at the end of the scene. Costumes were formalized, but real spears, torches, chariots, and horses were used.

The orchestra became part of the auditorium in Rome, reserved by law for those of privileged rank, who seated themselves there on a variety of portable chairs and litters. The orchestra was no longer needed as part of the performance area because the chorus had long since ceased to be an integral part of drama. The tragedies of Seneca, in the 1st century AD, included a chorus because they were patterned after Greek models. But they never achieved the popularity of earlier comedies, especially those of Plautus and Terence. These works had at first been performed on temporary wooden stages that had been erected on a convenient hillside and sometimes surrounded by temporary wooden seating.

Until the late republic, a puritanical Senate had banned all permanent theatre building within the city of Rome itself as decadent. Thus, theatres there were temporary structures, set up in the Campus Martius for the duration of public games. In 55 BC, however, the triumvir Pompey the Great built Rome's first permanent stone theatre. Another public stone theatre was built in Rome in 13 BC and named after Marcellus, son-in-law of the emperor Augustus. Both were used for the *scaenae ludi* ("scenic games"), which were part of religious festivities or celebrations of victory in war and which were paid for by triumphant generals and emperors. During the Roman Empire civic pride demanded that all important cities have theatres, amphitheatres, and, in many instances, a small, permanently roofed theatre (*theatrum tectum,* an odeum, or music hall) as well. In fact, it is from outlying cities of the empire such as Arausio (Orange), Thamagadi (Timgad), Leptis Magna, Ṣabrāth, and Aspendus that archaeological evidence provides most of the firsthand knowledge of Roman theatre building. The best preserved Roman theatre, dating from about AD 170, is at Aspendus in modern Turkey.

Vitruvius' treatise on architecture. Literature is another source for knowledge of Roman theatre. *De architectura libri decem* ("Ten Books on Architecture"), by the Roman architect Vitruvius (1st century BC), devotes three books to Greek and Roman theatre design and construction. The author gives general rules for siting an open-air theatre and for designing the stage, orchestra, and auditorium. These rules are based on principles of Euclidian geometry in matters of layout and proportion. His dicta on the provision of good sight lines from auditorium to stage are generally sound. Apart from that, however, his treatise is not very helpful. He mentions changeable scenery but is vague about what was involved. Vitruvius' notion of acoustics, which he claims is based on theory as well as practice, appears to be vaguely associated with Greek ideas of musical theory but has since been proved to have no scientific or mathematical basis. Indeed, his views on this important matter were to cause problems for almost 2,000 years.

The odeum. Vitruvius has nothing to say about the roofed odeum (or odeon, "singing place"), which, according to some authorities, represents the high point of theatre building in the ancient world. Theatre history has, unfortunately, largely overlooked these buildings. Excavation work has revealed more than 30 of them, in a wide range of building materials. Odea were apparently

first built in Athens under Pericles (5th century BC). They continued to be built throughout the Hellenistic Age and also in the Roman Empire up to the time of Emperor Severus Alexander (3rd century AD). They range in size from one with a seating capacity of 300–400 to one of 1,200–1,400. Experts disagree as to their specific purpose and use but claim they exhibited a refinement of detail and architectural sophistication found in no other Greco-Roman buildings devoted to the performing arts. They are most often found in Greek cities dating from Hellenistic times, on the grounds of private villas built by Roman emperors from Augustus to Hadrian, and in major cities of the empire, usually dedicated to the emperors. One of the most imposing, which also boasts the greatest span for a wooden trussed roof in the ancient world, was the Odeon of Agrippa, named after the emperor Augustus' civil administrator. This Roman building in the Athenian agora, dating from about 15 BC, is beautifully detailed, with an open southern exposure and a truncated curvilinear bank of seating. It achieves an atmosphere of great dignity and repose, despite the vast size of the room. In the last years of the Roman Empire the odeum was, it is claimed, the only remaining home of the performing arts, because by this time open-air theatres had long been given over to sensational and crude popular entertainments.

Odeon of Agrippa

Greek and Roman theatre building influenced virtually all later theatre design in the Western world, the theatres of the Spanish Golden Age, the English Elizabethan period, and the 20th-century avant-garde, with its experiments in primitive theatre-in-the-round techniques, being exceptions to this pattern. The architectural writings of Vitruvius became the model for the theatre building of the later Renaissance and early Baroque periods.

(G.C.I./C.Ba.)

DEVELOPMENTS IN ASIA

Although the emergence of Asian theatre was not simultaneous with that of ancient Greece and Rome, it merits discussion here rather than as an appendage to the history of Western drama.

India. Indian theatre is often considered the oldest in Asia, having developed its dance and drama by the 8th century BC. According to Hindu holy books, the gods fought the demons before the world was created, and the god Brahmā asked the gods to reenact the battle among themselves for their own entertainment. Once again the demons were defeated, this time by being beaten with a flagstaff by one of the gods. To protect theatre from demons in the future, a pavilion was built, and in many places in India today a flagstaff next to the stage marks the location of performances.

According to myth, Brahmā ordered that dance and drama be combined; certainly the words for "dance" and "drama" are the same in all Indian dialects. Early in Indian drama, however, dance began to dominate the theatre. By the beginning of the 20th century there were few performances of plays, though there were myriad dance recitals. It was not until political independence in 1947 that India started to redevelop the dramatic theatre.

In the 4th century a codification was written of the *śāstra,* or the staging conventions of the dance. It lists not only the costumes, makeup, gestures, and body positions but also any plots considered unsuitable, and it is the most complete document of stagecraft ever compiled. There is no scenery in Indian dance, although there are usually a few properties, such as a three-foot-high brass lamp. A curtain is used, however, by troupes that dance *kathākali,* an ancient danced drama of southwestern India. The curtain itself is a cloth rectangle that is held between the stage and a large lamp by two stagehands.

The dancers perform a group of preliminary dances behind the curtain until they make an important entrance called "peering over the curtain." In this, a character fans the lamp by pulling the curtain in and out until the flames are spectacularly high. The dancer, still hiding his face, displays his hands and legs at the borders of the curtain. At the climactic moment the dancer pulls the curtain aside, displaying his awesome makeup, and stagehands remove the curtain until the next dramatic entrance.

Classical Indian drama had as its elements poetry, music, and dance, with the sound of the words assuming more importance than the action or the narrative; therefore, staging was basically the enactment of poetry. The reason that the productions, in which scenes apparently follow an arbitrary order, seem formless to Westerners is that playwrights use much simile and metaphor. Because of the importance of the poetic line, a significant character is the storyteller or narrator, who is still found in most Asian drama. In Sanskrit drama the narrator was the *sūtra-dhāra,* "the string holder," who set the scene and interpreted the actors' moods. Another function was performed by the narrator in regions in which the aristocratic vocabulary and syntax used by the main characters, the gods and the nobles, was not understood by the majority of the audience. The narrator operated first through the use of pantomime and later through comedy.

The narrator's role

A new Indian theatre that began about 1800 was a direct result of British colonization. With the addition of dance interludes and other Indian aesthetic features, modern India has developed a national drama. Two examples of "new" theatre staging are the Prithvi Theatre and the Indian National Theatre. The Prithvi Theatre, a Hindi touring company founded in 1943, utilizes dance sequences, incidental music, frequent set changes, and extravagant movement and colour. The Indian National Theatre, founded in Bombay in the 1950s, performs for audiences throughout India, in factories and on farms. Its themes usually involve a national problem, such as the lack of food, and the troupe's style is a mixture of pantomime and simple dialogue. It uses a truck to haul properties, costumes, and actors; there is no scenery.

China. The most noticeable contrast between China and other Asian countries is that traditionally China has produced virtually no dance. The classic theatre of the Chinese is called "opera" because the dialogue is punctuated with arias and recitatives. Of the amazingly detailed written record of Chinese theatre, the first reference to opera was during the T'ang dynasty (618–907). The development of the opera style popular today took place during the Manchu rule of the 19th century. The Empress Dowager, the last hereditary ruler of China, was so enamoured of opera that she had a triple-deck stage (representing heaven, hell, and earth) constructed in the summer palace at Peking. The most important individual in Chinese theatre of the 20th century, Mei Lan-fang, an actor and producer, was the first to apply scholarship in reviving ancient masterpieces and opera forms.

In general, Chinese theatrical performances start in the early evening and conclude after midnight. The performance itself consists of several plays and scenes from the best known dramas. The audience drinks tea, eats, and talks, and there are no intermissions. The stage itself has a curved apron, covered only by a square rug. On one side is a box for the orchestra, which plays throughout the evening. There is neither a curtain nor any setting to speak of other than a simple, painted backdrop. The virtual absence of scenery accentuates the elaborate and colourful costumes and makeup of the actors.

The Chinese theatrical performance

During a typical performance, the members of a Chinese theatre audience stop talking to each other only at climactic moments. The actors are concerned with their movements only when they are at the centre of the stage; when they stand at the sides they drink tea and adjust their costumes in full view of the audience. An interpretation of this behaviour was the view of the 20th-century German dramatist Bertolt Brecht that a Chinese actor, in contrast to a Western actor, constantly keeps a distance between himself, his character, and the spectator; his performance is mechanistic rather than empathic.

Property men walk around on stage setting up properties for the next play before the preceding one is finished. There are usually very few properties, only a table and a few chairs. A chair may act as a throne, a bench, a tower if an actor stands on it, a barrier if he stands behind it, and so on. A curtain suspended in front of two chairs represents a bed. Doors and stairs are always suggested: an actor mimes opening a door and taking a high step when he "enters" a room.

There are a number of stage conventions; all entrances, for instance, are from a door stage left, and all exits through a door stage right. After a fight scene, the man who is defeated exits first. Wind is symbolized by a man rushing across the stage carrying a small black flag. Clouds painted on boards are shown to the audience to represent either the outdoors or summer. Fire, however, is always represented realistically, either by the use of gunpowder or by pyres of incense. The Chinese feel that Western dramatic realism atrophies the imagination.

Japan. Japan is unique in Asia in having a living theatre that retains traditional forms. When an attempt is made in the West to recreate the original production of a Greek tragedy or even a play by Shakespeare, its historical accuracy can only be approximated. In Japan the traditions of stagecraft and costumes for both drama and dance have remained unaltered. Japanese staging developed far earlier than did that of the West; by the time of Shakespeare, for instance, the Japanese had already invented a revolving stage, trapdoors, and complex lighting effects.

Nō theatre

Although there are many kinds of theatre in Japan, the best known are the Nō and the Kabuki. Nō was developed by the late 14th century and was first seen by Westerners in the 1850s. It developed from the *dengaku,* a rice planting and harvesting ritual that was transformed into a courtly dance by the 14th century, and from the *sarugaku,* a popular entertainment involving acrobatics, mime, juggling, and music, which was later performed at religious festivals.

Two performers and adherents of Zen Buddhism in the late 14th century, Kan'ami and his son Zeami Motokiyo, combined the *sarugaku* elements with *kuse-mai,* a story dance that uses both movements and words. Soon *dengaku* elements were added, and the distinctive Nō style slowly emerged. Like the Zen ways of tea ceremony, ink drawing, and other arts, Nō suggests the essence of an event or an experience within a carefully structured set of rules. There are scores of Nō theatres in Japan today, even though the design of a Nō theatre is so stylized that it is not usable for other types of performances. The Nō stage is a platform completely covered by a curving temple roof. The audience sits on three sides of the stage and is separated from it by a garden of gravel, plants, and pine trees.

Masks are used, though they are restricted to the principal dancer and his companions. The male characters are costumed in brilliant stiff brocades and damasks well suited to the grandiose posturing of the actors. The female roles are played in bright flowered brocades. The outer robes of both sexes are of a fine-woven gauze, light and suitable for the gliding dances when sleeves and fans float in the air. Mask carving is an important art in Japan, and Nō masks add considerable beauty to the traditional robes. Most costumes are based on the classic court hunting dress of the Heian (794–857) and Kamakura (1192–1333) periods.

Kabuki staging techniques

Kabuki troupes, originally composed only of women, developed in the early 17th century. By the 1680s Kabuki had become an established art form, and curtains and scenery were introduced. Kabuki was first seen in western Europe during the latter part of the 19th century, but it was not until the 1920s that it was accepted there as something more than quaint. The work of the Russian film director Sergey Eisenstein was influenced by the Kabuki troupe that toured the Soviet Union in 1928, and Kabuki staging devices were tried out in theatres in the Soviet Union, France, and Germany; one Kabuki actor, in turn, brought back Russian techniques that influenced the Japanese theatre.

A Kabuki theatre in Tokyo is one of the largest legitimate theatres in the world, with a 91-foot- (28-metre-) wide stage and seating for 2,599 people. Running through the audience and connecting the stage with the rear of the auditorium is the platform runway, called the *hanamichi.* It is utilized for significant entrances and exits, processions, and dance sequences. Its purpose is to unite the actor and audience by moving the actor out of the decorative background. Originally there were two runways, with a connecting bridge at the rear of the auditorium. Because of economic pressure to seat more people and the influence of Western architecture, the second *hanamichi* was removed in the early 20th century.

The scenery for Kabuki may be as elaborate and complex as that found anywhere; the stage, for instance, may be a house, a forest, and a river simultaneously. Some settings are triple-level palaces, with the actors using all levels at once; others have only a simple backdrop.

Kabuki costumes are of the Edo period (1603–1868), when Kabuki is considered to have been at its height. Wigs and makeup carefully conform to classical tradition, enabling habitual playgoers to recognize the type of play and characters at a glance. Many of the costumes are much exaggerated; all are designed to accentuate dramatic movement. Courtesans and heroes, for instance, wear stilts that raise them several inches off the ground.

Bali. Balinese theatre is included here as representative of theatre in the smaller nations of Asia, such as Thailand, Kampuchea (Cambodia), Laos, Malaysia, the Philippines, and Vietnam, in all of which drama consists almost exclusively of dance. Balinese dancing may take place anywhere; usually it is executed in front of a temple or a pavilion used for community meetings. The audience sits on three sides of the performers or, occasionally, in the round. The musicians, called the gamelan, sit on one side of the stage area.

Balinese scenic "devices"

There are neither settings nor visible indications of scene changes; location is suggested by the dialogue or the facial expressions and gestures of the actors. A scenic "device" is employed at the beginning of each section of the dance; for instance, the dancer makes a gesture called "opening the curtain." The hands, palms out, are in front of the face; they separate on a diagonal line to reveal the figure, stopping only when the full, formal posture of Balinese dance is reached. (Ho.B./C.Ba.)

THE MIDDLE AGES IN EUROPE

In terms of performances and theatres, Roman drama reached its height in the 4th century AD, but it had already encountered opposition that was to lead to its demise. From about AD 300 on, the church tried to dissuade Christians from going to the theatre, and in 401 the fifth Council of Carthage decreed excommunication for anyone who attended performances on holy days. Actors were forbidden the sacraments unless they gave up their profession, a decree not rescinded in many places until the 18th century. An edict of Charlemagne (*c.* 814) stated that no actor could put on a priest's robe; the penalty could be banishment. This suggests that drama, most probably mime, had ridiculed the church or that it had tried to accommodate religious sensibilities by performance of "godly" plays.

The invasions of the barbarians from the north and east accelerated the decline of Roman theatre. Although by 476 Rome had been sacked twice, some of the theatres were rebuilt. The last definite record of a performance in Rome was in 533. Archaeological evidence suggests that the theatre did not survive the Lombard invasion of 568, after which state recognition and support of the theatre was abandoned. Theatre did continue for a while in the Eastern Roman Empire, the capital of which was Constantinople, but by 692 the Quinisext Council of the church passed a resolution forbidding all mimes, theatres, and other spectacles. Although the effectiveness of the decree has been questioned, historians until recently used it to signify the end of the ancient theatre.

The assumption now is that although official recognition and support of performances were withdrawn and theatres were not used, some remnants of at least the mime tradition were carried on throughout the Middle Ages. Christian writings suggest that performers were familiar figures. For instance, two popular sayings were "It is better to please God than the actors" and "It is better to feed paupers at your table than actors." Apart from the mime tradition, one Roman playwright, Terence, retained his reputation through the early Middle Ages, probably because of his literary style. (Ho.B.)

Women performers

Women performers were widespread during the period as jugglers, acrobats, dancers, singers, and musicians. There were women troubadours and jongleurs, and many of the

French chansons are written from the point of view of female narrators, notably the *chansons de mal mariée,* or complaints by unhappily married women. Generations of ecclesiastical authorities protested against the great choruses of women who poured into churches and monasteries on feast days, singing obscene songs and ballads. Complaints are recorded from the 6th century AD to the 14th about women taking part in licentious public performances on festive occasions. Women were also active participants in the later mumming plays; the *London Mumming* of *c.* 1427 was presented by an all-female cast, while in the Christmas *Mumming at Hertford,* the young king Henry VI saw a performance consisting of "a disguysing of the rude upplandisshe people compleynynge on hir wyves, with the boystous aunswere of hir wyves."

Church theatre. Medieval religious drama arose from the church's desire to educate its largely illiterate flock, using dramatizations of the New Testament as a dynamic teaching method. It is doubtful whether there is any connection between the drama of classical times and the new rudimentary dramatizations that slowly grew into the miracle and mystery cycles of plays in the Middle Ages. As early as the 10th century in Switzerland, France, England, and Germany, short and simple dramatic renderings of parts of the Easter and Christmas liturgy of the mass were being performed. As these short scenes grew in number, small scenic structures, called mansions, *sedum, loci,* or *domi* (the Latin words for seats, places, and homes, respectively), were placed at the sides of the church nave. At these were acted stories of the Nativity, Passion, or Resurrection, depending upon the particular season of the Christian calendar. At the conclusion of each scene the congregation turned its attention to the next mansion, so following a succession of scenes set out at intervals around the nave. Gradually, the performance of liturgical drama passed out of the hands of the clergy and into those of the laity, probably via the trade guilds of craftsmen, which were also religious fraternities. More and more secular interludes crept into the dramas—to such an extent that the dramas moved out of the church building into the public square. The individual plays became linked in cycles, often beginning with the story of the creation and ending with that of the Last Judgment. Each play within the cycle was performed by a different trade guild. Many of the plays from different cycles have survived and can still be seen in parts of England. (G.C.I./C.Ba.)

Play cycles

Staging conventions. A number of staging conventions that evolved in the church were to continue throughout the Middle Ages. Apart from the mansions there was a general acting area, called a *platea, playne,* or *place.* The methods of staging from these first liturgical dramas to the 16th-century interludes can be divided into six main types. The first involved the use of the church building as a theatre. In the beginning, for Easter tropes (embellishments of the liturgy), a tomb was set up in the north aisle. As dialogue was added, the entire nave was used, and within this space different localities were indicated by mansions. A few mansions housed numerous elaborate properties, particularly those for the Last Supper. Some mansions had curtains so that characters or objects might be revealed at a particular moment or concealed at the end of an episode. Sometimes the choir loft was used to represent heaven and the crypt to represent hell.

The second type of staging evolved by the 12th century, as drama began to outgrow the capacity of the church to contain it. As long as the action was confined to the central theme, it could be played in an arrangement of mansions down the length of the nave. But as the subject matter extended to include both Old and New Testament history, the action was transferred to a stage outside the west door of the church. In 1227 Pope Gregory IX decreed the removal of what had become a show from holy ground to the marketplace or an open field. During the same period the language of the plays began to change from Latin to the vernacular. When drama was first taken outdoors, the crucifix was placed at one end, no doubt where it would have appeared above the altar in the church. Mansions were placed alongside each other, usually in sequences reflecting earlier church performances.

A third type of staging was the so-called stationary setting, found outside of England, which involved placing the mansions in a wider range of locales. Here the audience accepted three conventions. One was the symbolic representation of localities by the mansions; the second was the placing of the mansions near each other; and the third was the use for acting purposes of such actual ground as was enclosed by or in front of each mansion (Figure 5). The mansions were placed in either a straight or a slightly curved line, and all of the scenery was visible simultaneously. Because of their scope, many of the plays were divided into parts separated by intermissions ranging from one to 24 hours. During the intermissions, mansions were changed. Also, some mansions might represent more than one location; the identity of the mansions was announced before each segment of a play. It is difficult to know exactly how many mansions were used; in a play at Lucerne, Switz., in 1583, for instance, 70 different locations were indicated, though only about 32 mansions were actually used.

Stationary setting

The two mansions almost always present were those representing heaven and hell, set at opposite ends of the playing area. The earthly scenes were set in the middle, and the two opposing mansions were supposed to represent man's dual nature and the choices that faced him. In the 15th and 16th centuries, heaven was usually raised above the level of the other mansions. Sometimes heaven had a series of intricate turning spheres, from which emanated the golden light of concealed torches. The hell mansion was designed to be the complete opposite of that of heaven; some portions of it, for instance, were below stage level. Sometimes hell was made to look like a fortified town, an especially effective image when Jesus Christ forced open the gates to free the captive souls. The entrance to hell was usually shaped like a monster's head and was called Hell's Mouth, emitting fire, smoke, and the cries of the damned.

The mansions of heaven and hell

The fourth type of staging was in the round. In France

and England particularly, surviving Roman playhouses were used for drama, and the mansions were probably placed in a circle. The play *Castle of Perseverance* from this period was intended to be performed within a moated round. Within the moat was an earthen bank on which the mansions were placed. Within the bank was a circle of flat earth with a tower structure in the centre. Members of the audience perambulated in the centre from mansion to mansion. The actors dressed in a small tent outside the round. Entry to the circle was over one bridge. The remains of several of these rounds still exist, the principle one being Piram Round in Cornwall.

Processional staging

The fifth type of staging employed movable settings. Processional staging was particularly popular in Spain. The wagons, called *carros,* on which the scenery was mounted were positioned next to platforms that had been erected in every town (Figure 6). Developments were somewhat different in England and the Netherlands. There, the mansions themselves became portable, being called pageant wagons in England and *wagonseel* in the Netherlands. Beneath the raised platform was a curtained space with room for the actors. Although the number of settings available was the same as for the mansion presentation, only one wagon was visible at a time; the audience remained stationary, and the successive pageants were wheeled into place before it. Sometimes the pageant wagons were quite elaborate structures: a realistic ark, stocked with animals and possibly floated on water, might be constructed for the story of Noah and the Flood; or an ingenious model of a whale, able to contain an actor within its belly, might be used for the story of Jonah.

Special effects, which were very popular, became so complex and numerous by the 15th century that many scenes were added to show them off. For flying, a fixed setting was often placed against a building equipped with pulleys and windlasses on its roof. Additional flying machinery was also hidden inside the heaven mansion. Angels, souls released from limbo, devils, and fire-spitting monsters could be shown flying. The machinery became so complex that 17 people were needed simply to operate the hell scenes at a theatre at Mons, in what is now Belgium. Trapdoors were used for sudden appearances, disappearances, and substitutions of dummies for actors in scenes of violence. In a production involving Barnabas' burning at the stake, bones and entrails stuffed in the dummy gave off a realistic smell.

Morality plays

The morality plays, which first appeared in the 14th century, made use of no scenery or complex properties. Although some were performed indoors, most were offered outside on a stage that anticipated the English Elizabethan public theatre. A fixed facade was built at the rear of a large platform, and there were three openings at stage level that could be used to show interior scenes. A second level included similar openings, and a third level had a throne for the figure being honoured by the morality.

The last type of staging, and the one about which least is known, was the curtained platform (see Figure 6). Toward the end of the Middle Ages itinerant professional actors who performed interludes required only a curtain behind them for staging. (Ho.B./C.Ba.)

Courtly diversions. Another kind of theatre flourished in the courts—more or less impromptu entertainments, deriving from the medieval love of tournament. Essentially secular diversions, they were most sumptuously costumed and caparisoned, with the emphasis on spectacle. This type of theatrical entertainment grew in popularity throughout Europe, culminating during the 16th century.

Another manifestation of courtly theatrical display took place on the triumphant entry into a city of a prince and his entourage after victory in war or on the occasion of a neighbouring ruler's visit. Public participation was usually invited, and sometimes mandated, to help augment the sense of occasion. Such entertainment was followed by private festivities held at court. On occasion, a group of strolling players would also be invited to perform in the great hall or courtyard of the palace.

The theatre of the Middle Ages was essentially one of participation, and throughout its development it never lost an intimacy between actors and audience. It was a theatre that combined realism with considerable symbolism.
(G.C.I./C.Ba.)

DEVELOPMENTS OF THE RENAISSANCE

Just before 1500, Italian amateur actors were performing classical comedies on stages with no decoration except for a row of curtained booths. By 1589, complex painted scenery and scene changes were being featured in production in Florence. And by 1650, Italy had developed staging practices that would dominate European theatre for the next 150 years.

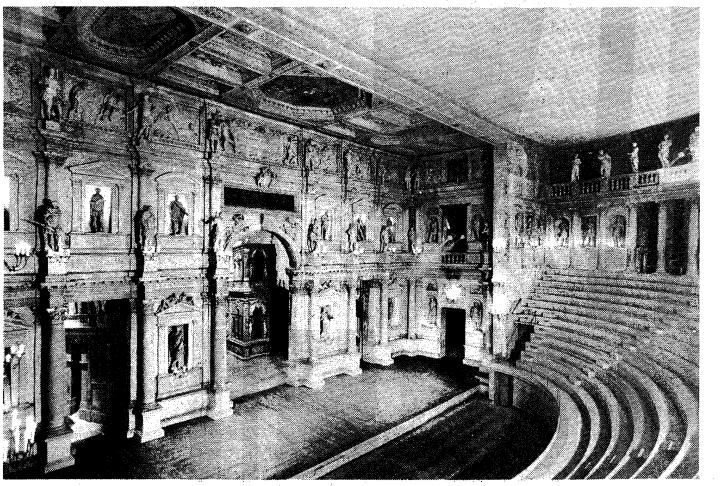
In the beginning of the Renaissance, there were two distinct kinds of theatrical productions. The first was of the type presented by the humanist Julius Laetus at the Accademia Romana, a semisecret society he founded in the mid-15th century for the purpose of reviving classical ideals. In terms of staging, several medieval-type mansions were clustered to form a single large unit. There were, however, two elements not found previously. One was that the mansions were probably framed by decorative columns. This was the first movement toward the framework that would develop into the proscenium arch—the arch that encloses the curtain and frames the

stage from the viewpoint of the audience. (The first permanent proscenium was built in the Teatro Farnese at Parma, Italy, in 1618–19, a temporary one having been constructed by Francesco Salviati 50 years earlier.) The second innovation was that the mansions, by being linked, were treated as components of a general city street. In 1508 at Ferrara a background painted according to the rules of perspective was substituted for the mansions; the scene included houses, churches, towers, and gardens.

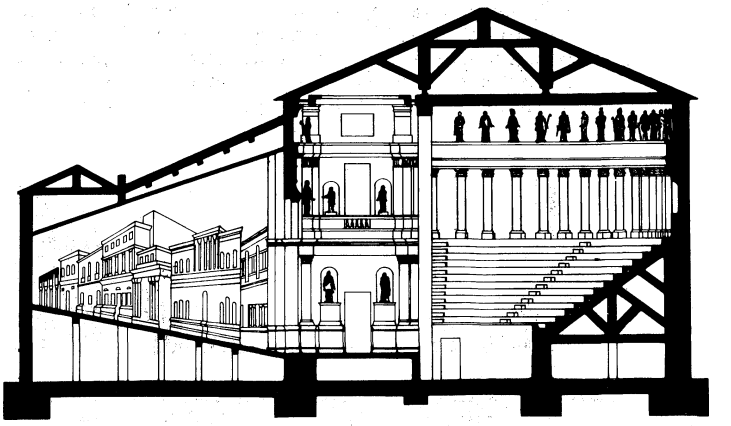
The revival of theatre building in Italy. The revival of theatre building, first sponsored by 16th-century ducal courts and academies in northern Italy, was part of the general renewal of interest in the classical heritage of Greece and Rome. The ruins of classical theatres were studied as models, along with Vitruvius' treatise on classical architecture. There were, however, new conditions that fundamentally affected design. First of all, the theatre's move indoors gave rise to problems of lighting and acoustics. Second, the newly formulated laws of perspective in painting, when applied to stage and scenic design, brought about a profound change in the effect of a stage on an audience. The first Renaissance theatres, like those of early antiquity, were temporary wooden constructions in gardens, ballrooms, and assembly halls. Sometimes they were hastily erected affairs, put up to celebrate the births and weddings of ducal offspring or to commemorate victories in war. The theatrical performances given were mostly of allegorical pageantry, but the scenic spectacle was calculated to dazzle the eye and often succeeded. One court vied with another for the services of painters, sculptors, architects, and innovators in stagecraft. Such artists as Leonardo da Vinci, Michelangelo, Vasari, Bramante, Raphael, and a host of other Italian painters, sculptors, and architects, as well as poets, such as Tasso, and musicians, such as Monteverdi, strove to please and exalt the reputations, real or imaginary, of their princely patrons.

Elaborate spectacle

A more sober attempt to revive the classical theatre was made by the academies, organized by upper-class gentlemen who assembled to read and, on occasion, to participate in and to support financially productions of classical drama. The plays were generally of three kinds: contemporary poetic dramas based on ancient texts; Latinized versions of Greek dramas; and the works of Seneca, Terence, and Plautus in the original. Toward the middle of the 15th century, scholars discovered the manuscripts of the Roman writer Vitruvius; one of these scholars, the architect and humanist Leon Battista Alberti, wrote *De re aedificatoria* (1452; first printed in 1485), which stimulated the desire to build in the style of the classical stage. In 1545, Sebastiano Serlio published his *Trattato de architettura,* a work that concentrated entirely on the practical stage of the early 16th century.



The treatise of Serlio



Serlio's treatise on the theatre had three especially significant items. The first was a plan for an auditorium and stage that assumed a rectangular hall, with spectators arranged in the same pattern as in the Roman *cavea* (*i.e.,* the tiered semicircular seating area of a Roman theatre), the difference being that the semicircle of the audience was cut short by the sidewalls. Second, his three types of stage designs—tragic, comic, and satiric—were the same as Vitruvius' classifications. Third, for the stage, he started with a Roman acting platform, but instead of the *scaenae frons,* he introduced a raked platform, slanted upward toward the rear, on which the perspective setting of a street was made up of painted canvases and three-dimensional houses. Since the perspective required that the houses rapidly diminish in size with distance, the actors were able to use only the front houses. Serlio used three types of scenes, all with the same basic floor plan. Each required four sets of wings (*i.e.,* the pieces of scenery at the side of the stage), the first three angled and the fourth flat, and a perspective backdrop.

Palladio's Teatro Olimpico

The Accademia Olimpica in the little town of Vicenza, near Venice, commissioned a famous late Renaissance architect, Andrea Palladio, to design a theatre. This, the Teatro Olimpico, was the first permanent modern indoor theatre, and it has survived intact (Figure 7). Palladio thoroughly researched his subject (the outdoor classical theatre of Rome) and without knowing it designed something now considered very close to a Roman odeum. It is a scaled-down version of an outdoor Roman theatre, with shallow open stage and a heavily sculptured, pedimented, permanent background. A colonnade of heroic proportions, surmounted by sculptured figures, surrounds a steeply stepped bank of seating. Overhead is a painted sky. To promote an intimate stage–auditorium relationship, he used a flattened ellipse in planning the seating, rather than the classic half circle. The interior was to be lit by tallow candles mounted in wall sconces. Palladio died before the building was finished, and his follower Vincenzo Scamozzi completed the work in 1585. Behind the five stage entrances (attributed to Scamozzi) are static, three-dimensional vistas of streets receding to their separate vanishing points; it is not certain whether this was the intent of the original design. In performance, the theatre is efficient if the auditorium is full, and speech carries quite well because of the small volume, flat ceiling, modulated sidewalls, excellent vertical sight lines, and direct hearing lines from all seats to the stage. The exterior is an ungainly, masonry-walled structure with a wood-trussed, tiled roof.

In 1588–89 Scamozzi designed the Teatro all'Antica, a small court theatre for the Gonzaga family at Sabbioneta.

Unlike the Teatro Olimpico the stage here is a single architectural vista behind a shallow-raked open platform, after the manner of the stage illustrated by Sebastiano Serlio (Figure 8). At Sabbioneta a divided horsehoe-shaped bank of seating leaves an empty arena, at floor level, in front of the stage. This space, backed by the permanent bank of seating, can be used for additional seating, but it also accommodates other uses and paves the way for the most famous and influential of all Renaissance theatre buildings, the Teatro Farnese.

Teatro Farnese

The Teatro Farnese lies about 12 miles west of Sabbioneta at Parma, in a palace of the Farnese family. The theatre, designed by Giovanni Battista Aleotti and built in 1618 (but not used until 1628, to celebrate the marriage of a Medici daughter to a Farnese son), was the first proscenium theatre to be designed for movable scenery (Figure 9) and is the earliest large-scale indoor theatrical facility to have survived. It was severely damaged by fire bombing in World War II but has since been restored to its former glory. There has also survived an extensive catalog giving details of events held there, including some contemporary comment on performances. The catalog describes the variety of uses to which the theatre was put: drama, opera, and ballet were performed on stage; equestrian acts and sumptuous balls were held in the spacious arena between stage and seating, which could also be flooded to a depth of two feet and used for mock naval battles; and, in addition, the theatre accommodated such court ceremonies as ambassadorial receptions, proclamations of state, and princely extravaganzas. The Teatro Farnese has windows (as did the Teatro Olimpico and the Teatro all'Antica at Sabbioneta before it) behind and above the banked seating, which helped to illuminate the space during daytime use; tallow candles or animal-fat lamps, in wall and overhead fixtures, were the only source of nighttime illumination for this and all interior theatres until the introduction of gas lighting in the 19th century. The Teatro Farnese set the style for stage and auditorium design over the next 250 years, with the exception of the courtyard-patio (*corrales*) theatre in Spain and the Elizabethan and Jacobean theatre of England. (G.C.I./Ho.B./C.Ba.)

Developments in staging. In the latter half of the 16th century, intermezzi became a popular element of theatrical production. These entertainments, inserted between the acts of a play and totally unrelated to it, were generally on classical themes and were originally mounted during masked balls and banquets. The need to change settings rapidly for the alternating segments of plays and intermezzi encouraged the development of new devices for shifting scenery. The first solution to scene shifting adopted for intermezzi was derived from discussions of *periaktoi* found in Vitruvius. Nicola Sabbatini's "Manual for Constructing Theatrical Scenes and Machines," published in 1638, listed three main methods of changing scenery: one used *periaktoi;* the second maneuvered new wings around those already there; and the third pulled painted canvas around the wings to conceal the previously visible surfaces. In addition, the author explains how to change the flat wings near the back of the stage by sliding them in grooves or turning them like pages in a book. All of Sabbatini's devices indicate a considerable simplification of Serlio's wings (*e.g.,* the substitution of painted details for three-dimensional ones).

The demands of scene changing required that flat wings replace the angled ones. The problem of transferring a perspective picture successfully to a series of flat wings was not solved until 1600. By 1650 angled wings were completely outmoded; at each wing position as many flats were set up, one behind the other, as there were settings. Scenery was changed by removing the visible wings to reveal the set behind. Grooves were made in the stage floor to support the flats and facilitate their movement. The background was painted on two flats, called shutters, which met at the centre of the stage; and cloths that could be rolled up were occasionally used.

The chariot-and-pole system

The final step in scene-shifting was introduced by Giacomo Torelli in 1641, when he perfected the chariot-and-pole system. According to this system, slots were cut in the stage floor to support uprights, on which flats were mounted. These poles were attached below the stage to chariots mounted on casters that ran in tracks parallel to the front of the stage. As the chariots rolled to the centre of the stage, they carried the flats into view. An elaborate system of winches, ropes, and pulleys made it possible to change every part of a setting by turning a single winch. This invention, adopted by every European country except England and Holland, was the standard method of shifting scenery until the end of the 19th century.

The Italians were particularly taken with special effects and delighted in elaborating on medieval practices. Most

of the special effects were associated with the intermezzi and involved the replacement of biblical characters of the Middle Ages by pagan deities. Machines capable of flying up to 50 characters might be used. According to Serlio, moving mechanical figures representing men, animals, and objects were cut out of pasteboard and drawn across a scene by invisible wires. In many productions clouds that engulfed the stage would hide the activity of lowering painted cloths and flats (Figure 10). The front curtain was used to conceal the scenery and increase amazement at the beginning of a performance. At first the curtain was dropped, but, as this was hazardous, the roll curtain was soon adopted.

Commedia dell'arte

Alongside the theatre of the aristocracy existed the enormously popular commedia dell'arte. The term commedia dell'arte only began to be used in the mid-18th century, though it has since come to denote the traveling companies of actors whose masked, improvised farces enjoyed a period of great popularity in Italy and throughout Europe in the 16th and early 17th centuries. The origins of the commedia are questionable, though it seems most likely that it derived from an ancient tradition of popular dancing and buffoonery, combined with stock characters from Roman comedy. Popular legend associates commedia performances with improvised acting in the open air, but evidence suggests that the commedia was not infrequently performed in enclosed spaces, since its emergence in the early 16th century proves it to be quite clearly a commercial theatre. The development of the commercial theatre, perceived by Vasari in the 16th century as an extraordinary innovation, parallels the emergence of the commedia companies, known for at least a century and a half as performers of *commedia mercenaria* (mercenary commedia), *commedia all'improvviso* (improvised commedia), *commedia delle maschere* (mask commedia), and, in France, as the *comédie italienne.* The basis of the commedia companies was continuity; roles and plots were transmitted orally, often from generation to generation. The companies traveled constantly and performed in hired indoor spaces, only occasionally on outdoor stages, making use of perspective scenery when they could but relying primarily on the skills of individual actors. Particularly famous were Francesco Andreini and his wife, Isabella, who was a playwright and poet in her own right, besides being a successful actress, Tiberio Fiorillo, and Vicenza Armani, whose arrival in many cities was accompanied by ceremonial cannon fire.

The commedia dell'arte is best remembered as a theatre of stock types that later degenerated into pantomime clowns but that caught and held the imagination of audiences across the centuries. In fact, the greatest significance of the commedia has often remained hidden; its emergence as a specific form of theatre in the 16th century marks a fundamental change in the history of Western theatre as a whole. In the precommercial theatre, performance was characterized by the mutual participation of actors and audience. In the commercial theatre, where actors have to sell themselves to the audience, the emphasis shifts away from the role of the audience onto the skills of the actors. So the commedia dell'arte began as a festive people's theatre of the medieval world and became an actors' theatre. Its rise to fame and popularity marks the precise moment of the start of the theatre industry.

The birth of the theatre industry

The 16th and 17th centuries in France. In 16th-century France most theatrical activity was associated with the Confrérie de la Passion, a Parisian organization set up for the performance of mystery cycles. In 1402 the company was granted permission to stage any mystery play, but by 1548 it had been forbidden to produce sacred mysteries, this satirical forum for the lower clergy having proved to be too much for the ecclesiastical authorities. The company was granted, instead, complete control over secular drama, and they converted the Hôtel de Bourgogne into a theatre. The sets consisted of paintings of houses, unusual for the variety of localities represented within the same stage area.

Despite the number of critics seeking to hold to the classical "unities"—*i.e.,* the notion that a play should concern a single course of action set in one day, in one place—popular sentiment inspired plays with numerous settings. Such a play could be presented by the use of curtains, by changing scenery, or by a third method, the *décor simultané,* which was utilized by Laurent and Mahelot, the designers for the Confrérie. In this scheme, several localities were represented on the stage at the same time—each on a different portion of the stage—using angled mansions of wooden frames covered with canvas. When a play needed more mansions than could be fitted onstage at once, units were converted by removing the canvas coverings or by opening curtains to show an interior scene. Molière inherited a permanent town square set when he moved into the Petit-Bourbon in 1658.

The Elizabethan stage. During the early part of the 16th century, there were two distinct types of theatre in England. One was represented by small groups of professional actors who performed in halls, inns, or marketplaces. The location of a play was established by the words and gestures of the actors. As in the commedia dell'arte, these localities had little significance. The second type of theatre, found in the London area, was made up of amateurs, usually university students, performing for the royal court and assorted gentry. The audience and the actors were educated, acquainted with the classics, and knowledgeable about theatre in other countries, particularly France. The stage was probably set with buildings made of laths, covered with painted canvas, with cloud borders masking the upper part of the acting area.

The significant achievement of the Elizabethan stage was connected with the theatres of professional acting groups, not the court theatre. During the second half of the 16th century, as they became successful, the troupes no longer needed to remain itinerant. In 1576 the first permanent public theatre, called simply the Theatre, was erected by the actor James Burbage. The building boom continued until the end of the century; the Globe, where Shakespeare's plays were first performed, was built in 1599 with lumber from the demolished Theatre.

The rise of permanent public theatres

The typical Elizabethan stage was a platform, as large as 40 feet square (more than 12 metres on each side), sticking out into the middle of the yard so that the spectators nearly surrounded it (Figure 11). It was raised four to six feet and was sheltered by a roof, called "the shadow" or "the heavens." In most theatres the stage roof, supported by two pillars set midway at the sides of the stage, concealed an upper area from which objects could be raised or lowered. At the rear of the stage was a multileveled facade with two large doors at stage level. There was also a space for "discoveries" of hidden characters, in order to advance the plot; this was probably located between the doors. Some scenes took place in a playing area on the

second level of the facade, but, again, historians disagree as to which scenes they were.

Properties were occasionally carried onto the platform stage, but from extant lists it is obvious that they were few in number. Some properties were so cumbersome that they remained onstage throughout a performance. Smaller properties were probably revealed in the discovery space, and servants carried some properties on and off. It appears that the audience was not concerned by the scenic inconsistencies.

All of the theatre buildings were round, square, or octagonal, with thatched roofs covering the structure surrounding an open courtyard. Spectators, depending on how much money they had, could either stand in the yard, which may have sloped toward the stage, sit on benches in the galleries that went around the greater part of the walls, sit in one of the private boxes, or sit on a stool on the stage proper.

The importance of this type of theatre was its flexibility. In some ways it was similar to earlier attempts to reconstruct the *scaenae frons* of the Romans; it had the facade and the entrance doors. The Elizabethan theatre differed in that it had a main platform, an inner stage, and an upper stage level that made movement possible in all directions instead of simply along the length of a narrow stage.

Spain's Golden Age. Religious drama developed in Spain during the Middle Ages only in the northeast because the Moors occupied the remainder of the peninsula. During the 16th century, as Spain became the most powerful country in Europe, it started to develop a sophisticated theatre. Following a period of interest in classical drama and the introduction of printing, in the late 15th century there appeared Juan del Encina, the founder of modern Spanish drama. Although the origin of professional status among players is obscure, it is known that actors in Spain were being paid as early as 1454. The popularity of the theatre mushroomed in the 1570s, and among the playwrights of this era were such masters as Lope de Vega, Cervantes, and Calderón de la Barca.

During this Golden Age in Spain, the theatre assumed a form more flexible than that of the Italian or French stages. The model was that of the *corrales*—courtyards enclosed by the backs of several houses—in which the earliest troupes had performed. The staging arrangements were almost identical to those in contemporary London. The stage itself was a raised platform, without a front curtain or a proscenium arch but with a permanent facade at the back. Stages were about 28 feet long and 23 to 30 feet deep. The open platform was usually backed by a facade of two levels, with pillars dividing the lower level into three openings. The second level, basically a gallery, usually represented towers, city walls, or hills.

Spanish staging conventions, like those of the Elizabethan theatre, tended to be simple. To denote a change of location, an actor merely exited and reentered. Occasionally, a curtain might have been used to augment the scenic effect, being drawn aside to permit upstage action. As with Shakespeare, however, locale was suggested by poetic discourse rather than by visual symbolism. The stage probably derived directly from the medieval wagon platform that had been used in the public square. Backstage were the actors' dressing rooms and stage property rooms. A shallow roof, supported by the primary backstage structure, extended partway over the platform, though probably not far enough to require any additional support. Three kinds of scenic background were utilized: the facade; the curtains concealing the facade, which were used when the location was not particularly important; and medieval-type mansions, which were sometimes erected on the main stage. As spectacle increased after 1650, painted flats with doors and windows were set into the facade in place of curtains. After a period of time, awnings were rigged over the seating, and, eventually, the addition of a permanent roof made it an indoor theatre. Seville at one time boasted seven permanent theatres; the most important in Madrid was the Corral de la Cruz, opened in 1579. The *corrales* themselves, enclosing a square or rectangular courtyard, were unroofed until the 18th century; when roofs were added, a row of windows was added under the eaves. Seating consisted of benches on the ground level and balconies set in the containing walls for wealthier patrons. A special boxlike gallery, called the *cazuela,* the "stewpot," was assigned to women spectators. Above the *cazuela* were galleries for members of the city government, the clergy, and the aristocracy.

BAROQUE THEATRES AND STAGING

The combination of two artistic innovations—the formulation of the laws of perspective in the 15th century and the production of the first opera in 1597—provided the foundation for the Baroque theatre, which was to last until the 19th century. During this era all countries were brought into the same orbit, although Italy remained the primary inspiration. The classically inspired drama of the 16th century gave way to a variety of entertainments—intermezzi, ballet, masques, and opera. The invention of new means of presenting spectacular visual effects encouraged the installation of more and more elaborate machinery in theatre buildings. The result was that spectacle dominated all other aspects of production. (Ho.B./C.Ba.)

Court theatres. The Baroque architectural style, beginning in Italy and spreading across Europe, dominated theatre building between about 1650 and 1790. Its chief characteristics are refinement in detail of the proscenium stage and of the Renaissance horseshoe-shaped auditorium and seating plan. The innovations of the period were introduced in the private court theatres. As many as five shallow balconies were stacked vertically in the auditorium. For the first time there appeared an orchestra pit in front of the stage, sunk below ground level. The stage floor, which previously had extended only a few yards back from the proscenium arch, was now deepened to accommodate scenery, equipment, and dancing.

The rise of grand opera and ballet

With the rise of grand opera and ballet, inventors and designers were called upon to provide increasingly elaborate, portable, perspective scenery and complicated stage machinery, both above and below stage, to effect scene changes (nearly always carried out in full sight of the audience). Famous names of this period include the Italians Giacomo Torelli and the Bibiena family, whose ingenious settings were unrivaled for originality. A rigid court etiquette dictated that the lines of perspective should provide a perfect stage picture from the point of view of the royal box, which directly faced the stage. Since, moreover, the building of theatres was controlled by the ducal or imperial purse, a rigid architectural formalism, varying only in detail, became the fashion, not to be broken until late in the 19th century. The auditorium was planned in tiers, a vertical stratification that reflected the ordering of society by class. A good example is the French court theatre at Versailles (1769), designed by King Louis XV's architect, Jacques-Ange Gabriel (Figure 12). For a court theatre, its stage is exceptionally well equipped, mechanized in the manner of the Bibiena family, with an overhead pulley system for flying drops and borders, while the flat wings and shutters making up the elaborate scene were mounted on frames attached to carriages that ran on rails beneath the stage and so could easily be changed. Engravings of the time indicate that the court theatres were used for balls, concerts, and the like, as well as for stage performance. Though small, these costly court theatres witnessed the first productions of many operas by composers such as Haydn and Mozart, and they also played an important part in fostering the development of classical ballet.

Public theatres. *The opera house.* There were two kinds of public theatre in the 18th century. One was a logical development of the earlier private court theatres, reflecting a sophisticated, urban, aristocratic demand for theatre as entertainment. The Teatro alla Scala (1776–78) in Milan is a good example of the numerous theatres erected by 18th-century nobility in the capitals of Europe. Public theatres such as La Scala differ from private court theatres only in the size of the auditorium and stage. Whereas Versailles had seated fewer than 700 in the auditorium, La Scala could accommodate more than 2,000. Opera, generally including a ballet, was by this time the most popular form of entertainment, especially in Italy.

La Scala

The Restoration playhouse. The other kind of public theatre, peculiar to England, was the Restoration playhouse. The Baroque horseshoe-shaped auditorium, with its deep stage and orchestra pit, was generally in favour all over western Europe, fixing the design and style of opera houses in particular. In it the actor played in front of elaborately painted scenery and behind the proscenium arch. The Restoration playhouse, however, while borrowing the fully rigged stage of the Baroque theatre, provided, in addition, a deep apron stage thrusting out from the proscenium, upon which most of the action took place. Thus, the actor played, as it were, in the auditorium and away from the scenic backing; the English, with their Shakespearean tradition, were loath to abandon the intimate contact between actor and audience that the Elizabethan theatre had allowed. At either side of the forestage were doors by which actors entered; above these doors were additional boxes, for spectators, stacked one above the other in the Baroque manner.

Influence of technical achievements. Theatre lighting in this period was provided by wick-fed illuminants concealed behind the wings and proscenium arch and at the edge of the stage apron. In the auditorium either a large,

single, central fixture, as at La Scala, or a number of smaller ceiling fixtures, as at Versailles, was the custom. All were kept burning during performance, and the habit of lighting the auditorium persisted until late in the 19th century. (G.C.I.)

The court masques served to introduce Italian staging to England. The masques were allegories designed to honour a particular person or occasion by comparing them favourably with mythological characters or situations.

Influence of Inigo Jones

Inigo Jones, the foremost English architect of his time, produced masques and other entertainments at the English court from 1605 to 1640. He had visited Italy between 1596 and 1604 and was the individual most responsible for acceptance of Italian stage design in England. From his sketches it is known that Jones went through several phases in his designs, starting in 1604 with the *décor simultané,* mentioned above, in which different localities were represented on different portions of the stage. In 1605 he introduced simple perspective settings—two painted representations of houses with a painted back shutter. The same year he experimented with *periaktoi,* creating a globe, with no visible axle, that revolved to reveal eight dancers sitting inside.

His masques all had painted proscenium arches, into which he set a falling curtain. By 1635 Jones designed a setting that utilized four angled wings, like Serlio's, and four shutters at the rear, three of which could be drawn to the sides in two parts (Figure 13). Jones' design for a masque in 1640 is considered the first design of the Baroque theatre in England. Four sets of side wings were placed on each side of the stage, each wing consisting of two flats. There were four shutters at the rear, with each dividing into two parts for easy removal. Each wing had either a header (*i.e.,* a horizontal unit that joins two upright wings, to form a flat arch) or a sky border (a horizontal piece of scenery, designed to look like the sky, which masks the space above the set). To give the illusion of distance, the side wings were made in exaggerated perspective, with each succeeding wing in significantly smaller scale than the one preceding. The disadvantage of using smaller sized flats toward the back of the stage was that if the actors stood too close to them the illusion would be destroyed. The actors were therefore restricted to the front of the stage. In successive decades, attempts were made to give the stage area greater depth by multiplying the number of flats on each side. In sum, with the exception of the chariot-and-pole system of scene changing, Jones introduced all of the major Italian developments into England.

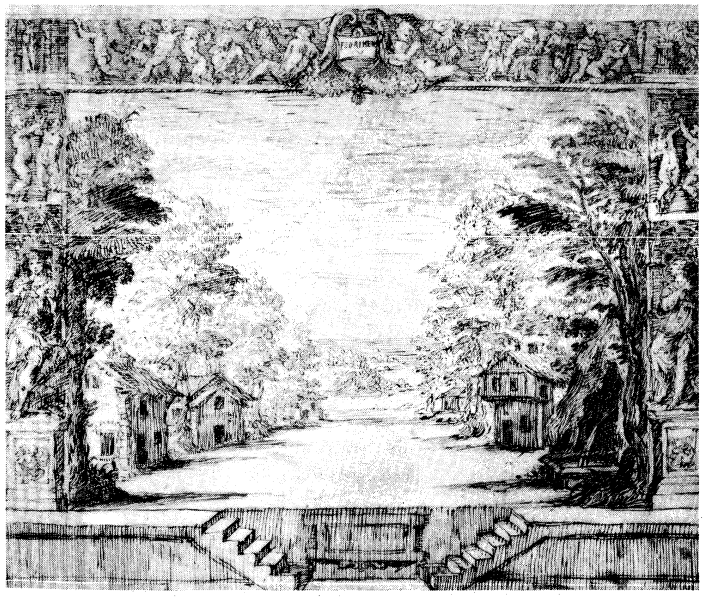

Figure 13: Stage designed by Inigo Jones in the Italian manner for a production of *Florimène,* 1635. In the Devonshire Collection, Chatsworth, England.

After Inigo Jones, English scenery practices and stage conventions were similar to those of Italy. Sets were changed by sliding them in grooves in the stage floor and overhead. Since the curtain was raised after the prologue and remained up throughout the performance, all scene shifting was in view of the audience. It was not until 1750 that an "act drop" was used; previously, even intermezzi were performed in front of a full stage setting.

As interest in spectacle increased, the scene painter became more important, and by the late 18th century each theatre had two or more permanent scene painters. The best known designer around the end of the 18th century was Philip James de Loutherbourg, a painter; from 1771 he worked for the actor-manager David Garrick as scenic designer at the Drury Lane Theatre in London, and he is credited with changing the orientation of design from the architectural to the landscape era, thus marking the end of the Baroque in England. He was one of the pioneers of the cut cloth, a double back cloth in which there was an opening in the one nearer the audience that revealed a vista painted on the back one. He also utilized transparent scenery; in one production he cut the moon out of the canvas back cloth, replaced it with gauze, and lit it from behind. The importance that Loutherbourg's landscape painting of the back cloth assumed is shown by the fact that the Drury Lane pantomime of 1779 was specially written for the scenery he had designed while on a trip to Derbyshire. His depiction of actual places in England started a vogue for "local colour." Loutherbourg's single most important contribution, however, was that he achieved a unity of design because he directed both the scenery and the lighting and effects of a single production.

Loutherbourg's contributions

Scenic design. Significant changes in scenic design were made by Italy's Bibiena family, of whom the best known members were Ferdinando, Francesco, Giuseppe, Antonio, and Carlo. Around 1703, at Bologna, Ferdinando introduced angled perspective. Previously, stage design was based on one-point perspective using a single vanishing point, in which all lines appear to recede with distance toward one point at the centre of the background. Bibiena, however, used perspective with two vanishing points; if this technique were used to render a large, flat building as seen from one corner of it, for example, the base and roof lines of one side extended into the distance would appear to meet at some point off to the right and those of the other side at another point off to the left. Furthermore, by locating these points quite low, Bibiena gave the structures the effect of immense size. Buildings, walls, or courtyards were placed in the centre of the set and vistas at the sides, and the scale of settings, which had previously been designed to make the scenery an extension of the auditorium, was altered. The front wings were painted as though they were only the lower part of a building. The result of these innovations was that Bibiena's sets seemed so large that they created a feeling of fantasy (Figure 14). Despite its apparent size, though, an angled-perspective setting required less stage space than one with a central alley. Many of the settings divided the stage into a foreground, for the actors, and a background, for distant objects. A drop, designed to resemble a series of arches or columns, often marked the rear of the acting area.

Angled perspective designs

Another designer who developed the angled scene independently of Bibiena was Filippo Juvarra, a major Italian architect of the early 18th century, who began his work, as did many artists of the period, with the decoration of court entertainments. Some of his most intriguing scenic designs, in terms of architectural fantasy, were executed for a marionette theatre owned by his patron. These designs are of particular interest to theatre historians because Juvarra usually included plans of the stage settings showing exactly how the wings were placed. Juvarra's sets were basically curvilinear, leading the audience's eye to the foreground instead of the sides. In several sketches he designed a permanent set with a large archway opening up to a series of vistas, which varied from a landscape to a perspective corridor. His designs foreshadowed the interest in landscape that was not to find its complete development until almost a century later.

In the second half of the 18th century, several new

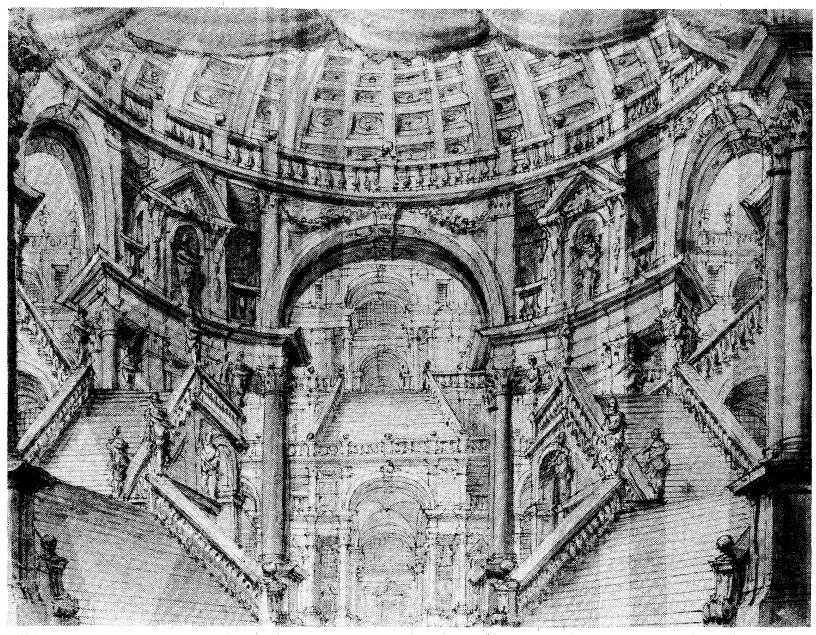

Figure 14: Drawing for an interior setting by Giuseppe Bibiena. In the Victoria and Albert Museum, London.

Late 18th-century developments

directions in thinking led to stylistic changes in scenery. One was the increased interest in history, spurred by the rediscovery of Pompeii in 1748. Scenery of classical ruins overgrown with vines became popular. Plays based on folk literature were produced with Gothic architectural settings. The most important new direction was that scenic designers introduced "mood"; they started to emphasize light and shadow to create an atmosphere. The best known artist of this period was the Italian engraver Giambattista Piranesi, who executed more than 1,000 engravings of Roman ruins and prisons. He did not particularly apply himself to the theatre, yet his designs were inspired by contemporary stage settings and were in turn themselves an inspiration for other designers.

Developments in France and Spain. Although Italian-style scenery was introduced to the French court before, it was not popular until after 1640. The first theatre in France with a permanent proscenium arch and a stage designed for flat wings was constructed in 1641 for Cardinal de Richelieu. In 1645 an Italian designer, Giacomo Torelli, popularly called "the great sorcerer," was imported by Richelieu's successor, Jules Cardinal Mazarin, to design for the new theatre, the Palais-Royal. In 1646–47 Torelli remodeled the Palais-Royal to accommodate his invention of the chariot-and-pole system of scene shifting. Pierre Corneille, the founder of French classical tragedy, was commissioned to write *Andromède* for the remodeled theatre (Figure 15). Although the play progressed through spoken episodes, each act provided an excuse for Torelli to introduce elaborate machinery, including the revolving stage. Until Torelli, the changing of scenery had marked a structural break in the dramatic presentation. Torelli put aside all previous methods, which were so distracting to the audience, and introduced set changes within, rather than at the ends of, the scenes. The audience was mesmerized by the scenery mysteriously changing while the action of an opera or ballet proceeded without interruption.

For the wedding of Louis XIV, in 1660, Gaspare Vigarani went to France from Italy to build the Salle des Machines, the largest theatre in Europe. It was 226 feet long, only 94 feet of which was occupied by the auditorium. Its stage, 132 feet deep, had a proscenium arch only 32 feet wide. One of Vigarani's machines, 60 feet deep itself, was used to fly the entire royal family and their attendants on stage for the finale. Vigarani was succeeded by his son, who was in turn followed by the Jean Berains, father and son.

Designs of the Jean Berains

The Berains established a distinctly French style of design, emphasizing heavy lines, curves, and encrusted ornamentation. They usually designed only one set for each act but used many machines and special effects. This combination of static scenery and dynamic machinery was to remain in vogue in French opera through the 18th century. After 1682 the influence of the court on public theatre declined. After 1690 the King became so puritanical that plays were no longer encouraged.

In contrast to court opulence was the Comédie-Française, for which a theatre was built in 1689 from a converted tennis court. The stage was equipped for flat wings and shutters, but since scene changes were few, the machinery was minimal. The typical background for tragedies was the *palais à volonté* (literally "palace to order"), a neutral setting without particularized details. For comedy the typical scene was *chambre à quatre portes* ("room with four doors"), an informal interior. By 1700 Paris had two types of theatres, epitomized by the Opéra, with its Baroque scenery and machines, and the Comédie-Française, which did not rely on spectacle.

The first true spectacle in a public theatre was the 1755 production of Voltaire's *Orphelin de la Chine* (*Orphan of China*), with its supposedly accurate Chinese scenery and costumes. Subsequently the Comédie-Italienne, permanently performing in Paris, introduced local colour and increased the use of spectacle. Giovanni Nicolò Servandoni, originally a Florentine who lived in Paris from 1724 to 1746, translated Italian styles to French taste. His use of perspective gave the illusion of space without falling back on the obvious geometry that characterized the High Baroque. He took over as director of the Salle de Machines, where his work in its turn influenced the designers of Italy and Germany. At the Opéra, as opposed to public theatres, spectacle was used throughout the 18th century. Its best known designers included the painter François Boucher. And although many famous painters designed settings, there is still no comparison with the works of the Italians of this period. The financial problems of the theatres did much to prevent a forward thrust in French design. Ironically, the most sumptuous spectacle of the latter part of the 18th century occurred in France in 1794, after the Revolution: the National Convention decreed "The Festival of the Supreme Being," designed by the painter Jacques-Louis David and conducted by the revolutionary government leader Robespierre—Neoclassicism in the service of the Republic.

After the 1760s, theatres were built in the Italian style, with ovoid auditoriums and enlarged stages. By the 1780s, when the standing pit fell into disuse, all of the spectators were finally seated, off the stage. The seated pit was not to become accepted in France until the 19th century.

In Spain during this period, theatre began to decline. Although Italian-style scenery was used occasionally, it was not common until brought from Florence in 1626 by Cosimo Lotti, who staged many outdoor productions on the grounds of the Buen Retiro palace in Madrid. For one, he built a floating stage on a lake, and the special effects included a shipwreck, a water chariot drawn by dolphins, and the destruction of Circé's palace. This production was lit by 3,000 lanterns, and the spectators watched from gondolas. In 1640 Lotti built a permanent theatre in Madrid, the Coliseo, which probably had the first proscenium arch in Spain. The next decade saw a decline in both court and public theatres. By 1650 the Coliseo was reopened, but its popularity had diminished by 1700. By the late 1600s Spain had lost most of its economic and political power, and its theatre through most of the Baroque was a watered-down version of Italian concepts.

Developments in northern Europe. One country outside the Italian influence during this period exhibited an interesting theatre plan. In 1638 Jacob van Campen, an architect, designed a theatre in Amsterdam that had no counterpart elsewhere in Europe. The auditorium was elliptical, with two tiers of boxes on one side opposite a stage facade with open balconies over the sides. The facade itself consisted primarily of pillars with cornices above them, and painted panels, representing different localities rather than a unified setting, were set between the pillars. The whole concept of the panels was probably directly derived from the simultaneous stage of the Middle Ages.

The constantly shifting politics of northern Europe, and particularly of Germany, in the 16th and 17th centuries was the primary cause for the late development of professional theatre in this region. Theatre in Germany owes its impetus to the English troupes that started touring the country in the early 17th century. At first, the English performed in courts, and by 1650 they were traveling across the country regularly. To attract the non-English-speaking audience, the troupes gradually inserted German phrases, speeches, and then whole scenes. As early as 1626, German actors were joining the troupes, and by 1680 English actors had been completely displaced. Because Germany was politically divided and there were no large cities, the troupes had to travel constantly to find new audiences. To attract the disparate spectators, a company might have as many as 100 plays in its repertoire. These conditions combined to make it impossible to rehearse and mount plays with any great professionalism.

First Viennese opera house

Between the mid-17th and the late 18th century the aristocracy ignored public theatre in favour of opera. The first Viennese opera house was built in 1652 by Giovanni Burnacini and is similar to the courtyards of Italian Renaissance palaces in the two levels of its auditorium, framed by a double arcade of rounded arches. Italians played an important part in every aspect of theatre at the imperial court until the late 18th century. The first performance at the Viennese opera house was of an Italian opera.

In the public theatre, the work of the manager Johann Friedrich Schönemann led to the establishment in 1767 of the Hamburg National Theatre, the first noncommercial public theatre, subsidized by a group of rich citizens. This marked the beginning of a movement that gained force during the next decade and can be found even today in East German theatre. The prevailing attitude was that theatre is a cultural institution that, like museums, should be available to all citizens.

This movement toward permanence greatly influenced the evolution of staging in the 18th century. As audiences grew larger, and as cities developed, a troupe was able to reduce the number of plays in a repertoire, and this in turn led to better productions. And as the theatre building grew in size and substance, the chariot-and-pole system of scene shifting was introduced. Interest in historical accuracy of sets and costumes was stimulated by the chivalric plays popular in the 1770s. During the next two decades dramatists were writing plays that relied on complex set pieces, including bridges and walls. Doors and windows were set up between the wings, marking the first development toward the box set—a set representing three walls of a room, the fourth being the plane of the proscenium.

Early Russian staging. Russian theatre can be traced back to the pagan rituals of the ancient Slavs, the later Christian festivals, and, in the Middle Ages, the mixed rituals of these two influences. As early as the 10th century there were mummers, called *skomorokhi*, probably itinerant comedians who performed in small towns and villages. Suffering the same fate as the actors of western Europe during the early Middle Ages, the mummers were the victims of measures taken by the princes as well as the church. Their specialties were trained-animal acts, usually with bears, and puppet shows. The Greek Orthodox Church introduced some morality plays in Russia, but they were limited in scope and number. Since the mass was celebrated in the vernacular, the church did not need the aid of morality plays for the dissemination of its message. At the beginning of the 17th century, the only theatre using a literary text and a trained company was the drama brought from Poland to the Ukraine.

The Tsar's theatre

In 1672 the first public performance of a play was offered in Moscow. A special theatre was built in the Tsar's residence; there seems to have been no scenery outside a fir tree on either side of the stage, although there was a sliding curtain. The Tsar (Alexis), who was so excited that he sat in the theatre for 10 hours on the day of the first performance, paid for the founding of a theatrical school. The problem with the theatre during the next 80 years was precisely that it had been founded on the Tsar's order: it

was attached to the court and subsidized by the aristocracy (who chose German directors); it assumed political overtones and aimed at pleasing only the monarchy.

The beginning of change came in 1730, when an Italian group brought the commedia dell'arte, elaborate sets, and machinery to Moscow. During the next 10 years, Italian opera and ballet were also introduced to Russia. Despite the success of foreign companies, the significant event was the birth of the national theatre in 1749. This enterprise was open to the public, and, although it was popular, lack of funds made it a weak rival to court theatre. Its impact lay in the fact that it introduced the concept of theatre to a large audience.

By the end of the 18th century, companies were touring the major cities, and privately owned theatres were being opened. In general, only the aristocracy patronized the theatre, and nobles established their own serf troupes. One prince, who owned 21,000 serfs, established his own ballet, opera, and dramatic companies. Owners occasionally rented their troupes for public performances, until the abolition of serfdom in 1861. Little is known of the staging of their productions beyond the fact that it was imitative of French and Italian theatre.

DEVELOPMENTS IN THE 19TH CENTURY

Theatre in France after the Revolution. Under Napoleon, French theatre was little different from that of the 1780s, specializing in Neoclassical drama. Popular drama, as performed by what were known as "boulevard theatres," introduced melodrama, a form that was to dominate theatre in the 19th century. Melodrama, in turn, by popularizing departures from Neoclassicism and capturing the interest of large audiences, paved the way for Romantic drama.

The dramatic debut of Romanticism is dated at 1830, when public pressure forced the Comédie-Française to produce Victor Hugo's *Hernani*. After a spirited opening at which Hugo's Bohemian claque overwhelmed the staid regular theatregoers, Romanticism was victorious and ruled the Parisian stage for 50 years. The grandiose bombast of Romanticism did not overturn the Baroque, it merely diluted it; the formal artificial structure was broken into sentimental, melodramatic episodes depicting the distraught hero buffeted by an unfeeling world and the awesome elements. The melodramas introduced natural disasters that were significant to the plot, so that emphasis could be placed on special effects and spectacle. Dramatists also deliberately included exotic locales or examples of local colour, so that a variety of historical periods and fantastic sets would hold the attention of the audience. Throughout the 19th century, architectural perspective was replaced by neo-Gothic sentimentalization of nature. Painted Romantic scenery, in the style of Loutherbourg, was the rage in France.

Staging of Romantic drama

The two important designers of this period were Jacques Daguerre, who was also the inventor of the daguerreotype, an early photographic technique, and Pierre-Luc-Charles Ciceri, the most important designer of this period. The panorama, a major scenic innovation, was invented in 1787 and first used on the London stage in 1792. The panorama was set up in a circular building in which the audience, sitting on a central platform, was totally surrounded by a continuous painting. Daguerre started his career as one of the first panorama painters. He went on to invent the diorama, in which the audience sat on a platform that revolved to show paintings on proscenium-like stages. Although the scenery remained stationary, Daguerre created the illusion of constant change by controlling the light on the semitransparent sets. The panorama was more popular than the diorama because it did not depend on the ability to alter stage lighting. Its shape, though, was altered to resemble the diorama. The next development in spectacle was the moving panorama, in which a continuous scene was painted on a long cloth, hung from an overhead track, and attached at both ends to spools. When the spools were turned, the cloth moved across the stage so that the actors with their carriages and other props could move from one location to another without changing wings and drops. The sky borders were dispensed with, and flats of architectural units or natural objects forming an arch were placed at the front of the stage, through which was seen a distant view painted on a curved panorama stretching across the back and sides of the stage.

Ciceri's importance arose from his abilities to depict local colour, ruins, and historical backgrounds. He founded the first scenic studio in Paris independent of a theatre, with specialists in various types of design. After the opening of the new Opéra in 1822, interest in spectacle was so great that promptbooks were published, describing scenery and special effects and how they could be adapted for theatres with less equipment.

Ciceri's contributions to staging

By the end of the 19th century, the process of scenic design and construction had become standardized. The director gave the requirements to the scenic designer, who made cardboard models. The scenery was constructed by the theatre's carpenters and then sent to a scenic studio for painting. (Ho.B.)

German Romanticism and Naturalism. The 19th century in Germany was a study in contrasts. The beginning decades saw the rise of Romanticism, which, 50 years later, was still strong, primarily in the figure of the composer Richard Wagner. The century's middle decades of political and economic disillusionment before the unification of Germany were conducive to the emerging Naturalist school, the philosophy of which was first embodied in the Meiningen Players, organized in 1866 by George II, duke of Saxe-Meiningen.

By the middle 1820s, after the defeat of Napoleon, the political turbulence in Germany led to municipal control over the theatre and strict censorship. Repertoires consisted of "safe" classics and insipid new plays, resulting in competent but uninspired theatre. This competence was reflected in the staging. One of the few important designers of this period was Karl Friedrich Schinkel, who had been trained in both Italy and Germany. He introduced the diorama in Berlin in 1827.

One true innovator during the first half of the 19th century was Ludwig Tieck, who advocated realistic acting on a platform stage. With the help of an architect, he tried to reconstruct an Elizabethan public stage. He also championed the open stage in the belief that pictorial realism destroys the true illusion of the theatre. Invited by William IV of Prussia to stage *Antigone* at the court theatre in Potsdam in 1841, Tieck extended the apron in a semicircle over the orchestra pit and built a *skēnē* as the only background for the drama. In 1843 he adopted Elizabethan conventions to the proscenium theatre for a production of *A Midsummer Night's Dream*. Using the front part of the stage as a large open space, he built a unit in the rear consisting of two stairs leading to an acting area eight feet above stage level. The stairs framed an inner stage below the platform. He then hung tapestries at right angles to the proscenium, thus masking the sides of the stage. Although Tieck was universally respected, it was not until the 1870s that his innovations received widespread support. The works of Wagner and Saxe-Meiningen were responsible for this change in the public's attitude.

Wagner's works were the dramatic culmination of Romanticism and the contribution it was destined to make to modern theatre practices. German Romanticism was in great part a protest movement against the dominance of French Neoclassicism. Instead of structuring dramatic action according to fixed patterns of logical progression, the Romantics wanted dramatic structures born of human experience. This stress on what was to be called "organic form" was a protest against the received tradition of dramatic theory and staging practices. German Romanticism, also known as Sturm und Drang ("Storm and Stress"), a movement generally attributed to the influence of the young Goethe at the end of the 18th century, turned to a revival of the Gothic style of the Middle Ages to escape Neoclassicism. The new middle-class audiences identified with the lonely soul against the world—a sentimental world of windswept mountain crags and gloomy, mouldering castles.

Wagner's impact

Romanticism later broke into two camps. The first of these, called historical Romanticism, held that history is

continuous, and that once its import has been grasped, the present can be recognized to be as "historical" as anything that occurred in the past. The second Romantic group, with which Wagner was associated, was concerned only with the use of history to reach absolute truths. Wagner believed that the study of history leads ultimately to prehistory and thus to transhistorical mythology, the realm of absolute truths. What is particularly interesting is that the first type, historical Romanticism, eventually found its home in the theatre in the realist school. Wagner's myth-Romanticism faded by the late 1800s, although Romantic contributions to staging exerted their influence well into the 20th century.

Wagner wanted to use myth to reunite modern man with the passion from which rationalism, the industrial process, and capitalism had separated him. For him, the theatrical manifestation of the myth was the music drama, and he hoped to combine music, acting, stage space, design, and lighting to establish the primeval mood of myth (Figure 16). To house his music drama, Wagner designed the Festspielhaus in Bayreuth, which opened in 1876, marking a rejection of the Baroque stratified auditorium and a return to classical, democratic principles of theatre design. The seating is fan-shaped, a belated acknowledgment of the fact that good lateral sight lines are essential for the enjoyment of performances on a proscenium stage. Wagner did away with the box seats, from which the wealthier theatregoers had watched each other instead of the stage for hundreds of years. Another striking feature is the absence of any radial or parallel aisles. Side aisles and two vomitory exits provide the only access to seating, thus further concentrating and compressing the main body of seats in front of the proscenium. Wagner had the orchestra lowered into a pit (the "mystic gulf"), so that it became the hidden source of an enveloping sound.

The stage itself was raked upward toward the rear, and the scenery was shifted by using the chariot-and-pole system. Wagner introduced a system of steam vents to make a steam curtain to hide scene changes. For him the theatre could no longer be the aggregate of the parts contributed by various hands. The ideal was the *Gesamtkunstwerk* ("total work of art"), in which all the elements of performance would be integrated. Nothing could be left to chance; all must be directed toward the same end.

The Meiningen Players

At the time Wagner was introducing his music drama, George II, duke of Saxe-Meiningen, began to take an interest in the theatre of his court. The theatre itself, built by his father in classical-revival style in 1831, had a facade decorated with pillars crowned by a Greek pediment. The building contained not only the auditorium and stage house but also an assembly hall for balls, banquets, and other nontheatrical festivities. Saxe-Meiningen tried to create the illusion of reality with accurate spectacle and lifelike acting. He studied the distinctions between nations within the same historical period; the result was unprecedented historical accuracy (Figure 17). Saxe-Meiningen also insisted on using authentic period furniture, and the success of his troupe led to the opening of theatrical supply houses. The Duke designed all scenery, properties, and costumes for his troupe. Costumes were made of authentic materials. Characters appearing in chain mail wore chain mail and not some lighter substitute. Swords were of authentic weight. In this way, it was reasoned, the actor's physical sensation of wearing the costumes induced empathetic feelings for the character, and these feelings formed the basis of "lifelike" acting. Saxe-Meiningen viewed scene design as similar to architectural design in that it shapes whatever activity it shelters. He insisted on the continuous and direct relation between the design of a set and the actors' movements within it. Among his innovations is the abandonment of the practice of using only pastel colours for scenery; instead of sky borders as overhead masking, he used richly coloured banners, foliage, and other devices. Saxe-Meiningen was one of the first designers to break the surface of the stage floor into different levels.

From 1866 to 1874 the troupe performed only in Meiningen; for the following 16 years it toured 38 cities in nine countries. It had enormous impact on the history of the theatre, as it achieved complete illusion in every facet of its productions. Saxe-Meiningen is considered the single most important influence on the directors who inaugurated 20th-century stagecraft; he introduced the pictorial massing of crowds. He coordinated and controlled the work of his actors and established the ensemble as the basis for creative work in the theatre. There were no stars in the Meiningen Players. Casting policy required that actors play leading roles in some productions, subordinate roles in others. The supernumeraries were subjected to the same discipline, and the crowd was sectionalized under the leadership of actors. Actors were required to learn practical skills appropriate to their roles. The Saxe-Meiningen movement toward unified productions influenced other major figures such as André Antoine in France and Konstantin Stanislavsky in Russia, great apostles of realism and the founders of modern theatre.

Influence on others

However disparate the aims of Saxe-Meiningen and Wagner were, they had a great deal in common. Between them they established the principle that a production should be subordinated to the will of one individual who directs and integrates all aspects of the preparation. The profession of theatre director came into being with their vision of theatre.

Russian imperial theatre. Russian drama in the 19th century also got off to a slow start because of strict government censorship, particularly after 1825. This atmosphere was conducive, as in Germany, to the flowering

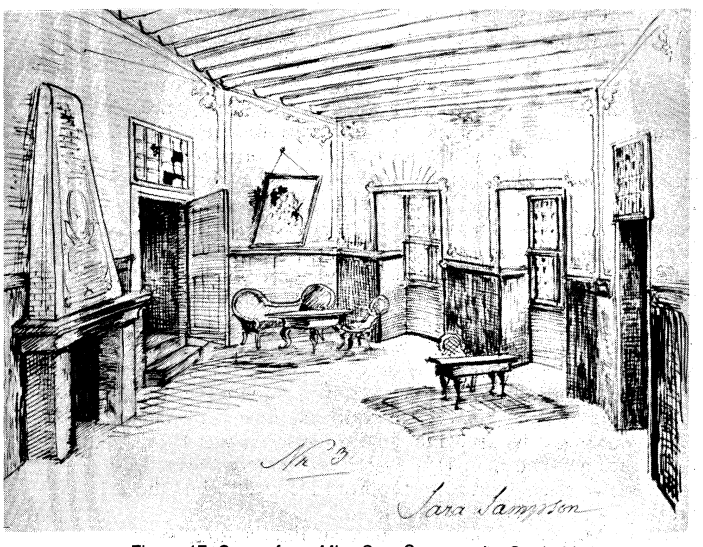

Figure 17: Scene from *Miss Sara Sampson* by Gotthold Ephraim Lessing, designed about 1884 by George II, duke of Saxe-Meiningen. In the Staatliche Museen, Meiningen, East Germany.

of Romanticism, especially as manifest in patriotic spectacles. Melodrama, Shakespeare, and musical plays were the backbone of Russian repertory until the 1830s. The best known plays of the new realistic school were those of Aleksandr Ostrovsky, Nikolay Gogol, and Ivan Turgenev.

Until 1883 the imperial theatres, under strict government controls, had a monopoly on productions in Russia's two major cities, Moscow and St. Petersburg. It was not until the monopolies were rescinded that public theatre was able to expand, although the state troupes, such as the Bolshoi in Moscow, continued to offer the most professional productions.

Through the 1850s each theatre had its own few stock settings. The box set had been introduced in the 1830s, but it was to take several decades to become popular. Realism began to dominate scenic design by the 1850s, particularly at the Maly Theatre in Moscow. Historically accurate settings began to appear in the 1860s, when one theatre hired a historian to help the designer of Aleksey Tolstoy's *Death of Ivan the Terrible.* Previously, settings had followed the neutral style of the German designer Alfred Roller, whose pupils were the major designers for the state theatres. The unified production techniques of Meiningen were not seen in Russia until the Moscow Art Theatre flourished at the beginning of the 20th century.

Historical accuracy

British theatre and stage design. In 19th-century Britain the audiences shaped both the theatres and the dramas played within them. The upper class favoured opera, while the working class, whose population in London alone tripled between 1810 and 1850, wanted broadly acted theatre with scenic wonders and machinery. And as the audience grew in number, the Georgian theatre building, which was small and intimate, began to disappear.

In the early 19th century an important designer was William Capon, who utilized pieces set at various raked angles and elaborate back cloths as an alternative to flats and wings. His sets were also large enough not to be overpowered by the larger theatres. One of Capon's sets, depicting a 14th-century cathedral, was 56 feet wide and 52 feet deep. His sets were historically accurate even though the practice of having several designers work independently on the same production was still in effect.

The productions of John Philip Kemble, the manager of first the Drury Lane and then the Covent Garden, marked the shift from Neoclassicism to Romanticism in English stage design. He valued theatricality over historical accuracy, as the audience demanded an increased use of spectacle with each passing year. As melodrama became more popular, the effects multiplied until, in an 1820 production of *King Lear,* the storm noises were so realistic that Lear could not be heard. In 1823 Kemble began to reverse this trend and started to use accurate sets and costumes for Shakespeare, and within 15 years historical accuracy was dominant.

Rise of Romanticism

Another important contributor to the history of staging was Lucia Vestris, an actress and manager at the Olympic Theatre. She controlled all the elements of a production and combined them into a single, integrated unit. She also was enamoured of spectacle and is credited with introducing the box set on the London stage in 1832, although there is some evidence pointing to its use as early as 1794. In this new set, the sidewalls of rooms were built solidly from front to back so that the actors, instead of entering as usual between side wings set parallel to the footlights, came in through doors set on hinges. She treated the box set realistically, attaching knobs to doors, for example.

Introduction of the box set

By the 1840s, because of political conditions, many theatres were bankrupt. The next 20 years saw a gradual recovery, with few dramatic innovations in design. One important manager of this era was Charles Kean, a pictorial realist, whose first major attempt to ensure accuracy in every production detail was made in 1852 with *King John.* In the following year, Kean gave the audience a printed list of authorities consulted with regard to the authenticity of each production. In mounting Shakespeare as lavishly as possible while at the same time emphasizing historical accuracy, Kean practically buried his actors in historical costume, settings, and pageantry.

In the second half of the 19th century, burlesque, extravaganza, and musical drama held the largest audience appeal. The music hall also came into prominence, as incidental entertainment was separated from drama. In the period from 1860 to 1880, the theatre continued to expand, and the number of buildings alone increased 50 percent in the first 10 years. The first manager of significance was Charles Fechter, who revived interest in the box set. He also discontinued entrances from the wings, heretofore a standard practice of actors even when the wings represented solid walls. Fechter also used a stage that sank by hydraulic mechanism, later perfected by the Germans, which allowed scenery to be shifted in the basement (see below *Development of stage equipment*).

Influential managers

The most important management team was that of Sir Squire Bancroft and his wife, Marie Wilton, at the Prince of Wales Theatre. Producing plays by Thomas W. Robertson, they succeeded in melding character and stage business. Spectacle was no longer embellishment but an emphasizing of realistic visual details. The Bancrofts' productions also finally won general acceptance for the box set; they were as accurate in modern plays as in Shakespeare; and they firmly anchored the acting behind the proscenium arch. Theatre boxes had been replaced by open balconies, which no longer extended to the proscenium wall. This made it possible for the Bancrofts and others to lower the proscenium arch. In 1880 they even extended the arch downward on either side and across the floor of the stage to emphasize the analogy of the picture frame. Modern, realistic interior settings were constantly used, and the acting was keyed to the settings. Although Fechter had employed realistic stage business as early as 1860, the Bancrofts were the first to standardize it and make it a tradition.

The greatest of the actor-managers was Sir Henry Irving, the manager of the Lyceum Theatre from 1878 to 1901. The best known designers of the period, Hawes Craven and Joseph Harker, worked for Irving. He hired historians to advise on the accuracy of productions and enlisted easel painters such as Sir Lawrence Alma-Tadema to design scenery for *Cymbeline* and *Coriolanus* and Sir Edward Burne-Jones for *King Arthur.* After Irving saw the Meiningen performances in London in 1881, he modeled his Shakespearean productions on what he had seen. Irving was also the first manager to use the front curtain to hide major scene changes, and he completely darkened the auditorium during performance, as Wagner had done.

The widespread changes in staging methods during the 19th century were possible because of changes in architecture and the development of machinery. The complex scenery of the Victorian theatre required increased flying around the stage, with a complicated counterweight sys-

tem, and this in turn fostered one of the most popular features of the staging of this period—the flying of actors as well as scenery.

During this period the arrangement of the stage floor also changed to fit the requirements of spectacle. After 1850 the stage floor was usually constructed so that floorboards could be removed for raising and lowering machinery between the joists. Sometimes a vertical panorama would run from overhead through a groove in the floor. The changes in stage floors made possible new scenic effects to meet the audience demand. The traps of the Elizabethan and Georgian eras, for instance, were greatly elaborated. The most famous trap was a "ghost glide," a sort of dumbwaiter that made actors appear to rise from the earth and glide through space.

As stage lighting improved with the introduction of gaslight (see below *Stage lighting*), the deficiencies of two-dimensional scenery in terms of realism became increasingly apparent. The taste for verisimilitude led Edward Godwin, the father of Edward Gordon Craig, frequently to commission three-dimensional scenic elements for his productions. Since the groove system of scene-changing was unsuitable for such pieces, he dispensed with it and hired a crew of 135 stage hands. The new trend also rendered the naked stage obsolete, for reasons of gravity. Irving, who was instrumental in accepting new developments in lighting, also introduced black masking pieces at the front of the stage to prevent light spill. Irving's importance to theatre is comparable to that of Saxe-Meiningen. His emphasis on pictorial realism marks the high point of British theatre before World War I.

Theatre and stage design in America. The first recorded performance of a play written by an American was in 1690 at Harvard College. The first permanent American theatre was built in Philadelphia in 1766; it was made of brick and imitated English buildings in arrangement and general architecture. In 1752 Lewis Hallam, a member of a distinguished theatrical family, arrived with a troupe from England, thus marking the beginning of professional theatre in America. The theatre in America for the next 40 years was similar to British provincial theatre, with simple sets for easy traveling; few cities could yet afford theatre buildings. By the 1790s, however, troupes were based in Boston, New York City, Philadelphia, and Charleston, S.C., and many permanent theatres were being erected.

The first decades of the 19th century brought not only multiplication of playhouses in the larger Eastern cities but also the extension of theatre to interior regions. The frontier spirit was embodied by Samuel Drake, who took the first company west (to Kentucky) in 1815. Drake designed an adjustable proscenium that could be set up in any large room. The front curtain was a roll drop (lowered from behind the proscenium arch), and three sets of wings (one each for exteriors, ornate interiors, and simple interiors) and six roll drops (including a garden, a street, and a wood) completed his scenic repertoire.

Theatre on the frontier

After 1825, New York City had higher standards of theatrical production and more theatre buildings than any other city in America. Although decoration and furnishings created an impression of luxury, the early urban theatres were in fact filthy and rat-infested. They had little or no fire protection, and between 1820 and 1845, no fewer than 25 theatre buildings burned down. Although most productions used stock sets and props, occasionally an elaborate or specific set was added. Interest in historical accuracy was not a major production concern until 1830, when Charles Kean visited with his Shakespeare troupe from England.

During the latter third of the 19th century, the general scenic trend was toward greater naturalism, with particular emphasis on local colour. The major design innovations came from the managers of troupes permanently based at a theatre. One such manager was Edwin Booth, whose new theatre, opened in 1869, introduced several new concepts in the United States. The most important innovation was that the stage floor was flat and had no grooves; elevators raised set pieces from the 50 feet of working space below the stage, and flying machines moved other pieces into the 76 feet of overhead space. In Booth's new theatre he abandoned the apron and used box sets almost exclusively.

Innovations of Edwin Booth

Another important manager was Augustin Daly, who furthered the trend of realism. While the members of his troupe changed considerably during its three-decade history, it was the best example of the permanent stock company in the history of the American theatre. Daly stressed the unity of every production and controlled each element himself. His first success, *Saratoga,* by Bronson Howard, in 1870, was the first play to give a realistic picture of American life of the day.

Steele MacKaye, also active during this period, holds a unique place in theatre as an actor, manager, playwright, inventor, and designer. In an age of mechanical inventions, producers were seeking a means of effecting scene changes that would not require an intermission. In 1879, MacKaye filed a patent for a "double stage," a feature he subsequently introduced in the Madison Square Theatre in New York City. He built an elevator platform on which one scene might be set while an earlier scene was being played below. The new scene was then merely lowered, with its own stage floor, to the appropriate level, while the previous scene rolled back behind it.

Among MacKaye's other mechanical innovations were a folding theatre chair with coatrack attached, a sliding stage, a theatre ventilation system, the first installation of an electric lighting system in a theatre (1885), devices to produce cloud, ocean wave, and rainbow effects, the substitution of overhead lighting for footlights (which had been in use since the early Baroque period), and a process for fireproofing scenery. For financial reasons, some of his more grandiose schemes were never executed. For the World's Columbian Exposition in Chicago in 1893, for example, he designed a "Spectatorium" for musico-spectacle-dramas; it called for a sky dome that encircled the stage, a curtain made of light, a sliding stage for scene changes, and an auditorium seating 10,000 people.

In 1896 six men formed the Theatrical Syndicate, which acquired almost complete control over American theatre. They were interested only in commercially profitable works, such as productions featuring performers with large followings. The major opposition to the syndicate came from David Belasco, a producer and playwright. Belasco's aim as a producer was to bring complete realism to the stage, and it is difficult today to appreciate how spectacularly far he carried this pursuit (Figure 18). In 1879, in his production of *The Passion Play,* the story of Jesus Christ from birth to Resurrection, he arranged for a live flock of sheep to be herded onstage. When the actor James O'Neill (father of playwright Eugene O'Neill), who played Christ, was dragged before Pontius Pilate and crowned with thorns, members of the audience fainted. And after

the performance, when O'Neill walked around the city, people sank to their knees and prayed to him. The play aroused such religious frenzy that Jews were assaulted on the street outside the theatre, and a court injunction forbade further performances.

The power of the Theatrical Syndicate was so great that in 1904 Belasco was forced to rent Convention Hall, a leaky building in New York City, for his productions. During the first performance there was a violent rainstorm, and the audience had to sit through the last act holding umbrellas. Belasco's productions became so popular that the syndicate was finally forced to compromise with him, thus breaking their stranglehold on the American theatre.

THE EVOLUTION OF MODERN THEATRICAL PRODUCTION

Underlying the theatrical developments of the 19th century, and in many cases inspiring them, were the social upheavals that followed the French Revolution. Throughout Europe the middle class took over the theatres and effected changes in repertoire, style, and decorum. In those countries that experienced revolutionary change or failure, national theatres were founded to give expression to the views and values of the middle class, whose aspirations in these cases coincided with a more general movement of national liberation. In western Europe a different pattern of development emerged, varying considerably in each country but having the unified features of a demand for "realism" on the stage, which meant a faithful reflection of the life-style and domestic surroundings of the rising class in both its tragic and its comic aspects; an adjunct to this development was the demand for increased decorum and cleanliness in the auditorium.

In England, where the Industrial Revolution was more advanced than in the other European countries, the middle class had to struggle for its own theatres against the entrenched power of the two patent houses (licensed by the Crown), Drury Lane and Covent Garden, which had enjoyed an almost total monopoly of dramatic theatre since 1660. As early as 1789, attempts were made to evade the legal restrictions on building new theatres. The Reform Bill of 1832, which enfranchised the propertied middle class and established its political power, led to the Theatres Act of 1843, which gave London a "free theatre." The expected flood of new theatre buildings did not occur, and no major building took place for 16 years. This is probably because there were already sufficient illegal theatres in operation when the act was passed. The boulevard theatres of Paris experienced less trouble in establishing themselves. The rise of the middle-class theatres caused the decline of both the patent houses in London and the Comédie-Française—the national theatre of France. After much political struggle, centring particularly around censorship, the Comédie-Française, unable to compete with the boulevard theatres, capitulated and presented the plays of the new school for the new audiences.

Theatres Act of 1843

As the new class came into the theatres, the theatres were cleaned up. Samuel Phelps at The Sadler's Wells Theatre instituted audience controls that drove out the old audience and paved the way for respectability. The Bancrofts, as representative as any of the new movement, took over the run-down Prince of Wales' Theatre, cleaned up the auditorium, and placed antimacassars on the seats. They also dropped the melodrama and attracted a wide audience with the social comedies of Tom Robertson, making a considerable fortune in the process.

Throughout the 19th century, cities throughout Europe and North America exploded in size, and industrial centres attracted labour to their factories and mills. The working-class suburbs of cities and the industrial towns created their own demand for entertainment, which led to the construction of large theatres.

Accelerating this change was the growth of the railways. The pattern of theatre was disrupted in England as productions were mounted in London and sent on tour. The old provincial stock companies folded and theatres became touring venues rather than producing houses. A breed of managers arose who made money from the possession of the bricks and mortar property rather than by presenting their own productions. In the United States the Theatrical Syndicate established great fortunes from the New York theatres and the almost unlimited touring circuit that the railways opened up. The change in status from enterprise to industry gave rise to the commercial theatre systems of the West End in London and Broadway in New York City. Improvement in travel in general made it possible to increase the links between the two systems early in the 20th century, and the exchange of productions further extended the possibilities of profitable exploitation.

The impact of the railroad

Modern theatre began around 1885 with the revolt of the younger generation against the material injustices of society. Those in revolt founded so-called independent theatres to present a more critical or scientific view of the workings of society or so-called art theatres to rise above vulgar materialism with the establishment of aesthetic standards. The independent theatres took the Meiningen Players as their starting point. The art theatres looked to Wagner for inspiration.

The new Naturalism. The first of the independent theatres was the Théâtre-Libre ("Free Theatre") founded in 1887 by André Antoine, who made his living as a clerk for the Paris Gas Company. The Théâtre-Libre was an amateur theatre with no home of its own. It hired rooms or theatres where they were available and sold tickets for its performances to a closed membership. In this way it avoided censorship. Antoine's original intention was to present plays that had been rejected by the Comédie-Française, and thus the repertoire was eclectic. The major impact the group made was with a number of naturalistic plays. The theatre was at this time lagging behind literature, and, although Émile Zola had written an essay entitled "Naturalism in the Theatre" in 1881 and had produced what is seen as the first Naturalist play, *Thérèse Raquin,* in 1873, no theatre devoted itself to a Naturalist policy until Antoine founded the Théâtre-Libre.

Following on the scientific developments and the philosophical skepticism of the 19th century, the social reformers of the last two decades of the century probed into the causes of human behaviour and postulated that the meaning of human character was to be found in its interaction with the physical, social, and economic environment. The new theatre demanded "truthfulness" not only in the writing but also in the acting and stage setting. The actors were expected to ignore the audience and to behave and speak as though they were at home. Antoine is normally credited with being the first to require an actor to turn his back on the audience; from this style of acting arose the concept of the "fourth wall" separating the stage from the audience. Behind this "wall"—invisible to the audience, opaque to the actors—the environment portrayed was to be as authentic as possible. Antoine himself designed rooms and then decided which wall would be "removed." In *The Butchers,* he hung animal carcasses on the stage.

The "fourth wall"

It is possible, however, to overestimate Antoine's commitment to Naturalism, since a great deal of his repertoire was not naturalistic and the descriptions of several of the Théâtre-Libre presentations show an imaginative experimentation with lighting effects that goes well beyond creating realistic temporal and atmospheric conditions. The first production of the Théâtre-Libre had no scenery at all but only a few pieces of furniture borrowed from Antoine's mother, yet it was this production that set the Naturalist style. Zola, the philosopher of the movement, had deplored the fact that the Naturalist theatre began by creating an external representation of the world instead of concentrating on the inner state of the characters. Strindberg showed that a few carefully selected properties could suggest an entire room. With the ideas of Antoine and Strindberg, the days of flapping canvas doors and kitchen shelves painted on the walls of the set came to be numbered. The more natural and detailed the acting became, the more it clashed with a painted background.

Antoine's innovations did much to establish the principle that each play requires its own distinct setting. In 1906, as director of the state-subsidized Théâtre de l'Odéon, he produced classical plays in which he strove for realism not by means of period decor and costume but by re-creating theatrical conventions of the 1600s.

The new pattern of theatre set in France was imitated in Germany during the same period. Otto Brahm modeled his theatrical society, the Freie Bühne, founded in Berlin in 1889, after Antoine's Théâtre-Libre. Its first production was Ibsen's *Ghosts*. On the basis of this and other examples, it could be said that Ibsen pioneered the repertoire, Saxe-Meiningen the staging methods, and Antoine the organizational form for a range of small, independent theatres springing up throughout Europe.

The Freie Volksbühne

With both ideological aims and theatrical tastes in mind, members of the German middle-class theatre audience formed an organization called the Freie Volksbühne in 1890 for the purpose of buying blocks of tickets and commissioning performances and even productions for its membership, which included a large working-class element. Early in its history the organization split between the Freie Volksbühne, who were attempting to make theatre available to a wider audience, and the Neue Freie Volksbühne, who had specific Socialist attachments and policies. Eventually the two arms recombined and were able not only to subsidize performances but also to build their own theatre and mount their own productions.

During the 1890s in France, a similar program of democratization was attempted. One of the prime movers in this was Romain Rolland, whose book *The People's Theatre* (*Le Théâtre du peuple*, 1903), inspired similar movements in other countries.

In England the works of Ibsen aroused great interest and attracted the attention of the censors. The first English independent theatre was organized by Jack Thomas Grein, and its first production in 1891 was Ibsen's *Ghosts*. Grein's intention of finding British writers of the new drama was frustrated until the arrival of George Bernard Shaw, the most famous Ibsenite of them all, in 1892, with his first play, *Widowers' Houses*. Shaw remained the mainstay of the independent theatre movement in Britain. His preeminence in the independent theatre in England coupled with the success of Arthur Wing Pinero in the commercial realist theatre led to a major innovation in staging in England. Both playwrights participated in the casting of their plays, which in Pinero's case led to a break away from the old stock company casting and the institution of casting to type. Shaw was able to impose his own interpretation and stage direction on the production of his plays.

Russia also followed the pattern of the independent theatre movement that developed in France, Germany, and England (see below *Developments in Russia and the Soviet Union*).

Reactions to Naturalism. The Théâtre-Libre had scarcely been established when the reaction against Naturalism got under way. Symbolism developed out of a total opposition to the philosophy that lay behind Naturalism. It sought an intuitive and spiritual form of knowledge, regarded by its proponents as higher than that which science could provide. If Naturalism attacked the materialist values of society from a critical and reformist standpoint, Symbolism rejected them altogether. In their manifesto of 1886 the Symbolists suggested that subjectivity, spirituality, and mysterious internal forces represented a higher form of truth than the objective observation of appearances. The Belgian Maurice Maeterlinck, the most successful Symbolist playwright, gave as his opinion that an old man sitting at his table, surrounded by silence, was more dramatic and true-to-life than the lover who strangles his mistress in a tirade of jealousy. The Symbolists drew for example and inspiration on Wagner and on the later plays of Ibsen. They were influenced by the poets Mallarmé and Baudelaire, and the latter's poem *Correspondences*, which finds comparative values in colours and musical notes, is often seen as the first manifesto of the movement. The expressive paintings of Gauguin were also influential.

The Symbolist theatre

The first of the Symbolist theatres was the Théâtre d'Art started by the French poet Paul Fort in 1890. Fort was principally concerned with the power of the poetic text but nevertheless made some ingenious contributions to staging. In his production of the Frenchman Pierre Quillard's play *The Girl with the Cut-off Hands* (1891), the actors intoned their lines behind a gauze curtain, backed by a gold cloth framed with red hangings. In front of the gauze, a girl in a long blue tunic repeated the actors' lines and commented on their feelings. This is the first instance in which the setting of a play derives entirely from the ideas of the director and the designer rather than from tradition or from direct evidence in the text of the play itself. The setting for *The Girl with the Cut-off Hands* is a visual image, suggested by the play but not dictated by it. It is a poetic vision and does not place the play in a specific context.

In 1893, Aurélien Lugné-Poë founded the Théâtre de l'Oeuvre. Guided by the belief that the spoken word creates the scenery, Lugné-Poë attempted unity of style instead of illusion of place and employed such painters as Henri de Toulouse-Lautrec, Maurice Denis, Odilon Redon, Édouard Vuillard, and Pierre Bonnard. Lugné-Poë's production of Maeterlinck's play *Pelléas and Mélisande* typified his technique—no furniture or props were used; the stage was lit from overhead, most of the time to a level of semidarkness; a gauze curtain created the illusion of mist; and backdrops painted in gray tones conveyed a general air of mystery. The one production of the Théâtre de l'Oeuvre that has had the greatest historical significance was not seen as anything more than a scandalous, schoolboy joke in its own time. Alfred Jarry's *Ubu roi* ("King Ubu") was produced in 1896, with nonrealistic settings and costumes. All the scene settings were displayed simultaneously on a backdrop, and the costumes and makeup were deliberately grotesque, as was the acting style, an amalgam of buffoonery, the horror of Grand Guignol, and extravagant mock-tragedy.

Production of *Ubu roi*

Far from posing an alternative to the materialist values of the bourgeois audience, the first line of *Ubu roi* attacked the audience's values head on. When Firmin Gémier, in the title role, advanced to face the audience, looked directly into their eyes, and uttered the first scandalous word of the text, "*merdre*" ("excrement"), a pattern was set that has been followed by many avant-garde theatre companies throughout the 20th century. The dialectics of conflict had shifted from being contained within the stage area to being opened between the stage and the auditorium. If an attack on the audience were to be mounted effectively, however, the separation of stage and auditorium had to be diminished. Various attempts were subsequently made either to contain stage and auditorium in a single unified spatial area or to adapt existing spaces in order to break through the barrier imposed by the proscenium arch.

The influence of Appia and Craig. The two most important theoreticians and designers of the non-illusionist movement were the Swiss Adolphe Appia and the Englishman Edward Gordon Craig. Appia began with the assumption posited by Wagner that the fundamental goal of a theatrical production was artistic unity. Appia felt, however, that the incongruity of placing three-dimensional actors in front of two-dimensional settings, which many of the stage reformers rejected, was intensified by the mythic, symbolic nature of the Wagner operas. He concluded that there were three conflicting elements in production—the moving three-dimensional actor, the stationary vertical scenery, and the horizontal floor. He categorized stage lighting under three headings: a general or acting light, which gave diffused illumination; formative light, which cast shadows; and imitated lighting effects painted on the scenery. He saw the illusionist theatre as employing only the first and last of these types. Appia proposed replacing illusory scene painting with three-dimensional structures that could be altered in appearance by varying the colour, intensity, and direction of lighting. The solid structures, according to Appia, would serve to create a bond between the horizontal floor and the vertical scenery and enhance the actor's movements, which were rhythmically controlled by the music of the score. The lights, too, would change in response to the musical score, thus reflecting or eliciting changes in emotion, mood, and action. In creating a scene, Appia conceived of light as visual music with an equal range of expression and intensity.

Appia elaborated his theory through a series of proposed designs and mise-en-scènes (complete production plans) for Wagner's operas. He was brutally rebuffed by Wagner's widow, who considered his projects the work of a

madman. Intensely shy, he created only a few designs and realized even fewer productions. His influence spread largely through his three books on staging and lighting design published from 1899 onward, one exemplary performance in a private theatre in Paris in 1905, and his collaboration with Émile Jaques-Dalcroze. Jaques-Dalcroze was a fellow Swiss who developed, and published in 1906, a system of physical exercises that he called eurythmics, intended to inculcate in the student a sense of rhythm and control over it. The exercises made liberal use of space and grew into an expressive dance movement. For Appia, eurythmics became a part of his integrated system of production. In 1912, at Hellerau on the outskirts of Dresden, as part of one of the first garden city developments in Europe, a large hall was built to the design of Appia and Jaques-Dalcroze. Stage and auditorium were united as a single rectangular hall without proscenium or separate lighting. The walls and ceiling were hung with translucent silk through which beams of light filtered. The lighting equipment comprised 10,000 lamps, all controlled by a gigantic console capable of fine gradations of intensity. Appia designed an abstract scenic architecture of platforms and steps that could be arranged in a variety of combinations. Every trace of illusionistic scenery was dispensed with, and the setting served only as a structural foundation for the rhythmic, gymnastic movements of the players. The few performances, which were interrupted by the outbreak of World War I, were attended by many of the leading innovative directors in Europe at that time.

Eurythmics

The use of diffuse light solved one of the most vexatious problems of electric lighting—how to blend the individual beams. This problem was equally trying in the illusionist theatre, where the consciousness of separate lightbeams coming from distinct mechanical sources ruined the naturalistic effect. The backdrop remained as a large, finite, painted expanse that any reasonable amount of light revealed to be of a different order than the three-dimensional pieces in front of it. It also necessitated, because of the critical rising sight lines from the stall seats, a series of hanging borders to mask the top limits of the cloth. As lanterns began to be hung on bars above the stage, the number of borders increased. The Austrian producer Max Reinhardt is credited with the frustrated cry, "Will no one rid me of this dirty washing?"

To address this problem the lighting designer Mariano Fortuny y Madrazo constructed a dome that backed the stage area with a gentle curve and overhung the stage. At first he covered the dome with white translucent cloth, an extension of an earlier experiment in which he hung strips of cloth from the ceiling of the stage and diffused light through them. Later the dome had a plaster surface and the lights were diffused by reflection, playing on its inside surface. Instead of a flat, restricted backdrop there was now a spacious vault that created an impression of indeterminate distance. The dome was expensive and very cumbersome to maneuver and was soon replaced by a cyclorama (horizon or sky-cloth), which is still used today. This consists of a cloth stretched over a semicircular framework to mask the rear wall and corners of the stage. Some modern theatres have been built with a permanent plaster cyclorama.

The Fortuny dome and cyclorama

The Fortuny dome and the cyclorama became essential tools of the scenic illusionists, but their invention served the anti-illusionists equally well, as they gave a sense of space beyond the finite limits of the stage, gave solidity to the stylized decor, and silhouetted the rhythmic action of the players against a background of diffused light. Edward Gordon Craig, the son of the designer Edward Godwin and the actress Ellen Terry, began his career as an actor in Irving's company and became a designer at the turn of the century, just before the publication of the first of his many books on the theatre. Craig and Appia met in 1914 and shared a deep admiration for each other's work and a great deal of agreement on conceptual matters. There were, however, certain crucial differences. The most fundamental of these arose out of their differing backgrounds. Appia began his work with Wagner, and for him the music dominated and controlled the work. Craig was an actor before becoming a designer and director, and for him all the elements of production were of equal value. Appia had no apparent interest in theatre history, whereas Craig had an abiding interest in it. Appia was a retiring, contemplative thinker; Craig was a polemicist.

Whereas Appia's work followed a continuous developing line, Craig's was characterized by a restless experimentation. His early productions of Purcell and Handel operas at the start of the century explored the use of the "frieze" or "relief" stage—a wide, shallow stage surrounded by drapes, structures in geometric shapes, and a lighting system that dispensed entirely with footlights and side lighting and used only overhead sources. In order to facilitate this and make colour changes possible, Craig devised an overhead bridge accessible from both sides. Although Craig's designs stressed vertical planes as against Appia's horizontal ones, in the operas he utilized a series of levels for the action. His designs for Purcell's *Dido and Aeneas* used no wings or borders. The back drape ascended to the flies (space over the stage from which scenery and lights can be hung), and the proscenium was very low in contrast to the great width of the stage. The sides of the setting were enclosed by curtains hung at right angles to the proscenium arch. What impressed many of those who were present was the use of colour symbolism in the costumes, settings, and lighting and the extraordinary consistency with which Craig manipulated all of the elements of the mise-en-scène.

Craig's operatic productions

One of Craig's most interesting scenic innovations was a flexible structure made of hinged screens, which permitted a fluid readjustment of space during performance. He experimented with movable proscenium arches for adjusting the stage opening to suit the play or scene. His experiments with all sorts of materials and the effects of coloured light upon them greatly increased the resources of the stage. He proposed placing the lighting control booth at the rear of the auditorium, which is the current practice, to allow the lighting engineer to coordinate the lighting to the actors' movements.

Perhaps Craig's main contributions to the development of staging were his advocacy of the need for one artist to control the production and his insistence upon the study of theatre history. The controlling artist for Craig, unlike Wagner and Appia, was to be the director. If the theatre was ever to become a mature art form in its own right, rather than a haphazard conglomeration of bits and pieces of other art forms, it needed a controlling genius to discipline and coordinate the interaction. Craig's own productions bear out his ability to realize this scheme, and he encouraged the work of a group of gifted directors who followed him.

In the process of working out his thesis, Craig addressed himself to the question of the actor. The actors of Craig's day (like the theatres and their machinery) were ill-equipped for carrying out his production schemes. For the Purcell productions, he used a high percentage of amateurs who could be taught to carry out his instructions. The professional actors of the conventional late-19th-century theatres were not very sophisticated in their technique. Craig was not alone in complaining of the inadequacy of the established actors in light of the new theatre. The French Symbolists debated whether the actor would have to be banished from the stage before any serious theatre could be created. Even Eleonora Duse, the great Italian actress, declared that for the theatre to be saved all actors would have to die of the plague. Craig's writings were virulent in his scorn for the actor whose idiosyncrasies constantly imposed themselves between the work and the audience, whose wayward, fickle emotions and feelings constantly sentimentalized and diminished the theatrical effect. He was not opposed in principle to all actors; his admiration of Irving, his mother Ellen Terry, and Duse was profound, and he considered Isadora Duncan a supreme artist, but he did promote the concept that he called the *Übermarionette* ("Superpuppet"). Craig's intention is not fully clear—whether he envisioned mechanical figures that would defy the physical restrictions of the human body or, as seems more likely, puppets that would be controlled from inside by human beings, children, or dwarfs. Nevertheless, he joined a growing chorus of people calling

The problem of the actor

for the elimination of individual actors' idiosyncrasies and the "dematerializing" of the stage and propelled these demands into public debate.

Although the *Übermarionetten* were never realized, the principle was accepted. Later directors such as Meyerhold, Reinhardt, and Copeau recognized the necessity of a studio-school attached to their theatres and of regular training for the actors in advanced techniques, if they were to be able to realize their concepts on stage and eliminate the interference of actors' own egos and emotions. From this flows the present acceptance in the West of a long and intense period of training as necessary for all actors entering the profession. The Eastern theatre, which Craig and those following him have continually returned to study, has always understood this necessity.

Importance of study of theatre history

Craig's understanding of theatre history was linked to a revival throughout Europe of the study of theatre history. Craig's opinion was that it would be impossible to create a new theatre without making a serious study of previous theatres. He ascribed the short life of some innovative theatres to the fact that they had not adequately studied their predecessors. The study of theatre history spread widely enough to embrace the long-established Oriental theatre forms. Craig's own productions drew on Japanese theatre, the Greeks, and the Baroque and Romantic periods. The most important effect of this research and use of theatre history was to liberate stage production from the narrow confines of contemporary style and fashion. If the past could be incorporated into the present, an almost limitless range of production possibilities was opened up. This liberation, in turn, increased the demands made upon the actors.

Other developments in the study of movement. The Frenchman François Delsarte laid stress on a connection between mental attitude and physical posture and discovered that one's emotional state is communicated through one's physical appearance. Eventually Delsarte codified his observations in a chart of gestures, which was used as a guide for expression and characterization by many amateur theatre companies in the middle years of the 20th century. The further elaborated discipline of reflexology, which seeks to analyze mind–body interaction, was developed by a variety of philosophers and psychologists and was very influential in the early years of the Soviet Union (see below *Developments in Russia and the Soviet Union*).

The work of Isadora Duncan

Another theorist of movement, the American-born dancer Isadora Duncan, was the daughter of a disciple of Delsarte, and reflexology was at the heart of Duncan's dancing. It is not surprising that, in addition to Dalcroze's eurythmics, Duncan should have inspired the development of educational dance. Reflexology is also the root from which spring the contemporary areas of drama therapy and the use of games and improvisation in actor training.

Duncan rejected the narrow and inhibiting classicism of the Russian ballet and returned to the Greeks for inspiration. Her dances were realizations of "soul-states," which she regarded as emanating from the solar plexus. By using her feelings and physical responses to the music as the impulse for movement, she removed dance from the domain of the highly trained ballet dancer and demonstrated its wider potential.

Duncan's work was important to those searching for answers to the problems posed for the actor by non-Naturalist theatre, since it showed a way to gain direct access to deep feelings without resorting to psychological analysis. Unfortunately, though, Duncan offered no systematic prescription for accomplishing this. Duncan herself was a sufficiently disciplined artist to impress Edward Gordon Craig as a solo performer. What her approach lacked, however, was a disciplined framework by which other performers could be trained and an extension of the movement vocabulary that might widen the range of theatrical purposes to which it could be put.

Impact of electricity

Development of stage equipment. From a technical point of view, the harnessing of electric power exerted a greater influence on stage design and production techniques than any other single invention. Stage lighting, as opposed to mere stage illumination, became raised to the status of an art form and revolutionized stage decoration, stage design, and stage form in that order. For the first time since the theatre moved indoors during the Renaissance, adequate and safe illumination became possible. But beyond mere function and safety there was inherent in the medium a flexibility and subtlety that has allowed it to become an integral part of scenic effect and to heighten visual expression for artistic purposes (see below *Stage lighting*).

Beyond the development of stage lighting and the theories and techniques pioneered by Appia and Craig, electricity provided the solution to many of the problems that were arising with respect to scene changing. The demand for rapid changes of cumbersome naturalistic sets coincided with demands for a dematerialized stage that could flow smoothly from one symbolic vision to another. In addition, those seeking to "retheatricalize the theatre" wanted an open stage on which scene changes could be accomplished simply and rapidly. New inventions and instrumentation made practical many of the theoretician's ideas, and these were adapted by designers, directors, and stage engineers on both sides of the Atlantic, with the greatest centre of innovation being Germany.

In 1896 Karl Lautenschläger introduced a revolving stage at the Residenz Theater in Munich. Elevator stages permitted new settings to be assembled below stage and then lifted to the height of the stage as the existing setting was withdrawn to the rear and dropped to below-stage level. Slip stages allowed large trucks to be stored in the wings or rear stage and then slid into view. New systems for flying were developed. Hydraulic stages made it possible to raise sections of the stage, tilt them or even rock them to simulate, for example, the motion of a ship. All of these mechanisms required larger backstage facilities, higher flying towers, greater depth and width of stages, and increased understage space.

German theatres began as early as 1890 to incorporate mechanized orchestra pit apron lifts, which provided a means for altering the point of contact between stage and auditorium (actor and spectator). Confrontations between actor and audience were the prime concern of Georg Fuchs, who founded the Künstler Theatre in Munich in 1907. He held that, in order to be relevant, the theatre must reject the picture-frame stage and the Italianate auditorium. He proposed an indoor amphitheatre in which, on a projecting stage, the action could be thrown forward into the audience space. According to Fuchs, the stage designer should not try to produce an illusion of depth since depth is part of the theatre architecture and cannot be added by scenery. Fuchs's view was the culmination of the search for three-dimensionality that had passed through five essential stages since the 18th century. At first, an illusion of depth was achieved by painting perspective scenery on canvas; then the ground plan of the set was rearranged to envelop the actor with the set. The third phase was the introduction of objects for the actor to touch. With Appia and Craig there came the realization that an actor's movement manifests itself in contrast to inanimate objects, such as platforms and other masses. Fuchs introduced the final phase joining the playing space to the area in which the audience is situated. In Fuchs's theatre, designed by Max Littman, the acting area could be extended forward by covering the orchestra pit, and the size of the stage opening could be changed by adjusting the inner proscenium, which had a door at stage level and a balcony above. The floor of the stage was divided into sections, each of which was mounted on an elevator so that it could easily become a platform. Four cycloramas, surrounding the stage, could be changed electrically.

Evolution of three-dimensionality

The influence of Reinhardt. The director who was best placed to utilize the freedom afforded by the study of theatre history and the new mechanization was Max Reinhardt. Reinhardt began as an actor at the Deutsches Theater in Berlin, as part of the Naturalist Freie Bühne company, in 1893. In 1900 he joined a small cabaret theatre and began introducing plays into the entertainment. Later, he returned to control the Deutsches Theater, to which he added the smaller Kammerspiele next door. In these theatres and elsewhere he initiated a series of productions that made Berlin one of the outstanding theatrical centres

of Europe. Not only did Reinhardt feel at home in two theatres—one small and intimate, the other a medium-size house—he actually preferred the alternation of size and styles. In 1910 he staged *Oedipus Rex* in the Zirkus Schumann, an amphitheatre, in an attempt to recapture the union of actors and audience that had existed in classical Greek theatre. From 1915 to 1918 Reinhardt directed the Volksbühne, and in 1919 he opened his own theatre, the Grosses Schauspielhaus, which had an open stage and the full complement of stage machinery (Figure 19). This theatre was obviously derived from the Dionysian theatre at Athens, and he hoped that it would embody modern life as the arena had embodied the Greek community.

The Grosses Schauspielhaus

Reinhardt was not a traditionalist, however (he showed a completely different approach when he converted a ballroom in Vienna into a formally designed intimate theatre); rather, he was a true eclectic whose more than 500 productions represented virtually every style. He believed that theatre, which had become shackled to literature, must be offered instead for its own sake. He reexamined the physical layout of the theatre building and the spatial relationship between the actors and the audience. Believing that the director must control every facet of a production, Reinhardt worked closely with his designers, Ernest Stern, Alfred Roller, Oscar Strnad, Emil Orlik, and the Norwegian Expressionist painter Edvard Munch. His productions usually featured a particular motif or the staging conventions of a historical period. After beginning with a three-dimensional, drab naturalism, he adapted the abstract solids that Appia had inspired and later applied surface decoration derived from contemporary art movements such as Art Nouveau, the Vienna Sezession, and Munch's Expressionism. He used unit settings with detachable parts ("plugs") and revolving stages that revealed different facets of the same construction; he adapted the conventions of Oriental theatre; and he mounted open-air productions of the medieval *Everyman* in the square outside the cathedral in Salzburg. Reinhardt exerted a strong influence on the designers of the German Expressionist cinema as well as on stage artists. In fact, the first productions of Expressionist plays were mounted under his management. His eclecticism helped to reconcile the differences between conflicting movements by romanticizing the realistic and fleshing out the idealistic with solid structures.

Reinhardt made one further great contribution to the development of stage production. Although he exerted considerable power and was the controlling genius behind several theatres, his way of working was significantly different from that envisaged by either Craig or Appia. Craig saw the director as the despot exercising rigid control over all aspects of the production, whereas for Appia (and Wagner before him) the poet was the initiator of the production and the figure whose word was law. Reinhardt diplomatically combined the talents of a team of collaborators. He was careful to gather around him gifted colleagues, designers, dramaturges, and engineers. Bertolt Brecht served early in his career as a member of the Reinhardt collective. This process of cooperation rather than direction produced one significant feature that is still the strength of the German theatre on both sides of the border. In order to control the complexity of his productions, to incorporate his research into the rehearsals and later performance, and to coordinate the work of all collaborators into the production plan, Reinhardt's productions required a *Regie-buch* that went much further than all previous promptbooks. The *Regie-buch* became a plan for the production, incorporating interpretive ideas as well as staging concepts. This concept was later utilized by Brecht and developed into the *Modellbuch* ("model book"), a full record of the production that could be used as a pattern for succeeding productions.

The *Regie-buch*

British innovations. While most English productions during this period were in the realistic tradition, several steps were being taken toward nonillusionistic staging. One director, Sir Frank Benson, began by mounting plays in the realistic style of Sir Henry Irving but by 1900 had started to simplify his staging. He produced Shakespeare's plays with only a few stock sets, focusing primary attention on the actors. William Poel, also producing Shakespeare, attempted to re-create an Elizabethan theatre. Throughout Europe at this time there was a considerable revival of interest in seeing Shakespeare's plays performed with something approaching the original effect. The various social and theatrical pressures that had resulted in the truncating, rearranging, and rewriting of the plays throughout the 18th and 19th centuries had dissipated. Unfortunately the plays were also in danger of disappearing under the weight of the settings of both the historical Romantic style and the new theatre machinery.

Between 1912 and 1914 the actor-manager Harley Granville-Barker staged Shakespeare in such a way that the action could be continuous, an approach influenced by his having worked with Poel. He remodeled the Savoy Theatre by adding an apron, or extension of the stage, and doors in front of the proscenium. He divided the stage into three parts—the apron, a main acting area, and a raised inner stage with curtains. This permitted a continuous flow of action and eliminated the rearrangement of scripts that had previously been necessary for nonillusion-

istic staging. Norman Wilkinson and Albert Rutherston, artists with reputations outside the theatre, were his principal designers, and their settings typically consisted of brightly painted, draped curtains. Granville-Barker's style and particularly the use of drapes in the settings reflect clearly the influence of Craig's early work for the Purcell Operatic Society.

Influence of the fine arts. The development of the modern theatre and its staging techniques took place during a period when even more radical changes were taking place within the fine arts. In fact, it would be true to say that many of the developments in staging arose primarily out of innovations in painting. Much of Craig's work is influenced heavily by the work of William Blake and the Pre-Raphaelites. The Symbolist theatres in Paris enlisted many of the innovative painters of the time, such as Denis, Vuillard, Bonnard, Sérusier, and Toulouse-Lautrec.

Painters in the theatre

Concurrently with developments in the arts, and often underlying them, innovations in technology were radically altering human perception of the world. The advent of photography, and subsequently motion pictures, created new ways of seeing and new perceptions of movement and time. These perceptions were also being altered by the development of motorized transport, through the coming of the railways, the automobile, and the airplane. In a related context, the growth of colonial empires and improvements in transportation brought Europe into contact with many disparate cultures and their aesthetic traditions. Developments in psychology led in the first decades of the 20th century to increased understanding of the communicative power of design and thus to the principles of modern advertising.

For the theatre, these developments had several profound effects. The first was the new scenography of the Symbolists, of Appia, Craig, and others. Scenic art ceased to depict natural settings or specific locales and became more suggestive, seeking to arouse the imagination and the emotions. Along with the experiments in painting that emphasized the sensory, affective properties of the art over its imitative functions, it followed that artists in the theatre would investigate its affective potential.

The innovations of Kandinsky

The Russian-born artist Wassily Kandinsky, who is credited with producing the first purely abstract painting, created several theatre pieces on his way to full abstraction. These productions employed sound (even an offstage choir), light, moving structures, and human action, but this latter was purely functional and had no narrative or interactive significance. Kandinsky revised the Wagnerian concept of the integrated work of art, pointing out that it was based on the assumption that all the various elements of theatre brought together simultaneously in concert would produce an effect that was greater than the sum of the parts. Kandinsky's thesis was that this was a superficial conglomeration in which, no matter what the theoretical position might be, the elements alternated in supremacy. Appia had criticized Wagner for keeping conventional representational sets, and Craig had criticized Appia for being under the thrall first of the music and then of the dance. Kandinsky went further than even Craig and proposed that the theatre of the future would comprise three elements: musical movement, colour movement, and dance movement—*i.e.*, sound, colour, and mobile forms. All of these elements were of equal value. In his longer essay "Concerning the Spiritual in Art" (1914), Kandinsky set out in complex intellectual terms how this new theatre, based on spirituality rather than materiality, could be constructed.

Bauhaus experiments

Certain aspects of Kandinsky's theories were capable of rigorous testing. The Bauhaus, a German school of design founded in Weimar by Walter Gropius in 1919, where Kandinsky was a teacher and Oskar Schlemmer was head of the theatre section, conducted a series of experiments on actors' movements in space. Schlemmer and his colleagues devised elaborate costumes that transformed the actor-dancers into "moving architecture." By treating the stage as a black box, the researchers created a laboratory in which to examine the perception of a wide range of movements. Craig's concept of the *Übermarionette* became the subject of a series of experiments regarding the geometry of the human figure, the possible limits of the articulation of limbs, the extensions of movements into three-dimensional space, the restrictions placed on human movement by the force of gravity, and the ways in which dancers' movements work against gravity and cooperate with it. A range of dances were conceived and performed under the title of *The Triadic Ballet.* This work was a fantasy in which the dancers' costumes transformed them into "metaphysical anatomy." The ballet achieved the dematerialization of the stage as contrasting shapes in contrasting colours appeared to propel themselves along a variety of paths in three-dimensional space. Experiments were also made in rhythmic movement, mechanical theatre, light theatre, and projection. The Bauhaus group laid down no prescriptive plans as to what direction theatre should take but opened up a variety of possibilities, which were then offered for other artists to follow.

When the Bauhaus was closed at the start of the Nazi period, several members of the staff moved to the United States. Out of seminars and teaching laboratories, a line of work developed, largely instigated by John Cage and Merce Cunningham, that explored the use of chance in creating works of theatre and broke free from the concept of an integral composition. Cunningham created a range of dance works that favoured the occurrence of chance (or aleatoric) correspondences between the elements of the dance over the orchestration of effects by the choreographer. The U.S. choreographer and designer Alwin Nikolais also carried on work derived from the principles of the Bauhaus with his dance company.

During all this work, in its movement away from the depiction of nature, the position of the artist changed. In the anti-illusionist theatre, the artist became not only the means of putting across a message but to some extent the originator of it. At the heart of the Symbolist theatre was the old romantic concept of the artist as a creative genius with heightened perception and powers. Once this was linked to the idea of the work of art as a vehicle through which the artist could proselytize his views, the result was Expressionism.

Production aspects of Expressionist theatre. Expressionism in the theatre arose out of the same impulse to rebel against the materialist values of the older middle-class generation that gave rise to both the reformist Naturalist theatre and the aestheticist Symbolist theatre. This opposition was clearly expressed through the themes and often the titles of such plays as *Vatermord* ("Patricide"). The forerunners of Expressionism are generally accepted to be the German actor and playwright Frank Wedekind, who criticized the reformist Ibsenite movement for failing to attack the morality of bourgeois society, and Strindberg. Wedekind sought in his plays to expose what lay beneath the surface of gentility and decorum; in the process, he often introduced roles that served more as emblems than as realistic characters.

Strindberg's early plays are usually included in the Naturalist repertoire. After a period of personal crisis between 1894 and 1897, the form of Strindberg's plays disintegrated into dream visions or confessional monodramas in which everything is seen through the eyes of the single protagonist. The single focus of these plays was taken over by the Expressionists, as was the use of stereotyped characters—the Son, the Stranger, etc.

In addition to Wedekind and Strindberg, the Austrian painter and writer Oskar Kokoschka must be mentioned; in fact, some authorities would date Kokoschka's plays as the first truly Expressionist drama. His early plays, *Murder Hope of Women* (1909), *Sphinx and Strawman* (1911), and *The Burning Bush* (1913), seem to take Strindberg's painful depictions of the destructive relationships between the sexes and liberate them from any dependence on articulate speech. The plays are episodic and have no clear narrative. They are constructed out of violent visual images. Kokoschka is not remotely concerned with giving any sign or resemblance of surface reality whatsoever. In his view, the theatre, like painting, should communicate through "a language of images, visible or tangible signs, graspable reflections of experience and knowing . . . ." In this, Kokoschka was the first to break completely with the

literary tradition and to assert that the theatre communicates ultimately through a visual language.

Effects of World War I

The Expressionist period spanned the period of World War I, which changed the nature of the movement. Before the war Expressionism was largely concerned with screaming protests against rampant materialism and the loss of spirituality. In this period the coming war was seen as a necessary agent of purification for society. Many of the Expressionist dramatists died in the slaughter on the Western Front. Those who survived were transformed, and Expressionism took on a more overtly political complexion. The change from private protest to political argument was what made it possible to develop the techniques of the Expressionist theatre, and to extend them for wider use.

The major Expressionist theatre was Der Tribune, in Berlin. The Expressionist stage neither simulated reality nor suggested unreality. It existed in its own right as the platform from which direct statements could be made. Settings therefore tended to be abstract or, when specific, highly subjective. Techniques of distortion and incongruous juxtaposition expressed either the ideological position of the director or dramatist or the state of mind of the protagonist, or both. In Expressionist plays the walls of houses might lean at sharp angles, threatening to crush the protagonist; windows might light up like eyes spying on the secret and intimate; trees might take on the shape of the skeleton signifying Death. In this way, instead of simply forming the milieu for the action, the setting became a dramatic force. This aspect of Expressionism has been appropriated to great effect by the cinema, in which camera angles and special lenses can render the ordinary expressive. Leopold Jessner in his stage production of *Richard III* (1920) placed Richard at the height of his power at the top of a flight of steps. The steps below Richard were crowded with soldiers in red cloaks with white helmets. The effect when they knelt was of Richard sitting on top of a mound of skulls with a river of blood flowing through them.

The action of many Expressionist plays was fragmented into a series of small scenes or episodes. This style of theatre was called *Stationendrama* ("station drama") and was clearly derived from the principles of the medieval mystery plays. This led to a consideration of the scene in the theatre as being self-contained. Significance and meaning derived from the juxtaposition or accumulation of scenes rather than from a continuous narrative progression from scene to scene, and from this it followed that there need be no consistency of setting. In Ernst Toller's *Man and the Masses* (1920) the scenes alternated between reality and dream throughout the play.

Characterization in Expressionist drama

The characters in Expressionist drama were often impersonal or nameless. Very often they served to illustrate some aspect of the protagonist's thought or feelings or expressed aspects of the world and society. In Toller's *Transfiguration* (1918) the soldiers on the battlefield had skeletons painted on their costumes. Characters were frequently presented as fragments of a unified consciousness. Crowds were often not differentiated but were used in mass to express or underline the power of the protagonist's position. Expressionist roles often required actors to express aspects of character through the use of isolated parts of the body. The character of Dr. Strangelove in Stanley Kubrick's film of that name, whose right arm must be restrained from giving the Nazi salute of its own volition, makes comic use of an Expressionist technique.

Expressionist use of stage space

Two further developments can be attributed to the Expressionist movement. The director Leopold Jessner capitalized on the earlier innovations in stage design. His use of steps and multiple levels earned his stage the name *Treppenbühne* ("stepped stage"). He utilized screens in the manner advocated by Craig, and his productions illustrated a plastic concept of stage setting, which allowed the action to flow freely with minimum hindrance. Some of Jessner's productions relied heavily on steps and levels for this plasticity, but in others he used solid three-dimensional setting features standing in three-dimensional space. Jessner reclaimed and utilized the full space of the stage. In his 1921 production of *Othello,* a central rostrum served a variety of spatial functions. Upon his arrival in Cyprus, Othello and the accompanying crowd flooded out of a trapdoor at the rear of the rostrum and poured over the top of it onto the front stage; Othello, moving no further than the top of the rostrum, appeared to rise from a sea of people, towering above them. In a later scene, this same rostrum supported Desdemona's bed, with drapes towering into the flies, surrounded by space. The isolated solid unit within the total stage space has become a distinctive feature of contemporary set design and staging.

The second contribution of the Expressionist movement was to bring the mask back into common usage. Initially, the mask signified typical or depersonalized characters; later, it became a device for distancing the audience from the characters altogether, as it was used by Brecht in *The Caucasian Chalk Circle* (1948) and other plays.

Expressionism was relatively short-lived, although there was a brief revival of the theatrical mode in the 1960s when casts of actors dressed in black jeans and sweaters sat on boxes on black-curtained stages and intoned their lines as the ego, id, and libido of someone's psychological crisis. Nevertheless, Expressionism contributed to the modern stage a range of techniques that have become the stock in trade of most directors and designers; though in most contemporary cases the influence of Expressionism has been mediated through Brecht (see below *The influence of Brecht*).

The influence of Piscator. The great German theatrical director Erwin Piscator trained as an actor and began his professional career during World War I, running an entertainment theatre for fellow soldiers in Belgium. After the war Piscator set out to create a theatre that had a clear place and function in a world that also contained machine guns and artillery shells. His first such efforts brought him into association with the Dadaists.

The Dadaist movement

Dada began as an oppositional movement in Zürich in 1916 at the Cabaret Voltaire. In neutral Switzerland a group of artists that included Hugo Ball, Emmy Hennings, Tristan Tzara, and Jean Arp took on the mantle of Alfred Jarry. Whereas Jarry had assaulted the audience through an unusual play, the Dadaists began the disintegration of form entirely. Songs were written with only sounds for lyrics. Ball wrote verses without words. Tzara shredded manuscripts and recited from pieces reassembled randomly. Nonsensical sketches were performed in outlandish cardboard costumes. The painter Marcel Janko constructed masks that, according to Ball, inspired "passionate gesture, bordering on madness." For some, Dada was anti-art; for others, it was a new direction in art. Dada was an extension of the Expressionist movement although what was expressed was not passion or the search for spirituality but derision and withering contempt.

Dada's contribution to staging lay in destroying all accepted notions of what the stage should be and should express and in attacking the cultural values of the audience in particular and society in general. This precedent later gave a powerful lead to many antiestablishment groups and artists after 1968 whose objectives have been described as "offending the audience" or "disrupting the spectacle." Dada left Zürich and spread through Germany in the postwar period of the 1920s. One art form engendered by Dada was that of photomontage, in which graphics and edited photographic images were combined to convey propagandist images. The principal artist in this field was John Heartfield, who had changed his German name of Helmut Herzfelde during World War I as a gesture of protest, and who contributed many designs for Piscator. In one of his montages, the vapour trails of five airplanes soaring over the ruins of the Spanish town of Guernica were altered to resemble the fingers of a skeletal hand. The principle of montage became important in Piscator's work.

Photomontage

Piscator later commented that Dada had shown the way forward but was not enough. A more overtly political and direct form of theatre was needed, and this theatre, unlike any of the concepts of the Volksbühne movement, should be allied to the political struggle of the proletariat.

The proletarian theatre, consisting of both amateurs and professionals, played in workers' halls and established the principle of free admission for the unemployed, which freed the theatre from its bourgeois status as an economic

commodity. Piscator further eroded traditional relationships with a number of innovations in staging. In *Russlands Tag* ("Russia's Day"; 1920) the setting was a map, which established the political, geographical, and economic context for the play. In *Konjunctur* ("Conjunction"; 1928) this principle was extended to a larger stage. The play dealt with oil speculation, and the setting was a series of oil derricks. As the play progressed, the number and size of the derricks grew. The setting became part of the action and an environment for it, and the growth of the setting became a comment on the action of the play. In the *Rote Rummel Revue* ("Red Riot Review"; 1924), produced for the German Communist Party, Piscator began the action with a fight in the auditorium. The protagonists came out of the audience to argue their points of view and commented on the action of the various scenes. In *Tai Yang Erwacht* ("Tai Yang Awakes"; 1931) the setting, designed by John Heartfield, extended from the stage along the walls of the auditorium. A conspicuous feature of Piscator's propagandist productions was the climactic singing of "L'Internationale," the Socialist and Communist anthem, by both actors and audience.

Political theatre

Piscator established the political relevance of his work in a number of ways. In a revolutionary production of Schiller's *Die Räuber* (*The Robbers*) performed at Jessner's Staatstheater in Berlin, Piscator costumed and made up the minor character Spielberg, a noble character driven by society to crime, to resemble Trotsky. The German theatre in particular has since that time tended to interpret classic plays in a contemporary light. In Piscator's production of *Sturm über Gottland* ("Storm over Gothland"; 1927), which is set in the 14th century, a filmed prologue showed the major actors moving toward the camera, metamorphosing in the process from historically costumed characters to representations of modern historical figures; the protagonist, for example, turned into Lenin. In *Paragraph 218* (1929), which was about abortion reform, a tour was organized that used the performances to initiate discussion. Such associated discussions have since been a strong part of women's theatre and other political forms.

In several productions, Piscator dramatized or inserted verbatim political documents, news reports, or direct quotations from public figures. In one instance, an injunction was taken out by supporters of the former kaiser to prevent such a use of a direct quote in a 1927 production of Aleksey Tolstoy's *Rasputin.* Piscator offered the former kaiser a contract to appear in person. When this was rejected, the performance was stopped at the point in the show at which the quote would have been delivered and an actor explained the censorship ban. Direct comment of this kind was used frequently by Joan Littlewood and the Theatre Workshop company in Britain in the 1950s and '60s to comment on political actions and to establish common cause with the audience.

Piscator's use of film in theatre

The most important and advanced scenic device used by Piscator was projected film. In *Trotz Alledem* ("In Spite of Everything"; 1924) the second of his revues for the Communist Party, Piscator acquired through a contact a large quantity of war newsreel footage, which had never been shown because the censor considered that it would adversely affect war morale among the civilian population. The screening of the film as part of the whole stage montage lent an added authenticity to the documentary material presented in front of it and created a sensation. In this instance it established a principle, which has been built on by other political and documentary playwrights and directors, that one function of the political stage should be to make manifest what is concealed in politics.

Piscator established three distinct uses of film in his productions. What he called didactive film presented objective information and up-to-the-minute facts as well as historical ones; it gave the spectator facts about the subject of the production. Dramatic film contributed to the development of the action and served as a "substitute" for the live scene; where live scenes wasted time with explanations, dialogues, and action, film could illuminate a situation in the play with a few quick shots. Film commentary accompanied the action in the manner of a chorus. It addressed the audience, drew attention to important developments in the action, leveled criticism, made accusations, and provided important facts. Piscator should also be credited with the innovation of the jotter screen, a small, auxiliary screen onto which facts, figures, titles, dates, and other bits of information can be projected.

Piscator's work veered from the austere proletarian theatre productions to a lavish use of modern machinery in other productions. In Toller's *Hoppla, wir leben!* (*Hurrah! We're Alive;* 1927), a multiroomed house structure allowed projection onto a variety of screens in juxtaposition with live action. In *The Good Soldier Schweik* (1928) the actors performed among cutout caricatures drawn by George Grosz. In this production, Schweik on his travels marched against the direction of a moving treadmill at the front of the stage. Brecht later employed this idea with considerable success in *Mutter Courage und ihre Kinder* (1941) as Courage and her children pulled her wagon against the direction of the revolving stage.

There are two other innovations that Piscator added to the repertoire of staging devices. He conceived that the postwar world was too complex in its political and economic operations for any one playwright to comprehend it totally. He took the concept of the dramaturgic collective from Reinhardt and extended it to make it the basis of his production method. Writers, dramaturges, economists, politicos, and statisticians worked together to produce a script. Existing play scripts were subjected to analysis and restructuring by the collective. The second invention was the "stage of destiny." A great deal of Piscator's life was spent trying to realize a project for staging Tolstoy's novel *War and Peace.* When he finally accomplished this ambition, the judgments of history were incorporated into the narrative.

The style of theatre that Piscator propounded, using montage and juxtaposition of short independent scenes to create dialectical and often contradictory effects, he called epic theatre. Brecht, who had served in Reinhardt's dramaturgic collective and played an even greater part in Piscator's, appropriated this term for his own theatre. He also adapted and advanced many of the ideas and methods of Piscator's work.

Futurism in Italy. Although it produced one major dramatist, Luigi Pirandello, in the period between the two world wars, the Italian theatre contributed very little to staging or theatre production. What was important was the work of the Futurists led by Marinetti. This movement predated the Dadaists, but its politics were oppositional only with respect to the liberal democrats. Far from attacking war, the Italian Futurists welcomed it. They embraced and glorified the machine culture of the 20th century. Their theatre presentations were scandalous. On one occasion they smeared the seats with glue so that the audience would stick to them; they sold the same ticket to more than one person and provoked fights in the audience. The content and shape of their presentations were similarly designed to shock, provoke, and antagonize the bourgeois audience. With the accession to power of Mussolini's Fascists, whom they supported, their aggression diminished and they became absorbed into the establishment.

Borrowings from music hall and variety shows

The Futurists built their performances upon an examination of the techniques and forms of music hall and variety shows. The variety stage clearly held an audience's attention without the use of such stable theatrical elements as plot, characterization, and even dialogue. The Futurists went further, using variety forms and techniques without motivating reason or logical content, and created abstract theatre. Later the Dadaists took over many of their ideas in a different cause. What unified Futurist performances, however, was the concept of attractions. An attraction was whatever element in a particular act held the audience's attention. Variety bills were constructed to produce an effective and contrasting variation of types of acts—acrobats opened the show, a solo juggler concentrated the attention, a singer or whistler capitalized on this concentration, a musical act expanded it further, a chorus line of girls kicked in unison, and a climactic situation raised anticipation for the entry of the solo star comedian. The Italian Futurists never really exploited the full possibilities of this concept, which was taken much further in Russia.

Developments in Russia and the Soviet Union. *The great directors.* Until 1883 there were only five state theatres in Russia. When the embargo on non-state theatres was lifted, private initiatives followed. The most important of these was the Moscow Art Theatre (after 1939 the Moscow Academic Art Theatre), formed in 1898 by Konstantin Stanislavsky and Vladimir Nemirovich-Danchenko. The repertoire of the Moscow Art Theatre was less contentious than those of the other independent theatres, and it was the first of these theatres to emphasize theatrical production rather than censored or neglected plays. Stanislavsky had been deeply impressed by the work of the Meiningen Company and particularly by the discipline imposed on rehearsals by the Duke's stage manager, Ludwig Chronegk. In order to produce theatre in which all the elements were fully integrated, Stanislavsky decided that an autocratic, if not despotic, director was necessary.

The Moscow Art Theatre

His first production, Aleksey Tolstoy's *Fyodor Ivanovich,* which Stanislavsky had rehearsed on a country estate and designed on the basis of detailed research into costumes and historical settings, caused a sensation. Later Stanislavsky came to the opinion that the Meiningen approach was successful in creating an external unity of effect but deficient in transforming the internal techniques of the actors. The actors merely imitated the outward behaviour of the characters. With plays increasingly calling for a deeper understanding of psychological motivation, Stanislavsky saw the necessity for a more complex and subtle technique for transforming the thought processes and emotions of the actor into those of the character. The role of the director was thus transformed from that of despot to a combination of coach, teacher, and psychologist. Stanislavsky devoted the rest of his career to perfecting his famous "method," by which actors assumed the "identity" of their characters; it must be stressed that his was a method and not a style—each production was created in its own specific style. His early stage settings were overwhelmingly naturalistic, impressively detailed and accompanied by a vast array of sound effects. Fortunately, at the outset of the Moscow Art Theatre work, the plays of Chekhov formed a major part of the repertoire, and Chekhov argued successfully for a more selective style of setting and against the drowning of his plays by choruses of birds and frogs. Stanislavsky is credited with being the first person to produce a systematic study of the actor's craft. His influence and that of his Moscow Art Theatre are still to be seen in much of the theatre produced on the world's stages.

Stanislavsky's "method"

Vsevolod Meyerhold was one of the actors in the original Moscow Art Theatre, playing among other roles Konstantin in *The Seagull* and Tussenbach in *Three Sisters.* In 1905 Stanislavsky, sensing the difficulties of approaching nonrealistic theatre through the acting methods of the Moscow Art Theatre, asked Meyerhold to open a studio to investigate nonrealistic approaches to acting. Meyerhold's work in the studio appears to have been more imaginative than disciplined, involving painters, poets, musicians, and actors in a series of multimedia experiments. Prior to the Revolution he was director of the imperial theatres in Leningrad. After the Revolution he became head of the Soviet theatre organization. In both these areas, Meyerhold carried on the experimental work begun in the Moscow Art Theatre.

The early work of Meyerhold

Meyerhold's early experimental work followed the patterns laid down by Craig, Appia, and Fuchs, committing him to a "theatricalized" theatre and anti-illusionism. In his production of Blok's *Fairground Booth* (1906) and his subsequent writings on this work, Meyerhold explored the concept of a theatre of the grotesque. A disjointed rather than a uniform style—the contrasting of the comic and the tragic rather than their reconciliation in the tragicomic, the dispelling of illusion by blatant theatrical devices, the use of distorted perspectives—seemed to him the most appropriate style for 20th-century theatre. Other writers, directors, and artists were also concerned with the development of the grotesque at that time, but Meyerhold's productions of the Blok play and of Andreyev's *Life of Man* (1906) were high points, representative of a line of theatrical work that utilizes mixed forms in the theatre to express the contradictions and inconsistencies of life. The Theatre of the Absurd of the 1950s and early 1960s took this technique further to demonstrate that life is not merely inconsistent but fundamentally absurd.

Meyerhold's staging of Molière's *Dom Juan* (1910) was a key production in the process of "retheatricalizing" the theatre. Meyerhold used his historical research to reproduce many of the features of the early Baroque theatre. He built over the orchestra pit and extended the stage area forward by about 20 feet. He abolished the curtain, so necessary to the theatre of illusion, and conducted set changes in full view of the audience. The stage was lit with hundreds of candles and the auditorium remained lighted during the performance. The intention was to extend the experience of theatregoing beyond the mere watching of a play. The disposition of the auditorium and the circumstances under which people arrived at the theatre were to be part of the experience. Meyerhold believed that bright light inspired a festive mood in the spectators when they arrived at the theatre and that this disposed the actors to respond with equal enjoyment.

The Russian preoccupation with the physical aspects of performance not unnaturally led to a decline in respect for the written text, which became only one subservient means the theatre had at its disposal for creating enjoyable experiences. Of much greater importance to the Russians, since the text could be cut and reshaped and rewritten at will, was the physical technique of the actor. Throughout his studio period before the Revolution, Meyerhold

was exploring circus movements, commedia dell'arte, and Japanese theatre in order to devise a new system of training actors. Both he and his younger contemporary Yevgeny Vakhtangov in their productions placed great emphasis on the rhythmic control of stage action and the physical agility of the actors. After the Revolution the demand for a popular theatre of ideology intensified this research and increased the numbers searching.

Meyerhold's "biomechanics"

Meyerhold codified his study of movement in a system known as biomechanics. The two roots of this term, in suggesting a living machine, also demonstrate the aim of the system. Meyerhold acknowledges a great debt to Frederick W. Taylor's work in all his writings on the subject.

Meyerhold constructed a set of 16 études as the basis of biomechanics. These études were chosen from an eclectic range of sources, including the circus, Chinese and Japanese theatre, and sport, and they formed the basis of his extended movement vocabulary. The études were sequences of precise muscular movements intended to evoke particular emotions in the performer. This process attempted to systematize the kinesthetic relationship between outer movement and inner feeling, to enable actors to experience this relationship, and to train them to control it.

Even after so short a time, it is not easy to reconstruct Meyerhold's biomechanics from the remaining evidence because of his fall from favour under Stalin. But, if the exact form of biomechanics has not survived, many of the underlying principles of Meyerhold's movement studies have, and the example of his training program is embodied in the work of many of the present-day advanced theatre groups. Less well known is the work of Vakhtangov, which is important because of the ways in which he combined the inner techniques of Stanislavsky with the external expressive techniques of Meyerhold. An investigation of the work of Jerzy Grotowski shows the continuation of this process and many of the specific techniques (see below *The influence of Grotowski and the Polish Laboratory Theatre*).

Later experiments

Like Piscator, Meyerhold experimented with the use of film, projected images, and graphics in his productions, and there has been some largely irrelevant controversy as to who copied whom. The period after the Revolution saw many of the Constructivist ideas used in architecture and design taken over into the theatre. The settings from Meyerhold's Constructivist period featured complicated stage machinery. All attempts at illusion were stripped away to reveal skeletal frameworks with moving parts. The abstract platforms and steps of Craig, Appia, and Jessner had entered the machine age. The sets, whatever their other origins, are the logical outcome of Meyerhold's study of movement and his efforts to reveal the mechanics of the actors' articulation. But Meyerhold and his designers were not content to provide a neutral acting area. The Constructivist settings were incorporated into the action, and the actors' movement was coordinated with the shape, dimensions, functions, and movements of the setting.

This emphasis on the rhythms of performance led Meyerhold to conceive of a theatre, designed but never built, in which all the dressing rooms opened directly onto the stage so that the actors could remain constantly aware of the stage proceedings. It has been said of Meyerhold that his rehearsals looked like performances and his performances looked like rehearsals. Against the prevailing approach of Stanislavsky, epitomized in the "building" of a character, Meyerhold instituted a holistic approach whereby the actors did not "mark" the actions but gave prototypical performances in rehearsal. Each rehearsal then produced a more complex prototype, and the process continued into the public performances. This approach is the one accepted now by many advanced theatre groups.

What unites Meyerhold and Piscator is their concept of an infinitely variable theatre within an oval shell, which would provide the total means to construct the environment and stage–audience relationship best suited for each production. Piscator commissioned plans for such a theatre from Walter Gropius, director of the Bauhaus. The project was called *Totaltheatre.* A remarkably similar building was designed for Meyerhold. Neither were ever built.

Other Russian directors

The Russian theatre during these years produced many other talented and innovative directors. Three who deserve mention are Nikolay Evreinov, Aleksandr Tairov, and Nikolay Okhlopkov.

Like Craig in England and Meyerhold in his own country, Nikolay Evreinov looked to the history of theatre as the true basis for freedom and innovation. In 1907–08 he mounted a cycle of medieval plays through which he wished to capture the artistic essence of each kind of stage, unconfined by pedantic reconstruction. A cycle of plays from the Spanish Golden Age was presented in a large hall—each play given an original setting to re-create the atmosphere of the original performances. One play was set on boards and trestles in an innyard, another given a court setting with the full effects of the Baroque theatre.

Evreinov also began to explore the relationship between theatre and life, particularly how the processes of acting in the theatre related to social strategies. His work has had a considerable influence on the development of psychodrama and the therapeutic process of acting out concealed traumas. He also anticipated the sociological school of theatre analysts and acting coaches of the 1960s and '70s.

Aleksandr Tairov used abstract settings of Cubist design and took the training of his actors so far as to posit the idea of the actor-dancer. The European tours of his Kamerny Theatre in the 1920s aroused special interest in France and sparked off a run of emulators.

Nikolay Okhlopkov, claimed Meyerhold, was the ideal biomechanical actor. His later work as director of the Moscow Realistic Theatre was innovative in the manner in which he planned the shape and relationship of both stage and audience for each individual production. His centre-stage production of Gorky's *Mother* had subordinate stages and a walkway behind the audience. He experimented with stages in front of, behind, within, and above the audience. His intention was to revive the festival spirit and incorporate the audience into the spectacle, and his methods were not restricted to the spatial. In *The Iron Flood,* a play about guerrillas in the Russian Civil War, the audience was kept outside the theatre until the Red Army arrived to break open the doors and the audience flooded into the auditorium. The stage in this production was obliterated and replaced by an embankment running along one side of the room with small promontories jutting out into the audience, breaking up any fixed focus in order to make the audience follow the fluid action. The theatre laboratories of Grotowski and Odin Theatre follow the Okhlopkov tradition in their handling of space.

Russian Futurism—Suprematism. The Russian Futurists, or Suprematists, declared their lineage from Jarry and their affiliation with the Italian Futurists in their first manifesto "A Slap in the Face of Public Taste" (1912). They differed from the Italians in that they were internationalist rather than nationalist in their politics and that their performances developed beyond the early antibourgeois, anti-art cabaret and variety shows that characterized both Italian Futurists and the Dadaists. The early Russian Futurist activities consisted of provocative street actions and cabaret performances, but with *Victory over the Sun,* an "opera" created in 1913 by the writer Alexey Kruchenykh, the composer Mikhail Matyuchin, and the painter Kazimir Malevich, they produced a work that expressed modern machine culture. The piece had affinities with Kandinsky's Expressionist pieces in that the setting consisted of geometric forms, pieces of machinery, and fragments of typography. The text consisted of nonsense syllables and words without syntax. The costumes and masks were designed to eliminate the human element by transforming the actors into machines. An offstage accompaniment of battle noises, cries, and discordant choral and solo singing provided the score. The whole work optimistically predicted a new age when man's mechanical inventions would supplant the Sun as the source of power. Later generations were to be more concerned with the dangers inherent in the realization of that proposition.

According to the composer Matyuchin, *Victory over the Sun* represented the first occurrence on a stage of the disintegration of traditional text, staging, and musical

harmony. In retrospect, this production and the other Futurist works, including the early works of the poet Vladimir Mayakovsky, appear as extreme examples of a feverish experimentation concerned with separating analytically the various components of theatrical performance and resynthesizing these elements into new relationships. This analytical investigation and experimentation characterized the work of Kandinsky, Oscar Schlemmer, and the Bauhaus group as well; the work of the Expressionists, Piscator, and later Brecht began the resynthesis.

Theatrical manifestos

The theatre since the advent of Naturalism had been prone to producing manifestos of various kinds. As time went by, these declarations became less concerned with what theatre should be doing and more concerned with defining what theatre was. From Appia, Craig, and Fuchs onward there was a consistent body of theatre theory that had little to do with dramatic theory. The play and the playwright diminished in importance. The old dramatic criticism based on playtexts and how these were interpreted by actors lost relevance in the new world. The concept of genres such as tragedy, comedy, and farce collapsed as more and more theatre productions attempted to cope with experiences that could not be categorized so neatly.

Film, declared Lenin, was the most important of the media. The availability of resources for films that had an educational purpose rather than a commercial one stimulated filmmaking and the study of film as an art form. The director Dziga Vertov's manifesto for Soviet film sets out to free film from intrusive elements such as music, literature, and theatre. The "theatre" that Vertov disclaimed was equally rejected by the theatre makers around him who derived inspiration from the developments in film. Sergey Eisenstein, who worked in theatre and film, developed further the Italian Futurist concept of the montage of attractions. The implementation of this theory would eliminate all the random, haphazard nature of theatre, which Craig saw as destructive to any concept of the theatre as art. Whereas Craig put his trust in the intuitive genius of an individual director, the Russians tried to find a generally applicable theory. The artist-genius was replaced by the artist-theorist.

The propagandist theatre. Political theatre in postrevolutionary Russia combined agitation (the use of catchphrases and half-truths to exploit popular grievances) with propaganda (the use of historical and scientific arguments for purposes of indoctrination) in a form that came to be called agitprop. This form of theatre is explicitly intended to arouse the audience to action and to propagate the views and values of the sponsoring organization. In practice, the term agitprop is usually reserved for left-wing political theatre, though the form itself does not imply any particular ideology, nor is it restricted to politics. In fact, one of the greatest uses of agitprop techniques today occurs in commercial advertising. The reputation of political agitprop for poor aesthetic quality probably reflects the fact that many of the groups using it have viewed the political message as the raison d'être for the work and any aesthetic considerations have been deeply distrusted as interfering with its political purity.

Agitprop

Immediately after the Revolution the various arts were enlisted to further the propagandist aims of the Bolsheviks. Ships and trains were decked out with a variety of communicative devices ranging from poster art to poets reading their work. In a country where few could read the newspapers, actors acted out the news stories in a Living Newspaper. In 1921 a group of Moscow actors formed the Blue Blouses, a company named for the workers' overalls its members wore as their basic costume. This group inspired the formation of other professional and amateur factory groups throughout the Soviet Union. Their work and methods set the standard for political theatre groups in other countries between 1921 and 1939.

Blue Blouse performances

The performances of the Blue Blouses were typically around an hour and a half long and began with a parade in which the actors presented themselves to the audience. The aim of this and similar groups was to be able to perform anywhere, and staging demands were extremely simple. The performances were montages comprising dramatic monologues, sketches, dialogues, mass declamations, and movement derived from dance and gymnastics. They frequently made use of animated posters for rapid cartoon characterization—similar to the photographers' dummy boards with cutout faces that permit tourists to be photographed as cowboys or bathing beauties. Music was a prominent element, including instrumental numbers and folk and popular songs, often with satiric lyrics. Film was rarely used, but the Blue Blouses made a specialty of using flickering light on slowly moving actors to create the illusion of silent film. The dance and gymnastic routines seem to have been the most conventional and apolitical forms, but they were in practice the Blue Blouses' greatest strength. In the process of moving scenic pieces, the actors could acrobatically combine to compose pictures, diagrams, and structures. One report of a sketch entitled "Industrialization" describes actors in costumes representing factories and power stations finally coming together to represent the government program for industrialization.

The Blue Blouses constructed their programs cleverly, juxtaposing the more overtly political pieces with the more entertaining pieces. The organization of a bill in this way was not new, since music hall and variety theatres had used this sort of planning for many years. What was new was the use of these skills for an ideological purpose, rather than simply to extract applause from an audience.

Ironically, the Blue Blouse movement was suppressed by Stalin in 1928. The reason seems to have been that the Blue Blouses saw satire as a legitimate part of their repertoire and proceeded to attack the inequities that followed the Revolution and the survival of prerevolutionary thought and class distinctions. In 1928 such a program was held to be counterproductive, and a more agreeable line of thought was called for. The doctrine that followed was called Socialist Realism, a political derivative of Naturalism that sought to present typical figures in a typical landscape. With state direction these were always liable to turn into idealized figures in an idealized landscape.

Influence abroad

Just before their disbanding, the original Blue Blouse group made a tour of Germany in 1927 to celebrate 10 years of the Revolution. The visit coincided with the presence in Germany at a Communist-backed congress of representatives from many other countries. As a result, there arose an international movement of workers' theatre groups performing, with varying degrees of skill, agitprop in the Blue Blouse mode. Whereas the Blue Blouses in their heyday could expect official support for their minimal required facilities, the groups in nonsocialist countries could not, and a new resourcefulness resulted. One of the many German groups formed had a furniture pantechnicon in which it toured the working-class tenement courtyards, lowering a side of the van to reveal a ready-made stage that could quickly be folded up and driven away in advance of a police raid. Groups elsewhere took their theatre to public gathering places, often symbolic sites. Groups performed in the streets, on the backs of flat motor trucks, at mass meetings in city squares, as well as on the steps of employment exchanges and government offices. The Korean resistance to the Japanese invasion was aided by agitprop groups that stayed one step ahead of the Japanese troops. Troupes of this kind were used later by the North Vietnamese during the Vietnam War. Agitprop has remained a consistent part of the Chinese government's education program in rural areas. The techniques of the Blue Blouses and other agitprop groups were emulated by the Teatro Campesino, the first of the Chicano theatres in the United States, which was founded in California as part of the farmworkers' union campaign for recognition in the mid-1960s.

Political festivals. In the years immediately following the Russian Revolution, mass spectacles were mounted in many Soviet cities. The subjects of these spectacles were drawn from events in the Revolution and the subsequent Civil War. They were a conscious attempt to create a new form of social ritual out of the celebratory reenactment of revolutionary events. They also represent an attempt to create a new proletarian art form, and in this they arose naturally from the broader movement to utilize art for social purposes. The former Futurists and Suprematists painted the fronts of buildings and exploited the bustling

atmosphere of street markets for their performances. The ideological point of such actions was that the theatres, concert halls, and art galleries had been the preserve of the privileged; proletarian artists proclaimed their allegiance by creating it in the streets.

Mass spectacle

It seemed only reasonable that Leningrad, which had seen so much of the high drama of the Revolution, should be the city that presented the most memorable mass spectacles. In 1920, five of these were presented, climaxing in *The Storming of the Winter Palace,* directed by Evreinov, with the help of the directors of the other spectacles. The performers numbered more than 8,000, and the spectators have been estimated at 100,000. A 500-piece orchestra provided accompaniment. The spectacle reenacted the events leading up to the October Revolution in Leningrad, on the site at which they actually happened.

The spectacles corresponded directly with the proposal by Rousseau and Diderot in 18th-century France that the theatre be made the church of the secular state. These productions were almost certainly influenced by the arguments of Romain Rolland for a people's theatre at the beginning of the century and were the most vivid examples of the large-scale revival of pageant theatre that was very strong in many European countries and North America between the two world wars. A change of Soviet policy in 1921 phased out the mass spectacles, though they have not disappeared entirely. The Bicentennial celebrations in the United States in 1976 included reenactments of the Battle of Lexington, among others. During the opening ceremonies of the Los Angeles Olympic Games in 1984, performers presented a "condensed" history of the settling of the United States. In the socialist countries the tradition is continued in more disciplined and less imaginative forms in military parades and the large athletic Spartakiades.

Influence in the West

As Soviet society settled into a more dogmatic and defensive period after 1921 and particularly after 1928, the unrestrained release of emotion sparked by the mass spectacles, the critical satire of the Blue Blouses, and the highly imaginative and often idiosyncratic experimental work of the directors came increasingly to be seen as dangerous to the state. In direct opposition to the direction in which 20th-century art was moving—*i.e.,* away from representation toward abstraction—the Soviet aesthetics branded any tendency toward abstraction as Formalist and established Socialist Realism, which was in effect a reduction of the older forms of Naturalism and psychological realism, as the official mode.

Developments in France. At the turn of the century, the preeminence of Paris as the centre of avant-garde theatre had declined and the lead had passed to Berlin and later Moscow. The revival in the French theatre produced a theory diametrically opposed to that of Meyerhold and Tairov. Jacques Copeau founded the Théâtre du Vieux-Colombier in 1913, arguing that the director's job was to translate faithfully a play into a "poetry of the theatre." Believing the actor to be the only important element in a production, he advocated the return to a bare stage. In the Vieux-Colombier he removed the proscenium arch to create a raised open platform. At the rear of the stage he placed an alcove with a balcony, a structure similar to that of the Elizabethan theatre. In a succession of productions and with great ingenuity this permanent setting could be transformed with minor alterations and adaptations to suit a whole season of varied plays.

Jacques Copeau

Copeau's reasoning was based on an assessment that the modern theatre had initiated a mass of new staging techniques but had singularly failed to find the new dramatists to maintain the literary standard of the theatre. He founded his theatre in hopes of attracting those new dramatists. This effort largely failed, and Copeau's contribution to the history of the theatre consists almost entirely in his approach to staging. The restriction of scenic means on the bare stage placed great stress upon the actor's ability to play in a variety of styles. In the school attached to the theatre, Copeau pursued a program of actor training very much in line with that of Meyerhold, encompassing exercises drawn from commedia dell'arte, folk theatre, masked theatre, Oriental theatre, and Dalcroze eurythmics. His actors trained with the Fratellini family, the great Italian family of circus clowns and acrobats. Copeau's aim was to equip his actors with a wide cultural understanding and a full range of physical and vocal skills. Rehearsals were improvisational. The discipline and self-denial inherent in Copeau's program provided an example for others to follow not only artistically and administratively but also morally. The line of influence from Copeau, his colleagues Charles Dullin and Louis Jouvet, and their students extends throughout the European theatre. The example of the Théâtre du Vieux-Colombier can be followed through many of the leading postwar European theatres, such as Giorgio Strehler's Piccolo Teatro of Milan and the Old Vic and the Royal Court theatres of London.

Developments in the United States. The currents of innovative stagecraft eventually reached the United States. The first migration was represented by the Viennese Joseph Urban, who when he went to the Boston Opera before World War I took with him an entire atelier of draftsmen and scenic artists. Urban moved into musical comedy and eliminated the acreage of painted vistas and box sets manufactured by the stock scenic studios.

The next change grew out of marginal experimental groups, such as the Provincetown Playhouse on Cape Cod in Massachusetts and the Neighborhood Playhouse in New York City, which fostered designers such as Robert Edmond Jones, Cleon Throckmorton, and Aline Bernstein (Figure 21). By the middle 1920s, their simple, tasteful romanticism had invaded Broadway as the groups had become commercial and as the more artistic theatre managers extended commissions to the free-lance designers. The industrial designer Norman Bel Geddes entered the growing ranks of theatre artists and devised grandiose projects and engineering marvels (Figure 22). With the impetus provided by ecstatic reports from Europe on the work of Reinhardt, Copeau, Meyerhold, and Tairov, American directors such as Arthur Hopkins and Philip Moeller attempted to synthesize the elements of production into a persuasive whole. The imaginative poetry of Robert Edmond Jones was balanced by the sensible craftsmanship of Lee Simonson for the Theatre Guild. Simonson as the exponent of "selective realism" was more attuned to the practicalities of the earthbound psychological problems that provided the staple fare of Broadway's "serious" drama.

Broadway staging

By the 1930s, scenery consisted of solid carpentry and tasteful furnishings that were tailored to the mood, atmosphere, and mechanical requirements of the individual play. The Urban style in musical comedy design was replaced by that of Albert Johnson—a style characterized by loose colour and calligraphic line that went well with the sharp revues that prevailed until World War II. In

staging musicals, a peculiar division persisted between the direction of the plot and comedy segments and that of the production numbers—the sumptuous song-and-dance displays under the separate supervision of a "stager" who was noted for his taste. Director-producer George Abbott surmounted this artificial departmentalization in an important step forward in the development of the rhythmic, lively musical show that became America's contribution to world theatre.

The Living Newspaper

The importation of Blue Blouse techniques, through direct exposure to German groups or through political theatre groups formed by ethnic immigrants, led to one sensational development in the United States. The Living Newspaper had been a relatively crude form of propaganda elsewhere. Under the Federal Theatre Project (1935) several Living Newspapers were produced, of which *Triple-A Ploughed Under* (1936) and *One Third of a Nation* (1938) are probably the best known examples. These productions were articulate documentaries of great sophistication. So impressive were they that the model was reexported into Europe as the basis for many documentary theatre productions. Another refinement of these techniques married to the skill of Broadway-experienced professionals produced the political revue *Pins and Needles* (1937), which was put on to aid a strike and which ran on Broadway for 1,108 performances.

The influence of Brecht. By 1936 a wide range of experimentation and innovation had established the parameters of the contemporary theatre. The training of actors in the Western theatre has since become more organized to take in concepts and programs from the earlier innovators. There are few schools today that do not acknowledge the work of Stanislavsky in their training. Less obvious but equally pervasive is the influence of Reinhardt and Copeau, largely by way of their pupils in teaching. And towering above all others (save perhaps Stanislavsky) is the figure of Brecht. It is reasonable to argue that Brecht absorbed, and in turn perpetuated, more influences than any other individual in the modern theatre.

Of central importance in establishing this argument is Brecht's essay "On Experimental Theatre" (1940), in which he reviews the work of Vakhtangov, Meyerhold, Antoine, Reinhardt, Okhlopkov, Stanislavsky, Jessner, and other Expressionists. Brecht traces through the modern theatre the two lines running from Naturalism and Expressionism. Naturalism he sees as the "assimilation of art to science," which gave the Naturalistic theatre great social influence, but at the expense of its capacity to arouse aesthetic pleasure. Expressionism (and by implication the other anti-illusionist theatres), he acknowledges, "vastly enriched the theatre's means of expression and brought aesthetic gains that still remain to be exploited." But it proved incapable of shedding any light on the world as an object of human activity, and the theatre's educational value collapsed. Brecht recognized the great achievements of Piscator's work, in which he himself played a significant role, but proposed a further advance in the development of so-called epic theatre.

Brecht's epic theatre

Brecht's Marxist political convictions led him to propose an alternative direction for the theatre that would fuse the two functions of instruction and entertainment. In this way the theatre could project a picture of the world by artistic means and offer models of life that could help the spectators to understand their social environment and to master it both rationally and emotionally. The main concept of Brecht's program was that of *Verfremdungseffekt* ("alienation"). In order to induce a critical frame of mind in the spectator, Brecht considered it necessary to dispense with the empathetic involvement with the stage that the illusionary theatre sought to induce. Generally, this has been understood as a deadening coldness in the productions, but such an interpretation proceeds from a general ignorance of Brecht's own writings on the subject. Rather, he insisted, as Appia, Craig, and the Symbolists did before him, that the audience must be reminded that it is watching a play.

Brecht's ideas can be approached through the image presented by the theatre he chose to work in on his return to East Germany in 1947. The auditorium of the Theater am Schiffbauerdamm is lavish to the point of fantasy, decorated with ornate plaster figures. The stage, by complete contrast, is a vast mechanized scenic space in which everything is clearly exposed to view as theatrical and man-made. In the contrast between the comfort of the auditorium and the science of the stage lies the condition of Brecht's theatre. The audience was there to be entertained but also to think scientifically.

Many of the techniques of Brecht's staging were developments of earlier work. The use of three-dimensional set pieces in a large volume of space clearly derived from Jessner. His delight in the use of machinery and in particular the revolving stage came from Piscator. The insistence on the actors' demonstrating through the physical disposition of the body their *gestus* ("attitude") toward what is happening derived from Meyerhold, though with Brecht the *gestus* was always socially based. The clearest of his alienation devices, the projection of captions preceding the scene so that the audience knows in advance what will happen and therefore can concentrate on how it happens, derived from Piscator's jotter screens and film captions.

Brecht acknowledged in his work the need for the actor to undergo a process of identification with the part, and he paid tribute to Stanislavsky as the first person to produce a systematic account of the actor's technique. Brecht required his actors to go beyond Stanislavsky and to incorporate a social attitude or judgment into their portrayal. Characterization without a critical judgment was in Brecht's view seductive artifice; conversely, social judgment without the characterization of a rounded human being was arid dogmatism. The theatre of mixed styles and means that Meyerhold and others constructed to cope with the grotesque experience of modern living was transformed by Brecht into a political principle. He used mixed means and styles to expose the contradictions, inconsistencies, and dialectics of situations and characters. Brecht's strongest theatrical effects were created through

the juxtaposition of inconsistent attitudes in a character. Although the settings in Brecht's productions were clearly theatrical, the costumes and properties were not. Great care was taken to make each property and its use authentic for the period or character (Figure 23). In Brecht's theatre, if a chicken were to be plucked the actor did not mime or roughly approximate the action—the chicken was plucked. Costumes had to make clear the social class of the persons wearing them. This places Brecht directly in the line with the Meiningen Players, though again the *gestus* is particularly social rather than historical.

Rehearsal methods

Brecht's methods of rehearsal were especially innovative. The methods worked out in his own company, the Berliner Ensemble, established a directing collective well advanced beyond those of Reinhardt and Piscator. In Brecht's theatre, the director, dramaturge, designer, and composer had equal authority in the production. The designer had a special function; in addition to designing the sets and costumes, he also produced, for early rehearsal purposes, a series of sketches of key moments in the action. The rehearsals became a process of testing hypotheses about the play and its production. What held the collective together and made the method workable was the story, or fable. All the elements of production were synthesized for telling this story in public. At some points the music conveyed the meaning, at other times the setting, or the actors, or the words did. Brecht often invited observers to the rehearsals in order to test the clarity of the story. The process of testing could continue into the performance period. When the company was satisfied that the staging was correct, the production was photographed and a *Modellbuch* was prepared with photographs set against the text to show the disposition of the stage at all times and to mark significant changes of position on the part of the actors. The *Modellbuch* was then available (in a more advanced form than the designer's sketches) as the basis for any subsequent productions.

The *Modellbuch* has aroused resentment on the part of directors who prefer to respond freely to the text. Brecht's intention was not to limit but to provide a document as scientific evidence of an experiment that could be used in further research. Since the finished text was, in any case, only one facet of the fable, the model book gave evidence of other aspects of the story and its telling.

Brecht's influence on the contemporary theatre has been both considerable and problematic. His Marxist views have proved a real stumbling block to his assimilation in the West, and his use of formalist techniques in the service of entertainment has presented difficulties in the socialist countries. There is no doubt that the settings and costumes of his productions are the features that have most influenced the contemporary theatre. Contemporary design exhibits in many ways the influences of his staging.

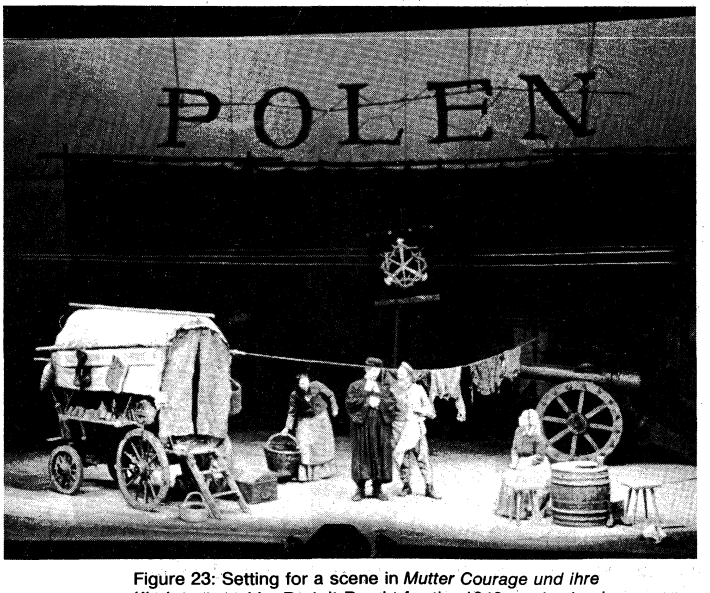

Figure 23: Setting for a scene in *Mutter Courage und ihre Kinder*, staged by Bertolt Brecht for the 1949 production by the Berliner Ensemble.

Theatre building after World War II. After World War II, Germany was left with hundreds of bombed-out theatres and opera houses; within 20 years (1950–70) more than 100 of them had been restored to their former state or else had been redesigned and rebuilt along contemporary lines. The chief innovator in stage design and mechanization was Walther Unruh, whose work is exemplified by the Deutsche Oper in West Berlin. There, the stage is cruciform in plan, employing lifts under the main stage, a sliding revolving stage with trapdoors upstage, and sliding stages right and left of the main stage; thus, it completes the process toward mechanization begun at the turn of the century by providing means for shifting fully plastic settings with great speed. The combination of stage engineering with acoustic sophistication and continental seating makes this building arguably the greatest modern opera house.

Beginning in the late 1950s, the United States and Canada constructed theatres, concert halls, and a variety of multipurpose facilities by the hundreds, in the greatest theatre-building boom ever known in the Western Hemisphere. The two fundamentally opposing conceptions of theatre design—proscenium style and open stage—predominate. The Alley Theatre, in Houston, Texas, is a fine example of the more radical school. In the United Kingdom the director Sir Tyrone Guthrie advocated a return to the open-stage techniques in his productions of Shakespeare at the Edinburgh International Festival of Music and Dance. Moving to Stratford, in Ontario, Canada, and assisted by stage designer Tanya Moiseyevich, Guthrie designed the Festival Theatre, which represents a fusion of the classical auditorium with the stage of Shakespeare. The experiment, with modifications, was repeated in 1963 at Minneapolis, where the Guthrie Theater was designed to Guthrie's specifications. The Guthrie Theater, while it is reminiscent of his earlier theatre at Stratford, exhibits a studied asymmetry in plan and section in contrast to the older theatre's ordered symmetry. A number of new British theatre buildings have been built in emulation of this design.

(G.C.I./C.Ba.)

Internationalism in the theatre today has erased national and local styles in decor and staging. The great leap in facilities for travel and the network of international festivals throughout the world has greatly facilitated the cross-fertilization of styles and influences. It is not surprising that the resulting eclecticism of taste has imposed certain imperatives on theatre design. This has also been affected by an interaction of economic factors. Theatres occupy prime sites in city centres. In the post-World War II building boom, these sites became targets for property speculators seeking to exploit them for more profitable purposes. The return on investment and capital costs in theatres is very low in comparison with other fields of investment. In Britain a vast number of theatres disappeared completely in the decade following 1945.

Economic factors

The keynote in the postwar rebuilding of theatres has been flexibility. Eclecticism in style has led to demand for flexible auditoriums. In response to directorial demand, a number of theatres were built in Scandinavia in which the size and relationship of stage and auditorium can be adjusted by mechanical means.

It has become customary for many contemporary theatres to have a studio theatre attached to a main-house theatre. These studios are usually well-equipped "black boxes" with adaptable seating that allows a limited variety of forms of presentation—usually end-on, half-thrust, full-thrust, and arena staging. The National Theatre in London has three auditoriums of different types. The Royal Shakespeare Company has three auditoriums in Stratford and also uses some improvised areas; the company has two auditoriums in London. This variety of facilities lends flexibility to production planning. Less commercial productions can also be mounted in the studio theatres when the risk is too high to give them main-house runs.

The rise of alternative theatre spaces. The search for flexibility in designing a multipurpose hall that could be

used for theatre, music, exhibitions, and sporting events has rarely been successful. The acoustic needs of theatre and music are widely different, and acoustic shields (suspended or freestanding panels used to alter the acoustic properties of a space) are at best corrective devices. Nevertheless, economic factors have frequently dictated that this is the only possible way in which smaller communities can be provided with performance spaces, and the design of such spaces is becoming more sophisticated and efficient.

The adverse economics of Broadway has severely restricted the range of productions that can be presented in those theatres. Investment is high and the risk of losing all has led to a policy that favours mass-appeal productions such as the musical, which can at least produce a high box-office return. Experimental productions stand little chance of finding a backer. Since the 1950s the sterility of Broadway has been countered by a growth of small Off-Broadway theatres, and, in turn, so-called Off-Off-Broadway. Nontheatre buildings have been pressed into use—cafés, garages, fire stations, churches, lofts, and shops. The example of the converted theatres in New York City spread to other countries. In many cases these theatres have been the home of innovative companies for many years. Otherwise they have formed the basis of a new touring circuit for small companies. The growth of the study and practice of theatre in educational institutions, starting in the United States in the 1930s and spreading to Europe after World War II, led to the formation of many small experimental and radical theatre groups in the 1960s and '70s. These groups formed the nucleus of the companies adapting and playing the informal theatres.

One further reason for the development of adaptable, flexible, and multipurpose theatre spaces has been the pattern of decentralization followed by many Western governments since World War II. In France, in particular, there has been a government policy of subsidizing theatre away from Paris through the founding of *maisons de la culture* ("houses of culture") and *centres dramatiques* ("dramatic centres"). The dual policy has been to create the facilities for a range of cultural activities in the towns and cities of the provinces and to establish theatre companies touring in specific areas from a home base. The development of lightweight electronic equipment, particularly lighting control, has greatly facilitated touring.

The influence of Grotowski and the Polish Laboratory Theatre. The other major tendency in today's theatre arises from an investigation of the sources of the theatre's uniqueness and strength. The prophet of this search was the French dramatist and poet Antonin Artaud, with his vision of a total, visceral theatre with the potency and terror of primitive myths. As was the case with Craig and Appia, his actual performances were few, but his writings inspired many directors, such as Peter Brook in England, Gerald Savory in France, and Jerzy Grotowski, whose Polish Laboratory Theatre, a fiercely dedicated acting ensemble, sought to cut through the bonds of the polite literary tradition to rediscover basic human drives and conflicts. The actors in the Laboratory Theatre undergo exhaustive exercises designed to break down the layers of superficial technique and repressions. Each production is conceived as a unique entity, requiring its own playing space and actor–audience relationship; the rectangular hall-theatre is rearranged according to the dictates of each production. Grotowski relies on his own dramaturgical skills in freely molding the texts and on his architect-designer for the carving of the space in which the ritual takes place.

Poor theatre

Grotowski's form of theatre is often called poor theatre on account of the simple circumstances in which it takes place. This characteristic recalls Copeau's idea of "the greatest possible effect from the least possible means." The internationalism of the theatre is now such that groups modeled on Grotowski's have appeared throughout the world. Eugenio Barba, of Odin Theater in Holstebro, Den., a pupil of Grotowski, has formulated the ideological position of these theatres under the term third theatre. His book *The Floating Islands* (1979) examines a theatre existing independently that creates from whatever material resources are at hand. Barba has sought to return to theatre as a way of life, seeing this pattern in the origins of the commedia dell'arte, the wandering players, and in Molière's company. The third theatre groups give performances, but they insist that the relationships engendered by their work, inside and outside the company, are the criteria by which they judge it. The members of the Odin Theatre have established a form of bartering in which they exchange their work for some cultural offering from the people of the regions they visit.

Because the third theatre is a way of life, the actors' "work" is a full-time activity. Actors have their own daily training regimen. The actors' work is enriched by the acquisition of other skills, particularly the techniques of Oriental theatre.

Because of the crippling expense of mainstream Western theatre and the development of these experimental groups, the theatre in the late 20th century has become highly polarized. On the one hand, there are "rich" commercial productions that rely heavily on technological spectacle; on the other hand are the small "poor" experimental groups exclusively centred on the art of the actor. Consequently, the traditional centres of theatre are losing their potency, except in their power to divert. The sources of real theatrical advance and interest are now dispersed throughout the world, and one is as likely to find exciting work in New Guinea as in New York City and London.

The component crafts of theatrical production

SCENIC DESIGN

Historical development. The execution of scenic effects passed from the guilds in the late Middle Ages to artists, with their apprentices and assistants, during the Renaissance and the Baroque and to commercial scene-painting studios from the mid-19th century until today. Each tiny Baroque state maintained a court painter and staff to embellish the court revels, masques, and operatic presentations. Large permanent companies such as the Paris Opéra, La Scala in Milan, Covent Garden in London, and the Vienna State Opera employed their own artists and shops. The independent actor-managers, stock companies, and traveling troupes and acts of the late 1800s ordered stock settings from firms that were prepared to turn out acres of mountain crags, sumptuous temples and palaces, picturesque hovels, and town squares. Historical research was crammed into every meticulously painted border, side wing, and backdrop, but no thought was given to the particular requirements of the individual scripts.

Stock settings

The major firms printed illustrated catalogs so that single hangings or complete backgrounds could be ordered by number through the mail. Leading managers, such as Sir Henry Irving in England and Max Reinhardt on the Continent, and the French art theatres commissioned painters who either did the painting themselves or supervised its execution from their sketches. In the United States, even on Broadway, the standard procedure well into the 1920s was for the actor-producer-director to dispatch a ground plan to the scenic shop, which made up a coloured model based on research and, after approval of the design, made the finished setting. The scenic artists who made such settings were highly skilled artisans, with thorough art schooling; though they frequented art galleries and museums, they seldom attended the legitimate theatre. As a result, free-lance designers with a better understanding of theatre began to play a greater role on the New York stage, and studios arose that catered to their new, personal styles. Bergman Studios, for example, executed works by Robert Edmond Jones, Lee Simonson, Norman Bel Geddes, Donald Oenslager, and Jo Mielziner, and Triangle Studios, an outgrowth of the Urban migration from Vienna and Munich, concentrated on musical comedies. Generally, carpentry, painting, property, and drapery shops were separate businesses. Not until the 1950s would all branches of scenery making in New York City be found under one roof. With the decline of theatrical activity, the all-in-one studio became an economic necessity. In London, the shops remain separate. Major theatres in Europe and most resident theatres in the United States maintain their own shops. The support facilities of the major West German theatres resemble small industrial concerns.

Contemporary procedures. Design procedures are fairly similar throughout the world. First, the script is studied closely and notes are made of mandatory action and mechanical requirements. Next, there is a consultation with the director on a production scheme. Thumbnail sketches are expanded into colour renderings or a model, if the structure is complex or the setting is primarily plastic, usually on a scale of one-half inch to one foot. Extensive research is undertaken and incorporated into the designs. Upon approval, the sketches are translated into working drawings. The execution shops are sent a ground plan, a section to determine masking and light placement, elevations of all units, and all details that require larger scale. The designer does not break down the elements into construction pieces or into actual framing or building details; this is done by the layout man in the scenic form. Usually there is a great deal of questioning and discussion between the artist and the technicians over the mechanics and the use of materials before the final drawings are consigned to the shops.

The modern scenic shop

In spite of the marginal financial status of the legitimate theatre, the physical layout of a modern scenic shop is extensive; vast amounts of space and equipment are required for the wide variety of designs to be translated into solid items, especially in the rush of preparations for the theatre season. Templates for flats, which once occupied the major amount of floor space, have been supplanted by three-dimensional fabrication, with scene-shifting wagons and overall stage decks. More recently, a blacksmith shop has been a requirement, since metal has replaced lumber in the scaffolding and in delicate open-tracery sets. The power tools, both for lumber and for metal, and all the workbenches are mounted on casters for mobility; essentials such as traveler tracks, winch motors, and the material stock for immediate use are stored around the edges. The paint shop also has required a larger space since looser, wetter techniques were adopted and bulk objects replaced flats and drops, which could be painted on upright frames. The drapery department produces soft maskings, drapes, upholstery, and any other special scenery covering. Vacuum form machines turn out ornaments wholesale and also make sizable, lightweight plastic objects that could not be carved in Styrofoam or wood. The drafting layout room is where mechanical problems are solved, the work is distributed, and models are translated into working drawings. Working models have come back into use to represent the sculptured units on the open stages that have replaced traditional flat scenery of the peephole tradition. If there is room, an acting company may practice on an elaborate structure for a few days before it is moved to the theatre. Ideally, the electrical shop is incorporated into the scenic complex to service the units that onstage will come within the province of the production electrician.

Properties, once produced in quaint workshops, are now a part of the scenic firms' mundane output. Celastic casting (the production of plastic props) has taken over from wood turning and whittling. The procurement of ready-made props, furniture, and dressing is handled by the property master, but the artistic choice resides with the designer. On today's open stages the primacy of properties demands the absolute rightness of every object in the visual ensemble. The theatre has sheltered the last remaining medieval craftsmen, the scenic painters and the blacksmiths; the production property master is the last all-around handyman.

The work of the stage staff is now much more demanding in skill, and the heads of departments need a wider range of knowledge and experience than in the days of box sets and flatting. Special businesses, employing the cream of the available theatre technicians, have been established to bridge the technical gap (particularly in the field of engineering) between the designer's demands for a particular production and the resident technicians' range of skills. These firms also fulfill a research function in pioneering new technical solutions to problems.

Increasing specialization

Theatre design has become an extremely specialized field. Stock sets have almost completely disappeared, each production having its own specifically designed setting. There are still possibilities for artists from other branches of the fine arts to design sets—David Hockney, the painter, has contributed designs of great distinction. The collaboration between the choreographer Merce Cunningham and the visual artist Robert Rauschenberg, both of the United States, has had a long and successful history. Most designers, however, now go through a formal training and are considered to have entered a profession. Many designers specialize in either set or costume design, and since 1950 there has arisen the new profession of lighting design (see below). Prior to this time, directors frequently arranged their own lighting with or without the cooperation of the set designer. The complexity of modern lighting equipment has created the need for a specialist. In spite of this trend, there remain some artists—Franco Zefferelli, for one—who almost singlehandedly design their own productions.

The development of design has come to be closely tied to economic developments. It is split between large lavish spectacles able to compete with film and television and a minimalist theatre that seeks to survive by stressing those elements that clearly distinguish theatre from film and television. The former clearly favours the development of more spectacular ingenuity, particularly in the field of engineering. The latter tends more subtly to create innovative designs in constrained circumstances. There have been signs in many theatres of a return to the principle on which the Elizabethan theatre was built—simple settings and lavish costumes (with the addition of dramatic lighting effects).

The work of the designer is being made much easier by the development of computer graphics. Three-dimensional pictures can be constructed on a screen, and these can incorporate specific sightlines from critical seats in the auditorium. Designs are drawn up on the basis of ground plans and elevation drawings and then demonstrated by a model. (Ho.B./C.Ba.)

STAGE LIGHTING

Historical development. The classic Greek *theatron* was built in the open air, usually on a hillside, and placed so that the afternoon sunlight came from behind the audience and flooded the performing area with light. The larger Roman theatres were also outdoors, but the added luxury of coloured awning stretched over the spectators softened the glare of the sun. Later, in the Middle Ages, the miracle and mystery plays were performed outdoors on the front steps of the church and the adjoining square. In England, the pageant wagon, complete with actors and properties, was drawn through the main street of a town. Until the 16th century, the theatre continued to be basically an outdoor institution.

Under the patronage of the aristocracy in Italy, private performances, pageants, and tableaux began to be given indoors. Serlio, the Italian architect, gave considerable attention to theatre design and in a treatise written in 1545 discussed theatre construction and the creation of lighting effects. He recommended placing candles and torches behind flasks filled with amber- and blue-coloured water. Palladio's indoor theatre, also in Italy, used the common everyday light sources: torches, pine knots, open wick lamps, and tallow candles. In England at the end of the 16th century, the Globe Theatre was used for summer performances of Shakespeare's plays, but in winter performances were given in the completely enclosed Blackfriars Theatre. Artificial light, mainly candles, was used in several indoor theatres to light the stage and the auditorium.

Beginnings of artificial lighting

In the early 17th century, Inigo Jones introduced several innovations in lighting and stagecraft, using reflectors to intensify the light sources and making use of colour on stage. The earliest known definite description of stage lighting may be found in *Sciena d'Comoedia* (1628) by Joseph Furtenbach. He describes the use of oil lamps and candles set in a row along the front edge of the stage but out of sight of the audience as well as vertical rows of lamps behind each wing at the sides of the stage. The common method of lighting the stage and auditorium was by means of tallow candles. As seen in old prints, these candles were mounted in crude hoops or chandeliers, which were hoisted aloft on pulleys to hang in dripping splendour. Gold decorations applied to the interior of the audito-

rium caught the many reflections. The inconvenience of the lighting system was that candles were expensive and hard to control. The twisted wicks had to be constantly trimmed during the performance, and this was the duty of the snuff boy. A transformation from light to darkness was effected by the agile skill of the candle snuffers.

When David Garrick used footlights at the Drury Lane Theatre in 1765, he masked the candles with metal screens. By 1784, when Richard Brinsley Sheridan managed the Drury Lane, all lights used to illuminate the stage were out of sight, hidden by the now familiar wings and borders.

A floating oil wick lamp was replaced after 1783 by the Argand oil lamp, in which the cylindrical wick was enclosed in a glass chimney to steady the flame and provide a brighter, whiter, and cleaner light source. And so the chimneyed oil lamp replaced the candle, but it was still hung in clusters above and bracketed to the walls. At the Haymarket Theatre in London, the oil lamps had chimneys of white and green glass that were controlled by levers, so that raising or lowering the chimneys could effect light changes. Actually, the result merely made the actors and scenery visible. Stage design and stagecraft had now advanced as far as was technically possible under the limitations of low-intensity stage lighting.

Introduction of gas lighting

The first major advance in several centuries was the introduction of gas lighting. A Scottish engineer, William Murdock, developed a practical method to distill gas from coal for illumination. The first successful adaptation of gas lighting for the stage was demonstrated in the Lyceum Theatre, London, in 1803 by a German, Frederick Winsor. The Chestnut Street Opera House in Philadelphia installed a gas lighting system in 1816 and supplied its own gas by installing a gas generator on the premises. (Gas stations and city mains did not come into use before 1850.) The advantages of gas lighting were immediately realized and exploited, despite the initial cost. No new methods of lighting, however, were devised for stage lighting. The conventions remained the same: footlights (*i.e.*, a row of lights across the front of the stage floor); borderlights (a long horizontal row of lights used for the general lighting of the stage from above); and striplights (a row of lights, usually mounted in a trough reflector and placed in the wings to illuminate specific portions of the stage or setting).

Even without a chimney, an open gas jet flame was brighter than oil lamps or candles. The additional advantage was control; by varying the control valves from a central point, a smooth increase or decrease of light could be effected, and at variable speeds. For the first time, to add to the realism of the play, the auditorium lights could be darkened. Elaborate central control systems were devised, with a main regulator, branch mains, more and more regulators, branch mains, and valves. This growing array of valves and pipes was organized into circuits and displayed on the "gas table"—the forerunner of the modern switchboard.

But there were also disadvantages to gas: namely, heat, offensive vapours, and the serious fire hazard of the open flame. A protective code was established to provide guards, screens, and glass chimneys and was made compulsory. In 1890, after the introduction of electric lighting, the incandescent gas mantle was developed. Although the mantle greatly improved the quality of light—brighter and whiter—the hazards of fire still remained.

Introduction of the limelight

Although Thomas Drummond, a British engineer, invented the limelight in 1816, it did not come into general use until some 30 years later. Limelight is produced by directing a sharp point of oxyhydrogen flame against a cylindrical block of lime. The tiny area of lime becomes incandescent and emits a brilliant white light that is soft and mellow. As the lime is slowly consumed by burning, the block of lime has to be slowly and constantly turned by an operator to supply the flame with a fresh surface. Since the brilliant area was very small, the addition of a mirrored reflector was necessary to give accurate control.

The intensity of the limelight permitted it to be directed onto the stage from the auditorium. Since it offered control as well as intensity, the limelight was quickly adapted to follow individual performers around the stage. The sharpness produced by the small point source made possible the creation of realistic effects, such as sunlight and moonlight, and moving effects, such as clouds, water, and fire.

Electrification. An advance of great importance was the introduction of the electric carbon arc, which was exhibited in experimental form in 1808 by Sir Humphry Davy. The Paris Opéra developed the earliest electric arc effect—a beam of sunlight—as early as 1846. By 1860 the Paris Opéra had also developed a lightning machine, a rainbow projector, and a luminous fountain. Most important, the company made the earliest spotlight, a carbon arc and reflector housed in a hood, which included a lens and a shutter.

Development of incandescent light

The next great advance in lighting was the development of the incandescent electric lamp, in which light is produced by a filament electrically heated to incandescence. The invention of a practical electric lamp by Thomas Edison in 1879 marked the beginning of the modern era of stage lighting. Gas was quickly discarded; within one year the progressive Paris Opéra introduced the new system. Two years later, at the Electrotechnical Exposition in Munich, a small theatre was erected that used electric lighting exclusively for both stage and auditorium. The success of the experiment received worldwide acclaim. In London the Savoy Theatre was the first to install the new lights; while in Boston the Bijou Theatre followed the new trend in 1882. The following year, 1883, the Landestheatre in Stuttgart, the Residenztheatre in Munich, and the Staatsoper in Vienna were the first completely electrified theatres.

At the turn of the century, incandescent lamps were in almost universal use for stage lighting, but no new methods or techniques of lighting appeared. The conventional footlights, borderlights, and striplights were merely electrified, and the arc light was used for concentrated light sources. Gradually, new improvements provided brighter lamps that were both more durable mechanically and available in larger wattages. Metallic filaments replaced carbon, and, finally, drawn tungsten filament lamps appeared in 1911. The use of inert gas in place of a vacuum produced lamps of even higher efficiency and larger sizes. The introduction of concentrated coil filaments made practical the development of the incandescent spotlight. And the refinement of the incandescent spotlight added an exciting new tool for the advance of stage lighting and the further development of stagecraft. Gradually the arc spotlight was replaced by the new incandescent spotlight, which provided all the advantages of flexibility and control.

In his music dramas, Wagner suggested new possibilities for the use of light and design in a unified production—a lyrical synthesis. Adolphe Appia and Gordon Craig gave tremendous impetus to the new plastic stagecraft. Their conception of the stage was a cubic volume of space bathed in a continuous play of functioning light. All the vast optical effects of Baroque design previously obtained with paint were now possible by means of light.

About 1902, in Germany, Mariano Fortuny y Madrazo developed an elaborate system of soft reflected light using arc lights bounced off coloured silk fabrics. The simulation of natural lighting was remarkable, but the entire mechanism was too bulky and intricate and required the construction of a special theatre. In the course of his experiments, Fortuny evolved a dome-shaped cyclorama, a rear wall surfaced in plaster. Flooded with light, it gave the illusion of infinite space and was the perfect means of simulating spectacular sky and background effects. Because it was dome-shaped, however, it occupied a large amount of stage space and tended to distort optical projections. In modified form, as a curved, hanging cyclorama, it became an indispensable tool of the new stagecraft. Earlier, Sir Henry Irving had used transparent coloured lacquers to coat lamps to produce colour effects, using separate circuits for each colour. Irving was also the first producer to introduce organized light rehearsals in his productions. David Belasco, with his electrician Louis Hartman, developed a standard of realism in stage lighting that anticipated the motion picture and that remains in effect in today's theatre. In their lighting laboratory, Belasco and Hartman developed and refined many new lighting instruments.

Individual sources were developed and used to light the acting areas from above the proscenium as well as from the auditorium.

The first dimmer boards

The earliest types of electrical dimmer board—a centralized control of the intensity of all of the lights—followed the conventions of the gaslight era. Groups of resistance-type dimmers were permanently wired to particular circuits in the footlights or borderlights. The only open or flexible dimmer circuits were the floor pockets (*i.e.*, electrical outlet boxes set in the floor of the stage) used to accommodate a wide variety of floodlights and special effects. Like the pipes and rubber tubing of the gas mains, all electrical circuits were wired solid. The location of the large banks of resistance dimmers in permanent installations of this kind was backstage in the wings and in close communication with the stage manager, who could see what was happening on stage. Later, however, even in large Broadway musicals, the array of portable switchboards may be (and is sometimes) relegated to the cellar or some other place with a scant view of the action on stage.

With the inception of individual spotlights for controlled-area illumination, in contrast to the earlier banks of footlights and borderlights, there arose a need for a flexible patch panel, in which temporary connections of such lights could be easily made and controlled. A group of spotlights could now be placed for the most effective direction, colour, and overall intensity. It became possible, for example, to place several spotlights together to achieve the realistic effect of an actor lighting an oil lamp, upstage right, without flooding the entire set with light.

The first electricity that was commercially available was direct current. For arc lights and resistance dimmers, today or 50 years ago, direct current presents no problems, and many theatres still draw their main supply of electricity from direct current. Most up-to-date theatres have the benefit of alternating current, which allows the use of more advanced dimmers.

Use of colour in stage lighting

The use of colour in stage lighting adds immeasurably to the realistic and atmospheric mood of a setting. Through the use of contrasting colours, the power of light to reinforce plastic qualities may be enhanced, and accents of appropriate intensity may be obtained. Coloured glass is the oldest medium of coloured light still in use in the theatre. As glass does not fade and comes in a variety of pure colours as well as some tints, it may be used in permanent installations for footlights or borderlights. Glass is available in cast roundels or in sheets; in sheet form, it is cut into narrow strips and mounted in holders to protect it as it expands and contracts with changes in heat. On the negative side, glass is heavy, fragile, and expensive, and its colour range is limited.

Gelatin is an expendable colour medium made of purified animal matter that is dyed and dried in sheets. It comes in a wide range of colours, it is cheap, and its light-transmission properties are excellent. Gelatin, however, is affected by moisture, and it deteriorates rapidly under heat. Plastic colour mediums are now available in the same range of colours as gelatin and have the advantages of durability, resistance to water, and strength. Although plastic costs more than gelatin, it lasts about five times longer. Later plastic colour mediums have been made of Mylar, which is virtually indestructible and more resistant to heat than sheet glass, which is much more expensive.

Light sources. The earliest incandescent spotlight used a rather heavy plano-convex lens. The socket assembly with attached reflector moved forward and backward in the housing in relation to the lens and widened or narrowed the spread of the beam of light. As higher wattage lamps appeared, larger diameter lenses were required, and soon they grew too bulky. Larger and more practical spotlights were made possible by the adaptation of the Fresnel, or stepped, lens, a type of lens invented in the 1820s, consisting of thin concentric sections that allow much more efficient use of a light source and, therefore, much smaller lamps. A slightly pebbled effect on the rear of the lens helped give an even, soft light with soft edges. Fresnel spotlights became available in wattages as low as 50 or, with a 24-inch lens, as high as 10,000.

Illumination sources. The refinement of the coiled filament made possible the development of the tubular lamp, which in turn made possible a second type of spotlight, the ellipsoidal reflector spotlight. This type of spotlight uses an ellipsoidal reflector to gather the light at the focal point of the reflector. In front of the reflector, the beam of light is shaped by means of adaptable shutters, an iris, or a predetermined pattern. One or two lenses are used as an objective to project the image. The field of the beam is of even intensity, and a hard or soft edge can be obtained by focus adjustment. The focal lengths of the lenses can be changed if necessary to compensate for the length of throw or to widen or narrow the field. Special wide-angle lenses are useful in projecting patterns, such as leaves, at close distance. Available in a range from 250 to 3,000 watts, the ellipsoidal spotlight is a highly efficient and versatile light source. The larger ellipsoidal spotlight can also be fitted with coloured quartz patterns of any design, from realistic clouds to abstract rotating patterns. Used in combinations at different intensities, a cyclorama can be flooded with light in either bold or subtle patterns.

The ellipsoidal reflector spotlight

Borderlights and striplights are available with wiring for control in three circuits. Older types had reflectors that produced a soft, even blend; later versions use a range of highly efficient sealed-beam lamps, such as the quartz halogen sealed-beam lamps, which are available in a variety of wattages and reflectors—from flood to narrow spot. Mounted in striplights, the sealed-beam lamps have become a versatile and effective source, either for lighting large surfaces or as a strong backlight wash. Television and motion-picture lighting has rapidly developed such sources, which were initiated in the theatre.

Use of floodlights

A floodlight is a refined version of the old bunchlight—a half dozen old filament lamps grouped into a square housing, usually painted white on the inside to serve as a reflector. Later, a single large-wattage lamp replaced such multiple lamps. Floodlights today are usually ellipsoidal reflectors in a wide or narrow beam. The reflectors are mat-finished, accommodate a variety of lamp sizes, and do not require a lens. The quality of light is soft and diffused; it is ideal for a wash of light over a drop or a cyclorama. Usually, more than one circuit is used to achieve a variety of colour changes. Large banks of fluorescent lamps with colour filters are effective in lighting a large and very high cyclorama, but the difficulty in dimming fluorescent sources has limited their use.

The parabolic "beam" projector was developed for outdoor lighting and slightly modified for stage lighting. The familiar carbon arc searchlight, which throws an intense narrow beam of light several miles into the night sky, is a simple parabolic unit without a lens. Such a searchlight consists of a strong pinpoint source (the arc) and a large parabolic reflector of silvered glass. The same simple optical principles were adapted to incandescent lamps for floodlighting the exteriors of buildings. The output is highly efficient, but to reinforce it and control it a lens can be added in front of the source. Used in a phalanx as far offstage as possible, beam projectors can serve as a strong source to give the effect of long rays of sunlight streaking across the stage. A most significant advance was made by hanging beam projectors so that they provided backlighting; this resulted, for the first time, in the actors' being strongly separated from the background, creating an illusion of depth and a haze.

Projections and special effects. A significant amount of lighting equipment has been developed for "special effects." Standard effects include moving clouds, water ripple, fire effects, rain or snow, painted rainbows, and fireworks. For practicality, most special effects are built around a standard spotlight housing. The effect head, containing a painted or photographic transparent disk and the mechanism for revolving it, is placed in front of the spotlight housing. An additional objective lens is used to magnify and focus the image.

The oldest effect projector, dating from the World War I era, is the Linnebach lantern, often called a "scene" projector. It is simple both in principle and in construction. A concentrated light source is placed in a deep black box, and a painted slide is placed on the side of the box left open; since light travels in straight lines, the design

painted on the glass is thus projected against a drop on-stage, greatly enlarged, at a relatively short distance. Since no lens is used in a Linnebach lantern, the light source must be powerful and concentrated. The design must be simple and bold, for any line narrower than the point source itself will be lost. The overall effect is stylized and borders on the abstract. Rear projection with at least two projectors is required for any ambitious production. Large incandescent lights replaced the original carbon arcs in the Linnebach lantern.

About mid-20th century there was renewed interest in the use of projections. Fortunately, the development of new projection equipment provided a powerful instrument to produce effects not possible before. In the post-World War II years at the music festivals at Bayreuth, Ger., Richard Wagner's grandson Wieland reduced three-dimensional scenic elements to the barest essentials and then flooded the stage with multiple, overlapping projected patterns. In later years more scenic elements were added to give variety of texture and depth to the flow of light and pattern. Still later at the Festspielhaus in Salzburg, Austria, the productions of Wagner's music dramas designed by Gunther Schneider-Siemssen elaborated this concept to achieve even more dramatic and sumptuous productions; he filled the vast, extra-wide stage with patterns of light in depth, softened with scrims (loosely woven meshes that diffuse the light) and translucent drops (backdrops with sections dyed to transmit some light). The Czechoslovakian designer Josef Svoboda did more than any other contemporary designer with "visions in space." For some productions, Svoboda used a direct, journalistic approach, massing three-dimensional screens to create a montage effect with slides and film. Polyvision, a production conceived and executed by Svoboda for the Czech pavilion at the 1967 international exhibition at Montreal, was a brilliant multimedia experience. In his other productions, which were equally stylized but more indirect and abstract, he used alternating surfaces of scrim and scenic elements to catch the patterned light, cast complex shadows, and float in depth before a seemingly infinite background.

Svoboda's productions

Innovative contributions to lighting and the use of projections were also made in dance. The American Alwin Nikolais made very original use of dancers, costumes, light, and projections to form moving geometric and abstract designs. At times, the moving bodies of the dancers become the screen for the projections. The Robert Joffrey Ballet, which is also based in New York City, in its production *Astarte,* created a unique combination of film and slides on a moving, pulsating screen.

Lighting controls. The dream of a practical system of remote control of lighting has always tantalized designers. Relays for remote switching have been commonplace for years. Motor-driven dimmers have proved practical for controlling auditorium lighting but for stage lighting are too cumbersome, expensive, and limited in speed control and are unpredictable in responding to changes. Banks of resistance and transformer switchboards were too bulky to be installed in a light booth at the rear of the auditorium with a clear view of the stage.

The first primitive but successful remote-controlled dimmer was used in 1890 but not perfected until later; it used a reactor coil operating on a relatively small amount of direct current to control a huge amount of alternating current.

Remote control became a reality largely as the result of the development by George Izenour of Yale University in 1948 of a dimmer using the thyratron, a type of electron tube. His concept brought continuous and instantaneous control to remote systems for the first time. In addition to its simplicity of operation, the development gave the lighting designer the facility for an "infinite" combination of preset cues. It also became practicable to install the control console at a vantage point in the auditorium from which the lighting designer (or operator) could see every nuance of lighting on stage.

Meanwhile, transformer manufacturers achieved a major breakthrough in design with the development of new magnetic alloys. The result was a reactor with great efficiency and speed. This new reactor, combined with the silicon rectifier, another post-World War II development, resulted in a device called a magnetic amplifier, which has no moving parts or tubes and can control large amounts of alternating current with no time lag.

Tube manufacturers, meanwhile, were furthering the development of the transistor, namely, the silicon-controlled rectifier, or SCR, a transistor-like device that can handle heavy currents and perform in the same manner as the thyratron tube but with the advantage that it is compact, lightweight, inexpensive, efficient, and long-lasting. Control consoles using all three types of dimmers are in current use.

The design of lighting control boards is no longer a matter only of electrical engineering, in which the only concerns are engineering requirements or code specifications. Previously, the lighting designer had to make the most of whatever the engineers had given him. Now the remote lighting-control console gives the lighting designer a flexible, artistic tool. Freed from the limitations of the mechanical controls and of the personnel who would operate them, the lighting artist can concentrate on the execution of his concept. No longer is there any reason for the mechanical limitations to interfere with the lighting.

Advances in stage lighting

The biggest advance in stage lighting control in recent years has been the ability to record instantly and recall on cue the entire contents of a stage picture. A video display unit can present the information on the lighting state for any cue in an easily readable form. The present systems work on a principle of one dimmer for each light in order to eliminate cross patching of circuits. In the previous generation of preset boards, each lantern was equipped with a number of dimmers and several cues could be preset. On cue the board cut from one set of dimmers to another to effect the change. The memory system board is much more flexible and is probably capable of even further development and sophistication. The development of memory system boards and new lighter weight dimmer packs are a material help to touring.

Lighting design. In the era of painted wings and drops, the standard illumination was an even, flat wash from footlights and borderlights. Architecture and furniture, including tables and chairs, were painted into the background with heavy shadows and exaggerated perspective. The actors had to resort to grotesquely heavy makeup to convey any facial expression, while their very presence (and every movement) was visually in conflict with the forced perspective of the painted scenery. By contrast, the impressive effects of modern lighting made it seem almost limitless in its possibilities. Borrowing effects from Rembrandt and other painters, the theatre designer began to "paint with light"—putting light where he wanted it and taking it away from where he did not want it. Thus, romantic effects were born, such as that of the lone figure in a shaft of searing light, isolated by darkness. The first requisite of stage lighting, however, is visibility. Good illumination provides plasticity and modeling of the actors and of the inanimate objects. Superior lighting is orchestrated to underline the development of the drama.

Many plays permit no approach other than realism, which must be achieved by suggestion. Nature provides the model. On a cloudy day, the overcast sky diffuses the direct sunlight and produces a soft, shadowless light of low intensity and cool colour. Intense "sunlight" on stage and the attendant light of the bright sky together produce reflected light that diffuses or fills in shadows, while the ambient light of the stage "Moon" reflected from sky, trees, and buildings is too weak to wash out the shadows. So, by means of the direction, diffusion, and intensity of light, as well as its colour, it is possible to suggest time, place, and season.

The means of suggesting natural lighting indoors are more arbitrary. The simulated sky or sunlight seen through a door or window—a scenic element provided by the dramatist and the designer—is essential to indicate the time of day or night. To render the feeling of bright daylight flooding a room, the strong motivating light (*i.e.*, light that suggests the direction of its source) must be supplemented with additional light from other directions for adequate illumination. If only a sliver of sunlight creeps through a parted curtain in a dark room as the scene begins, the mood may be retained as the scene progresses as the illumination of important areas is slowly increased. Artificial light indoors is easier to suggest because it more closely approaches the normal quality of stage lighting. Actual light fixtures are used on stage to suggest the sources of the light, and opaque shades can be used on some of these fixtures so that they cast actual patches of light against walls and furniture. The exteriors seen through doors and windows are darkened and different in colour from their appearance in a brightly sunlit scene. The walls fall off in shadow even though the general illumination is more diffused and even than in daylight. Light serves as a unifying medium for the stage composition. It is a mobile and changing accent that reinforces the action, sustains the mood, and focuses the attention of the audience. Light and shade, brightness and contrast, define the size and shape of objects, but it is colour that creates emotional response, mood, and atmosphere.

The dynamic potential of lighting is best realized when the changes of light underscore and propel the development of the drama. The first real attempt at creating space and a real haze on stage (in a depth of 30 feet) came into being with the use of backlighting—light emanating from the rear of the stage rather than the front—which made the actors appear to be pulled away from the background (Figure 25). At first, parabolic beam projectors were used to achieve this effect, then ellipsoidal spotlights, and later, in some instances, sealed-beam parabolic reflector lamps. The ellipsoidal reflector spotlights afford the best control and the least spill. The beam projector may be deployed in a battery offstage to create the illusion of paths of sunlight or moonlight or a strong sidelight or crosslight. For strong crosslight, clusters of low-wattage units were supplanted by powerful ellipsoidal spotlights, hung low. With the addition of lamps attached to the auditorium's boxes, or box booms, besides the lamps already on the balcony rail or ceiling coves, modern lighting began to take shape. The open stage of the musical and dance furthered the development of effective lighting.

Use of backlighting

In bold outline, modern lighting can be described in terms of a square consisting of a lucid pattern of strong

The square pattern of modern lighting

(Right) Alfred DeSio

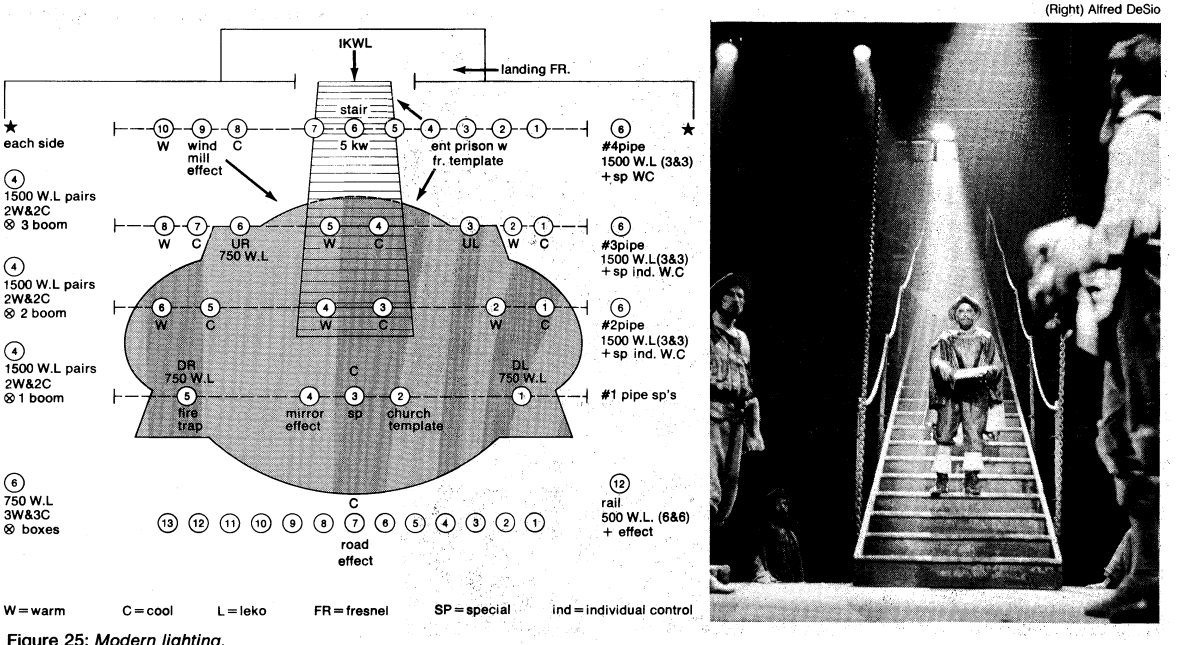

Figure 25: *Modern lighting.*
(Left) Light plan for *Man of La Mancha.* (Right) Scene in the New York production showing the use of backlighting.

backlight, paths of strong crosslight, and the necessary fill light from the front from the boxes and first pipe (*i.e.,* lights hanging from a horizontal pipe just inside the proscenium) on stage, plus special lights as needed. Richer colours are used in the backlighting and crosslighting. Lights creating warm and cool effects are wired to circuits that allow them to be controlled right, centre, and left stage. The crosslighting coming from offstage and from the box booms is usually less saturated in colour. The lights on the balcony rail give a pale wash—passive illumination to produce visibility without destroying the sharp modeling of the backlighting and sidelighting. Special lights, in colour or clear, cut through particular areas from the box booms and the pipes on stage.

When box sets began to go out of style, and suggestive sets, skeletal fragments without ceiling and walls, were introduced, the necessary lighting technique was already within reach in the layouts for musicals. There was need for more special lights, different circuiting, softer colours, more pattern projections, and more intricate, overlapping changes of light. The pattern of back, sides, and front, however, still holds; it is a clear-cut, three-dimensional approach, with distinct functions meshing into a controlled pattern.

For the most part, ellipsoidal reflector spotlights are used to cover acting areas from all locations. Fresnel spotlights are used for area washes or to accent plastic scenery elements. The appearance of scenery as it is illuminated by the lighting intended for the acting areas is totally unpredictable; it is necessary to provide separate blending or accent lighting for most plastic scenery. Patterned projections, such as leaves or abstract patterns, may be used in wide-angle, ellipsoidal spotlights to project on scenery that is solid or even made of gauze.

The three-dimensional approach to lighting developed within the confines of the proscenium stage; it is also valid for the thrust stage or arena theatre. For theatre in the round, the predominant angles for lighting tend to be sharper and also to be steeper, to avoid spill into the audience area that would disturb the spectators. The ellipsoidal reflector spotlight is used for all acting areas, and an added high hat (a hollow tube that extends six to 12 inches) will confine unwanted spill as well as hide the lens and colour frame.

In simple language, lighting is a matter of hanging the right instrument in the right place and focusing on the right target. Stage lighting cannot be mastered except through the observation and experience that are necessary to learn the practical and aesthetic functions of light. It is essential to know the physical characteristics of different light sources and how and when to use them to best advantage. It is also mandatory to learn the complexities of control and how to build lighting changes. Stage lighting must be more than good illumination. Light must be used as a subtle flux, exerting a subconscious influence that unifies all the media of the theatre.

The creative concept formed for lighting a production requires that the essential qualities of the play be understood and absorbed. The theme or main line of the script may suggest an overriding motif: enervating heat, damp clamminess, dappled sunlight, cold penetrating north light, a feeling of being in limbo or underwater. The final choice must satisfy the particular qualities of the production and the concepts of the playwright, director, and actors, as well as the designer. Attending run-throughs in the final period of rehearsals reinforces previous impressions and suggests refinements in the rhythmic changes of light required. The actors' performances suggest lighting changes that can enhance the emotional range of the total performance.

(Ra.Ho.)

STAGE MACHINERY

In the modern theatre, a variety of mechanisms are used to erect, position, and manipulate scenery. These devices fall into three categories: hoists, lifts, and horizontal drives.

Use of hoists

Hoists are used for flying (*i.e.,* raising or lowering) scenery up to or down from the stage penthouse; lifts are used to bring up scenic elements from beneath the stage floor; and horizontal drives are used to slide platforms, flats, and large properties from the wings onto the visible part of the stage or from one area of the stage to another.

Hoists are the most common type of mechanism in the theatre, and there are three types: counterbalance, electrical, and fluid drive. The simplest method of hoisting is by counterbalancing, and there are two types: the hemp system and the iron-counterweight system. In the hemp system, sandbags and iron ingots are used as a counterbalance. Four to six lines are attached to a batten; each line passes over its associated "loft block" and then goes to the master headblock sheave. The iron-counterweight system is similar except that the lines are made of wire rope and the operating rope is not directly attached to the hoisting line. Instead, it is a fixed system, held between the master headblock sheave and a fixed-tension sheave. For counterweighting, there is an arbor or carriage in which the iron weights are placed. Finally, there is a lock-rail combination to ensure the safe use of the counterweights.

In an electrically powered stage hoist system, electricity may provide only the pulling power while still requiring counterbalancing (electrical counterweight-assisted hoists), or it may provide the lifting ability and the force needed to counterbalance (pure-power hoists). There are two types of electrical counterweight-assisted hoists, traction drive and linkage drive. In the traction-drive system, the hoisting line-counterweight system is not directly coupled to the electric motor drive, and slippage may occur during acceleration and deceleration of the payload. It varies according to velocity and the weight of the payload. Consequently, traction-drive hoists are utilized only when a relatively constant weight is lifted at a constant velocity, such as the asbestos curtains, light bridges, and orchestra shells. The linkage drive is similar to the traction-drive hoist, except that the hoisting lines are attached directly to the motor.

The second category of electric hoist is the pure-power type, in contrast to the counterweight-assisted type. It consists of a motor (usually placed on a gridiron), a brake, a gear reducer, and a drum around which several hoisting lines wind. At the Metropolitan Opera House in New York City, there are 110 motors linked into a single console that can be run by a single operator.

The third type is the fluid-drive system, in which an electric power unit is used to run a fluid piston, which in turn moves the hoisting lines. Advantages to this system are that the electric generator does not have to be physically near the fluid drive, so the system is virtually noiseless, and that the operator may divide the power between any number of pistons, a feat not possible with an electric motor alone.

Use of lifts

Lifts are used in the theatre to move platforms, actors, scenery, and other production elements above or below the stage floor. In contrast to the hoist, which is supported by the over-stage structure, the lift is supported and guided by the stage floor or the cellar floor below the stage. The two general types of lifts are the architecturally integrated and the temporary production apparatus.

Architecturally integrated lifts must be designed in accordance with local building-safety codes: in New York City, for instance, only two types can be built into a theatre. One of these, the direct-plunger lift, is hydraulically driven, using a piston attached to a portion of the stage floor. The piston operates under hydraulic pressure (like the pure-power hoist) and is expanded and collapsed to elevate the associated platform. The other type, the screw-actuated lift, is either electrically or hydraulically driven and coupled to a vertical screw through a nut in which the upper end of the screw is connected to a portion of the stage floor.

The layout and installation of permanent architecturally integrated lifts must be carefully determined; the frequency of use and the type of events to be accommodated must be envisioned, along with the attendant inflexibility of the permanent mechanization of the stage floor. In general, architecturally integrated lifts are successfully employed where they are designed to meet the specific production needs of a permanent resident company.

Use of horizontal drives

Horizontal drives are used to rotate, propel, and project scenery, actors, properties, etc., from offstage areas onto the acting area. To meet audience demand for rapidly

changing scenery, designers often utilize a system of horizontally moving platforms. Although the articulation of horizontal motion on the stage is unlimited, there are several established configurations that are easily identifiable. These include the wagon, in which scenery is built on a low platform mounted on casters so that it can be quickly rolled onstage and offstage; the jackknife stage, similar to the wagon except that it is anchored at one corner from which it pivots onstage and offstage; and the revolve or turntable, in which several settings are built on a huge circular platform, or turntable, which is revolved so that only the appropriate setting may be seen through the proscenium. In each of these, the scenery may be changed when the unit is offstage and then rolled back on. Treadmills and revolving segments are also used. (W.Cr./C.Ba.)

COSTUME DESIGN

Theatrical costumes are neither historical nor contemporary; they elaborate a style and convention of their own. Their success in any production depends in large measure on the designer's ability to understand and interpret the director's production concept. The spirit of the production and the director's aims may call for special emphasis on certain characteristics in clothing. Designs may be copies of period costumes or may attempt only to evoke a period.

Museums and other repositories of the decorative and literary arts are rich sources of inspiration. Since the subject of theatrical costume design is so closely related to the art and history of dress, the reader's attention is called to the article DRESS AND ADORNMENT, in which these topics are treated comprehensively.

Historical development. *Classical theatrical costume.* Theatrical costumes were an innovation of Thespis, in Greece in the 6th century BC, and theatrical costumes are still called "the robes of Thespis." Athenians spent lavishly on the production and costumes at the annual drama contests since each poet was given a wealthy citizen, the *chorēgos,* who, encouraged by the honour of a separate state impresario's prize, tended to make the event a demonstration of his spending power.

The earliest tragedies were played in long, rich robes similar to those worn by the priests of Dionysus. To increase the height and importance of the principal actors, Aeschylus introduced the buskin, Asiatic elevated boots, called *kothornoi* in Greek, which became one of the chief characteristics of the Greek tragic actor. The soles increased in thickness according to the status of the wearer. To balance his height, padding often was used to add bulk to the actor's stature. Members of the chorus did not wear these boots so that they could dance with ease. The performers were clad in stage tunics, chitons, which were long-sleeved, high-girdled, and elaborately embellished, as were their long and short cloaks (himations and chlamyses). Aeschylus was renowned for the brilliant mounting and costuming of his tragedies, and by the time of his death, in 456 BC, a traditional tragic costume had evolved. Each costume was in a symbolic colour.

Greek masks

The most important feature of the Greek costume was the mask, which indicated the character's age, sex, station, and customary mood. The masks were made of linen, cork, or wood and were skillfully carved and painted. Their funnel-shaped mouths are thought to have acted as megaphones to amplify the voice. In his *Onomasticon,* Julius Pollux, a Greek writer of the 2nd century AD, gives a detailed account of the special features accorded to each character. He enumerates 30 masks used in tragedy and lists the characteristics of the comedy series, which are particularly exaggerated and grotesque. The *onkos,* a high ornate headdress, crowned some masks, adding height and thus importance to the wearer.

In the Doric mimes and Old Comedies, the upper class characters wore stage chitons and cloaks, and the lower classes and slaves wore short tunics, revealing pendant phalli. These character tunics were often worn under light-fitting vests and over grotesque padding of torso and buttocks (Figure 26).

Mimic horses, satyrs, bird figures, and other animal imitations were much in evidence. Aristophanes, in *The Wasps, The Birds,* and *The Frogs,* calls for all manner of such figures and clothing. Actors performed in skins and wore horses' heads, birdlike visors, and mock wings.

In the later comedy of Menander, the phallus and mythological elements were abandoned, for his intention was to represent urban life, and the costumes worn reflected this intention. Masks became more stereotyped; they were used over and over again for character parts in different plays. Colour symbolism still held great importance.

Roman drama had its indigenous roots in the Etruscan mimetic dances. Mime without masks, together with acrobatic dancing, became a favourite part of the day's entertainment at the games or circuses. Plays, too, were among the diversions; to satisfy the crowd's taste for realism and sensation, legions of spectacularly dressed soldiers were introduced to the tragedies. Costumes for tragedy were modeled on Greek styles; by Roman times the name *cothurnus* (from *kothornoi*) had come to designate the tragic genre itself. Kings and queens in tragedies wore appropriate padding, tall wigs, and sleeved *syrma* (the robe corresponding to the chiton). Bands of bright hues decorated the costumes of happy characters, and gray, green, or blue those of fugitives. Gods and goddesses were distinguished by their insignia; seers were clad in woolen garments over a shorter, less full *syrma;* and huntsmen rolled a purple shawl around their left arms. Slaves wore leather jackets and light breeches or braids indicating their barbarian origin. In the *fabula palliata,* Roman comedies on Greek subjects and based on Greek models, actors wore chitons and the pallium, a cloak resembling the himation. In tales of Rome based on Greek models, and *fabula togata,* actors were costumed in the mantle and toga. The heroes of plays dealing with Roman history, called *fabulae praetextatae,* wore togas with the *praetexta* decoration indicating magistrates.

The *fabula Atellana,* rustic plays originating in southern Italy, were given both public and private performances. In the homes of patricians, young noblemen often took the parts of the standard characters—the bragging, greedy Maccus, the stupid Bucco, the foolish miser Pappus—wearing masks to disguise their identities. Their masks, known as *personae,* were decorated with hair; they were not worn by professional actors until introduced by the actor Quintus Roscius in the 1st century BC. Before their introduction, wigs (*galeri*) were worn. Also, Italian comedians wore a flat slipper called the *succus.*

Roman mime costume

The garment peculiar to mime productions was a gay coloured patchwork jacket called *centunculus,* and this name became applied to mime actors in general. At Corneto, a tomb painting depicts Stupidus (the fool of the mimes) wearing another coat covered with coloured patches, a tall pointed cap decorated with a tassel, and a square, short cloak known as a *ricinium.* Because of this garment, the mime players were also known as *riciniati.* The producers of the mimes also provided their perform-

ers with gigantic phalli. "The mimes," it was said, "pulled down the gods and heroes from on high and provided them with phalli."

As drama in Rome declined, the mimes introduced plays on the theme of the oldish cuckold and the frail and plotting lover, which became most bawdy and obscene during the 6th century AD, as did the pantomimes featuring lavish licentious entertainments. Such entertainment continued to be presented until the fall of the Roman Empire later in that century. Through the Early Middle Ages, jugglers, fools, and small mime troupes roamed through Europe, but a record of organized drama has yet to be found.

Medieval costume. Originally, mystery plays were performed before the altar, with the actors, priests, and clerics wearing church vestments. The miracle plays, which retold incidents in the lives of saints, were also originally played by clerics and actors. Inventories were kept of garments made and bought, and these lists indicate that Adam and Eve were clad in close-fitting white leather, God in bishop's robes, and Jesus in a simple white robe. Cain, Abel, Joseph, Lazarus, and other biblical characters would appear in contemporary clothes, hoods, pourpoints or doublets, or loose gowns. A female character was indicated by the simple addition of a kerchief on the head. During the 12th century, when the performances moved outside the church, priestly vestments were still the main costumes.

When European craft guilds became responsible for the mounting and dressing of these productions, their scenic plans became ornate and ambitious, and the early simplicity was lost. The exotic robes, angels with gilded limbs, halos, and ornate wings may be seen in the paintings of the 15th-century Flemish masters Lucas van Leyden, Memling, and Van Eyck. Satan and his devils enjoyed great popularity with the large audiences. Their grotesque masks, lashing tails, fangs, and snouts in lurid blacks, reds, and blues are well recorded by artists of the period. There is a large collection of devil masks preserved at the Tiroler Landesmuseum Ferdinandeum in Innsbruck, Austria.

In the morality plays, concerned with allegorical subjects, that became popular toward the end of the 14th century, costumes personified the virtues and vices, life and death, and similar abstractions. The Bible stories and morality dramas were also taken through the streets on two-story pageant carts; these processions of gorgeously dressed groups and tableaux can be seen in 15th-century paintings such as Piero di Cosimo's "Triumph of Theseus and Ariadne" and Botticelli's "Triumph of Chastity."

Renaissance costume. From the early 14th century, in addition to religious performances, secular theatre also developed in the form of popular celebrations, spectacles, royal and ambassadorial entries, weddings, and other lavish entertainments that surround the royal courts. A monarch entering a town or dominion would do so with a large entourage in full pomp and heraldic dress. These entrances included a series of stops at stages placed at various intervals en route. *Tableaux vivant* and mimes were performed in costumes similar to those worn in the mystery and morality plays. With the gradual decline of church power and the revival of classic ideas, Renaissance designers found their inspiration in the myths and legends of Greece and Rome.

Costumes of royal celebrations

Countries and designers competed in the sumptuousness of their displays. The progresses in England, *entrées* in France, *trionfi* in Italy were based on the triumphal processions of the ancient world. The monarch or emperor was glorified as the hero, and his entourage and vassals appeared in semiclassical grandeur. There were floats of allegorical figures and legions of splendour such as Caesar had never dreamed.

The Italian designers, who included artists as eminent as Leonardo da Vinci, led the field. Costume plates of specific festivals indicate the awe-inspiring splendour of these occasions.

At court, the tragic, comic, and satiric dramas of classical theatre were revived, with the addition of entertaining entr'actes. From these descended the intermezzi—pantomimes that included song and dance. Again, the designers wished to appeal to the eye of the Renaissance public. The designer in charge of theatrical productions for the court of Mantua in the mid-16th century explained in his treatise on stagecraft that the Italian object was to captivate and charm the audience:

> I tell you especially that I make efforts to dress the actors always in as noble a fashion as is possible for me, but in such a manner that there is a sense of proportion among them, in view of the fact that the rich costume . . . particularly in these times when pomp is at its highest peak, adds much reputation and beauty to comedies, and even more to tragedies. I would not hesitate to dress a servant in velvet or colored satin, as long as his master's costume were embroidered or decorated with gold, so rich that there would be maintained the proper proportion between them. . . . I do my utmost to dress the actors very differently from one another, and this is of great help, both in adding beauty and in facilitating the understanding of the plot.

In 1589 the sophisticated Florentine court produced an intermezzo called "Harmony of the Spheres," a spectacular type of masque, with music, that was the immediate forerunner of opera. Etchings of the Grand Ducal fetes in Florence of 1606, 1608, 1615, and 1616 show groups of dancers in towering plumed classical helmets, Roman costume, and cuirass (body armour) worn over doublets, with Roman labels hung from the cuirass, over breeches and hose, to cover the thighs. The Renaissance developed these labels into an exaggerated ornate skirt and named it the *tonneler.* Each item of costume was decorated with a profusion of curved ornaments, flowers, vines, and animal and human forms, suggestive of Baroque design.

Strongly influenced by these Florentine specialists during a visit to Italy, Inigo Jones transformed English court masques and entertainments in the early part of the 17th century. The Duke of Devonshire's archives at Chatsworth preserve his designs. Through him, English designs followed the Italian pattern: breastplates molded to the body, plumes, helmets, and various Roman kilts mixed with modified elements of contemporary dress. Ladies' costumes followed the dress of the period more closely but strove for a looseness and for the transparency of fabric typical of classical dress. Decolletage and low-cut bodices were much in evidence, with bosoms often veiled with gauze. The cost of these costumes was borne by the wearers, the lords and ladies of the court. There seemed at times no limit to their embroidered, bejeweled luxury and fine headpieces.

Early English costumes

Little pictorial evidence of the first public theatres in England survives. It is known, however, that the best part of the actors' wardrobes were gifts from wealthy patrons. One drawing of Shakespeare's *Titus Andronicus* dated 1595 shows contemporary costume mixed with *costume à la romaine* similar in design to the courtly work of Inigo Jones. Mixtures of styles and periods were accepted by the audiences. Certain famous characters such as Shakespeare's Sir John Falstaff became identified with a particular type of dress; a sketch that Inigo Jones made of Sir William Davenant in *The Temple of Love,* produced in 1635, was inscribed: "a roabe of russet Girt low w^{t} a great belley . . . the sleeues shorte . . . buskines to shew a great swolen legge . . . a great head and balde. Like a Sr Jon fall staff."

In Italy, the commedia dell'arte presented a multiplicity of character and types. Their fine costumes evolved from garments representing different Italian provinces and rustic personalities and gradually became stylized, subject to the dictates of changing taste. To make the costumes decorative or funny there were exaggerations in form and colour. The characters of the lovers appeared in contemporary street clothes, and comic personages in curious or grotesque garb with leather half-masks (Figure 27). They were ideal theatre clothes for they identified the characters, allowed complete freedom for movement and acrobatic dancing, and charmed the spectator with their amusing devices, patterns, and colour motifs. A typical character, Arlecchino, originally dressed in shreds and patches, emerged by the 17th century in a suit of red, blue, and green triangles arranged symmetrically and joined together with yellow braid. One hundred years later, the triangles became diamonds, and his soft cap was exchanged for a pointed one. Now as Harlequin he still appears as a central character in English pantomime, carrying his original

Figure 27: Typical costume worn by players in commedia dell'arte. Anonymous German engraving of Arlecchino, early 18th century. In the Victoria and Albert Museum, London.
By courtesy of the Victoria and Albert Museum, London

wooden sword and wearing his black mask. A fine pictorial record of the commedia characters may be seen in the works of the 17th-century French artists Jacques Callot and Antoine Watteau.

The commedia dell'arte performed throughout Europe and was especially popular at the French court. Molière's company also toured France in improvised farces based on the style of the commedia. Actors in his comedies played in contemporary dress, but they also performed with the King and court in brilliantly dressed spectaculars at Versailles. Texts were by Molière, music by Jean-Baptiste Lully, and costumes and decor by Jean Berain.

The introduction of actresses

The Restoration of the English monarchy in 1660 led to the opening of theatres again, and the great innovation was the introduction of actresses. Talented, confident, and flamboyant ladies replaced the Elizabethan boy actors. Records indicate that "splendidly clothed" persons lent costumes, and wardrobe keepers now aided players in selecting from available stock. The ladies chose the gown most becoming and elaborate. No attempt was made at character dressing or historical accuracy.

Costume in Baroque opera and ballet. A galaxy of specialists joined the courts of Louis XIII and Louis XIV, with Giacomo Torelli, the chief originator of Baroque theatre, arriving from Venice. This monumental scenic style included magnificent colonnades, temples, palaces, and scenes so lavish that only the great ruling houses could afford them. Designers such as Torelli brought great prestige to their patrons. An outburst of Baroque opulence bore witness to the power and splendour of the Sun King. In France in the early 17th century, the designer Daniel Rabel worked inventively, producing many witty and droll effects and costumes of grotesque conception. Burlesque costume had found its way to amuse the court.

Henri Gissey and the great Jean Berain were attached to the Royal Cabinet of Louis XIV. Gissey is most famous for his celebrated Carrousel (1662), a horse spectacular never since surpassed in its magnificence—500 noblemen in plumed regalia escorted by a greater number of elaborately dressed attendants. Costumes represented different nations, each having a particular colour scheme: the Romans were in red and gold led by the King; the Turks in black and yellow; the Indians in white and gold; the Americans in green and gold. The marvelous scene played in front of the Louvre was indeed the grandest fantasy in costuming, with both horses and riders decorated in full Baroque trappings.

Chroniclers record gorgeous costumes appearing in ballet, opera, and dramatic offerings; gold brocades covered with lace, diamonds, emeralds, ribbons, and immense trains graced the stages of France. The French surpassed the Italians in their opera costumes, which were richer than any elsewhere. In the designs of Jean Berain there is a homogeneity of style that is the mark of a great master. In 1680 women first appeared on the operatic stage. Berain's costumes for them were serious and noble in style, based on contemporary court dress. Their tight bodices and flared basque shirts had decorative overskirts with trains; they followed an almost uniform silhouette. The headdress, also carefully designed, was a formal arrangement of feathers or lace. Male garments were in the Roman style, the tunic fitting tightly to the chest, worn with *tonneler* (short skirt), high boots, and cape. To avoid monotony, Berain devised an amazing variety of ingenious trimmings—embroideries, fringes, slashings, puffs and paddings, inlaid ornamental motifs, pastes, and semiprecious stones to punctuate every small decorative panel and part (Figure 28). Scaly bodies, bejeweled ones, serrated leaves—every elegant or fantastic theatrical device was used to create a sophisticated ensemble. Berain coordinated all aspects of scenic decor in an equally in-

Berain's costumes

dustrious way and as a decorative artist dominated French and European taste and costume design.

After Berain died in 1711, the sumptuous Baroque of the early years of Louis XIV declined. Berain's son Jean succeeded his father as court designer and carefully documented his father's drawings, which are now kept at the Musée de L'Opéra and at the Victoria and Albert Museum in London.

By 1721 Claude Gillot's designs for the ballet *Les Éléments* showed a great change in taste. Heavy fabrics and embroideries used by Berain were replaced by lighter, more delicate weights and appliqués. Ladies' costume, following the caprices of the contemporary modes, included a panier. Peasant and rustic characters began to appear and were most popular with the court, in beribboned garments of pastel satins and silks. Extensive records of these costumes exist in the form of engravings.

Costume of the 18th and 19th centuries. Jean-Baptiste Martin, who was appointed designer for the Paris Opéra in 1748, devised decorative and amusing Rococo variations for the male dancer's traditional costume. Incas, Africans, Chinese, and Mexicans graced his ballets, and under his direction the *tonneler* took on an elliptical shape.

All the elegance and sophistication seen in Rococo court circles of Louis XV were brought to the stage by Martin's successor, Louis-René Boquet. His designs were theatricalized versions of the new fashionable silhouette. Boquet clothes were delicate, artificial, and pale in tone, trimmed with garlands and Rococo finery. All Europe imitated the French ideas, the English and German facsimiles without Boquet's innate good taste.

Denis Diderot wrote in 1758 of the current fashions in the French theatre:

> Ostentation spoils everything.... Wealth has too many caprices: it can dazzle the eye, but not touch the heart. Beneath the garment that is overloaded with gilding, I never see more than a rich man, and it is a *man* I look for....
>
> Comedy ought to be played in informal dress. On the stage it is not necessary to be either more or less dressed up than one is at home....
>
> The more serious the play, the more austerity there must be in costume....
>
> What expense were not our actors put to for the production of *l'Orphelin de la Chine*? How much has it not cost them to rob this work of part of its effect?

Historical authenticity of 18th-century French costumes

In 1755 the great French actors Henri-Louis Lekain and Mlle Clairon, who were also bent on more simplicity and historical accuracy, dressed Voltaire's play *L'Orphelin de la Chine* without the hoops or overskirts of currently fashionable dress, while the men appeared dressed as Tartars and Chinamen. In 1789 the French tragedian François-Joseph Talma provoked a scandal by appearing in Voltaire's *Brutus* in a severely simple toga appropriate to the ancient Roman setting of the play.

In England David Garrick abandoned heroic Roman garments in favour of realistic, contemporary dress, which he designed himself to insure the simplicity he desired (Figure 29). The Irish actor Charles Macklin was first to play Shakespeare in authentic "ancient dress" when he appeared on the stage in 1773 as Macbeth in a Highland military habit.

Figure 29: David Garrick costumed for the role of Richard III; engraving by William Hogarth, 1746. In the British Museum.

Public knowledge of historical costume was increasing, though some critics disapproved, believing it weakened the plot. The thirst for historical accuracy won the day, in part because of the efforts of its major champion, the 19th-century playwright and antiquary James Robinson Planché. A playbill of a Planché production of 1824 read:

> Shakespeare's Tragedy of King John with an attention to Costume never equalled on the English Stage. Every Character will appear in the precise HABIT OF THE PERIOD, the whole of the Dresses and Decorations being executed from indisputable Authorities.... King John's Effigy in Worcester Cathedral... Queen Elinor's Effigy in the Abbey of Fontevraud.... Illuminated Mss in the British Museum, Bodleian and Bennet College Libraries... &c.

Planché's success amply reimbursed the management for the enormous expenditures required to make even the meanest extra's garments authentic. Correct costumes became the order of the day. The actor-manager Charles Kean splendidly mounted a series of Shakespearean productions in London in the 1850s. In Germany, August Wilhelm Iffland's productions closely followed the same reforms, and costume designers were urged to emulate the past.

Dancers, too, wished to be liberated from the pannier and *tonneler.* In *Pygmalion,* a ballet of her own composition, Marie Sallé danced in London in 1734 dressed only in a muslin robe like that of a Greek statue; she wore no panniers, petticoat, or bodice, and her hair was loose and without ornament. The French ballet master Jean-Georges Noverre had advocated drastic reform in dance dress as early as 1760. He proposed to put his dancers in simple draperies of contrasting colours, worn in such a manner to reveal the figure in movement. Both male and female dancers became increasingly impatient with the hampering Rococo conventions; and as dancing technique grew even more intricate, designers prepared innovations that anticipated the general development in fashion. By the end of the 18th century, every woman had abandoned her panniers and was "dressed only in a single muslin robe."

Dance costume

Civil codes at the start of the 19th century greatly aided those who would reform theatrical costume. The fashion for classic robes and tunics modeled on Greek and Roman patterns took to the streets; the high-heeled shoe was replaced by a flat slipper.

Leading French ballet designers of the 19th century were Auguste Garneray and Hippolyte Lecomte. The former's work shows ingenuity in adapting contemporary dress to suggest different lands and other periods. The latter was originally a painter of historical episodes; accuracy rather than imagination is the distinguishing quality of his designs. In 1832 the influence of the Romantic period was first seen in ballet with a production of *La Sylphide.* Eugène Lami designed for Marie Taglioni, the greatest dancer of her day, a muslin dress, an ethereal costume that became the new uniform of the classical dancer. This design is still worn today.

Opera and dramatic productions followed Planché's regard for period and regional detail. Unfortunately, the elaborate stage settings and the costumes were seldom coordinated successfully. This led the Duke of Saxe-Meiningen to design his own productions, as he wished to achieve an integrated style. He was the first of the directors who controlled all aspects of production. His example has been followed by the most prominent directors of the 20th century.

Amid spectacular scenery, large ensembles danced and mimed in fanciful versions of contemporary and historical dress in the ballet-extravaganzas of the 1880s (forerunners of the Folies-Bergères revues of Paris) that played at La Scala in Milan and the London Alhambra. The ingenious designer C. Wilhelm (original name C. Pitcher) translated insects, flowers, birds, and reptiles into dance costumes. The main interest, however, lay in framing the female figure, and most of the costumes were designed to reveal as much as the law permitted.

20th-century costume. At the turn of the century, the theories of Appia and Craig called for symbolism and voiced a strong reaction against the naturalism of Meiningen and the Moscow Art Theatre. Appia advocated

that stage costume should evoke and suggest, but never copy historical lines.

A painters' theatre arose after Diaghilev's presentation of the Ballet Russe in 1909 in Paris. The brilliant palettes and well-coordinated decors (of Bakst, Benois, and Roerich) were praised. Nathalie Goncharova's design for *Le Coq d'or* in 1914 was unprecedented in its use of vivid colours, chiefly shades of red, yellow, and orange, with other colours for discordant emphasis. The forms of the costumes and their decorations were based on Russian folk dress (of fairly recent times, though transformed and made uniquely of their epoch by the jagged influence of Cubism). Avant-garde artists of many of the flourishing movements of modern art—Cubists, Constructivists, Surrealists—brought about an acceleration of innovation in design concepts, which in previous centuries had evolved gradually throughout Europe.

Expressionist theatre costumes

Appia, Craig, and Diaghilev led others to experiment. Meyerhold's 1907 production of Leonid Andreyev's play *The Life of Man,* with expressionistic costumes designed by Theodore Komisarjevsky, was purely mechanical in its design. The German advocates reasoned that since the actor man is enclosed in the space of the stage, either the stage must be arranged according to the illusion of reality so as to fit the natural man or the natural man must be transformed to match the cubist and abstract space of the stage.

As modern dance evolved, its rapid rhythms and pace offered the costume designer new challenges and scope for original work. The productions of Merce Cunningham and Alwin Nikolais in New York City presented unique shapes that attempted to express the exploration of time and space. Nikolais made his costumes part of a total stage design, a theatrical abstraction of the way he saw man—as part of a socioeconomic mechanism, an agreeable but not a central part. Accused of dehumanizing the dancers, he maintained they are rather an expression of a greater state of being for man, of the experience of living in a world of motion, sound, colour, and action, which strongly affects them and is affected by them.

The rise of the American musical owes much to the close collaboration of the composers, writers, and choreographers with the designers. In a musical the costume designer's task is manifold. The designs must capture the spirit of the music and lyrics, interpret the period, heighten the characterization of the actors, and help the dancers in their varied, often athletic routines. The costumes for *My Fair Lady* (1956) and *West Side Story* (1957) were especially successful in these respects.

New concepts in 20th-century costume

The radical creative talents of Brecht created new production concepts and styles; the clothes worn conveyed to the audience in a satirical fashion not only a characterization of the wearer but also his social status. Another compelling force in contemporary experimental theatre, Jerzy Grotowski, conceived his production *Akropolis* at the Polish Laboratory Theatre as a poetic paraphrase of an extermination camp. There is no hero and no individuality among the characters. The costumes were bags full of holes covering naked bodies, and the holes were lined with material suggesting torn flesh; wooden shoes covered the feet, and anonymous berets the heads.

A form of 20th-century pageantry can be seen in the designs of Tanya Moiseyevich for the simple thrust stage of the Tyrone Guthrie Theater, Minneapolis, Minn., and the Festival Theatre, Ontario, Canada. For the brilliant productions of these theatres, with their deft handling of large crowd scenes, highly skilled costumers are engaged each season. The costumes and props that they make enhance the productions' limited scenic elements, recalling the style of the Greek classic theatre and that of Japan. The growth of such regional theatres in Europe and the United States has afforded many opportunities for costume designers. Most of the opera and repertory companies that operate in larger cities have their own well-established costume workshops.

Contemporary design. Coordination of costume sketches with the scenic and lighting designers' schemes is essential from the start. The line, shape, and colour of the entire company's costumes must be viewed in relation to the set and the production's lighting plot. Rough preliminary sketches are made and discussed, revised, and redrawn. A thorough and creative meeting of minds at this stage is invaluable. It may be necessary to call many production meetings before the final rough sketches are approved by the director.

The costume designer

The costume designer can now search for the appropriate fabrics. Fabric buying is a time-consuming and arduous task, conditioned by the size of the production budget. Costumes can be made from an enormous variety of materials; often what is needed can be located only with ingenuity and imagination in some unusual place. The correct weight and weave must be selected if the cutter and draper are to translate the sketches into fact. The fabrics must be suitable for shaping and molding the silhouettes and styles as indicated by the designer, and they must hold up for as long as the production runs. Heavy-textured wools, fine cottons, upholstery fabrics, industrial felts and rubbers, natural fibres, and man-made stiffeners help to create costumes for varied stage characters. When they are finally selected, small samples of the fabrics are stapled to the rough sketches.

Once the cast list is made known, final costume renderings can be completed. Many designers sketch details of all millinery, wig work, and accessories. Hand props, such as snuff boxes, are also often considered the costume designer's responsibility. Spectacles, parasols, and walking sticks also fall in this category.

The costume maker

The management submits approved final designs to costume makers and invites bids. The costumers estimate prices according to the number of man-hours required for manufacture and the price of the materials to be used. The designer often confers with the producer regarding the figures submitted by the costume makers. The designer may recommend a particular firm because it has the craftsmanship and skills required for a particular style of work. Contracts are finally drawn up and construction begins.

A costume house is staffed with experienced and creative craftsmen, who translate all items of the costume sketch into shapes fashioned in the chosen fabrics. Millinery, jewelry, armour making, and dyeing can often be supervised by the designer under one roof. The construction of costumes starts with the appropriate underwear and necessary padding. Corsets, hooped skirts, panniers, bustles, and petticoats form the base on which period silhouettes are fashioned; they are fitted on the actors before the basic muslin pattern of the overgarments. On the skills of the cutter, draper, and fitting hands rests the ultimate success of the finished garment. All fittings are crucial, and the designer normally is present to supervise.

At the second fitting, shoes, wigs, and headwear must be tried on; and at the third and final fittings, the complete outfit is presented for approval of the designer and cutter. The dress parade follows, usually held onstage before the appropriate setting. This parade, ideally, is held at least 10 days before the dress rehearsal to allow for revisions by the director. Despite the long continuing collaboration, the designer still may find himself spraying, re-dyeing, and artificially aging garments to make the stage picture perfect in every detail. Last-minute adjustments can be most satisfying. When the costumes are completed, the production's own wardrobe staff takes over responsibility from the costume house. Supplied with inventories and wardrobe plots, the staff takes care of all items during the run of the production. (M.H./C.Ba.)

THEATRICAL MAKEUP

Theatrical makeup is the practice of painting, enhancing, or altering the face, hair, and body of the actor with cosmetics, plastic materials, and other substances; it is also the collective term for the materials used in making up. Actors have used makeup in the theatre for a long time, not only to look their best and to transform their appearance but also to ensure that they will be seen and recognized by the entire audience. How well an actor is seen depends upon the distance between him and the farthest spectator and the amount of available light. Distances blur the features and make recognition of the actors extremely difficult for the spectators.

Historical development. It is impossible to say when the first actor daubed paint on his face in an attempt to make his performance more effective. Some maintain that Thespis, the first actor to step out of the chorus in Greek theatre in the 6th century BC, smeared his face with white lead and red cinnabar. He may have done so, but the very large size of some of the Greek theatres (containing up to 15,000 spectators) made the use of the masks a more practical solution. Not only did masks enable the actor to play more than one role but their larger-than-life size and exaggerated features enabled the audience to identify the actor's role from a distance.

Use of masks

The Roman theatre borrowed and continued the use of the mask. Evidently some actors thought that their own faces would be more effective, however, since there are contemporary descriptions of certain mimic actors with painted faces. Like the Roman mimes, the traveling actor-comedians of the commedia dell'arte in the 16th century developed a set of stock characters using masks. There may have been some continuity of tradition, for there are resemblances between the comedians' leather masks and those of the Roman farces.

As actors in the 17th century began to perform in permanent theatres, in which they were separated from the audience by the proscenium arch, they had to deal with the problem of making the face look distinctive in illumination from candles and oil lamps. It is probable that the actors adapted the cosmetics of fashionable ladies to their own use.

The use of cosmetics increased greatly during the 18th century. Women, and men to a lesser extent, painted their faces with lead oxide for a pale complexion and cinnabar (mercuric sulfide) for rouge. Both were poisonous compounds. With the widespread use of cosmetics it was noticed that the paler faces were easier to see in dim light. By the 1770s the use of white paint was general upon the stage even though it tended to conceal the expressive motion of the muscles.

The impact of artificial light

The introduction of limelight in 1816, of gaslight in 1817, and of arc lights in 1846 created the necessity for a more subtle use of cosmetics on the stage. The actor's palette consisted at this time of white chalk, carpenters' blue chalk, papers impregnated with red colouring, and India ink. Some actors were known to make up their faces with whitewash rubbed off the walls, dust scraped from red bricks, and black from a burned match, paper, or cork. Credit for the invention of greasepaint belongs to Carl Baudin of the Leipziger Stadt Theatre. Wishing to conceal the join between the front edge of his wig and the forehead, he mixed a flesh-coloured paste of zinc white, yellow ochre, vermillion, and lard. By 1890 theatrical greasepaints were available commercially in many colours, and other items of makeup also began to be manufactured for use in the theatre.

Contemporary practices. The practice of makeup in the theatre has changed greatly with the wave of vitality that swept over the theatre after World War II. As the stage was thrust into the auditorium and the audience was arranged experimentally on all sides of the acting area, the actor was brought closer to the spectator, making close scrutiny possible. Poorly executed and heavy makeup looked obvious, and several time-honoured practices had to be abandoned. Red dots in the corners of the eyes and the use of bright eyeshadow (which had first been used to counteract the effects of footlights) appeared ridiculous. Actors began to reject greasepaint in favour of a makeup that had been developed for the motion-picture industry, a water-soluble cake makeup capable of being spread in a thin wash of colour, making a completely natural look possible. The desire for naturalism in appearance became very important.

Many improvements in makeup techniques were developed primarily for films and television and rapidly adopted by the theatre. There has been a great change in theatrical wigs, for example, which once had a band of silk that was blended with colour into the forehead. This type of wig was not successful for film work since the join was obvious to the camera. A new type of wig was developed, and now most wigs for films and theatre are made with an edge of plastic lace into which hairs are knotted. When the lace is glued to the forehead the hairs seem to grow from the skin, resulting in a natural-looking hairline.

Film and television makeup artists have perfected the use of foam rubber and plastic facial appliances to the point that a young actor can be transformed into a very old man and yet withstand the scrutiny of a camera close-up. This process frequently takes a makeup artist and an assistant four or more hours to complete. Audiences accustomed to these miracles of transformation have come to expect the same verisimilitude in the theatre. But this kind of makeup requires more time than is generally practical in the theatre, and the cost can be prohibitive. Theatres cannot hope to compete with the motion-picture industry; one film budgeted $1,500,000 to transform a large cast of actors into realistic-looking apes.

There is a growing trend in the theatre to include makeup in the total production design. What was once considered the prerogative and responsibility of the individual actor is now being influenced by designers, directors, and, in some instances, by makeup artists. In most German opera houses, for example, singers are not allowed to do their own makeup. A staff of makeup artists assures that each makeup is executed as designed and that the style is consistent. This expert supervision has hitherto been considered possible only in the motion-picture industry or in commercial television because of costs, but government subsidy of theatres and television in England and other European countries has enabled the hiring of such specialists. Rubber latex makeup can be used on the stage to give the skin the textured look of extreme old age, to make bald caps, and to make realistic-looking false noses, jowls, and other forms of sagging flesh.

The ideology of many alternative theatre groups has led to a rejection of makeup. In these theatre companies the actor does not seek to hide behind a character but is present as himself in public, relating directly with the audience. The Living Theatre was one such company. Even when named roles were assigned, as in *Frankenstein,* the actor was clearly visible beneath the role. In theatre such as this, the use of makeup is anathema in its illusionistic sense but can be used in a ritualistic sense. Experiments in ritual theatre have resulted in the use of masks and highly decorative or symbolic makeup, as is found in the Chinese Opera or the Kabuki theatre. Laboratory theatre companies have concentrated on the actor's control of the processes of transformation. Grotowski encouraged the actor to try to transform himself without the help of makeup. If makeup were used only after all the other possible changes of character had been explored, then its use would be much more expressive. The growth of the alternative theatre circuit in Britain, which has brought performances to small intimate rooms, has similarly pushed the actor to try all other means of characterization without the use of makeup, which would appear grotesque at close range. The result is that many younger British actors do not use makeup at all, even on main stages. (S.D./C.Ba.)

Theology

Theology, meaning literally the study of God, is a discipline of religious thought that is restricted in its narrower sense, because of origination and format, to Christianity, but in its broader sense, because of its themes, to other religions. The themes of theology are God, man, the world, salvation, and eschatology (or the study of last times).

The article is divided into the following sections:

Nature of theology 608
Relationship of theology to the history of religions and philosophy 609
The significance of theology 609
Theological themes 610
Functions of theology 610

Nature of theology. The concept of theology that is applicable as a science in all religions and that is therefore neutral is difficult to distill and determine. The problem lies in the fact that theology as a concept had its origins in the tradition of the Greeks but that it obtained its content and method only within Christianity. Thus, theology, because of its peculiarly Christian profile, is not readily transferable in its narrow sense to any other religion. In its broader thematic concerns, theology as a subject matter is germane to other religions.

The terminological problem

The Greek philosopher Plato (*c.* 428–348/347 BC), with whom the concept emerges for the first time, associated with the term theology a polemical intention—as did his pupil Aristotle. For Plato theology described the mythical, which he allowed may have a temporary pedagogical significance that is beneficial to the state but is to be cleansed from all offensive and abstruse elements with the help of political legislation. This identification of theology and mythology also remained customary in the later Greek thought. In distinction to philosophers, "theologians" (as, for example, the poets of myth—*e.g.,* the 8th-century-BC Greeks Hesiod and Homer—or the cultic servants of the oracle at Delphi [Greece] and the rhetors of the Roman cult of emperor worship) testified to and proclaimed that which they viewed as divine. Theology thus became significant as the means of proclaiming the gods, of confessing to them, and of teaching and "preaching" this confession. In this practice of "theology" by the Greeks lies the prefiguration of what later would be known as theology in the history of Christianity. In spite of all the contradictions

and nuances that were to emerge in the understanding of this concept in various Christian confessions and schools of thought, a formal criterion remains constant: theology is the attempt of adherents of a faith to represent their statements of belief consistently, to explicate them out of the basis (or fundamentals) of their faith, and to assign to such statements their specific place within the context of all other worldly relations (*e.g.,* nature and history) and spiritual processes (*e.g.,* reason and logic).

Limitations

Here, then, the above indicated difficulty becomes apparent. In the first place, theology is a spiritual or religious attempt of "believers" to explicate their faith. In this sense it is not neutral and is not attempted from the perspective of removed observation—in distinction to a general history of religions. The implication derived from the religious approach is that it does not provide a formal and indifferent scheme devoid of presuppositions within which all religions could be subsumed. In the second place, theology is influenced by its origins in the Greek and Christian traditions, with the implication that the transmutation of this concept to other religions is endangered by the very circumstances of origination. If one attempts, nevertheless, such a transmutation—and if one then speaks of a theology of primitive religions and of a theology of Buddhism—one must be aware of the fact that the concept "theology," which is uncustomary and also inadequate in those spheres, is applicable only to a very limited extent and in a very modified form. This is because some Eastern religions have atheistic qualities and provide no access to the *theos* ("god") of theology. If one nonetheless speaks of theology in religions other than Christianity or Greek religion, he implies—in formal analogy to what has been observed above—the way in which representatives of other religions understand themselves.

Relationship of theology to the history of religions and philosophy. *Relationship to the history of religions.* If theology explicates the way in which the believer understands his faith—or, if faith is not a dominating quality, the way in which a religion's practitioners understand their religion—this implies that it claims to be normative, even if the claim does not, as in Hinduism and Buddhism, culminate in the pretention to be absolutely authoritative. The normative element in these religions arises simply out of the authority of a divine teacher, or a revelation (*e.g.,* a vision or auditory revelation), or of any other kind of spiritual encounter over against which one feels committed. The newly evolving discipline of the history of religions, which encompasses also religious psychology, religious sociology, and religious phenomenology as well as philosophy of religion, has emancipated itself from the normative aspect in favour of a purely empirical analysis. This empirical aspect, which corresponds to the modern conception of science, can be applied only if it functions on the basis of objectifiable (empirically verifiable) entities. Revelation of the kind of event that would have to be characterized as transcendent, however, can never be understood as such an objectifiable entity. Only those forms of religious life that are positive and arise out of experience can be objectified. Wherever such forms are given, the religious man is taken as the source of the religious phenomena that are to be interpreted. Understood in this manner, the history of religions represents a necessary step in the process of secularization. Nevertheless, it cannot be said that theology and the history of religions only contradict one another. The "theologies"—for want of a better term—of the various religions are concerned with religious phenomena, and the adherents of the religions of the more advanced cultures are themselves constrained—especially at a time of increasing cultural interdependency—to take cognizance of and to interpret theologically the fact that besides their own religion there are many others. In this regard, then, there are not only analytical but also theological statements concerning religious phenomena, particularly in regard to the manner in which such statements are encountered in specific primitive or high religions. Thus, the objects of the history of religions and those of theology cannot be clearly separated. They are merely approached with different categories and criteria. If the history of religions does not surrender its neutrality, since such a surrender would thereby reduce the discipline to anthropology in an ideological sense (*e.g.,* religion understood as mere projection of the psyche or of societal conditions), theology will recognize the history of religions as a science providing valuable material and as one of the sciences in the universe of sciences.

Contributions of the history of religions to theology

Relationship to philosophy. The relationship of theology to philosophy is much more difficult to determine, because it is much more complicated. The problems can here only be mentioned. If one does not adhere to the narrow concept of philosophy that reduces it positivistically to logic or epistemology (theory of knowledge) but rather understands philosophy as the discipline that attempts to explicate the totality of being, the difference between this latter interpretation of philosophy in relation to theology becomes apparent. If theology is responsible to an authority that initiates its thinking, speaking, and witnessing—*e.g.,* a document containing revealed truth, as well as the spiritual testimony related to it—philosophy bases its arguments on the ground of timeless evidence, an evidence with which autonomous reason understands itself to be confronted. Since, on the other hand, theology also uses reason and systematically develops its tenets—however much its critical reflections are based on religious convictions—there are many common areas that have partly complementary significance but that partly also lead to polemical tensions.

The significance of theology. *The religious significance of theology.* Just as in the case of religions themselves, so also their theological reflections are not limited to a special religious sphere, separated from common life. Whoever speaks of God and the gods speaks at the same time of man and of the meaning of existence. He makes therewith statements about the world, its conditions of being created, its estrangement from the purpose of creation (*e.g.,* sin), and its determined goal (eschatology or view of the last times). Out of these statements result normative directives for life in the world, not only for the purpose of gaining access to salvation but also for concrete ethical behaviour in the context of the I–Thou (or person to person) relationship, of the clan, of the nation, and of society. In ancient times, all aspects of life (*e.g.,* relationship between the sexes, hygiene, work, and other aspects) were determined religiously and permeated by cultic forms and practices. In this regard, every religion contains the totality of being that its "theology" intends to express—if one also includes certain rudiments of reflection in primitive religion in the concept "theology."

The scope of theological reflections

In primitive religions the tribe represents the pivot around which all world relations turn. The primeval (or mythical) time to which the tribe traces its own origins is also the time of salvation and fulfillment. Therefore, primitive religions primarily concern themselves with the ancestral cult. Involved in tribal concerns in the realm of religious thought are conceptions of mana (spiritual power, or force); *i.e.,* the teaching that tribal heads, medicine men, and sorcerers are subjects of special charisma (spiritual power or influence) and more potent powers of life. In Eastern religions, as in Western religions, this understanding is infinitely refined, developed, and theologically reflected. In regard to the relationship of man to the world, many Eastern religions (especially Hinduism) have a definite skeptically tinged negative view of all reality, which is especially pronounced in contrast to the Christian doctrine of creation. Though this doctrine points to a "happy event" in Christianity, the call to life and reality is understood in Eastern thought in the opposite manner:

Man and the world

> To be man implies being cut off from all true reality. Creation should have never happened, and its faults should be eliminated as soon as possible. . . . The illusion that I am is a calamity. Not death is to be explained, but rather birth. (Stephen Neill).

The cultural importance of theology. Since theology does not remain restricted to transcendent statements and to an esoteric and sacred realm, and since it rather encompasses all worldly dimensions (cosmology, anthropology, historiology, and other areas), it has always had important significance for cultural evolution and general intellectual life. Western historians hardly need to be reminded of the

fact that the Old Testament prophetic theology of history (*e.g.*, the 8th-century-BC Hebrew prophets Amos and Isaiah) has decisively influenced the origins of the concept *history* and, indeed, has made this concept possible in the first place. On Old Testament theology of history is based the understanding of history as a linear process, as directed to a goal (*i.e.*, the Kingdom of God), and as qualified by the characteristic of singularity. This view of history contrasts with a cyclical understanding of successive events; *i.e.*, the view that history repeats itself. The fact that university and school were originally initiated by the church (as is still very often the case in mission fields) is based on the fact that theology has thematized in its various subjects the various dimensions of life (nature, history, ethics, and other disciplinary areas). Also, much of modern philosophy has emerged out of theological themes and categories—in such modern thinkers as the existential philosophers Martin Heidegger and Jean-Paul Sartre and even in the Communist thinker Karl Marx remnants of this fact are still observable. Modern philosophy has, by and large, only gradually emancipated itself from this theological origin, but this emancipation also has taken place in a manner that has retained the dialectical relationship of theology and philosophy. That theological questions in the modern age of secularism are less openly posed than in the time of the Middle Ages does not reduce their lasting significance. They always reemerge, often in disguised form, such as in the quest for the meaning of life and existence or in the nihilistic resignation over against that quest; furthermore, they reemerge in the quest for the dignity of human existence, the inviolability of life, the determination of human rights, and many other such questions. A theologian such as the German-American thinker Paul Tillich has investigated specifically the secular realm in view of the relevance of these latent theological questions that are posed by modern man in his relationship to a constantly changing world.

The emergence of theological questions in a secular age

Theological themes. The themes discussed by theology are of universal dimensions. They encompass the doctrine of God, of man, and of the world. Even when no "doctrine of God" exists in the strict sense of the term, as in the case of what are sometimes called "atheistic" religions (*e.g.*, certain forms of Hinduism and Buddhism), man and the world are understood in the context of finality and therefore have religious aspects. The inclusion of the world in theological discussion also implies that behaviour in the world—that is, ethics—is included in theology; in some areas (*e.g.*, Confucianism) this aspect gains a dominating position. Ethical conceptions—derived from theological concepts in the broad meaning of theology—are developed in contradictory forms: they can lead to ascetic world denial but also to a definite world affirmation. The first form is realized in Buddhism and Hinduism, the second in Confucianism. In Christianity both forms are represented. The theological theme of the relation of man and the world has been described by the 17th-century French scientist and thinker Blaise Pascal as the doctrine of the "dignity and poverty of man"—*i.e.*, the doctrine of creation and fall—and, related to this, the proclamation of salvation and the presentation of a path to salvation. This path leads, in the various religions, into greatly diverging directions. It can be placed under the exclusive direction of divine grace (as in Amida Buddhism and in Protestant Christianity); it can be left to the activity and initiative of man (as in Confucianism); or it can be characterized by a combination of the two principles (as in Zen Buddhism and in the Roman Catholic combination of grace and merit). Finally, theology also includes among its various themes statements concerning the process and goal of history (eschatology), especially concerning the relation of secular history and history of salvation.

Functions of theology. The vastness of theological interests and aspects implies that theology can master the material with which it is confronted only within a broad spectrum of partial disciplines. Since theology is based on authority (revelation), and since this authority is documented in the Holy Scriptures (especially in Christianity), it is constrained to engage in philological and historical studies of these sources and, related to these studies, also with hermeneutical (critical interpretive) questions. This historical task broadens into a concern with the history and tradition of the religion that a particular theology represents. In this concern many difficult and controversial questions arise, including whether and to what extent the canon (scriptural standard) of the sources of revelation is glossed over and modified by tradition and what normative value the modifying tradition has or should have. These problems play an important part in the relationship between Protestantism and Catholicism, even though the problems are also treated independently by each confession.

Controversial questions in theology

The question of truth posed by theology requires the constitution of a discipline that specifically concerns itself with fundamental questions (systematic theology). Its task can be determined in the following manner: (1) It has to develop the totality of religious teachings (dogmatics, or the doctrine of faith). (2) It has to interpret man's existence in the world and, related to this, to determine the norms (ethics derived from faith) for action in the world—*e.g.*, for the disposition toward one's fellow man and toward societal and political structures and institutions. (3) It further has to represent its claim to truth in the context of confrontation with other claims to truth and with other criteria of verification (apologetics, polemics). As part of this concern, theology's task is to explain reasonably, in view of historical relativism, the absolute claim of the truth that it represents. Related to this is the modern-day task of coordinating its doctrine of creation or its doctrine of the revelation of the transcendent (*e.g.*, the Christ event in Christianity) with the world view of modern natural science and its thesis of the immanency of being—*i.e.*, of being that is self-contained. Another aspect of this task is the confrontation with other religions' claim to truth, which can lead to vastly different results: either—this is noted only as an example—it can lead to the thesis of the complementary positions of individual religions and therefore to tolerance (as for example in Hinduism as well as in some schools in the West) or to one's own religion's claim to be absolute (as in Christianity, at least among the most important of its representatives). But also, in the last mentioned situation, such a claim is widely modified. It can manifest itself by a total rejection of other religions as "devil's work," but it can also be expressed in an interpretation of other religions as first steps to and as seeds of a religious development, the completion of which it knows itself to be.

The vast dimension of theological themes implies that theology is, with its many disciplines, a microcosmic image of the university. Even though it is a science in which the believers or the adherents of a particular religion explicate and critically analyze the truth that is represented by them, it nevertheless has to remain free within the framework of this commitment, and it has to fulfill the responsibility of its scientific task on the basis of its own autonomy. The opposite of this freedom would arise when an institution (*e.g.*, the church) restricted the range of theological inquiry with normative claims, forcing the discipline therewith to assume ideological functions. The struggle concerning the freedom and limitations of theology—*i.e.*, concerning responsible criticism and authority—is a struggle that has accompanied the history of theology from the very beginnings to the present.

BIBLIOGRAPHY. FRIEDRICH SCHLEIERMACHER, *Brief Outline on the Study of Theology* (1850, reissued 1977; originally published in German, 1811, 2nd ed., 1830), is still the best picture of theology as a whole and all its parts. KARL RAHNER and HERBERT VORGRIMLER, *Theological Dictionary* (1965; originally published in German, 1961); and JOHN MACQUARRIE, *Twentieth-Century Religious Thought,* 2nd rev. ed. (1981), together cover a vast range of topics and themes of theology, past and present. GERHARD VON RAD, *Old Testament Theology,* 2 vol. (1962–65; originally published in German, 1957–60); and RUDOLF BULTMANN, *Theology of the New Testament,* 2 vol. (1951–55, reissued in 1 vol., 1965; originally published in German, 1948–53), are the most important texts dealing with Holy Scripture in modern times. MIRCEA ELIADE, *The Myth of the Eternal Return* (1954, reissued 1974; originally published in French, 1949); and OSCAR CULLMANN, *Christ and Time,* 3rd rev. ed. (1962; originally published in German, 1946), deal with Christianity as

a historical religion in contrast to nonhistorical interpretations of religion. ADOLF VON HARNACK, *History of Dogma,* 7 vol. (1895–1900, reissued 1976; 3rd German ed., 1894–97), is the classic study of the history of Christian theology in relation to Greek thought. The new disciplines of religious study, namely, the history and the phenomenology of religions, are introduced and illustrated by RUDOLF OTTO, *The Idea of the Holy,* 2nd ed. (1957, reissued 1980; 9th German ed., 1922); and *The History of Religions: Essays in Methodology,* ed. by MIRCEA ELIADE and JOSEPH KITAGAWA (1959). Modern theology, from the 18th century to the present, is treated in contrasting new ways by KARL BARTH, *Protestant Thought from Rousseau to Ritschl* (1959, reissued 1971; originally published in German, 1947), and *Church Dogmatics,* 4 vol. (1936–61; originally published in German, 1932–59); and PAUL TILLICH, *Perspectives on 19th and 20th Century Protestant Theology* (1967), and *Systematic Theology,* 3 vol. (1951–63, reissued 1975), are exhaustive treatments of the most fully developed theologies in Catholic and Protestant churches.

Principles of Thermodynamics

Thermodynamics is that part of physical science that is concerned with the conditions that material systems may assume and the changes in conditions that may occur either spontaneously or as a result of interactions between systems, including interactions such as heat, which cannot be described in terms of mechanics. It is basic to the distinction between mechanics and thermodynamics that according to mechanics all the energy of a system in any state is convertible to work, whereas according to thermodynamics only a fraction of the energy of a system in most states is convertible to work without other effects. The scope of thermodynamics has been steadily broadening since early in the 19th century as a result of a better understanding that has grown up of its underlying principles.

The word thermodynamics was derived from the Greek words *thermē* ("heat") and *dynamis* ("force"). The beginnings of the study of thermodynamics are found in the early 19th century in the study of the motive power of heat; that is, the capability of hot bodies to produce mechanical work. These early studies revealed several underlying principles, the most important of which are the first and second laws of thermodynamics. The discovery and clear enunciation in 1850 of the two laws by Rudolf Julius Clausius, a German mathematician and physicist, broadened greatly the scope of the subject. Throughout the rest of the 19th century it developed into a science, now known as classical thermodynamics, concerned primarily with physical systems in or passing through stable equilibrium states (the terms system and state are defined below). More recently thermodynamics has been extended to include physical systems in nonequilibrium states.

Although the development of thermodynamics, in contrast to other aspects of the study of physics, has progressed without regard to the details of the microscopic structures of physical systems, many scientists, beginning with Ludwig Eduard Boltzmann, an Austrian physicist, have felt that the laws of thermodynamics might be justified and explained by means of detailed microscopic descriptions of matter and the laws of mechanics (classical or quantum) and statistics. Work in this direction has resulted in the development of the branch of thermodynamics known as statistical thermodynamics, which, though it plays an important role in the evaluation of properties of systems, has not achieved one of its original goals, namely, the derivation of the laws of thermodynamics from the laws of mechanics. In particular, it now appears that the second law of thermodynamics is an independent law of nature. This particular point will be clarified below.

This article is divided into two parts. In the first part, the general principles of thermodynamics that apply to any physical system in any state—and the corollaries of these principles—are presented without reference to the detailed microscopic structure of matter. The presentation, therefore, encompasses both classical and nonequilibrium thermodynamics. In the second part, the detailed microscopic structures of physical systems are considered, and the states of such systems are discussed in the light of the laws of both quantum mechanics and thermodynamics. Quantum mechanics and thermodynamics are shown to be complementary parts of physical science, and they are neither separable nor are they derivable one from the other.

The article is divided into the following sections:

Historical overview of classical thermodynamics

Temperature is probably the earliest thermodynamic concept to attain operational status. Early in the 17th century Galileo, an Italian astronomer and physicist, devised a thermoscope that was a rudimentary thermometer. Soon thereafter a liquid-expansion thermometer with bulb and stem, open at the top, was devised in France by Jean Ray.

Early attempts to measure temperature

In 1640 the grand duke Ferdinand II of Tuscany, one of the founders of the Florentine Academy of Experiment, invented the sealed-stem alcohol thermometer. Such devices were put to clinical (determining degrees of fever), agricultural (incubation), and meteorological uses.

The purpose of these instruments was to measure a quantity, that had as yet been undefined, that was more objective in nature than the physiological sensations of hotness and coldness. An equilibrium concept was proba-

bly involved; namely, that all bodies exposed to the same atmosphere would ultimately attain the same degree of hotness or coldness, despite any contrary evidence of the senses. An associated concept of the equilibrium concept was that temperature is a driving potential that causes some influence to pass from one body to another of unequal hotness or coldness. Thus, when a body is taken from a warm room to the cold outdoors, its length begins immediately to decrease.

What was it that passed from one body to another at different temperatures? Was it temperature itself that was transmitted? The English philosopher and scientist Francis Bacon as early as 1620, and the Florentine Academy a few years later, began to make this distinction between this influence and temperature; but it was more than a century before Joseph Black, a chemist at the University of Glasgow, in 1770 made the distinction sharply. He showed by mixing equal masses of pairs of liquids of different temperatures that the temperatures of the two substances often changed by radically different amounts. Indeed, a large change in temperature of a solid body produced no change at all in the temperature of a mixture of ice and water or of water and steam. Temperature was not necessarily conserved or even transmitted in the process.

Black established the science of calorimetry, which led to the establishment of the caloric theory, based upon the following postulates: (1) Caloric is an all-pervading elastic fluid, the particles of which repel one another strongly. (2) Particles of caloric are attracted by particles of matter. (3) Caloric is conserved. (4) Caloric is either sensible (*i.e.*, change in caloric is associated with change in temperature) or latent. (5) Caloric has weight. These postulates were intended to account for expansion and contraction upon heating and cooling, variations in heat capacity, calorimetry, latent heat, and gain in weight of certain metals when heated in air (calcined). Frictional heating was subsequently accounted for by postulating that friction reduced the attraction between caloric and matter.

Toward the end of the 18th century, Count Rumford (Benjamin Thompson), an expatriate American colonial engineer and physicist, attacked the validity of the caloric theory on the basis of experiments intended to show that caloric could be created and, therefore, was not conserved. More refined measurements on the generation of heat by frictional work were made nearly a half century later by an English physicist, James Prescott Joule.

Carnot's heat engine

In 1824 Sadi Carnot, a French military engineer, introduced the concept of the heat-engine cycle, a concept that permitted a sharp distinction to be made between interactions of systems and changes in their states. Carnot then proved from conservation of caloric and the impossibility of the production of work without compensating changes in the environment that (1) a reversible cyclic engine is the most efficient possible means of producing work from heat, and (2) all reversible cyclic engines operating between the same pair of heat reservoirs must have the same efficiency. Although the proof, as it turned out, was invalid, Clausius asserted in 1850 that Carnot's principle is itself a basic postulate and is, in effect, what came to be known as the second law of thermodynamics.

In the decade of the 1840s Joule laid the foundations of the first law of thermodynamics by showing that the amount of work required to bring about a given change of state is independent of the kind of work (whether mechanical, electric, or magnetic), the rate of doing work, or the method of delivering it. Joule concluded that work can be converted into heat, with a fixed ratio of one to the other, and that heat can be converted into work. In 1844 Julius Robert von Mayer, a German physician and physicist, postulated that in a work-producing cycle the heat introduced must exceed the heat rejected by an amount proportional to the work. He deduced the value of the proportionality constant from calculation of cycles in a gaseous system.

In 1849 Lord Kelvin (William Thomson), an engineer of Glasgow, pointed out the conflict between the caloric basis of Carnot's arguments and the conclusions reached by Joule. In 1850 Clausius resolved the difficulty by stating explicitly the first and second laws of thermodynamics. Within a few years Clausius defined and named the property entropy that is conserved in all reversible processes, and derived from the second law the principle of increase of entropy.

The first law was stated by Clausius as follows: In all cases in which work is produced by the agency of heat, a quantity of heat is consumed that is proportional to the work done; and, conversely, by the expenditure of an equal quantity of work, an equal quantity of heat is produced. He applied this statement to a cyclic process in a system (a concept with which he credits Carnot) in order to obtain a statement of the first law in terms of work and heat without reference to alteration in the state of the system. This led naturally to a definition of the property energy—called mechanical energy by Kelvin and contracted to energy by J. Willard Gibbs, an American mathematician and physicist. Clausius stated the second law in the following terms: A passage of heat from a colder to a hotter body cannot take place without compensation.

Clausius' paper of 1850 marked the birth of the science of thermodynamics. Immediately thereafter, Kelvin, who had previously displayed an interest in the theory of temperature, proposed and discussed various definitions for thermodynamic temperature scales, including the one that now bears his name. James Clerk Maxwell, a physicist of Edinburgh and Cambridge, averred that two bodies each equal in temperature to a third body are equal in temperature to each other. This statement, which is sometimes called the zeroth law of thermodynamics, is an incomplete version of a condition for equilibrium, subsequently derived by Gibbs and others. Maxwell also devised a number of mathematical relations that now bear his name. Kelvin and Max Planck, a German physicist, later restated the second law, so as to avoid the undefined term compensation used by Clausius, in terms of the impossibility of a perpetual-motion machine of the second kind (see below).

In the years 1873–78 Gibbs published three papers that proved to be definitive as regards the conditions for equilibrium. These papers provided a mathematical method so orderly and systematic that they have served as the foundations of physical chemistry and many subsequent applications of classical thermodynamics.

At the turn of the century, the French mathematician Henri Poincaré addressed the problem of definition of temperature and heat and the statement of the first and second laws. In 1909 Constantin Carathéodory, a Greek mathematician teaching in Germany, presented an alternative logical structure in which he shunned use of the term heat. It is closest in method and spirit to that used here. He states the two laws as follows: First, an extensive property exists the increment in which is the work received by the system while surrounded by an adiabatic wall (an adiabatic wall being one that permits only work interactions between the system and its surroundings). Second, in the neighbourhood of any prescribed initial state are states that cannot be reached by an adiabatic process.

In 1918 Walther Nernst, a Nobel-Prize-winning chemist of Germany, stated the Nernst heat theorem, treated below, which is essentially the third law of thermodynamics, which rounds out the exposition of classical thermodynamics by providing a common base for values of entropy for all atoms or molecules that can be formed from simpler species.

Basic concepts and laws of thermodynamics

SYSTEMS, STATES, AND PROPERTIES

The description of physical phenomena is based on the concept of state of a system and the changes of state that occur either spontaneously or because of interactions with other systems. Knowledge of the states of a system is equivalent to knowledge of the outcomes of all possible observations on the system; namely, observations of all its properties.

The term system means any identifiable collection of matter that can be separated from everything else by a well-defined surface so that changes in everything else need not affect the condition of the collection. Examples of systems are a number of water molecules confined

within a watertight container, a thermonuclear plasma (a special collection of charged particles) confined by a suitably designed magnetic field, and the vapour of a solid within a cavity in the solid.

The particles of a system may have a finite rest mass, as do molecules, atoms, or electrons, or zero rest mass, as do photons. The number of particles of a system can be large, as in a cubic centimetre of tungsten, or small, as in a hydrogen atom.

At any instant of time a system is in a condition called a state, which encompasses all that can be said about the results of any measurements or observations that can be performed on the system at that time. The state at a given instant of time determines the properties of the system. A property is any quantity the value of which depends upon the state but not the history of the system. For a given state the value of a property can be determined by some type of measurement (some physical operation or test). When the values of all properties of two states are identical, the two states are identical; otherwise they are different.

Measurements and values compared

Because of unavoidable quantum mechanical considerations, a simple measurement, no matter how nearly perfect, will not yield the precise value for a property. In general, a very large number of measurements of the same kind is required to yield the precise value, each measurement performed on a duplicate of the system in the given state or on the same system reprepared in the same state and each yielding a different result. The value of a property is defined, therefore, as the sum of all the results of the measurements of the property divided by the number of measurements (in other words, the arithmetic average or expectation value of all the results of the measurements of the property). It will be shown below that a state can be described by a set of weighting factors, or probabilities, that enter into the evaluation of all properties.

Although an indefinite number of properties can be associated with a state, the values of these properties are not all independent of each other. The number of independent properties is either small or large, depending on the type of state in question; that is, on whether or not it is a stable equilibrium state. The meaning of the terms that define the various types of states will be given below.

WORK AND NONWORK

An interaction between two systems such that whatever happens in each of the interacting systems could have been brought about while the sole effect external to each system was the change in level of a mass in a gravity field will be defined as work; that is, work is an interaction that must satisfy a test: each of the interacting systems is separately required to experience the same changes as in the actual interaction, but, through alteration of circumstances external to that system, the effect outside of it is solely the rise or fall of a mass. If this test can be satisfied by both systems, then the original interaction is work.

It can be shown from experimental evidence that the following interactions conform to the definition just cited and are, therefore, work interactions: (1) the displacement of a point on the boundary of a system at which point a force is exerted in the direction of the displacement by another system (this is essentially the definition of work in mechanics, which is less general than the one given here, which covers interactions other than those considered in mechanics; the present definition implies that the force applied on a body by a stationary force field, such as gravity or an electrostatic field, results in no work, even though the body is in motion—for example, freely falling); (2) the electromagnetic interactions between primary and secondary coils of a transformer; and (3) the exchange of radiation emitted by lasers. Such radiation consists of wave particles, which are in order relative to each other as contrasted with those, for example, from an incandescent lamp, which are randomly arranged. On the other hand, it can be shown by virtue of the laws of thermodynamics that the exchange of radiation between a hot system and a cold system (such as blackbody radiation) does not conform to the requirement stated in the definition of work and is not, therefore, a work interaction.

Work is one of several distinguishable types of interaction that can occur between two systems. Any interaction that is not work will be hereinafter called nonwork. A special type of nonwork interaction that will be treated below in detail is a heat interaction. In general, an interaction is fully specified if the exact sequence of states, called the path, of each of the interacting systems is specified. In turn, the path of one of the systems and the interactions that occur specify the process experienced by the system. In an interaction that satisfies the definition of work, each system is said to be experiencing an adiabatic process.

The state and, therefore, the values of the properties of a system can change either spontaneously or as a result of interactions with other systems. During changes of state the values of certain properties are subject to limitations imposed by the laws of physics. The limitations imposed by thermodynamics are consequences of the first and second laws, which will be stated here in an unusually general way.

FIRST LAW

The first law is a statement of existence of a property called energy. It is based on the concept of work and can be stated as follows: For any process involving no effects external to the system except displacement of a mass between specified levels in a gravity field, the magnitude of that mass is fixed by the end states of the system and is independent of the details of the process. This law has many implications or corollaries, some of which are as follows.

Consequences of the first law

1. *Uniqueness of work values.* By virtue of the first law a unique number can be assigned to a work interaction between two systems. This number is n when n arbitrarily selected units of mass are displaced between two arbitrarily specified levels in a gravity field. The sign of work is selected positive when work is done by a system—that is, when the sole external effect would be the rise of a weight.

2. *Definition of energy.* By virtue of the first law, the work in an adiabatic process depends on the initial and final, or end, states only. It follows that a property of a system can be defined, called energy, such that its change of value between states A_1 and A_2 is equal to the work W_{12}^a involved in an adiabatic process that has A_1 and A_2 as end states. In terms of symbols, if E_1 and E_2 denote the energies of states A_1 and A_2, respectively, and W_{12}^a the work done in any adiabatic process connecting A_1 and A_2, the difference $E_2 - E_1$ is equal to the negative of W_{12}^a; *i.e.*,

$$E_2 - E_1 = -W_{12}^a. \qquad (1)$$

Energy is only partially defined by equation (1) because the difference between E_1 and E_2 does not specify the values of E_1 and E_2. An arbitrary value such as zero, however, can be assigned to E_0 of some reference state A_0, so that the energies of all other states are fixed by equation (1).

It will be shown below that by virtue of the laws of thermodynamics certain interactions that cause change of energy cannot be described as work. The corresponding process is, by definition, a nonadiabatic process. Because energy is a property, the energy change associated with any nonadiabatic process will equal numerically the work in any adiabatic process between the same end states.

It can be readily verified that energy is an additive or extensive property; that is, the energy of a whole is equal to the sum of the energies of its parts.

3. *Conservation of energy.* The magnitude of the work in an adiabatic process can be positive, negative, or zero, depending on the end states of the process, but zero adiabatic work does not necessarily imply identical end states. An adiabatic zero-work change of state may occur spontaneously in a system, as, for example, when an electrical capacitor discharges through an internal resistor. During such a process, equation (1) requires that the energy of the system remain invariant. This is the so-called law of conservation of energy, which is a consequence of the first law of thermodynamics. The first law, on the other hand, cannot be deduced from the law of conservation of energy.

A system that experiences an adiabatic, zero-work process is said to be isolated from all other systems in the environment.

4. *Impossibility of perpetual-motion machine of the first kind.* A perpetual-motion machine of the first kind (PMM1)

is any system that undergoes a cycle and has no external effect except the rise of a weight. The term cycle (or cyclic process) is defined as a process in which the initial and final states of the system are identical.

By virtue of the first law, the work of an adiabatic cycle must be equal to zero and, therefore, a PMM1 is impossible.

5. *The first law and relativity.* According to the general theory of relativity, the energy E of a system is equal to the product of its mass m and the square of the speed of light c in a vacuum, namely,

$$E = mc^2. \tag{2}$$

By virtue of the first law, the energy E of an isolated system is conserved. Therefore, equation (2) requires that the mass m of the system is also conserved, regardless of the processes occurring within the system (such as chemical reactions, nuclear reactions, and creation and annihilation of particles). Moreover, if the energy of a system is altered by virtue of an adiabatic or nonadiabatic interaction, the mass of the system must also be altered in accordance with equation (2). In most applications the energy transferred to or from a system is so much smaller than the total energy mc^2 of the system that the change in mass is negligible.

Conservation of mass

SECOND LAW

The second law is a statement of existence of stable equilibrium states. More than the first law, the second law distinguishes thermodynamics from other parts of physics. Because it has far-reaching implications concerning the properties and behaviour of matter, it is frequently invoked in discussions of philosophy as well as in discussions of physics.

Of the many statements of the second law, those of Clausius, Planck, and Carathéodory are the most notable. All of these statements imply the existence of a stable equilibrium state for given values of energy, the number of particles, and the constraints (see below)—an implication that is here taken to be the essential element of the second law.

The term equilibrium state means a state that does not change with time while the system is isolated from all other systems in the environment. Equilibrium state is sometimes confused with steady state: a steady state does not change with time even though the system, rather than being isolated, is interacting with other systems.

If a system is in an equilibrium state, a finite change of state may be caused by interactions with the environment, including those that leave no finite net effects in the environment. Several types of equilibrium states can be distinguished. Among these is the stable equilibrium state for which a finite change of state cannot occur, regardless of interactions that leave no net effects in the environment.

Consistent with its nature, a system might assume any one of a set of possible states, but some of the possible states may be prohibited by restrictions imposed by the environment. These restrictions are called constraints. For example, a given amount of gas may assume any of a large number of states. The same amount of gas, however, confined in a gas-tight container of fixed volume is restricted to states with volumes smaller than or equal to the volume inside the container. The possible states of the system that are consistent with the constraints will be called allowed states.

Constraints on systems and allowed states

The second law can now be stated as follows: Among all the allowed states of a system with given values of energy, numbers of particles, and constraints, one and only one is a stable equilibrium state.

The second law cannot be derived from the laws of mechanics (either classical or quantum). The second law asserts that a stable equilibrium state exists for each value of the energy, whereas in mechanics the only stable state is that of minimum energy, what is known as the ground state.

Some corollaries of the second law are as follows.

1. *State principle.* By virtue of the second law, stable equilibrium states exist, and a unique stable equilibrium state corresponds to each set of values of energy, numbers of particles, and constraints. The uniqueness implies the following corollary: the value of any property of a system in a stable equilibrium state may be expressed as a function of the values of the energy, numbers of particles, and constraints only. This corollary is known as the state principle.

2. *Reversible and irreversible processes.* A process is reversible if the system and its environment can be restored to their initial states, except for differences of smaller order of magnitude than the maximum changes that occur during the process.

If a system starts from any allowed state and reaches the corresponding stable equilibrium state with no net effect on the environment, then the process would not be reversible. For if it were, the system, starting from the stable equilibrium state, could undergo a process that ends at another state with no net effect on the environment. This conclusion, however, violates the definition of a stable equilibrium state. A process that is not reversible is called irreversible.

3. *Impossibility of perpetual-motion machine of the second kind.* It can be shown from the definition of a stable equilibrium state that a system in such a state can receive but cannot produce work. The plausibility of this corollary will be evident from the observation that work can always be used to change from any state to a nonequilibrium state by creating relative velocity of parts or compression to a smaller volume. If a system in a stable equilibrium state were to produce work, that work could be used to cause the system itself to end in a nonequilibrium state with no net effects on the environment—contrary to the definition of its initial state.

This corollary applies strictly only to systems of which the energy can be increased indefinitely, such as any system with particles free to move from one place to another or any system with translational degrees of freedom. Most practical systems satisfy this requirement. The generalization to systems that do not satisfy the requirement, such as a nuclear-spin system, is discussed below under *Negative temperature*.

A perpetual-motion machine of the second kind (PMM2) is any device that would deliver net work—*e.g.*, raise an external weight—while undergoing a cycle and interacting with a single system in a stable equilibrium state. A perpetual-motion machine of the second kind is a device that permits a system to violate the corollary stated above and is, therefore, impossible.

Prior to the discussion of the fourth corollary, it is necessary to define the terms mutual stable equilibrium and reservoir. Two systems A and B are said to be in mutual stable equilibrium if the combined system AB is in a stable equilibrium state. It can be readily verified that, if two systems are in mutual stable equilibrium, each system must be in a stable equilibrium state. Moreover, if the two systems are brought into communication so that interactions are not prohibited, no interactions will occur.

A reservoir R is a special kind of a system that provides useful reference states for applications of the laws of thermodynamics and satisfies the following conditions: (1) it is closed to the transfer of rest mass—*i.e.*, its boundaries cannot be crossed by material particles; (2) its constraints are invariant with time—for example, its volume has the same value at all times; (3) it passes through stable equilibrium states only; and (4) in the course of finite interactions it remains in mutual stable equilibrium with a duplicate of itself that experiences no such interactions. An example of a reservoir is a mixture of solid, liquid, and vapour water in mutual stable equilibrium while enclosed in a container.

Reservoirs as systems

4. *Work done by a system in combination with a reservoir.* A system A in combination with a reservoir R can experience a work interaction with other systems either directly or through an intermediate device X, or both, while X is undergoing a cyclic process (Figure 1). During this work interaction no rest mass is exchanged between A and R while the state of A changes from A_1 to A_2. The work done is denoted by W_{12}^R for processes in general and by $(W_{12}^R)_{rev}$ for processes that meet reversibility criteria.

By virtue of the first and second laws it can be shown

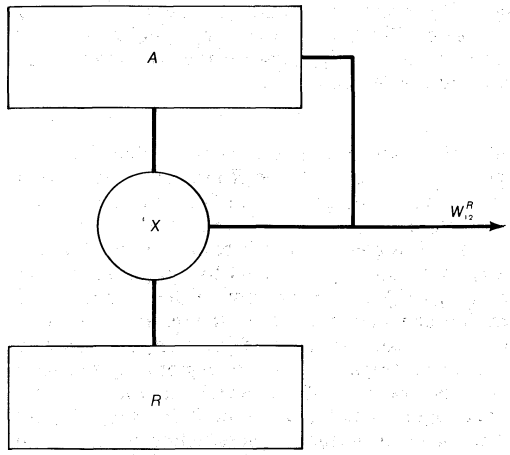

Figure 1: Production of work by a system *A* interacting with a reservoir *R* through an intermediate device *X* (see text).

that for a given change of state from A_1 to A_2, the work $(W_{12}^R)_{rev}$ is the same for all reversible processes and for all reservoirs in mutual stable equilibrium with each other; that is, $(W_{12}^R)_{rev}$ is fixed by the end states A_1 and A_2. Moreover, W_{12}^R cannot exceed $(W_{12}^R)_{rev}$ when both correspond to the same change of state from A_1 to A_2.

ENTROPY

The two laws of thermodynamics imply the existence of a property called entropy that is conserved in all reversible processes. Its definition is based on another property called available work.

Available work. Because for a given system and reservoir $(W_{12}^R)_{rev}$ depends on the end states of the system only, a property can be defined called available work (symbolized Ω, omega), such that its change of value between states A_1 and A_2 is equal to the work $(W_{12}^R)_{rev}$; that is (using the symbol $\equiv$ to imply definition),

$$\Omega_2 - \Omega_1 \equiv -(W_{12}^R)_{rev}. \tag{3}$$

It can be easily verified that available work is an additive or extensive property.

Definition of entropy. Because both energy and available work are extensive properties, the difference between them is also an extensive property. Entropy will be defined as the extensive property S the change of which, DS, in a change of state is equal to a positive constant c_R times the difference between the corresponding changes of energy DE and available work $D\Omega$ evaluated with respect to a standard reservoir. This definition can be written in the form of an equation; *i.e.*,

$$DS \equiv c_R\,(DE - D\,\Omega). \tag{4}$$

The symbol D denotes a change, finite or infinitesimal, in magnitude of the property the symbol of which it precedes.

The standard reservoir may be chosen to be a mixture of solid, liquid, and vapour water in mutual stable equilibrium, and an arbitrary value, as explained below, may be assigned to the constant c_R. Subject to subsequent considerations, an arbitrary value may be assigned to the entropy of an arbitrarily selected reference state of the system. Thereafter, by means of equation (4), a value may be found for any state, equilibrium or nonequilibrium, once values for E and Ω have been determined by appropriate measurements.

Entropy changes in adiabatic processes. If the process from state A_1 to state A_2 in system A is adiabatic—that is, system A experiences only work interactions—then the work done by A must, by equation (1), equal the decrease in the energy of A. For a reversible adiabatic process the work done must, by equation (3), also equal the decrease in available work, so that the difference between the decrease in energy and the decrease in available work must be equal to zero. It follows from equation (4) that for a reversible adiabatic process the entropy change of the system is equal to zero; that is, the entropy is invariant. Moreover, because the fourth corollary states that the work for any adiabatic process cannot exceed that for the reversible adiabatic process, it follows that for an adiabatic process in general the entropy change must be greater than or at least equal to zero. In terms of symbols these conclusions can be written as

$$(DS)_{rev}^{a} = 0, \text{ for reversible adiabatic processes,} \tag{5}$$

and

$$(DS)^a \geq 0, \text{ for adiabatic processes} \tag{6}$$

(the symbol $>$ means "greater than," and $\geq$ means "greater than or equal to").

Principle of increase of entropy. When equation (6) is applied to any process in an isolated system—*i.e.*, to an adiabatic process for which the work is zero—it becomes

$$DS \text{ (isolated)} \geq 0. \tag{7}$$

Thus, the entropy of an isolated system may remain constant or may increase, but a decrease of entropy in an isolated system is impossible. Because any process in any system may be conceptually changed to a process in an isolated system by including in the isolated system all systems with which the original system interacts, the conclusion represented by equation (7) is of great generality. Equation (7) is known as the principle of increase of entropy, although it may be more strictly said to be the principle of the impossibility of a decrease of entropy. According to this principle, whenever any process occurs in nature, the total entropy of all systems involved in the process must either increase or, if the process is reversible, remain constant.

STABLE EQUILIBRIUM

Criterion for stable equilibrium. Changes of state in an isolated system can occur only until the system reaches the unique stable equilibrium state consistent with the given values of energy, numbers of particles, and constraints. It follows from equation (7) that the entropy of the stable equilibrium state must be larger than that of any equilibrium or nonequilibrium state with the same values of energy, numbers of different particles, and constraints. By the same token, a criterion for stable equilibrium is that the entropy of the system should be at its maximum value for fixed values of energy, numbers of particles, and constraints.

Equations relating properties for stable equilibrium states. By virtue of the state principle, the simplest illustrations of the laws of thermodynamics are provided by applications to systems in or passing through stable equilibrium states. For the properties and the relations between properties of systems in such states can be expressed by means of relatively simple mathematical forms.

Composition of systems in stable equilibrium states

The term numbers of particles, as used in the state principle, implies certain species of particles. The set of species selected must be a minimum set in terms of which the composition of all allowed states may be described. Such a minimum set of species, which will be unique in the number of members for a given system regardless of the choice of species to make up the set, is called a set of components.

For a system A with given fixed values E of energy, n_1, $n_2, \ldots, n_k$ of the numbers of particles of components 1, $2, \ldots, k$ of the set of k components, and $\beta_1, \beta_2, \ldots, \beta_s$ of constraints $1, 2, \ldots, s$ of the set of s constraints, the uniqueness of the corresponding stable equilibrium state implies that the value of any property of A in that state must be fully and uniquely determined by the given fixed values. Moreover, for all stable equilibrium states, the values of a property F may be expressed as a mathematical function having a single value for each single set of values $E, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s$; that is,

$$F = F(E, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s). \tag{8}$$

Several relations like equation (8) for several properties may be manipulated mathematically to express the values of any property as a function of the values of any set of independent properties of stable equilibrium states. A set of independent properties is such that the value of each

property in the set can be varied without affecting the values of the remaining properties in the set.

Expressions for entropy and energy

Two functions of interest to subsequent considerations are those that relate the values of entropy S to the values of $E, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s$, and the values of energy E to the values of $S, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s$. These functions are denoted as

$$S = S(E, n_1, n_2, \ldots, n_k, \beta_1, \beta_2, \ldots, \beta_s) \tag{9}$$

and

$$E = E(S, n_1, n_2, \ldots, n_k \beta_1, \beta_2, \ldots, \beta_s). \tag{10}$$

In general, the change of entropy per unit change of energy, or of any of the numbers of particles, or of any of the constraints can be evaluated with the help of equation (9). The same remark applies to energy and equation (10). Such changes are called partial derivatives and are used to define a number of useful properties that have meaning for stable equilibrium states only.

Mutual stable equilibrium of closed systems. If two systems A and B that are closed to the transfer of rest mass taken together constitute a system in a stable equilibrium state, then the entropy of that system must be at a maximum for the value of its energy. One of the consequences of this requirement will be seen from a possible variation—a conceptual alteration of state consistent with the description of the system and the constraints imposed on it and its parts A and B by the environment—in which the energy of A is increased by a small amount denoted by dE_A, and that of B is decreased by the same amount, while both A and B pass through stable equilibrium states without changes of values of their constraints. The entropy of part A is correspondingly altered by the amount dS_A. This amount can be expressed as

$$dS_A = \left(\frac{\partial S_A}{\partial E_A}\right)_{n,\beta} dE_A,$$

in which $(\partial S_A/\partial E_A)_{n,\beta}$ denotes the rate of change of S_A per unit change of E_A as A passes through stable equilibrium states while its numbers of particles (n) and its constraints (β) are held constant, namely, the partial derivative of S_A with respect to E_A. A similar expression can be written for the entropy change dS_B of B, so that the alteration dS of combined system AB is given by the expression

$$dS = \left(\frac{\partial S_A}{\partial E_A}\right)_{n,\beta} dE_A + \left(\frac{\partial S_B}{\partial E_B}\right)_{n,\beta} dE_B. \tag{11}$$

It can be shown that if the entropy S is to be at a maximum for the given fixed value of energy $E_A + E_B$ of the combined system AB and for both positive and negative variations dE_A, then it is necessary that the two partial derivatives $(\partial S_A/\partial E_A)_{n,\beta}$ and $(\partial S_B/\partial E_B)_{n,\beta}$ be equal to each other, namely,

$$\left(\frac{\partial S_A}{\partial E_A}\right)_{n,\beta} = \left(\frac{\partial S_B}{\partial E_B}\right)_{n,\beta}. \tag{12}$$

The quantity $(\partial S/\partial E)_{n,\beta}$ of a system may be thought of as a potential that governs the tendency of energy to pass from one system to another. It can be shown that it is a "capturing tendency" in that if

$$\left(\frac{\partial S_A}{\partial E_A}\right)_{n,\beta} > \left(\frac{\partial S_B}{\partial E_B}\right)_{n,\beta},$$

"Capturing" and "escaping" tendencies

then dE_A may be greater than zero (energy may pass from system B to system A) in an actual process but not less than zero (because less than zero would be contrary to the principle of increase of entropy). Conversely, the reciprocal quantity $(\partial E/\partial S)_{n,\beta}$ may be thought of as an "escaping tendency."

Temperature. The potential that governs the flow of energy is called temperature. A scale of temperature may be defined in terms of any function of $(\partial S/\partial E)_{n,\beta}$ or $(\partial E/\partial S)_{n,\beta}$ that continuously increases or decreases with either. The scale commonly used in thermodynamics is the Kelvin scale of temperature. It is denoted by T and defined as

$$T \equiv \left(\frac{\partial E}{\partial S}\right)_{n,\beta}, \tag{13}$$

so that T becomes a measure of the escaping tendency of energy. The necessary condition, equation (12), for mutual stable equilibrium between two systems A and B is equivalent to an equality between the temperatures T_A and T_B of A and B, namely,

$$T_A = T_B. \tag{14}$$

From the observations that the work produced by the combination of systems A, X, and R used in the definition of entropy change is the decrease in energy of the combination AR and that for a reversible process the entropy of that combination is conserved, it is readily shown that the constant c_R in equation (4) is equal to the partial rate or derivative $(\partial S_R/\partial E_R)_{n,B}$ of the entropy of the reservoir R or the inverse of the temperature T_R of the reservoir. Because the magnitude of constant c_R is arbitrary, a selection of a value for it for a simple reservoir fixes not only the scale of entropy but also that of the Kelvin temperature. By international agreement the value of T for solid, liquid, and vapour water in mutual stable equilibrium is 273.16 K. Among the reasons for the selection of this five-digit figure is that it causes the temperature interval between the freezing and boiling points of water under a pressure of one atmosphere to be almost exactly 100 degrees. If any other reservoir R' is used with X and A, the change in entropy found from equation (4) for a change in state of system A from A_1 to A_2 will be the same as that found using R if constant c_R' is taken equal to the inverse temperature of the reservoir R'.

Entropy constant

When the number 273.15 is subtracted from the value of any given Kelvin temperature T, the result will be the Celsius temperature t, or t (degrees Celsius) $\equiv T - 273.15$.

Heat. An argument will now be outlined to prove that certain nonwork interactions are entirely distinguishable from work in that no fraction of any one such interaction will satisfy the definition of work.

If two systems A and B are in stable equilibrium states and each is under constant constraints, but they are not in mutual stable equilibrium, then an interaction could occur between them. By virtue of the third corollary of the second law, any such interaction must be a nonwork interaction; that is, its effects on at least one system, say A, could not have been produced while the sole external effect was the rise of a weight. In general, however, the effects on A could be produced while weights external to A are raised and, in addition, a change of state of B takes place. It can be shown that maximum work will be delivered to the weights if the process is carried out reversibly and each system passes through stable equilibrium states. A reversible cyclic device X (Figure 2) interposed between systems A and B will permit these conditions to be fulfilled. The device X may produce work, but the reversible interactions experienced by A with X and X with B cannot be work by virtue of corollary 3 of the second law.

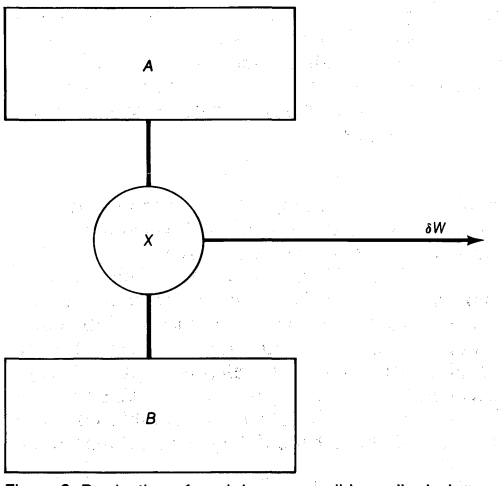

Figure 2: Production of work by a reversible cyclic device X that undergoes reversible nonwork interactions with systems A and B (see text).

For the reversible process just described it can be shown

from the functions that relate energy to entropy and other independent properties that the work δW that will be delivered to the weights is equal to the negative of the energy change dE_A of system A times the ratio $(T_A - T_B)/T_A$. This conclusion can be written as an equation; *i.e.*,

$$\delta W = -\frac{T_A - T_B}{T_A} dE_A. \tag{15}$$

In equation (15), the symbol d denotes an infinitesimal change of the value of a property, whereas δ denotes an infinitesimal amount of a quantity that is not a property or state function. Work is not a property of any system, and therefore δW is the appropriate way to indicate an infinitesimal amount of W.

Because dE_A is a measure of the magnitude of the interaction experienced by A with X, equation (15) expresses the work produced as a fraction of the magnitude of that interaction. As systems A and B approach mutual stable equilibrium, temperatures T_A and T_B approach equality, a necessary condition, and the fraction that represents the ratio of δW over dE_A approaches zero; that is, the work that can be obtained from the interaction between A and B through X becomes a vanishingly small fraction of the magnitude of the interaction. Moreover, it can be shown that then the interactions between A and X and between X and B are exactly equal, and each may be expressed as a product of temperature and entropy change $T_A dS_A$ and $T_B dS_B$.

In the limit, therefore, as T_A approaches T_B, the cyclic device X is no longer required, and the nature of the interaction approaches something completely distinguishable from work. It is this special kind of interaction that is called heat and denoted by the symbol Q. Moreover, for any process for which a system passes only through stable equilibrium states of fixed constraints and for a change of state corresponding to changes dS in entropy and dE in energy, the infinitesimal amount of heat $(\delta Q)_{rev}$ received by the system is given by the relations

$$(\delta Q)_{rev} = TdS = dE. \tag{16}$$

If the interacting systems pass only through stable equilibrium states, then the process will be reversible.

Heat is not a property of a system. Accordingly, the symbol δQ is used to denote an infinitesimal amount of heat but not the change in value of a property. Nor is heat contained within a system.

Meaning of heat

The term heat is used here in a special sense that is quite foreign to the popular conception of its meaning. A different term might have been used were it not for the historical association of the word heat with thermodynamics. It will be observed from the context that the word heat is reserved here for a very special kind of interaction between systems, which only by virtue of the laws of thermodynamics is entirely distinguishable from all other kinds of interactions, including the special kind called work. If a less restrictive definition had been used, then some of the relations between heat and entropy given here would not always hold.

Heat and flow of entropy. When a heat interaction occurs between two systems A and B that pass through stable equilibrium states, the process is reversible. For the combined system AB the process may be considered an adiabatic process for which the work is zero, so that, in accordance with equations (5) and (7) expressed in terms of subsystems A and B, $DS_A + DS_B = 0$. Because, from equation (16), DS_A is equal to $(\delta Q_A/T)_{rev}$ and different from zero, the heat interaction is associated with a flow of entropy from A to B if heat flows from A to B and conversely. By way of contrast, work in a reversible process leaves the entropies of the interacting systems unaltered.

To system B may be added a part that is not in a stable equilibrium state and that may experience an irreversible process without affecting the state of the other part or the interaction between A and B. Although the process as a whole is no longer reversible, the interaction is the same as before and could appropriately be called heat. A flow of entropy from A to B is still associated with the flow of heat from A to B, but the increase of entropy in B exceeds the amount that has flowed from A; that is, the statement $dS > \delta Q/T$ may be written for the irreversible process, and

$$dS \geq \frac{\delta Q}{T} \tag{17}$$

for processes in general.

For an adiabatic process equation (17) reduces to equation (6). For other processes equation (17) will apply provided that the only nonwork interactions are heat; that is, at least locally where the interaction occurs, the behaviour on each side of the boundary is the same as if both systems were passing through stable equilibrium states, with identifiable temperatures, and the process was reversible. It can readily be shown that certain nonwork interactions when used in place of δQ will not satisfy equation (17).

Inequality of Clausius. An inequality that was first stated by Clausius bears his name. It is as follows: For an irreversible cycle the sum of ratios, each of which is a heat δQ received by the system divided by the temperature T at which the heat is received, is always less than zero. When each amount of heat δQ is very small, the sum of the ratios $\delta Q/T$ can be represented by a cyclic integral, and the inequality of Clausius may be expressed by the relation

$$\left(\oint \frac{\delta Q}{T}\right)_{irrev} < 0. \tag{18}$$

(The symbol $\oint$ means to integrate over a closed path, the complete cycle.) The inequality of Clausius follows directly when the inequality of equation (17) is applied to each step of an irreversible cycle and summed up for all the steps, because dS, being the change in a property, sums up to zero. Application of the inequality of Clausius is restricted, of course, to processes for which all nonwork interactions are heat.

Work, heat, and change of energy. If work and heat interactions occur successively, then the total energy change dE will be the sum of the work effect $(-\delta W)$ and the heat effect δQ; or, by equations (1) and (16),

$$dE = \delta Q - \delta W, \tag{19}$$

the minus sign resulting from the conventions regarding the signs for heat and work.

Expression (19) for change of energy is applicable, of course, only to those processes for which the interactions are identifiable as heat and work. Because heat and work are limiting cases of actual processes, equation (19) is strictly applicable only where all interactions have been carried to these limits.

Reversible cyclic engine. By reference to the definition of heat, it will be observed that the reversible interactions between A and X and between X and B in Figure 2 are heat interactions in which one part of X is in equilibrium with A and another part with B, whether or not A and B are close to mutual stable equilibrium. Because the process for the combined system AXB is adiabatic, it can be shown that the heat δQ_B received by B is equal to the heat δQ_A received by A times the negative of the ratio of the temperatures of B and A; namely,

$$\delta Q_B = -\frac{T_B}{T_A} \delta Q_A. \tag{20}$$

The work produced by cyclic device X is, by equation (19), equal to the negative of the sum $\delta Q_A + \delta Q_B$, and, because of equation (20),

$$\delta W = -\delta Q_A - \delta Q_B = \frac{T_A - T_B}{T_A}(-\delta Q_A). \tag{21}$$

It is seen from equation (21) that X will produce positive work if $T_A > T_B$ and $\delta Q_A < 0$; that is, if heat flows from the hotter system to X and from X to the cooler system. The fraction η of the heat received from the hotter system that X converts to work is

$$\eta = \frac{T_A - T_B}{T_A}. \tag{22}$$

Reversible cyclic engines

This quantity is called the Carnot efficiency after Carnot, who, before the discovery of the first and second laws of thermodynamics, made the following statements concern-

ing the efficiency of engines working between reservoirs at specified levels of temperature: The efficiency of a reversible engine has a fixed value that is the same for all reversible engines and is greater than that of any irreversible engine.

An example of a reversible cycle in which a system receives all heat at one temperature and rejects all heat at another with reversible adiabatic changes between the two temperatures is the Carnot cycle, devised by Carnot. Its efficiency is given by equation (22).

Work-producing systems and devices. A problem of economic and social importance in heat engineering is the production of work to be used for practical purposes such as lifting weights, driving electric generators, propelling vehicles, or operating cutting tools. Work can be obtained from any system that is not in a stable equilibrium state as it changes toward a stable equilibrium state without changes in constraints. For example, work may be obtained by lowering a weight inside a closed system while causing—through appropriate levers, belts, and pulleys—a weight to rise outside. The production of work need not end until the internal weight has reached the lowest position in the gravity field that the configuration of the system permits. Similarly, an electric storage battery may produce work until it is completely discharged. The maximum work that can be produced by the system adiabatically will be obtained if the process is executed reversibly—that is, at constant entropy. The maximum work is only a fraction of the energy of the system. This fraction is larger the farther the system is initially from stable equilibrium; *i.e.,* the larger the difference between the maximum entropy corresponding to the initial energy and the entropy of the initial nonstable state. The fraction is equal to zero when the difference in entropy just described is equal to zero—namely, when the system is initially in a stable equilibrium state.

On the other hand, a system in any state, including a stable equilibrium state, can produce work when combined with a system in the environment that passes through stable equilibrium states but is not in mutual stable equilibrium with the first. The maximum work that can be obtained is the maximum possible decrease in the available work when the system in the environment acts as a reservoir, or it is the maximum possible decrease of one of the other availability functions discussed below when other conditions are imposed by the environment. In order to obtain this maximum, the work-producing process must be completely reversible. For example, if the system with the elevated weight described in the preceding paragraph is at a higher or lower temperature than the atmosphere, then further work may be obtained by interposing a Carnot heat engine between the system and the atmosphere, so that the system is gradually cooled or heated to the temperature of the atmosphere as heat flows to the engine and produces work. If the whole process is executed reversibly, then the maximum possible work will be produced.

The greatest sources of work are fuels found in nature that are either not themselves in stable equilibrium states—for example, uranium in a reactor—or are not in mutual stable equilibrium with the atmosphere from which they have been isolated in the course of geologic history—for example, the fossil fuels coal and petroleum. In either case, the maximum work can be obtained only by a reversible approach to stable equilibrium or mutual stable equilibrium.

In the case of uranium, a reversible nuclear reaction is required; for the fossil fuels, a reversible chemical reaction. A close approximation to a reversible chemical reaction is found in lead storage batteries used in automobiles for starting and for lighting. No close approximation to a reversible nuclear reaction has yet been realized in practice, although in principle such a reaction is possible.

Because the cost of work includes not only fuel costs but also capital costs that usually increase as irreversibility in the process is reduced, the economical means of producing work may in some respects depart radically from the reversible means. For example, in fossil-fueled central power stations, fuel and oxygen in the air enter into an irreversible chemical reaction that raises the temperature of the resulting products by about 2,000 degrees on the Kelvin scale and reduces the work available by about one quarter. Energy from these hot products is then transferred irreversibly across a large temperature difference to appear as heat added to liquid and vapour water that is the working fluid of a heat engine. The loss in work available is again about one quarter of that of the original fuel and air. Irreversibility in the heat-engine cycle accounts for another 10 percent, so that about 40 percent is actually realized as work delivered to the electrical distribution system.

Economical production of work

A Carnot cycle is an obvious but usually impractical means to produce work from heat interactions with hot products of chemical or nuclear reactions. Most commonly used is the Rankine cycle, in which heat is used to generate vapour from a liquid; the vapour is expanded through a work-producing engine, condensed to liquid as it rejects heat to the environment, and pumped back into the vapour generator. The Stirling cycle, which has had only limited application, passes through gaseous states only.

Simple systems

STABLE EQUILIBRIUM STATES

A closed simple system is one in which the numbers of particles of the various components are fixed and the only constraint provided by the environment is an upper value for the volume of the system. By virtue of the state principle, volume (regardless of shape) and energy become sufficient to determine a stable equilibrium state, and the number of independent properties is two. A system that is not influenced by capillarity and external force fields is a simple system. These conditions may be satisfied despite capillarity and gravity fields if homogeneous parts of the system are large, so as to have small surface-to-volume ratio, yet shallow in the vertical direction of the gravity field and free of electric and magnetic fields created by external bodies.

Definition of a simple system

For stable equilibrium states of a closed simple system, entropy S or any other property can be regarded as fixed by the two independent properties volume V and energy U; therefore, S can be expressed as a function of V and U of the form

$$S = S(V,U). \tag{23}$$

For a number of reasons the energy E of a simple system is denoted by a different symbol U and is called the internal energy. Alternatively, equation (23) may be solved for U in terms of S and V to give

$$U = U(S,V). \tag{24}$$

The energy change dU between two neighbouring stable equilibrium states can be expressed in terms of the corresponding entropy and volume changes, dS and dV, respectively, by means of the relation

$$dU = \left(\frac{\partial U}{\partial S}\right)_V dS + \left(\frac{\partial U}{\partial V}\right)_S dV. \tag{25}$$

The first partial differential coefficient has already been identified (by equation 13) as the Kelvin temperature. The second is the rate of energy change with change in volume in reversible adiabatic compression or expansion. It can be shown to be the negative of the pressure p that the system exerts on constraining walls. Substitution of the temperature T and the pressure p in equation (25) results in the equation

$$dU = TdS - pdV, \tag{26}$$

in which the first term in the right-hand member represents the heat and the second the work of a reversible process. It may be observed, however, that equation (26) holds for any change between neighbouring stable equilibrium states regardless of the nature of the process, because it is a relation between properties and changes in values of properties. But for the general process, the terms (TdS) and $(-pdV)$ are not in general equal to the respective heat and work that may be involved in the process.

By means of the criterion of stable equilibrium and equation (26), it can be shown that not only the temperature

but also the pressure must be uniform throughout a simple system in a stable equilibrium state.

Representation of states on diagrams. Because a stable equilibrium state in a simple system is determined by two independent properties, all such states may be represented by points on a surface in a space in which two of the three coordinates represent independent properties and the third the dependent property. Alternatively, the traces of planes of constant value of one property may be shown on a two-dimensional chart in which the coordinates represent the other two properties. Two common choices of the latter class are pressure–volume (p–V) and temperature–entropy (T–S) charts. An example of the former is shown in Figure 3 (left), with traces of planes of constant temperature from the pressure–volume–temperature space and of planes of constant entropy from the pressure–volume–entropy space. On the p–V chart the area under a curve of states represents the work done on a slowly moving piston that confines the fluid in a cylinder. On the T–S chart (Figure 3 [right]) the area under the curve represents the heat received by the system in a reversible process passing through the states represented by the curve. Because the

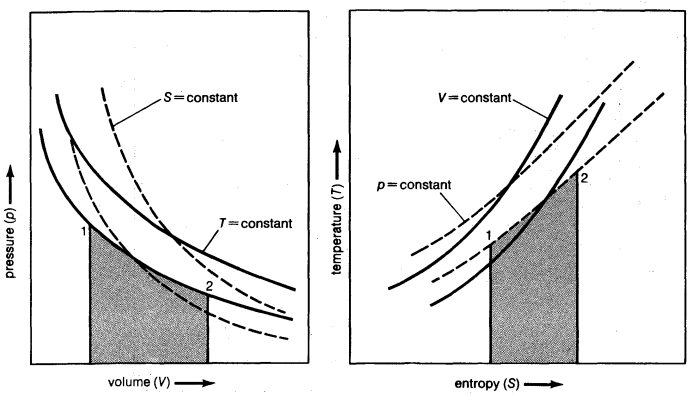

Figure 3: *Relationships between thermodynamic properties of systems.*
(Left) Relationships of pressure and volume of systems maintained at fixed temperature (T) or at fixed entropy (S). (Right) Relationships between temperature and entropy of systems maintained at fixed pressure (p) or at fixed volume (V).

change of energy of a system undergoing a cycle is equal to zero, it is seen from equation (19) that the cyclic integral $\oint \delta Q$ must be equal to the cyclic integral $\oint \delta W$. For a reversible cycle, TdS may be substituted for δQ and pdV for δW so that

$$\oint TdS = \oint pdV. \tag{27}$$

For any cycle, therefore, the area enclosed by the representation on the T–S chart is equal to that on the p–V chart; for example, the areas enclosed by the representations of the Carnot cycle in the p–V and T–S charts (Figure 4 [left] and 4 [right]) are equal.

Reversible constant-pressure process. The reversible process at constant pressure, because of its practical importance, warrants special consideration. Because for constant pressure the change in the product pV is also p times the change in V, pdV, it can be shown that the expression for the heat $(\delta Q)_p$ received by the system is equal to the change of an extensive property called enthalpy, which is defined by the relation $H \equiv U + pV$; that is,

Enthalpy

$$(\delta Q)_p = dH. \tag{28}$$

Thus, in any heating of a simple system in a such a way (for example, under a piston loaded by a weight) that its boundary expands slowly as it maintains constant pressure, the enthalpy of the system increases by the amount of heat added.

MAXWELL RELATIONS

For a closed simple system that assumes only stable equilibrium states, it follows from equation (26) that the partial derivative $(\partial T/\partial V)_S$ is equal to the negative of the partial derivative $(\partial p/\partial S)_V$. This equality is one of the Maxwell

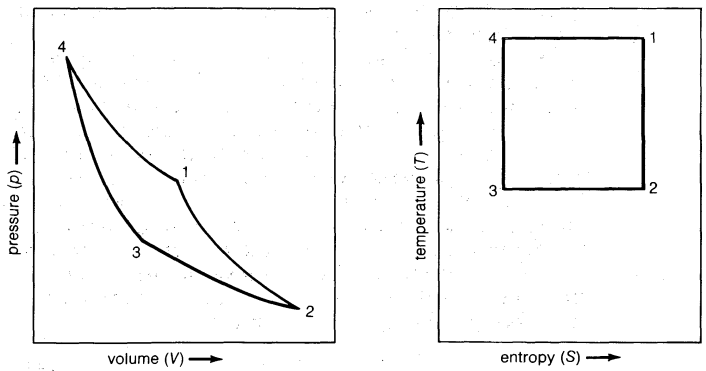

Figure 4: *Relationship between work done and heat received by a fluid undergoing a Carnot cycle.*
The lines from state 1 to state 2 represent reversible and adiabatic expansion of the fluid; from 2 to 3, reversible compression at fixed temperature accompanied by heat rejection; from 3 to 4, reversible and adiabatic compression; from 4 to 1, reversible expansion at fixed temperature accompanied by heat reception. The enclosed area (left) represents the net work done by the fluid during the complete cycle; it is exactly equal to the enclosed area (right) that represents the net heat flow to the fluid.

relations, named (as mentioned above) for the man who first stated them. The other Maxwell relations may be derived from the definitions of the thermodynamic properties enthalpy H, Helmholtz free energy Ψ, and Gibbs free energy Z (zeta); these definitions, respectively are:

$$H \equiv U + pV, \tag{29}$$
$$\Psi \equiv U - TS, \tag{30}$$
$$Z \equiv H - TS. \tag{31}$$

The Maxwell relations resulting from equations (26), (29), (30), and (31), are the following:

$$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V, \tag{32}$$
$$\left(\frac{\partial T}{\partial p}\right)_S = \left(\frac{\partial V}{\partial S}\right)_p, \tag{33}$$
$$\left(\frac{\partial S}{\partial V}\right)_T = \left(\frac{\partial p}{\partial T}\right)_V, \tag{34}$$
$$\left(\frac{\partial S}{\partial p}\right)_T = -\left(\frac{\partial V}{\partial T}\right)_p. \tag{35}$$

These four equations relate the entropy, a property whose value cannot be measured directly, to the properties pressure, volume, and temperature, all of which can be directly evaluated.

PHASE RULE

An intensive property of system A is defined as a property of which the value at a spatial point in a part of A approaches a limit independent of the size of the part as the size is reduced until it can no longer be identified as a system. As a system is subdivided into smaller and smaller parts, at some point a part becomes so small as compared with the extent of force fields between the parts that it is no longer isolatable and may not, therefore, be considered a system.

For certain stable equilibrium states of a simple system, parts of the system may assume different values of intensive properties; for example, liquid and vapour water may coexist in mutual stable equilibrium for which liquid and vapour parts have the same pressure and temperature but radically different densities. Each such part is called a phase. More generally, a phase of a system is the collection of all homogeneous parts open to the transfer of rest mass and having identical values of their intensive properties.

In the absence of chemical reactions and membranes that are permeable to one substance and not to another, the number of components of a phase of a multiphase system will be identical with the number of molecular species present in the whole system. As soon, however, as a chemical reaction is permitted in which some of these

species may be formed from others, then the number of components is reduced by one.

A closed simple system has two independent properties; a simple system open to the transfer of rest mass will have these same two plus the number n of components for the system, because the quantity of each component may be independently varied. On the other hand, the number of independent properties of the same simple open system is also equal to the sum $F+r$, in which F denotes the number of independent intensive phase properties and r the number of phases, because the F intensive properties fix the intensive states of the phases, and the r masses of the r phases fix the size of the system. From these remarks it follows that F is given by the relation

$$F = n + 2 - r. \tag{36}$$

The Gibbs phase rule

This is the phase rule of Gibbs. It reveals, for example, that for a single-component open system, such as water, the number of independent intensive properties may be 2, 1, or 0 if the number of phases present is 1, 2, or 3, respectively. Thus, for water vapour, temperature and pressure are independent properties; *i.e.*, after the value of one is arbitrarily selected, the value of the other may be arbitrarily selected. For coexisting liquid and vapour, either pressure or temperature may be considered the independent property; for coexisting solid, liquid, and vapour (the triple point), the values of all intensive phase properties are fixed by the nature of the substance, and the value of none may be arbitrarily selected. The triple-point temperature of water has been chosen as a fundamental point in defining the Kelvin temperature scale.

SIMPLE ONE-COMPONENT SYSTEMS

Phases. All systems that consist of a single pure molecular species, such as argon, oxygen, or water, exhibit largely common patterns of coexisting phases. A closed system of this kind, being a simple system, has two independent properties and the relationships between properties for stable equilibrium states may therefore be shown as a surface in three-dimensional space. The projection of one such surface onto the pressure–temperature plane is shown in Figure 5 (top) and onto a pressure–volume plane in Figure 5 (bottom). It will be evident from these figures that the solid may be heated under constant pressure until some liquid appears. Further heating increases the proportion of liquid present at constant temperature until the solid vanishes, leaving only liquid. Further heating increases the temperature of the liquid until vaporization begins, provided that the pressure is less than the critical pressure. Continued heating increases the proportion of vapour present at constant temperature until the liquid vanishes, leaving only vapour. The vapour may then be raised in temperature indefinitely or until chemical dissociation destroys the assumed purity of the molecular species.

At the critical pressure the coexisting liquid and vapour states are identical, and the vaporization process contracts to an infinitesimal process. At higher pressures no vaporization occurs. It becomes clear, then, that liquid and vapour states differ in degree rather than in kind, because any liquid state can be transformed to any vapour state by a process for which the system remains in a single-phase condition throughout. The same cannot be said of the transition from solid states to either liquid or vapour states.

Processes at constant volume and at constant pressure. When a simple system is heated at constant volume, no work occurs at the boundaries, so that the heat, according to equation (23), is equal to the increase in energy as well as to the product of temperature and increase in entropy:

Heat capacities

$$(\delta Q)_V = dU = TdS.$$

The heat of a constant-volume process is therefore equal to the area under the curve on a temperature–entropy chart. The constant-volume heat capacity is defined in terms of the partial derivatives of energy and entropy as follows:

$$C_V \equiv \left(\frac{\partial U}{\partial T}\right)_V = T\left(\frac{\partial S}{\partial T}\right)_V; \tag{37}$$

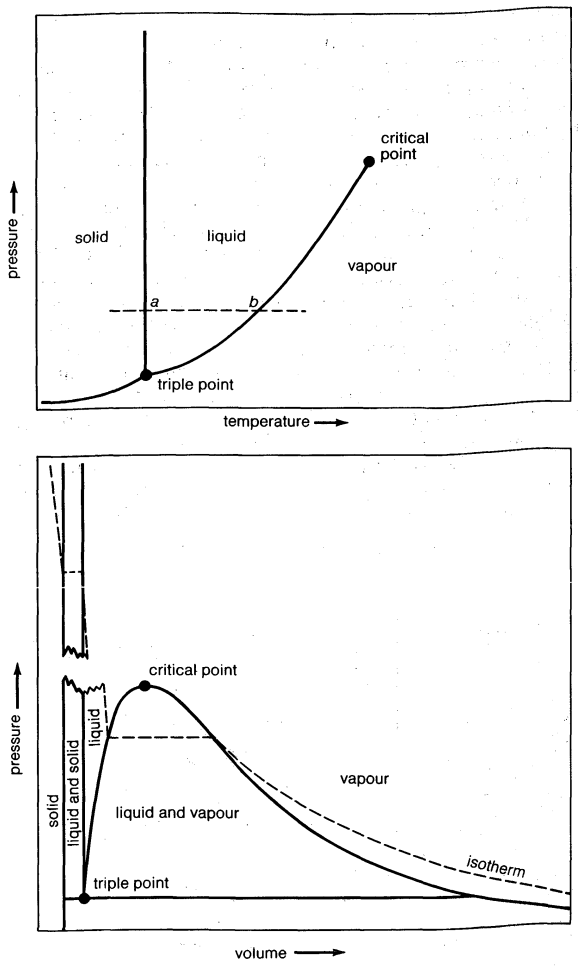

Figure 5: *Relationships between phases of a pure substance.* (Top) The horizontal broken line through *a* and *b* represents the effects of absorption of heat by a substance at a constant pressure. (Bottom) The broken line from lower right to upper left represents the effects of compressing a substance, initially entirely vaporous, while keeping the temperature fixed (an isothermal process).

and the constant-volume specific heat is defined similarly as

$$c_v \equiv \left(\frac{\partial u}{\partial T}\right)_v = T\left(\frac{\partial s}{\partial T}\right)_v, \tag{38}$$

in which lowercase letters denote values per unit of mass or per mole. By reference to equation (28) it will be seen by analogy that the corresponding definitions of heat capacity and specific heat at constant pressure are as follows:

$$C_p \equiv \left(\frac{\partial H}{\partial T}\right)_p = T\left(\frac{\partial S}{\partial T}\right)_p \tag{39}$$

and

$$c_p \equiv \left(\frac{\partial h}{\partial T}\right)_p = T\left(\frac{\partial s}{\partial T}\right)_p. \tag{40}$$

By means of Maxwell relations it can be shown that the difference between the two heat capacities is given by the product of two partial derivatives, both of which are fixed entirely by the relation between p, V, and T:

$$C_p - C_V = T\left(\frac{\partial p}{\partial T}\right)_V \left(\frac{\partial V}{\partial T}\right)_p. \tag{41}$$

When a phase change occurs during constant-pressure heating or cooling, the temperature is unchanged by the heating or cooling as long as both phases are present. The heat required in such a process to change a unit mass from one phase to the other is equal, according to equation (28), to an increase in enthalpy. It is called the latent heat of that phase change. Thus, a latent heat of fusion

h_{jl}, a latent heat of vaporization h_{fg}, and a latent heat of sublimation h_{ik} can be defined by means of the relations

$$h_{jl} = h_l - h_j = T(s_l - s_j), \quad (42)$$

$$h_{fg} = h_g - h_f = T(s_g - s_f), \quad (43)$$

$$h_{ik} = h_k - h_i = T(s_k - s_i), \quad (44)$$

in which subscripts *j, l, f, g, i,* and *k* refer, respectively, to solid in equilibrium with liquid, liquid in equilibrium with solid, liquid in equilibrium with vapour, vapour in equilibrium with liquid, solid in equilibrium with vapour, and vapour in equilibrium with solid.

In a two-phase region the change in any extensive property is directly proportional to the corresponding change in any other for a fixed value of temperature, and the pressure is a function of temperature only. From these observations and Maxwell relations (33) or (34), it follows that the rate of change of pressure with temperature change for a two-phase mixture is equal to the ratio of the entropy change to the volume change when a fixed quantity of the substance is changed from one phase to the other—*e.g.*, from liquid state to vapour state. Alternatively, the ratio of enthalpy change to volume change gives the rate of change of pressure with change in the natural logarithm (ln) of temperature:

The Clapeyron relation

$$\frac{dp}{dT} = \frac{s_2 - s_1}{v_2 - v_1} \quad (45)$$

$$\frac{dp}{d(\ln T)} = T\frac{dp}{dT} = \frac{h_2 - h_1}{v_2 - v_1}. \quad (46)$$

These equations are used to express the Clapeyron relation.

Equation of state. The mathematical relation between the pressure, volume, and temperature for stable equilibrium states of a closed simple system is called its equation of state. Although it will be subsequently shown to be a relation that does not completely specify the nature of the system, the mathematical relation is an important one because the three properties it relates are relatively easily measured.

Experimentally it is found that the relation between the pressure, volume, and temperature of a system is extremely complicated. No explicit mathematical expression has ever been devised that represents all the stable equilibrium states of any one simple system. Instead, equations have been proposed, each of which represents some limited range of states of a particular system. The complexity of equations of state ranges from that for a perfect gas with a single constant to those for liquid and vapour states, of which that for water is an example. Many equations in this category have between 10 and 100 constants, the values of which must be determined so as to fit experimental data.

For the range of liquid and vapour states of a pure molecular species, the general pattern of the *p-v-T* relation is best shown by drawing a graph of the quantity pv/RT versus the ratio of pressure to critical pressure. If v is taken to be the specific volume (the volume per unit mass) and R is chosen so that pv/RT becomes unity at zero pressure and infinite specific volume for any temperature, then a coincidence occurs: pv/RT is unity for every temperature for that substance, provided only that the specific volume is infinitely large. The constant R is called the gas constant of the molecular species.

The molecular weight of oxygen is 32 and the molecular weight M for any species is inversely proportional to the gas constant R of the molecular species. Thus, the molecular weight M of any species can be defined as 32 times the ratio of the gas constant of oxygen and the gas constant of the species:

$$M \equiv 32\,\frac{R\ (\text{for } O_2)}{R}. \quad (47)$$

It follows that the volume occupied by a molecular weight of a gas at very low pressure is the same for all gases for any selected pair of values of p and T. Moreover it is directly proportional to T and inversely proportional to p.

The universal gas constant

The product of molecular weight M and gas constant R is the same for all gases and is called the universal gas constant (denoted by $\boldsymbol{R}$). The result is an equation, called the perfect-gas equation of state, that appears frequently in the literature of thermodynamics; that is,

$$pv/\boldsymbol{RT} = 1, \quad (48)$$

in which v is the volume occupied by one molecular weight, or one mole, of gas.

The equation of state (48) applies, therefore, to any pure molecular species in states for which the specific volume is extremely large and the pressure, at finite temperature, is therefore extremely small. It holds within 2 percent for water vapour at a pressure of one atmosphere and with correspondingly better precision as the pressure is lowered. A gas that conforms to equation (48) is called a semiperfect gas.

By means of Maxwell relations and equation (23) it can be shown in the case of a semiperfect gas that internal energy, enthalpy, and both heat capacities are functions of temperature only and are independent of the effects of volume or pressure. Moreover, the difference $c_p - c_v$ between the specific heats is equal to the gas constant R when all three quantities are defined in terms of unit mass or, alternatively, in terms of molecular weight.

When quantum effects are not important, an approximate expression for the specific heat may be obtained from statistical thermodynamics. It is

$$c_v = \frac{f}{2}R, \quad (49)$$

in which f denotes the number of active degrees of freedom of the molecule (the number of independent ways in which the space configuration of the molecule may change). For a mass concentrated in a point, f would be three (corresponding to the three directions of translation), and c_v would be $3R/2$. With spatial distribution of the mass, additional degrees of freedom appear by virtue of rotation and vibration of the molecule. The number of such degrees of freedom active in a molecule depends, in accordance with quantum theory, on the temperature. In Table 1 are shown the molal heats of several gases at room temperature along with the corresponding number of degrees of freedom $c_v/(\frac{1}{2}R)$. For a monatomic gas this number of degrees of freedom proves to be three almost exactly; for diatomic gases it is nearly five (corresponding to two degrees of rotational freedom); and for more complex molecules, a number in excess of five, which implies vibrational degrees of freedom. For all except the monatomic molecule, the value of c_v increases with temperature as new degrees of freedom become active.

Table 1: Molal Specific Heats of Gases at Room Temperature

	c_v	c_p	$c_v/(\frac{1}{2}R)$	$c_p/(\frac{1}{2}R)$	$k = c_p/c_v$
He*	2.979	4.965	3.000	5.000	1.667
H_2	4.88	6.87	4.92	6.91	1.406
O_2	5.02	7.00	5.05	7.04	1.406
N_2	4.97	6.96	5.01	7.00	1.400
CO	4.97	6.96	5.01	7.00	1.400
H_2O	6.02	8.01	6.07	8.06	1.330
CO_2	6.81	8.80	6.86	8.85	1.292

*And all other monatomic gases.

The expressions for energy, enthalpy, and entropy of a semiperfect gas are as follows:

$$u = \int_{T_0}^{T} c_v dT + u(T_0), \quad (50)$$

$$h = \int_{T_0}^{T} c_p dT + u(T_0) + RT_0, \quad (51)$$

$$s = \int_{T_0}^{T} c_v \frac{dT}{T} + R \ln \frac{v}{v_0} + s(T_0, v_0)$$

$$= \int_{T_0}^{T} c_p \frac{dT}{T} - R \ln \frac{p}{p_0} + s(T_0, p_0); \quad (52)$$

in these equations the subscript 0 refers to an arbitrarily selected state.

Perfect gas

The perfect gas is a special case of the semiperfect gas—namely, that for which the internal energy and the enthalpy both depend upon temperature but the heat capacities are independent of temperature. The integrals of the previous expressions can now be resolved to give the following:

$$u = c_v(T - T_0), \tag{53}$$

$$h = c_p T - c_v T_0, \tag{54}$$

$$s = c_v \ln \frac{T}{T_0} + R \ln \frac{v}{v_0} + s_0,$$

$$= c_p \ln \frac{T}{T_0} - R \ln \frac{p}{p_0} + s_0, \tag{55}$$

in which s_0 denotes the arbitrary value of s at T_0 (for which u is zero) and at p_0.

For a reversible adiabatic process in a perfect gas, the following relations hold: $pv^k = \text{constant}$, $Tv^{k-1} = \text{constant}$, and $pT^{-k/(k-1)} = \text{constant}$; in these relations, k is the ratio c_p/c_v.

In 1873 the Dutch physicist Johannes van der Waals proposed the following equation, which in a qualitative way describes both the liquid and the vapour states of a pure species:

$$p = \frac{RT}{v - b} - \frac{a}{v^2}. \tag{56}$$

Van der Waal's equation

In this equation a and b are constants for any one species. Not only does this equation approach that of the semiperfect gas as v goes to infinity, but the equation also provides for a region of coexisting states that is capped by a critical state, as in actual substances. Below the temperature T_c (equal to $8a/27Rb$), three values of v correspond to each value of p. Pairs of high-volume and low-volume states, such as P and R (Figure 6), may be found at each pressure–temperature combination. The one pair for which the areas $PQbP$ and $QaRQ$ are equal can be shown to be the pair that can coexist in mutual stable equilibrium.

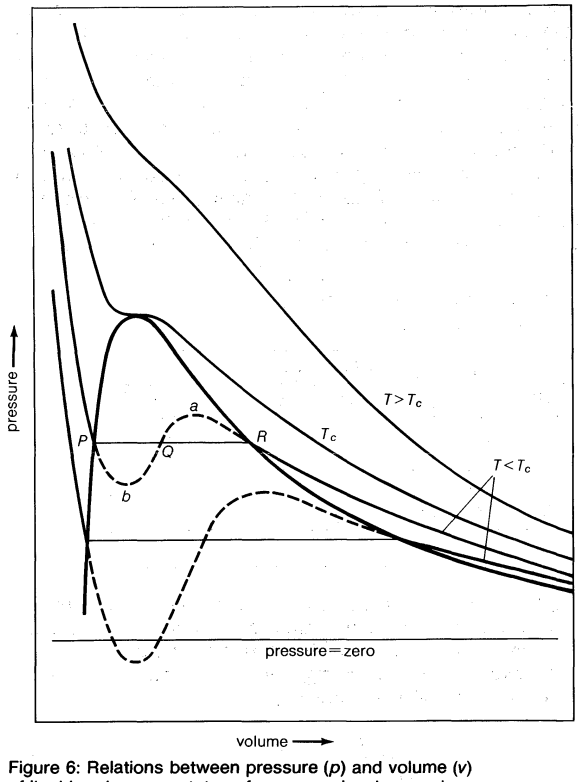

Figure 6: Relations between pressure (p) and volume (v) of liquid and vapour states of a pure molecular species at different temperatures according to the van der Waals equation (see text).

An approximate justification of the van der Waals equation can be made based in part on the Newtonian equation of motion for a collection of particles having the following characteristics: (1) the particles are uniform rigid spheres; (2) their diameters are appreciable fractions of the mean distances between them, except at infinite specific volume; and (3) they exert finite attractive forces, which vary with the distance between them, as well as infinite repulsive forces upon contact.

Equations of state, by proper assignment of values of constants, can be made to represent quantitatively (as contrasted with qualitatively for the van der Waals equation) the properties of many molecular species with fair precision. An equation has been developed that represents the properties of water within the precision of virtually all experimental measurements on the liquid and vapour phases of water.

Virial equations of state

A general type of equation of state, which can be made to fit almost any range of gaseous states at the expense of indefinite increase in the number of constants, is the virial form. It may be written as

$$\frac{pv}{RT} = 1 + B\rho + C\rho^2 + D\rho^3 + \ldots, \tag{57}$$

in which ρ denotes the density, and the coefficients B, C, D, . . . , called the second, third, fourth, . . . virial coefficients, are functions of temperature only. Substantial progress has been made in determining the forms of the functions B and C for the simpler molecular structures by means of models of the structure and force fields between them.

Critical point. The relationships between the various properties of a pure molecular species at and near the critical point have been the subject of many studies. It appears from these that certain mathematical singularities occur at the critical point, including an infinite value for the heat capacity at constant volume, which indicate that no continuous equation relating pressure, volume, and temperature can represent the actual variation in these properties for states closer than a few degrees in temperature to the critical point. A so-called scaling law has been devised to cope with the complications in the mathematical description of this region.

Fundamental equations. As was implied above by the development of the equation of state for a semiperfect gas, such an equation alone is not adequate to yield the values of energy u, enthalpy h, and entropy s. It must be supplemented by a knowledge of the variation of heat capacity with temperature.

A type of equation for which any of the properties p, T, u, v, s (or any algebraic combination of these) not explicit in it are found by differentiation is called a fundamental equation, and the corresponding function has been called a characteristic function. For a simple system, the four characteristic functions—specific energy u, specific enthalpy h, specific Helmholtz free energy ψ, and specific Gibbs free energy ζ—are expressed in terms of fundamental equations as follows:

$$u = u(v,s),\ T = \left(\frac{\partial u}{\partial s}\right)_v,\ p = -\left(\frac{\partial u}{\partial v}\right)_s, \tag{58}$$

$$h = h(p,s),\ T = \left(\frac{\partial h}{\partial s}\right)_p,\ v = \left(\frac{\partial h}{\partial p}\right)_s, \tag{59}$$

$$\psi = \psi(v,T),\ p = \left(\frac{\partial \psi}{\partial v}\right)_T,\ s = -\left(\frac{\partial \psi}{\partial T}\right)_v, \tag{60}$$

$$\zeta = \zeta(p,T),\ v = \left(\frac{\partial \zeta}{\partial p}\right)_T,\ s = -\left(\frac{\partial \zeta}{\partial T}\right)_p, \tag{61}$$

where the specific Helmholtz free energy ψ and the specific Gibbs free energy ζ are defined by

$$\psi \equiv u - Ts \text{ and } \zeta \equiv h - Ts. \tag{62}$$

SIMPLE MULTICOMPONENT SYSTEMS

Gibbs equation. The change of entropy dS between neighbouring stable equilibrium states of a simple system open to the transfer of rest mass can be expressed in terms of the corresponding change of energy dU, volume dV, and number of particles dn_i ($i = 1, 2, \ldots, k$) of the k components in the system. By use of equation (9) it can be shown that the expression for dS involves partial derivatives as coefficients that multiply the changes in the independent properties U, V, n_1, n_2, . . . , n_k:

$$dS = \left(\frac{\partial S}{\partial U}\right)_{V,n} dU + \left(\frac{\partial S}{\partial V}\right)_{U,n} dV + \left(\frac{\partial S}{\partial n_1}\right)_{U,V,n} dn_1 + \ldots + \left(\frac{\partial S}{\partial n_k}\right)_{U,V,n} dn_k, \quad (63)$$

in which subscript n denotes all of $n_1, n_2, \ldots, n_k$ that can be held constant. Upon identifying, as in equation (23), the first two partial derivatives in terms of pressure p and temperature T and introducing a new quality μ_i to be defined shortly, equation (63) becomes what is called the Gibbs equation:

$$dS = \frac{1}{T} dU + \frac{p}{T} dV - \frac{\mu_1}{T} dn_1 - \ldots - \frac{\mu_k}{T} dn_k. \quad (64)$$

Chemical potential

The quantity μ_i, which is called the chemical potential of component i in the system, is defined as follows:

$$\mu_i \equiv -T\left(\frac{\partial S}{\partial n_i}\right)_{U,V,n} \text{ for } i = 1,2,\ldots k. \quad (65)$$

Mutual stable equilibrium. Upon seeking the conditions that must be satisfied in order that two or more phases should be in mutual stable equilibrium while open to transfer of rest mass between them, it is unnecessary to consider any states for which any one phase would be in a nonequilibrium state if it were suddenly isolated. It is unnecessary because any change of state that could occur spontaneously while the phase was isolated would be one of many allowed changes of state when it was not isolated and would, therefore, serve as an indication that at least one spontaneous change is possible and that equilibrium does not exist.

It is sufficient, therefore, to consider only those states for which the individual phases are in stable equilibrium states when isolated. The Gibbs equation provides a general statement of the change of entropy of a simple phase that may exchange component substances with neighbouring phases as it passes through stable equilibrium states. If the formation of any new part unlike the existing parts is prohibited by the definition of the phase, then a set of stable equilibrium states is prescribed for which the Gibbs equation expresses changes in entropy between states in the set.

A heterogeneous system may be considered to be made up of several homogeneous phases, within each of which the formation of a new part is prohibited as proposed above. The states that these phases may assume consistent with mutual stable equilibrium may now be found by seeking out the state of maximum entropy of the whole system for a given volume and energy. This kind of procedure was used above to show that the phases of such a system must have equal temperatures. By similar reasoning it can now be shown that the phases must have equal pressures and equal values of the chemical potential μ_i of each component i present in all the phases. That is, among the necessary conditions for stable equilibrium of a multiphase simple system (*i.e.*, in the absence of force fields and capillarity) is uniformity throughout the multiphase system of temperature, pressure, and chemical potential of each component present in all the phases.

Of these conditions the one most open to exception is equality of pressure. In order for it to apply, an encroachment of the volume of each phase upon every other, for constant energy and composition of each phase, must be an allowed variation in state of the system. Wherever phases are separated by a rigid boundary, which may be permeable to one or more components, then equality of pressure between such phases is not necessary to mutual stable equilibrium.

If two phases are separated by a wall that is permeable to some components but not permeable to others, then equality of chemical potential of those other components across the wall is not necessary. An exception can be made as regards the potentials T, p, and μ_i in cases in which a transfer of energy, volume, and component i can occur at stable equilibrium in one direction but not in the other direction. Then a condition for mutual stable equilibrium becomes, because entropy is to be maximized, that the temperature in the phase that can receive energy but cannot supply it may be greater than or equal to the temperature in phases that can both receive and supply energy. Similar statements can be made in regard to pressure and the transfer of volume and in regard to chemical potential of component i and the transfer of that component.

These statements imply that potentials T, p, and μ_i are escaping tendencies for energy, volume, and component i, respectively. For equilibrium each escaping tendency must be balanced as between phases, unless the escape of one flux has reached its upper limit for a phase so that no further escape is possible. For such a phase it is necessary for equilibrium that the escaping tendency be not less than that in other phases, but it may be more. This consideration is relevant for certain quantum effects at low temperature, for two phases separated by a movable solid boundary that has come up against a stop and behind which the pressure may be greater than the pressure in front (but not less), and for exhaustion of a phase as regards one component.

From the definitions of enthalpy H (29), Helmholtz free energy Ψ (30), and Gibbs free energy Z (31), it is readily shown that the chemical potential can be expressed in alternative forms; that is,

$$\mu_i = \left(\frac{\partial U}{\partial n_i}\right)_{V,S,n} = \left(\frac{\partial H}{\partial n_i}\right)_{p,S,n} = \left(\frac{\partial \Psi}{\partial n_i}\right)_{V,T,n} = \left(\frac{\partial Z}{\partial n_i}\right)_{p,T,n}. \quad (66)$$

The last of these is known as the partial Gibbs free energy ζ_i of component i in the phase. In view of the definition of Z, μ_i may also be expressed in terms of the partial enthalpy h_i and the partial entropy s_i; thus,

$$\mu_i = \left(\frac{\partial Z}{\partial n_i}\right)_{p,T,n} = \left(\frac{\partial H}{\partial n_i}\right)_{p,T,n} - T\left(\frac{\partial S}{\partial n_i}\right)_{p,T,n} = \zeta_i = h_i - Ts_i. \quad (67)$$

In general, lowercase symbols with subscript i denote the partial property. For a phase of pure component i, any partial property is identical with the corresponding specific property—that is, the value of the property per unit mass, which is here taken to be the mole. The chemical potential of a component i in a mixture containing i is equal to the specific Gibbs free energy of i in a phase of pure i in equilibrium with the mixture through a membrane permeable to i alone.

A semipermeable membrane such as the one just proposed is one across which the pressure need not be balanced in order to maintain equilibrium. By definition of the membrane, encroachment of the mixture phase into the volume of the pure phase cannot occur, but the reverse encroachment can occur. The membrane must, of course, have sufficient structural strength to support the pressure difference.

The expression for the chemical potential of a semiperfect gas in terms of temperature and pressure is found from equations (67), (51), and (52). It proves to be the sum of a simple function of pressure p and temperature T plus a relatively complicated function $f_i(T)$ of temperature as follows:

$$\mu_i = RT \ln p + f_i(T), \quad (68)$$

in which the function $f_i(T)$ is different for different semiperfect gases i. For a given temperature, however, equation (68) indicates that the chemical potential increases with increase in pressure. That is, temperature being fixed, the escaping tendency increases as the pressure increases.

Three equations will be recorded here but not derived.

1. The Gibbs equation as an expression for the change in Gibbs free energy of a phase between neighbouring stable equilibrium states:

$$dZ = Vdp - SdT + \sum_i \mu_i \, dn_i. \quad (69)$$

In the equation the short notation $\sum_i \mu_i \, dn_i$ has been used

to denote $\mu_1 dn_1 + \mu_2 dn_2 + \ldots + \mu_k dn_k$, in which subscript $i = 1, 2, \ldots, k$ denotes a component substance.

2. The Gibbs free energy as a summation of products of chemical potentials and numbers of moles of component substances i of a phase:

$$Z = \sum_i \mu_i n_i. \tag{70}$$

Gibbs–Duhem equation

3. The Gibbs–Duhem equation, which relates for a phase the changes between stable equilibrium states in temperature, pressure, and numbers of moles of components:

$$SdT - Vdp + \sum_i n_i d\mu_i = 0. \tag{71}$$

Mixtures of gases. *Gibbs–Dalton rule for mixtures.* Gibbs revised the earlier rule of the 18th- and 19th-century English physicist John Dalton for determining the properties of a mixture of gases from the properties of the pure components. Two equivalent statements of the Gibbs–Dalton rule for mixtures are as follows: (1) The pressure in a mixture of different gases is equal to the sum of the pressures of the different gases as existing each by itself at the temperature of the mixture and with the same value of the chemical potential as it has in the mixture. (2) The pressure of a mixture of different gases is equal to the sum of the pressures of the pure components each existing as a phase in equilibrium with the mixture through a membrane permeable to the component.

Using single subscripts to refer to components in the mixture and double subscripts to refer to pure component phases, the Gibbs–Dalton rule takes the form

$$p = p_{11} + p_{22} + p_{33} + \ldots \tag{72}$$

for

$$T = T_{11} = T_{22} = \ldots, \tag{73}$$

and

$$\mu_1 = \mu_{11}, \mu_2 = \mu_{22}, \ldots. \tag{74}$$

In this notation p_1 would have no "operational" meaning because no instrument has been devised that can measure the pressure of component 1 when it is part of a mixture.

It can now be shown from the Gibbs–Dalton rule and the Gibbs–Duhem equation that the number c_i of mass units of component i in unit volume of the mixture (the concentration c_i of i in the mixture) is equal to the density ρ_{ii} or the inverse of the specific volume v_{ii} of i in the pure phase in mutual stable equilibrium with the mixture. The concentration c_i denotes the ratio of mass n_i of i in the mixture to the volume v of the mixture. It follows immediately that the density ρ (or $1/v$) of the mixture is the sum of the densities ρ_{ii} (or $1/v_{ii}$) of the pure phases.

Further application of the Gibbs–Duhem equation yields the following expressions for extensive properties:

$$U = nu = \sum_i n_i u_{ii},$$

$$H = nh = \sum_i n_i h_{ii},$$

$$S = ns = \sum_i n_i s_{ii},$$

$$\Psi = n\psi = \sum_i n_i \psi_{ii}, \text{ and}$$

$$Z = n\zeta = \sum_i n_i \zeta_{ii} = \sum_i n_i \mu_{ii} = \sum_i n_i \mu_i. \tag{75}$$

In these equations the mass n_i of component i in the mixture will be identical with n_{ii} the mass of i in the pure phase if the volume of the pure phase ii that is in mutual stable equilibrium with the mixture is made equal to the volume of the mixture. The result is in accord with Dalton's concept that each component behaves as if it were present alone.

A further conclusion that can be reached is that a Gibbs–Dalton mixture of semiperfect gases is itself a semiperfect gas. That is, for the mixture the ratio pv/RT is equal to unity if v is the volume per mole of all components and R the universal gas constant. If a specific gas constant is used and v is the volume per unit mass, then the mixture behaves as a semiperfect gas with a molecular weight M that is the mass m of the mixture divided by the total number n of moles of all components. It is also the average of the molecular weights M_i of the components, each weighted proportionately to the mole fraction y_i of that component in the mixture:

$$M = \frac{m}{n} = \sum_i y_i M_i.$$

Mixing gases. Some further results of the Gibbs–Dalton rule will be given here without proof. If a number of pure species are confined by thin partitions in separate parts of an insulated volume V in such quantities that their pressures are equal when their temperatures are equal, then when the partitions are removed (or destroyed), the gases will mix irreversibly without change in temperature, pressure, energy, or enthalpy. The change of entropy ΔS is greater than zero, as is appropriate for an adiabatic irreversible process. It is given by the negative of the product of the number n of moles of all components multiplied by the gas constant R and a mean logarithmic mole fraction:

$$\Delta S = -nR \sum_i y_i \ln y_i, \tag{76}$$

in which y_i denotes the mole fraction of the species i in the final mixture. Both the Helmholtz free energy and the Gibbs free energy decrease in the mixing process.

The Gibbs–Dalton rule holds in regions of state in which the pressure is low relative to the critical pressure of every component. Outside these regions an equation of state for a mixture may be devised from the equations of state of its components, with varying degrees of precision, by means of certain combining rules. One of these rules, proposed by the 19th- and 20th-century French physicist Émile Amagat, states that the volume of a mixture is the sum of the volumes of the pure components—each at the pressure and temperature of the mixture. A 20th-century U.S. chemist, James Alexander Beattie, later proposed a rule of more general application that prescribes how the coefficients in the Beattie–Bridgman equations for the pure components may be combined in order to obtain the corresponding coefficients for the mixture.

Vapour pressures of pure liquids. The vapour of a pure species may be in mutual stable equilibrium with its liquid at a flat interface at the normal or saturation vapour pressure corresponding to its temperature. The vapour may also, however, be in mutual stable equilibrium at a nonwetting porous wall that is permeable to vapour but not to liquid or at a curved interface, either of which can support a pressure difference between liquid and vapour. The effect of change in pressure of the liquid on the corresponding vapour pressure is called the Poynting effect. It is found by equating chemical potentials of liquid and vapour. For an incompressible liquid and a semiperfect vapour, the Poynting effect proves to be approximately proportional to the change in pressure on the liquid. For water at 40° C (104° F) the equilibrium pressure of the vapour increases by 1 percent when the pressure on the liquid is increased by a factor of 200.

The Poynting effect

Ideal solutions. When a solute is added to a volatile solvent, the volatility of the solvent is reduced. The effect is to reduce the pressure of solvent vapour that is in equilibrium with the liquid in proportion to the reduction in the mole fraction of solvent in the solution. Thus the effect on the volatility is the same for equal numbers of moles of different solutes in solution, the mole being measured as described by equation (47). This observation, which holds only for dilute or ideal solutions, is expressed in Raoult's rule. The rule states that at given pressure p and temperature T the pressure p_1' of pure solvent vapour in equilibrium with the solution is equal to the product of the mole fraction x_1 of solvent in the solution and the vapour pressure p_1° of pure liquid solvent at the pressure and temperature of the solution. By ignoring the small Poynting effect on the vapour pressure of the solvent, the rule of boiling-point raising may be derived from Raoult's rule by mathematical deduction. It is that the rate of change of boiling temperature T with mole fraction x_2 of solute 2, as solute is added to a dilute solution,

Raoult's rule

is equal to the rate of change of boiling temperature of pure solvent 1 with the logarithm of the pressure p_1° on the pure solvent. The mathematical statement of the rule of boiling-point raising is given by the relation

$$\left(\frac{\partial T}{\partial x_2}\right)_{x_2 \to 0} = \left[\frac{dT}{d(\ln p_1^\circ)}\right]_{x_2 = 0}. \qquad (77)$$

For water at 25° C (77° F) the value of $(\partial T/\partial x_2)$ is about 17° C (31° F) or, more practically, 0.17° C for each mole percent of solute regardless of the nature of the solute.

Figure 7 depicts a container in which volatile solvent liquid 1 is separated from a solution containing nonvolatile solute 2 by a wall M permeable to 1 only. The wall extends only part way to the top, leaving a vapour space with free access of vapour 1 from one liquid surface to the other. Because the pressure of vapour in mutual stable equilibrium with the solution is less, by Raoult's rule, than that in equilibrium with the pure solvent, the height of the solution surface must be greater than that of the pure liquid by enough to provide the appropriate hydrostatic head of vapour between them. The corresponding hydrostatic head of liquid, of course, is much greater and accounts, except for the head of vapour, for a substantial difference between the pressure of the solution and the pressure of the solvent with which it is in equilibrium through the semipermeable wall. This difference in pressure, which is required to prevent migration of solvent into the solution, is called osmotic pressure. With the usual approximations for a dilute solution and a perfect vapour, it can be shown by equating chemical potentials of solvent across the wall that the osmotic pressure P is approximately equal to the product of gas constant R, temperature T, and number of moles c_2 of solute per unit volume of solution.

Osmotic pressure

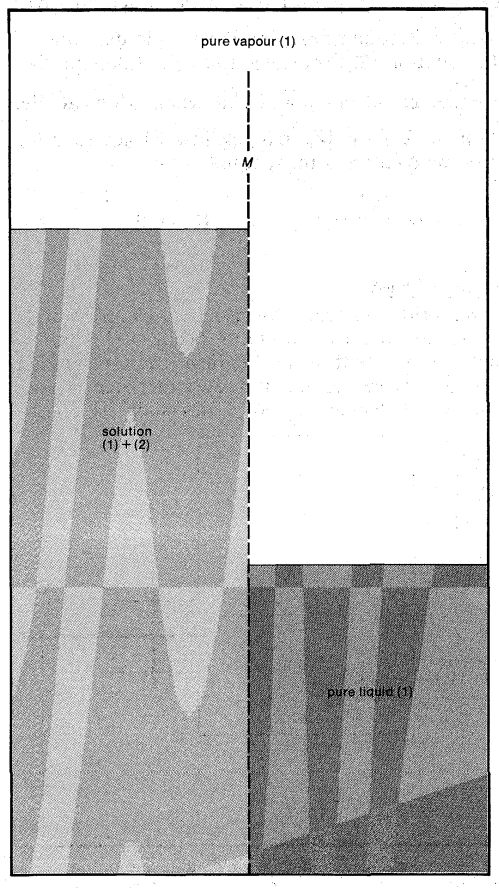

Figure 7: Equilibrium between a pure volatile liquid (1), a solution of nonvolatile substance (2) in liquid (1), and the vapour of substance (1). Substance (1) can pass through the membrane (*M*), but substance (2) cannot. The difference in the vapour pressures of solvent and solution causes the liquid levels to be unequal. The difference in pressure between pure liquid and solution is called the osmotic pressure (see text).

By means of the Gibbs–Duhem equation (71) and the assumption of perfect vapours for the two components of a binary solution, it can be shown that Raoult's rule requires that the pressure p_2^v of solute vapour in equilibrium with a solution is proportional to the mole fraction x_2 of solute in the solution; that is, p_2^v is equal to $k_2 x_2$, k_2 being a constant of proportionality. This relation is known as Henry's rule. Unlike Raoult's rule, in which the coefficient of x_1 is the vapour pressure of the pure solvent, the proportionality constant k_2 bears no simple relation to the properties of the components. Of course, if Raoult's and Henry's rules were to hold over the whole range of x_2 from 0 to 1, then k_2 would be the vapour pressure of pure solute. In general, however, the laws hold only for dilute solutions; that is, for x_2 nearly zero. An example of the variation of vapour pressures of a binary mixture of two completely miscible volatile species is shown in Figure 8, in which the distinction between Henry's rule constant k_2 and the vapour pressure p_2° of pure solute is made evident.

Henry's rule

Equation (68) for the chemical potential of a semiperfect gas can be used in combination with Raoult's and Henry's rules to show that any change in chemical potential of solvent in a solution between two states at the same temperature is proportional to the change in $RT \ln x_1$. Similarly, the change in chemical potential of solute is proportional to change in $RT \ln x_2$. Expressions for the chemical potentials, therefore, are

$$\mu_1 = RT \ln x_1 + \mu_1^\circ \qquad (78)$$

$$\mu_2 = RT \ln x_2 + \mu_2^\circ, \qquad (79)$$

in which μ_1° is the chemical potential of pure solvent ($x_1 = 1$) at the pressure and temperature of the solution. The quantity μ_2° is the chemical potential of pure solute in a hypothetical ideal-solution state for which x_2 is unity. Equations (78) and (79) indicate that the logarithm of the mole fraction of a component is the measure of the escaping tendency of that component.

When to an ideal solution at a given pressure and temperature is added some pure solvent starting from the same pressure and temperature, it can be shown that the total volume occupied by solution and solvent remains unchanged by the process of dissolving. Similar statements may be made concerning the total energy and total enthalpy. One consequence is that no heat flows to or from the fluids during this process of solution; thus, the heat of solution is zero, and the process is adiabatic. The total entropy, on the other hand, increases during the process of solution, as would be expected from equation (6) for an irreversible adiabatic process. In general, a similar addition of pure solute to an ideal solution will result in change in total volume, energy, and enthalpy, and the

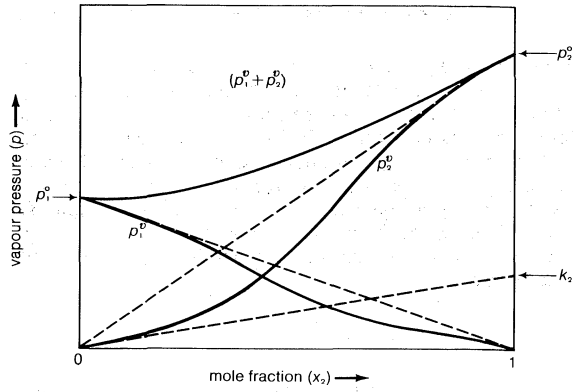

Figure 8: Variation of vapour pressure above solutions of two completely miscible volatile substances, 1 and 2, from pure 1 ($x_2 = 0$, $P_1^v = p_1^\circ$) to pure substance 2 ($x_2 = 1$, $P_2^v = p_2^\circ$). The Henry's rule constant, k_2, is shown as the tangent to the graph of p_2^v at $x_2 = 0$.

heat of solution will not be zero. The change in volume, energy, and enthalpy per unit of solute added will be independent of the composition of the solution over the range of ideality.

BULK FLOW

A kind of transfer of matter in which each elementary piece of the flowing fluid can be considered to be a closed and separable system bounded by a prescribed surface is called bulk flow. Contrasting with this definition is transfer of material by molecular diffusion, in which the flowing molecules cannot be considered to be closed and separable systems.

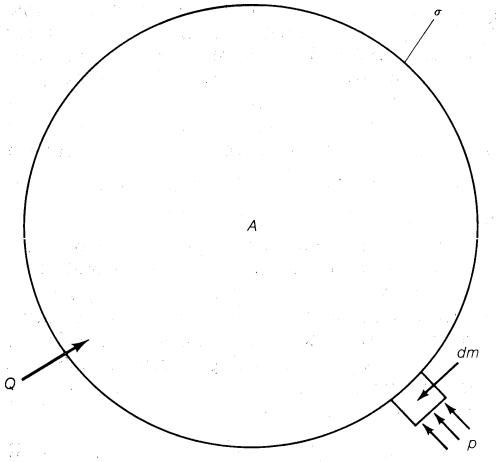

Figure 9: Schematic calculation of the change in energy of system resulting from the introduction of additional mass (see text).

Figure 9 shows a system A enclosed within a fixed boundary σ and an infinitesimal adjacent mass dm separated from A by a part of σ that is penetrable by A. The mass dm may be pushed across σ to join the larger mass inside. The work done by the surroundings on the combined system comprising A and dm will be equal to the product $pvdm$—namely, the pressure p multiplied by the specific volume v and the mass dm. This statement must be qualified by limiting it to slow motion of the boundary of dm and to zero shear effects in the fluid.

It can now be shown from equation (19) that the change in energy found within the boundary σ is the initial value of $E+pV$ for the mass dm, or $(e+pv)\,dm$, e denoting energy per unit mass. To this must be added any heat δQ that crosses the boundary of the combined system, and from it must be subtracted any work δW_x, called shaft work, that crosses boundary σ by virtue of torque in a rotating shaft or the equivalent. The corresponding statement for the energy change dE within σ when an infinitesimal mass of fluid dm crosses σ is

$$dE = (e+pv)dm + \delta Q - \delta W_x. \tag{80}$$

Equation (80) is sufficiently general to apply to otherwise simple systems that may change level in a gravity field and that depart from equilibrium to the extent that elementary parts acquire the uniform velocity φ. Then it may be shown by consideration of work in adiabatic processes that the energy e of unit mass is the sum of the internal energy u, the kinetic energy $\varphi^2/2$, and the gravity potential energy gz for height z above a datum level $z=0$, g denoting the gravity constant, which has the dimensions of acceleration:

$$e = u + \frac{\varphi^2}{2} + gz. \tag{81}$$

Equation (80) may now be repeated after substituting the enthalpy symbol h for $u+pv$:

$$dE = \left(h + \frac{\varphi^2}{2} + gz\right) dm + \delta Q - \delta W_x. \tag{82}$$

A special case of the problem of bulk flow is one for which inward flow and outward flow occur, each in one or more channels, and the state of the fluid within the control volume is the same at all times. The state of the control volume for which this assumption holds is called a steady state, and the flow condition is called steady flow. A simple example with single entry and single exit is shown in Figure 10. It would apply to a boiler, for which W_x is zero, and to a steam turbine, for which Q is nearly zero, as well as to many other engineering devices. Steady flow

The condition of steady state requires that dE be zero. The value of $\left(h+\frac{\varphi^2}{2}+gz\right)dm$ is then summed up over all entry and exit conditions. For the simple example of Figure 10, equation (82) indicates that the difference between $\left(h+\frac{\varphi^2}{2}+gz\right)$ at entry and exit when added to the heat Q' and shaft work W_x' passing inward across σ for each unit of mass entering must equal zero:

$$\left(h+\frac{\varphi^2}{2}+gz\right)_1 - \left(h+\frac{\varphi^2}{2}+gz\right)_2 + Q' - W_x' = 0. \tag{83}$$

CHEMICAL REACTIONS

Stable equilibrium states. An isolated closed simple system in which chemical reactions occur will attain a stable equilibrium state if those chemical reactions are left uninhibited to proceed as far as they will. Such a state is fixed by two independent properties such as energy and volume or temperature and volume, and it is called a state of chemical equilibrium. Among the properties of the chemical equilibrium state fixed by the two independent properties are the proportions of the molecular species present.

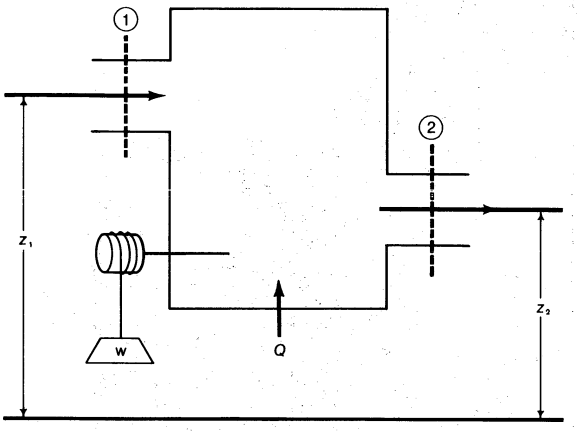

Figure 10: A system in a steady state in which the state of the fluid between boundaries 1 and 2 is the same at all times. The net mass flux across the entire boundary of the system must be zero. The heights of boundaries 1 and 2 above a datum are denoted z_1 and z_2 (see text).

When a chemical reaction proceeds at such a rate that chemical equilibrium is not achieved, each state passed through may be considered, for the purposes of analysis, to be a stable equilibrium state for which an anticatalyst has prevented chemical reaction. Between these states the system may experience chemical reaction in such degree as to produce a certain chemical aggregation in a second state different from that in the first. These states may be considered to have been achieved by successively removing and replacing an agent, such as an anticatalyst, that prohibits a chemical reaction. In the presence of such an agent each stable equilibrium state would correspond to a different set of proportions of species that would constitute a system with its own set of allowed states. To identify the state, therefore, it is necessary to add to the two independent properties required by the state principle an additional property that identifies the system. For example, for a mixture of molecules of nitrogen (N_2), hydrogen (H_2), and ammonia (NH_3) and the chemical reaction of formation of ammonia from the elements N_2 and H_2,

$$\frac{1}{2}N_2 + \frac{3}{2}H_2 \rightleftarrows NH_3,$$

the energy, volume, and some measure of the degree to which this reaction has proceeded in one direction or the other would be required to identify the system and its stable equilibrium state.

Heat in chemical reactions. For any chemical reaction in a simple system, for which heat Q and work W are the only interactions, the energy change ΔE is given, according to equation (19), by the difference between heat and work: $\Delta E = Q - W$. For a chemical reaction in a system held at constant volume, the heat $(Q)_v$, in the absence of other interactions, is given by the increment in energy:

$$(Q)_V = \Delta E. \tag{84}$$

For a chemical reaction in a system held at constant pressure, the heat $(Q)_p$ is given by the increment in enthalpy:

$$(Q)_p = \Delta H. \tag{85}$$

For steady flow between entry section 1 and exit section 2, the heat interaction, in view of equation (83), is the increase in enthalpy $H_2 - H_1$ between the two sections plus any shaft work W_x:

$$Q = H_2 - H_1 + W_x.$$

For a chemical reaction at constant volume in an isolated system, no change in energy occurs despite the large change in temperature that is usually observed, as may be seen from equation (84) in which $(Q)_V$ (and therefore ΔE) is equal to zero for an isolated system.

When values are sought in the literature for the properties E and H for use in the preceding equations or for S and Z for use in other equations, it is found that for different molecular species they are not available on a common base—that is, an arbitrarily selected zero state is used for each separate species independently of that for any other. It is necessary, therefore, to supplement data for the molecular species with data on change in values of properties when each species is formed from the chemical elements without change in pressure or temperature.

Equilibrium between chemically reacting species. Included in the description of a system is the set of possible states that the system may assume. The choice of this set is often arbitrary and may be made to suit convenience in approximating a real system and its behaviour. For example, a system consisting of a mixture of hydrogen and oxygen gases may or may not have included among its possible states those in which water has been formed by chemical reaction.

The description of a multicomponent system may or may not permit a certain chemical reaction in which some species are formed from others. Whenever a reaction is permitted that was not permitted before, the number of components, each of which must be independently variable, decreases by one. Moreover, one new kind of change of state is introduced—namely, a variation in which certain species leave phases in which they are actual components to form other species in phases in which these others are actual components.

For a reaction such that a moles of A combine with b moles of B, etc., to form k moles of K plus l moles of L, etc., the stoichiometric (chemical-reaction) statement is

$$aA + bB + \ldots \rightleftarrows kK + lL + \ldots. \tag{86}$$

This statement implies that the change Δn_A in number of moles of species A resulting from the reaction, when divided by the coefficient a, is numerically identical with similar quotients for the other species; *i.e.*,

$$\frac{\Delta n_A}{a} = \frac{\Delta n_B}{b} = \ldots = -\frac{\Delta n_K}{k} = -\frac{\Delta n_L}{l} = \ldots = -\Delta\xi. \tag{87}$$

The common value of the ratios, sometimes called the degree of reaction, is denoted by $\Delta\xi$. The stable equilibrium state in a system for which reaction (86) is allowed must be the state for which the entropy is at a maximum for all the states having given values of energy and volume of each phase. By reference to the Gibbs equation (64), it can be shown that this maximum is attained when the chemical potentials $\mu_A, \mu_B, \ldots, \mu_K, \mu_L, \ldots$ of species $A, B, \ldots K, L, \ldots$ are related as in the following equation, which is called the equation of chemical equilibrium:

$$a\mu_A + b\mu_B + \ldots - k\mu_K - l\mu_L - \ldots = 0. \tag{88}$$

Because for each component of a Gibbs–Dalton mixture of semiperfect gases the chemical potential may be simply expressed, as in equation (68), in terms of the logarithm of the partial pressure of the species in the mixture, the condition for stable equilibrium becomes such that a product of powers of the partial pressures $p_A, p_B, \ldots, p_K, p_L, \ldots$ is the same for a given temperature regardless of the proportions of the components that make up the mixture. This product is called the equilibrium constant in terms of pressure. For reaction (86) it is given by

$$\frac{p_K^k p_L^l \cdots}{p_A^a p_B^b \cdots} = K_p(T). \tag{89}$$

The variation of K_p with variation in temperature for a number of familiar reactions is shown in Figure 11.

From O.A. Hougen, K.M. Watson, and R.A. Ragatz, *Chemical Process Principles*, 2nd ed. (1957), used with permission of John Wiley and Sons, Inc.

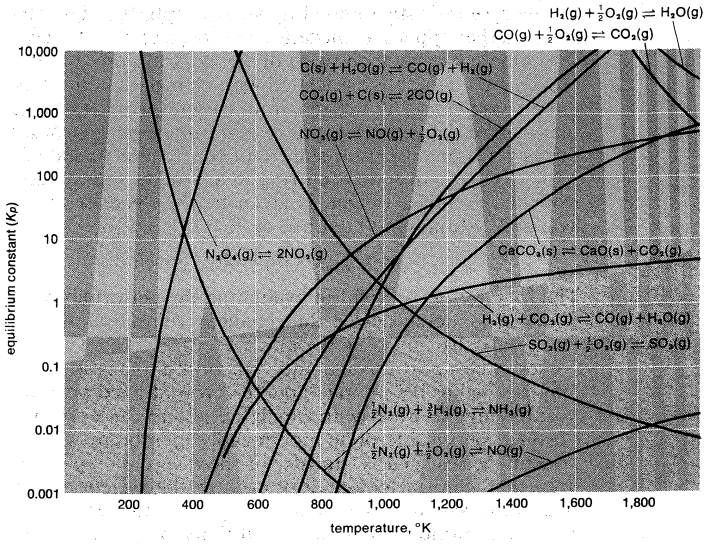

Figure 11: Variation in equilibrium constant, K_p, with variation in temperature for several chemical reactions (see text).

For a chemical reaction among the components of an ideal solution, a similar equilibrium constant is found for which the mole fraction x_I of component I is substituted in equation (89) for the partial pressure of component I:

$$\frac{x_K^k x_L^l \cdots}{x_A^a x_B^b \cdots} = K_x(T). \tag{90}$$

Equilibrium constants

When a gas mixture is not a Gibbs–Dalton mixture or a solution is not ideal, then a property called the fugacity takes the place of pressure in equation (89), and one called activity takes the place of mole fraction in (90). (For the definitions of these properties, see MATTER: *Solutions and solubility*.)

Because each of these so-called equilibrium constants changes with change in temperature, some knowledge of the rate of change of the value of K with temperature is of great value. This rate is expressed most simply as the rate of change of ln K with temperature, and it proves to be equal to the quotient of the change in enthalpy when the reaction occurs at constant pressure and temperature and the product RT^2. In non-ideal mixtures (or solutions) the change in enthalpy must be measured between a reactants state for which the fugacity (or activity) of each reactant species is unity and a product state for which the fugacity (or activity) of each product is unity:

$$[d(\ln K_a)/dT]_p = \frac{\Delta H^\circ}{RT^2}. \tag{91}$$

AVAILABILITY FUNCTIONS

The economic and engineering importance of a system in a given state is often determined by its available work Ω_R with reference to ambient systems as a reservoir. The function Ω_R, which was used above to introduce and define entropy, proves to be one of a number of availability functions (all of which were stated or implied by Gibbs in his papers of 1873 and 1877–78).

The decrease in Ω_R between two states of a system is the maximum work that can be obtained from the system and a reservoir at T_0, no net changes of state occurring in any other systems aside from, for example, the rise of an external weight. The maximum work is also the value of the work produced by system and reservoir in a reversible process and is a value common to all reversible processes joining the two prescribed states of the system. In view of equation (4) and the definition of the entropy constant c_R, the decrease in available work Ω_R may now be identified as the decrease in the quantity $(E - T_0S)$, in which the subscript 0 is introduced to refer to the reservoir. The value of Ω_R itself may be taken to be the maximum possible decrease in $(E - T_0S)$, which is also the decrease when the system changes to a state of mutual stable equilibrium with the reservoir.

If the system is surrounded by an atmosphere at temperature T_0 that applies a constant pressure p_0 at all interfaces with other systems, then some of the work discussed in the previous paragraph is associated with change in volume of the atmosphere. The net maximum useful work, $(W_u)_{max}$, that can be delivered by system and atmosphere to other things for a change from state 1 of the system to state 2, no net changes in state occurring in any other things aside from the rise of a weight, is given by the decrease in an availability function Φ defined as $E + P_0V - T_0S$:

$$(W_u)_{max} = \Phi_1 - \Phi_2.$$

The function Φ is useful in evaluating the performance of a work-producing device that changes volume as it uses up its capacity for doing work.

A less well-known availability function is that for a system exposed as before to a large reservoir at fixed pressure p_0 and temperature T_0 with which the system can exchange (through permeable or semipermeable membranes) component species; that is, transfer of these species can occur until the chemical potential of each in the system equals that in the reservoir. This availability function, denoted by Ξ, has a minimum value of zero. It is given by the relation

$$\Xi \equiv E + p_0V - T_0S - \sum_i \mu_{i0}n_i, \qquad (92)$$

μ_{i0} denoting the chemical potential of component i in the reservoir.

NEGATIVE TEMPERATURE

In the interest of simplicity, the third corollary of the second law was stated above as follows: A system in a stable equilibrium state can receive work but cannot produce it. Although this statement is satisfactory with regard to all ordinary systems, which are also called normal systems, recent developments in the theory of nuclear spins—the spinning of neutrons and protons of the atomic nucleus that contributes to both the angular momentum and the magnetic moment of the atom—have shown that some systems, which will be called special systems, in stable equilibrium states can produce work but cannot receive work.

Characteristics of special systems

A special system requires the following characteristics: (1) the energy of its allowed states has a finite upper limit; and (2) it must be coextensive in space with another system that shields it from work interactions that would change its volume or the velocity of its parts. For example, a lithium fluoride crystal may be considered to contain two distinct systems occupying the same space. The first, a special system, consists of the nuclear spins of the atoms of the crystal and has the energy of these spins. The second, a normal system, consists of the same atoms in the crystal, but its energy does not include that of the nuclear spins of the atoms. The stable equilibrium states of the two coextensive systems can be identified and distinguished because each comes to equilibrium in itself much more rapidly than they together approach mutual stable equilibrium.

It can be shown by reference to the second law of thermodynamics that for a closed special system the entropy–energy diagram is as shown in Figure 12. The curve ABC represents stable equilibrium states as well as the upper boundary for the region of all allowed states for given

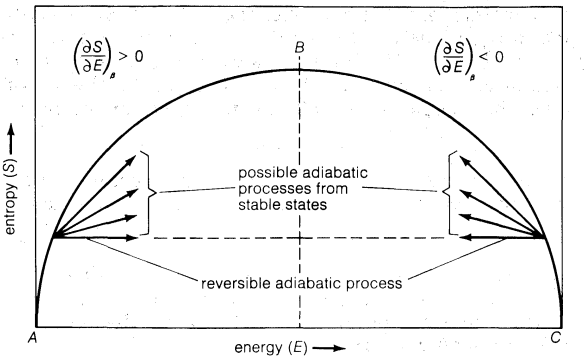

Figure 12: Entropy–energy diagram for a closed special system, for which negative absolute temperatures exist (see text).

values of constraints β. Normal stable equilibrium states, which a special system may assume, are those on the AB part of the curve. Special stable equilibrium states are those on the BC part of the curve, and for these special equilibrium states the energy decreases with increase of entropy. In view of the definition of temperature (equation [13]), the temperature is therefore represented by a negative number.

The significance of negative temperatures on the scale of hotness and coldness can best be described in terms of the reciprocal Kelvin scale τ, in which $\tau \equiv 1/T$. The possible range of values of τ is from minus infinity to plus infinity, with the hottest temperature possible at minus infinity and the coldest temperature possible at plus infinity. Thus, negative temperatures correspond to hotter levels (the direction of heat flow being from hot to cold) than plus infinity on the Kelvin scale. The so-called absolute zero on the Kelvin scale becomes plus infinity on the τ scale of temperature.

THIRD LAW

Valid calorimetric experiments at temperatures near zero on the Kelvin scale invariably are in accord with the following postulate, which is the third law of classical thermodynamics: The entropy of any finite system approaches a noninfinite value as the temperature on the Kelvin scale approaches zero.

States to which the third law is applied

The third law applies only to stable equilibrium states and implies that the heat capacity at constant constraints must go to zero at zero temperature. It follows that a substance cannot be treated as a perfect gas at temperatures near zero, because for a perfect gas the specific heat capacity at constant volume is constant, and the entropy, as given by equation (55), approaches minus infinity. For crystalline substances near zero temperature, the variation of heat capacity is often found to be proportional to T^n, n being greater than unity.

From the third law in combination with the second law, it can be shown that for any finite system all paths of stable equilibrium states for fixed values of constraints β_i must converge on a single value of entropy as they approach zero temperature, as shown in Figure 13.

From the curve of stable equilibrium states for constant values $\beta_{i'}$ of constraints β_i, a branching may occur, as shown by Pn of Figure 13, but the states along Pn cannot be stable equilibrium states. They may be metastable or unstable, and the constant-entropy process nk from one of these states to the corresponding stable equilibrium state can be neither reversible nor adiabatic. Moreover, the change at zero temperature from n to m may be a spontaneous irreversible change to a stable equilibrium

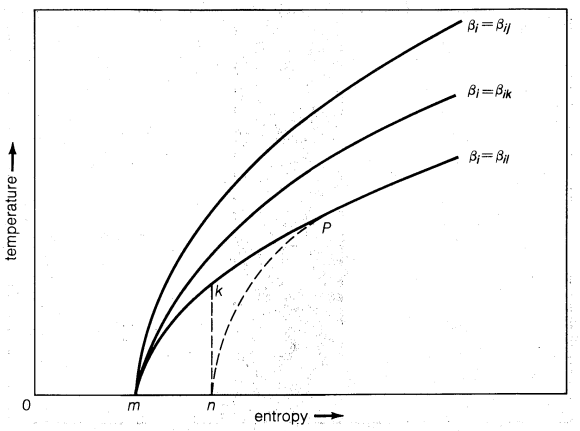

Figure 13: Convergence of values of entropy of stable equilibrium states of a system upon a single value at very low temperatures, as postulated by the third law of thermodynamics. For a given value β_{il} of constraint β_i, *Pm* represents stable equilibrium states and *Pn* metastable states (see text).

state. It follows that, as the temperature approaches zero, the magnitude of the entropy change in any isothermal reversible process approaches zero. This is the Nernst heat theorem, named for the Nobel-Prize-winning German chemist, which is a corollary of the third law as stated above. An equivalent statement is that, as the temperature approaches zero, the magnitude of the entropy change between any pair of stable equilibrium states at the same temperature approaches zero.

Nernst heat theorem

Because the change between stable equilibrium states may involve a change in value of a constraint, such as the volume, all states that can coexist in stable equilibrium at zero temperature must have the same minimum value of the entropy for the same mass. Moreover, if a system consisting of chemically reacting species can be brought into a stable equilibrium state by imposing appropriate electrostatic forces in an electrolytic cell, then the system must have the same minimum value of entropy whether in the reactants state or the products state.

It is appropriate now to assign the value zero to the minimum value of the entropy for a given system. The energy at any finite temperature for given values of constraints β may be found from the experimentally determined relation between the heat capacity C_β and temperature by integrating the product $C_\beta\, dT$ from temperature zero to temperature T:

$$[E - E_{(T=0)}]_\beta = \int_{T=0}^{T=T} C_\beta dT.$$

Similarly, the entropy at any finite temperature may be found by integrating the product $(C_\beta/T)dT$:

$$S_\beta = \int_{T=0}^{T=T} \frac{C_\beta}{T}\, dT.$$

It is possible, therefore, to determine the values of Gibbs free energy $(E + pV - TS)$ for chemically reacting species at some standard pressure and temperature and, from these values, the conditions for chemical equilibrium, including the equilibrium constants—all without experimental values for the chemical reaction as such between the species.

Force fields

NONRELATIVISTIC EFFECTS

When to the conditions for a simple system, gravitational, electrical, and magnetic constraints in the form of applied force fields are added, an additional term appears in the Gibbs equation for each additional constraint. Each added term is a product similar to the product pdV in that it represents the work done in a reversible process in which the value of a constraint is varied.

When a gravity field is applied to a system of mass small enough so that the field is affected by it only negligibly, a gravity potential γ may be defined as the increase in energy per unit mass of an elementary system as it is moved from a reference level ($\gamma = 0$) to the given level while entropy, number of particles, and volume constraint are held constant. The Gibbs equation (64) for a system of mass m then becomes

$$dS = \frac{1}{T}[dE + pdV - \sum_i \mu_i dn_i - md\gamma]. \qquad (93)$$

A simple and familiar condition for stable equilibrium that can be deduced from the Gibbs equation in form (93) is that for an otherwise simple fluid system in a gravity field, the rate of change of pressure with vertical distance is proportional to the density of the fluid. The proportionality factor proves to be g, the so-called acceleration of gravity.

A modification of the Gibbs equation similar to but more complicated than that given above for a gravity field has been devised to apply to a dielectric material, a material of which the electrically charged component species cannot move from one position in the material to another as it changes between neighbouring stable equilibrium states in an electric field between the plates of a capacitor. Another has been devised for a magnetic material in a magnetic field. (They will not be given here.)

RELATIVISTIC EFFECTS IN A GRAVITY FIELD

In an extremely intense gravity field, relativistic effects cannot be ignored. By combining the Einstein relation between energy and mass ($E = mc^2$) with the first and second laws, the following two conclusions are reached: (1) For stable equilibrium in a vertical column, it is necessary, as in nonrelativistic systems, that the temperature, $(\partial E/\partial S)_{n\beta}$, be uniform. (2) If a system is held at constant volume and lifted reversibly and adiabatically—that is, at constant entropy S—the pressure and temperature of the system both increase. More specifically, the increase in the natural logarithm of the pressure when the system is lifted from the level at which the gravity potential γ is arbitrarily assigned the value zero to a level at which it has the value γ is equal to the quotient of γ and the square of the speed of light c. A similar statement holds for temperature. Since the square of the speed of light c is a very large number, the effect on pressure and temperature will be small except in very intense gravitational fields.

The relation between temperature and gravity potential may be derived by consideration of a cycle in which a pure molecular species in a triple-point state (for example, solid, liquid, and vapour in mutual stable equilibrium) is lifted reversibly, adiabatically, and at constant volume from the reference level $\gamma = 0$ to the level γ, heated reversibly at constant temperature, lowered reversibly and adiabatically to $\gamma = 0$, and cooled to the original state. Because of the increase in mass in the heating process, the work of descent will exceed the work of ascent. The efficiency of this cycle may then be equated to that of a Carnot cycle in terms of temperature, as in equation (22), to obtain the desired relation.

Steady rate processes

Many applications of thermodynamics involve interactions between systems some or all of which are passing through nonequilibrium states. For example, chemical and nuclear reactions and flow of energy and matter are processes occurring in systems passing through nonequilibrium states.

Problems of analysis of nonequilibrium states

The analysis of nonequilibrium states is more difficult, both conceptually and numerically, than that of stable equilibrium states. For example, because the number of properties required for the description of nonequilibrium states is larger than that for stable equilibrium states, the mathematical relations between properties are correspondingly more complicated.

In the interest of simplicity, the following applications are restricted to systems in steady states having fixed time rates of change of extensive properties. These applications will be called steady rate processes.

APPROACH TO MUTUAL STABLE EQUILIBRIUM

If two systems *I* and *II* are each in a stable equilibrium state but not in mutual stable equilibrium, a process in

which they change toward mutual stable equilibrium will occur if they are connected by an intermediate system M. Depending upon the nature of the three systems and their states, the process that occurs may be caused by the transfer through M of energy alone or of matter with energy. The rate at which such transfer occurs will depend upon the initial departure from mutual stable equilibrium of systems I and II. By means of the first and second laws of thermodynamics and one additional postulate to them, a number of useful relationships between rates and potential differences or gradients may be determined for a large variety of rate processes, most of which are irreversible.

Generally it is possible to conceive of the process in M as being caused by two systems I and II, each of which would immediately assume a stable equilibrium state if the communication with M were suddenly stopped. To meet this requirement, the conductivity of matter or energy in I and II must be very great, so that whatever the influence on I of interaction through M with II, that influence will be felt uniformly through I and similarly with II. If the region is fluid, this result could be attained by minimal stirring of the fluid.

Under these circumstances, values of properties may be assigned to systems I and II. Region M, on the other hand, is in a nonequilibrium state. Nevertheless, values of intensive properties such as temperature and chemical potential of component i can be assigned to a point A in the region M by the method known as local isolation. This method consists of isolating a region comprising point A and measuring the intensive property for this region when it reaches a stable equilibrium state. The value of the property in the limit as the size of the region is reduced to the smallest consistent with isolation may be taken to be the value at point A.

Region M will be assumed to be in a steady state; that is, the rate of change of any intensive property of I, II, or M is negligible. Extensive properties of I and II, on the other hand, may change at a finite rate, and any such rate is called a flux. Thus, an energy flux J_u is defined as the negative of the change of energy of I per unit time and, because of steady state in M, the change of energy of II per unit time:

Fluxes of extensive properties

$$J_u \equiv -\frac{dU_I}{dt} = \frac{dU_{II}}{dt}. \tag{94}$$

Similarly a flux of component i is denoted by J_i and is given by

$$J_i \equiv -\frac{dn_{iI}}{dt} = \frac{dn_{iII}}{dt}. \tag{95}$$

Under the steady-state conditions assumed and with I and II each held at constant volume, any one flux must depend upon those differences in intensive properties between I and II that measure the departure from stable equilibrium. Among these may be differences in temperature, pressure, mole fraction of component i, potential of component i, etc. The choice of differences that is made is governed by the postulate to be employed. It is made by expressing the rate of entropy generation in the process in terms of the Gibbs equation and using the resulting expression to define conjugate pairs of fluxes and forces. Each flux is then expressed in terms of all the forces so defined.

The region M between I and II may be subdivided into vertical laminas dM, over any face of which, for interaction in one direction only, the values of all intensive properties are uniform. For any one lamina, therefore, constant-volume stable equilibrium regions I and II may be substituted for material adjoining M without altering the process in the lamina (Figure 14).

For steady state in dM the rate of entropy generation in the process will be wholly accounted for by changes of entropy in I and II. Because the Gibbs equation (64) states the entropy change of a phase such as I or II in terms of the temperature, chemical potentials of components, change in energy, and change in masses of components, it will yield an expression for the rate of entropy change in terms of temperature, chemical potentials, and rates of change of energy and masses. These rates of change

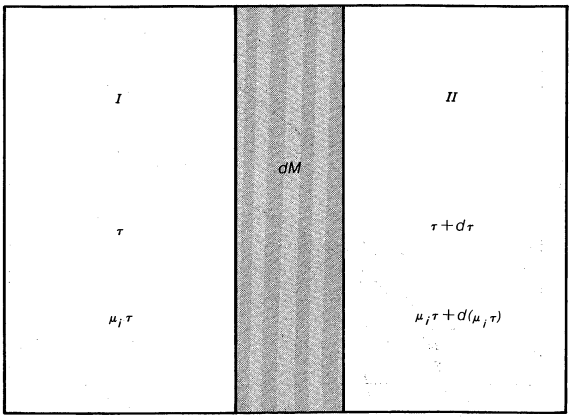

Figure 14: Two systems, *I* and *II*, each in stable equilibrium but not in mutual stable equilibrium, interacting through a thin intermediate system *dM*, which is in a nonequilibrium state. The symbol τ represents the quantity $1/T$, the reciprocal of the absolute temperature (see text).

are the fluxes, J_u and J_i, of energy and of component i, as indicated above. Because of the steady-state condition these fluxes may prove to be identical for regions I and II, but they will differ at most only infinitesimally for an infinitesimal thickness of the lamina dM.

The rate of entropy generation in the whole process is found by summing for regions I and II the rates of entropy change, one of which will be negative and the other positive, to get an infinitesimal difference between two finite rates. This rate of entropy generation will then be the sum of products of fluxes and differences between I and II of potentials. These products are $J_u d(1/T)$ and $J_i d(-\mu_i/T)$, symbol d denoting the difference between the value in II and the value in I of the potential in parentheses. Thus the expression for the rate of entropy generation $d\dot{S}$ is

$$d\dot{S} = J_u d\left(\frac{1}{T}\right) + \sum_i J_i\, d\left(-\frac{\mu_i}{T}\right), \tag{96}$$

in which $\sum_i$ denotes summation over all component substances $i = 1, 2, \ldots k$.

This last expression serves the purpose of identifying conjugate fluxes and forces; that is, for energy flux J_u the difference $d(1/T)$ is the conjugate force, etc.

Conjugate fluxes and forces

Each flux J_u, J_i of equation (96) is a function of the state of one of the stable equilibrium regions I or II and of the forces $d(1/T)$, $d(-\mu_i/T)$, with the further condition that, whatever the state, the flux will be zero when all forces are zero—that is, for mutual stable equilibrium. Purely mathematical considerations indicate that the functional relation between a flux such as J_u and the forces $d(1/T)$, $d(-\mu_i/T)$ is a very simple one, provided that the fluxes are small; *i.e.*, provided that the departure from mutual stable equilibrium is small. This functional relation is that the flux is equal to the sum of terms each consisting of a force multiplied by a coefficient L. From thermodynamic considerations it can be shown that the magnitudes of the coefficients L are fixed once the nature and states of regions I and M are fixed. They are independent of the magnitudes of the forces $d(1/T)$ and $d(-\mu_i/T)$. The functional relation is thus given by

$$J_u = L_{uu} d\left(\frac{1}{T}\right) + \sum_j L_{uj}\, d\left(-\frac{\mu_j}{T}\right) \tag{97}$$

$$J_i = L_{iu} d\left(\frac{1}{T}\right) + \sum_j L_{ij}\, d\left(-\frac{\mu_i}{T}\right), \tag{98}$$

in which the first subscript on an L refers to the flux and the second to the force term in which it appears. Although exceptions to them may doubtless be found, these equations are of general application to rate processes and become increasingly valid the more nearly all the fluxes approach zero. They are known as phenomenological equations, and the coefficients L are known as conductivities.

The Onsager reciprocal relation, the additional postulate

The Onsager reciprocal relation

referred to above, is as follows: The matrix of coefficients L of a set of equations such as (97) and (98), in which conjugate pairs of fluxes and forces are identified through expression (96) for the rate of entropy production, is symmetrical; that is,

$$L_{ij} = L_{ji} \text{ for } i, j = u, 1, 2 \ldots . \tag{99}$$

Lars Onsager, a Norwegian–American theoretical chemist, stated this new law in 1931 in an argument based on a principle of statistical mechanics called the principle of microscopic reversibility and a postulate that is closely related to the second law of thermodynamics. The new law was subsequently shown to be of general application in irreversible processes and was extended to a wide variety of phenomena.

Phenomenological equations

The phenomenological equations reduce to special forms for various special systems and force conditions and are known under different names. For example, Fourier's law of heat conduction (for the 19th-century French mathematician and physicist Jean-Baptiste Fourier), Ohm's law of electric current flow (for the 19th-century German physicist Georg Simon Ohm), Fick's law of neutral particle diffusion (for the 19th-century German physiologist Adolf Eugen Fick), and the law of ambipolar diffusion of positive and negative charges are all special cases of the linear phenomenological equations. The constants appearing in the laws just cited, such as electric resistance in Ohm's law, may be expressed easily in terms of the conductivities L of the phenomenological equations.

FLOW OF A SUBSTANCE THROUGH A BARRIER

A relatively simple application of the thermodynamics of rate processes is to the flow of a single-component substance through a barrier M under conditions such that the phenomenological equations (97) and (98) are valid. An example would be the flow of helium through a rubber membrane between two stable equilibrium regions I and II. The Onsager reciprocal relation is simply that $L_{u1} = L_{1u}$, subscript 1 referring to helium.

The two forces are the differences across the membrane $d(1/T)$ and $d(\mu_1/T)$. When the flux of helium is zero, then the difference $d(1/T)$ causes its conjugate energy to flow downgrade in temperature and upgrade in $1/T$. When the temperature difference and $d(1/T)$ are zero, then its conjugate helium will flow downgrade in chemical potential and in μ_1/T. Each of these forces, however, tends to cause its nonconjugate flux, as well as its conjugate flux, in one or the other direction. This behaviour is called coupling. In the absence of coupling, the coefficients L_{u1} and L_{1u} would both be zero.

By virtue of coupling, the two forces may be set in relation to each other so as to stop the flow of helium because of a balance between the opposing influences of the two forces. Such a steady state will be attained spontaneously if a temperature difference is maintained between I and II for a long enough period of time while the volumes of I and II are held constant. The flow of helium will eventually cease—or at least approach zero as a limit as time proceeds. A flow of energy will persist, however, in the steady-state condition by virtue of the temperature difference.

It can be seen from the second phenomenological equation (98) that the ratio L_{1u}/L_{11} is equal to the ratio of forces $d(\mu_1/T)/d(1/T)$ when J_1 is zero. From the two equations (97) and (98) taken together it can be seen that the ratio L_{u1}/L_{11} is equal to the ratio of fluxes J_u/J_1 when $d(1/T)$ is zero. Because the Onsager reciprocal relation requires that L_{1u} be equal to L_{u1}, it follows that the ratio of forces when J_1 is zero must equal the ratio of fluxes when the temperatures of I and II are equal.

By means of a simple thermodynamic analysis, the ratio of forces $d(\mu_1/T)/d(1/T)$ may be expressed in terms of the ratio of pressure difference to temperature difference dp/dT, which then proves to be proportional to the excess of J_u/J_1 for dT equal to zero over the enthalpy h_1 of helium in region I. The actual relation is

$$\left(\frac{dp}{dT}\right)_{J_1=0} = -\frac{1}{v_1 T}\left[\left(\frac{J_u}{J_1}\right)_{dT=0} - h_1\right]. \tag{100}$$

This relation gives the ratio of the pressure gradient to the temperature gradient for which the particle flow is stopped. Because it can be shown that for simple bulk flow J_u/J_1 is h_1 for fluid crossing any section in which the temperature is uniform in the direction of flow, it follows from equation (100) that bulk flow may be stopped even in a temperature gradient by zero pressure gradient. Whenever the energy flux per unit particle flux differs from h_1 in constant-temperature flow, then a pressure gradient is necessary to stop flow in a temperature gradient.

The Knudsen effect

Application of equation (100) to the flow of a perfect gas may be made for a porous plug with pore sizes very small compared with the mean distance travelled by gas molecules between collisions or compared to flow between emitting and receiving surfaces separated by a distance that is very small compared with the mean distance between collisions. For both of these the result is the same and can be shown to be

$$\left(\frac{dp}{dT}\right)_{J_1=0} = \frac{1}{2}\frac{p}{T} \tag{101}$$

or, for a finite length,

$$\left[\frac{p^I}{p^{II}} = \sqrt{\frac{T^I}{T^{II}}}\right]_{J_1=0}. \tag{102}$$

These relations describe what is known as the Knudsen effect.

The excess over the enthalpy flux of the energy flux across the barrier per unit of matter flowing when dT is zero is called the heat of transport and is denoted by q_1^*:

$$q_1^* \equiv \left(\frac{J_u}{J_1}\right)_{dT=0} - h_1. \tag{103}$$

It is the direct heat interaction that must be provided between regions II and I (Figure 14) when one unit of mass flows from I to II through M if the temperatures of I and II are to be maintained equal. Its magnitude can be found, in accordance with (100), by a measurement of the ratio dp/dT that corresponds to a flux J_1 of zero. The value found in this way for the heat of transport through a rubber membrane for nitrogen is −260 calories per gram mole and for hydrogen +100.

Statistical thermodynamics

Early mechanical theories of heat

The mechanical theory of heat was developed concurrently with thermodynamics. It relates heat to changes in the motion of the atoms and molecules of matter. The history of the theory can be traced back to the Greek philosophers Democritus (*c.* 400 BC) and Epicurus (*c.* 300 BC). The French philosopher Pierre Gassendi developed in the 17th century a theory in which all material phenomena are attributable to the indestructible motion of atoms. Although the English philosopher Robert Hooke, the German philosopher and mathematician Gottfried Wilhelm Leibniz, and the Swiss mathematician and physicist Daniel Bernoulli improved upon it in the 17th and 18th centuries, the theory was not firmly established until Joule demonstrated experimentally in the 19th century that a quantitative relation exists between heat and work when they produce identical effects.

After Joule's demonstration the theory developed rapidly into a science of major importance that became known as statistical mechanics or statistical thermodynamics. Its subject is the relation between the laws of thermodynamics and the details of the structure of matter. The development of this science, which can be traced through Hermann Ludwig Ferdinand von Helmholtz, a German physicist and anatomist; Clausius; Maxwell; and Boltzmann, culminated in the work of Gibbs, who in 1901 presented an exposition of statistical thermodynamics that excels in completeness, rigour, and generality. Although the exposition of Gibbs is stated in terms of classical mechanics, it is better adapted to quantum mechanics, which in some ways it anticipates.

Perhaps because Gibbs's contribution was not fully un-

derstood, a less general and less rigorous molecular statistics prevailed in the literature, with few exceptions, until after World War II.

GIBBSIAN STATISTICS

According to classical mechanics, the state of a system having N degrees of freedom (that is, independent ways in which the space configuration of the system may change) is fully specified by the values of N position coordinates $q_1, q_2, \ldots, q_N$, and N momentum coordinates $p_1, p_2, \ldots, p_N$. For example, the state of a system consisting of n point particles (particles without internal structure and therefore without internal degrees of freedom) is specified if the position coordinates along three Cartesian axes x, y, and z and the corresponding momentum coordinates along these same axes for each of the particles are specified. For such a system the number N of the degrees of freedom is equal to three times the number n of the particles of the system.

The position of a particle in space may be represented geometrically by a point in three-dimensional space having coordinates x, y, and z. The state of the particle involves not only the values of the coordinates x, y, and z but also the values of momentum component (which fixes the velocity component) p_x in the x direction, p_y in the y direction, and p_z in the z direction. These considerations suggest a mental extension of the concept of space to six dimensions, having coordinates x, y, z, p_x, p_y, and p_z. The state of the particle could then be completely described by a point in the six-dimensional space for which the values of x, y, z, p_x, p_y, and p_z are appropriately fixed.

The particle just discussed is said to have three degrees of freedom, and its state can be represented by a point in a six-dimensional space. A collection of two such particles might have six degrees of freedom, and the representation of its state would call for a 12-dimensional space. The number of degrees of freedom of a more complex system is the number of independent kinds of displacement to which the system is subject. The state of such a system having N degrees of freedom may be represented geometrically in classical mechanics by a point in $2N$-dimensional space having as coordinates $q_1, q_2, \ldots, q_N$, $p_1, p_2, \ldots, p_N$. This $2N$-dimensional space was called by Gibbs phase space.

Phase space

According to Gibbs, the term thermodynamic state of a system with N degrees of freedom does not necessarily correspond to a unique point in phase space, but to a set of probabilities of the system being in any one of the allowed points consistent with the constraints imposed on the system. Because any set of allowed states in classical mechanics forms a continuum, Gibbs introduced a probability density or distribution P, which he called the coefficient of probability, such that the product $P dq_1 dq_2 \ldots dq_N dp_1 dp_2 \ldots dp_N$ is equal to the probability of the system being in states having values of coordinates between q_1 and $q_1 + dq_1$, q_2 and $q_2 + dq_2, \ldots$, q_N and $q_N + dq_N$ and values of momenta between p_1 and $p_1 + dp_1$, p_2 and $p_2 + dp_2, \ldots$, and p_N and $p_N + dp_N$. For a given thermodynamic state, the distribution P will be a corresponding function of q's and p's. Furthermore, because a system must be at some one of the allowed states, the sum of all the probabilities must always be equal to unity or, by the same token, the integral of the distribution P over all q's and p's must be always equal to unity.

Various types of thermodynamic states correspond to particular mathematical forms of the distribution P. For example, Gibbs assumed without proof that, for the stable equilibrium states of a system with N degrees of freedom, the coefficient of probability P corresponding to the state $q_1, q_2, \ldots, q_N, p_1, p_2, \ldots, p_N$ of energy ε is equal to the number 2.718282 (the base of natural logarithms) raised to the $(\Psi - \varepsilon)/\Theta$ power, in which Ψ and Θ are constants; in other words, P is given by the exponential relation

$$P = \exp\left(\frac{\Psi - \varepsilon}{\Theta}\right). \qquad (104)$$

He called this distribution of probabilities a canonical distribution. Further discussion of Gibbsian statistics will be omitted because the quantum thermodynamics discussed below, though based on Gibbsian ideas, is more complete.

QUANTUM THERMODYNAMICS

Definition of state. In contrast to classical mechanics, a fundamental premise of quantum mechanics is that at a given time the most that can be said about results of measurements on a system is the probability of finding particular values of properties, such as coordinates and momenta, rather than the particular values that will be observed. This premise reflects the principle of indeterminacy first introduced by the German physicist Werner Heisenberg. It requires a description of the state of a system in terms of probabilities.

The principles of quantum mechanics may be stated by means of a number of mathematical formulations. Among these, the best known are the wave formulation by the German physicist Erwin Schrödinger, the vector formulation by the English physicist P.A.M. Dirac, and the matrix formulation by Heisenberg. The matrix formulation is especially suited to the exposition of quantum thermodynamics and is adopted below (for a discussion of matrices in general, see the article ALGEBRA).

Any property of a system that in classical mechanics may be expressed as a function of position and momentum coordinates is expressed in quantum mechanics by a matrix. For example, the Hamiltonian function of classical mechanics, which is the energy of the system, is represented by the Hamiltonian matrix. Matrix representations are used also for properties (such as spin) that have no classical analogue. The method of calculation of elements of matrices is specified by the principles of quantum mechanics.

Matrices and eigenvalues

Each matrix possesses eigenvalues; that is, a set of numbers that can be found by solving the characteristic equation of the matrix. The eigenvalues of the matrix of a property are real, as distinguished from complex, in the mathematical sense. Each one corresponds to a possible outcome of a measurement of the property performed on the system. For example, a measurement of the energy of a system in a given condition will yield any one of the real eigenvalues of the Hamiltonian matrix of the system. The number of eigenvalues of a property may be either finite, as with spin, or infinite, as with energy for most systems.

According to quantum mechanics, it is impossible to predict from knowledge of the condition of a system which eigenvalue a measurement will yield. Instead, the most that can be said at any instant of time is the probability that a measurement will yield a given eigenvalue.

The state of a system is defined as the set of all probabilities for the outcomes of all measurements that may be performed at a given instant of time. That is, the state of a system is represented by Table 2, in which $\overline{F}$, $\overline{G}$, $\overline{H}, \ldots$

Table 2: State of a System

property	$\overline{F}$	$\overline{G}$	$\overline{H}$	
Probabilities	$W(F_1)$	$W(G_1)$	$W(H_1)$	...

	•	•	•	
	•	•	•	

denote observable properties and in which $W(F_1)$ denotes the probability that any one measurement of property $\overline{F}$ will yield the eigenvalue $F_1, \ldots$; $W(G_1)$ denotes the probability that any one measurement of property $\overline{G}$ will yield the eigenvalue $G_1, \ldots$, and so forth. It can be shown that these probabilities can be combined to form a matrix $[\rho]$, called the density matrix. Conversely, a systematic procedure exists for determining from a given density matrix $[\rho]$ the probability $W(E_n)$ that a measurement of energy corresponding to the Hamiltonian matrix $[E]$ will yield the energy eigenvalue E_n of $[E]$. Again, the procedure yields the probability $W(F_m)$ that a measurement of property $\overline{F}$ corresponding to matrix $[F]$ will yield the eigenvalue F_m of $[F]$.

Values of properties. Because measurements of a prop-

erty $\bar{F}$ of a system in a given state yield different eigenvalues F_m, each with a probability $W(F_m)$ specified by the density matrix $[\rho]$ that represents the state, an expectation value or simply a value of the property corresponding to the given state is defined as the weighted average of the various possible eigenvalues, each eigenvalue being weighted by the probability that it will be observed. Symbolically, the value F of a property $\bar{F}$ may be represented as a sum over many terms, each of which is the product of a probability $W(F_m)$ and the eigenvalue F_m; that is,

$$F = \sum_m W(F_m) F_m, \tag{105}$$

in which the symbol $\sum_m$ denotes summation over all eigenvalues, and each eigenvalue is represented by a different symbol (different value of the subscript m) even when two or more eigenvalues have the same value. (For some matrices several distinct eigenvalues may have identical numerical values. The eigenvalues are then called degenerate.)

Reversible equation of motion. Quantum mechanics provides an equation, called the equation of motion, from which can be found the rate of change of the density matrix $[\rho]$ with time for some reversible and adiabatic processes. The equation will not be given here.

Conditions for equilibrium are found from the equation of motion. If the eigenvalues of the density matrix $[\rho]$ for an equilibrium state are denoted by $x_1, x_2, \ldots, x_m, \ldots$ and the eigenvalues of the Hamiltonian matrix $[E]$ by $E_1, E_2, \ldots, E_m, \ldots$, it can be shown that a necessary and sufficient condition for equilibrium is that the first eigenvalue x_1 be equal to the probability $W(E_1)$, that a measurement of the energy will yield the first eigenvalue E_1, the second eigenvalue x_2 be equal to $W(E_2)$, etc. Moreover, for equilibrium states the value of the energy E can be expressed as a sum of terms each of which is the product of x_m and E_m; that is,

$$E = \sum_m x_m E_m. \tag{106}$$

General expression for entropy. According to the first and second laws of thermodynamics, entropy is a state function of a system. Moreover, it must be invariant in any reversible adiabatic process. From these two conditions and the requirement that it be an extensive state function, the value S of entropy can be shown to be proportional to a mean of the natural logarithms of the eigenvalues of the density matrix. When $y_1, y_2, \ldots, y_m, \ldots$ denote the eigenvalues of the density matrix $[\rho]$ (corresponding to an arbitrary state, which is not necessarily equilibrium or stable equilibrium), the mean is calculated by weighting each $\ln y_m$ with the value y_m. In mathematical form this statement is expressed

$$S = -k \sum_m y_m \ln y_m, \tag{107}$$

in which k is a universal constant that proves to be the Boltzmann constant.

Pure states. A pure state is defined as one for which the eigenvalues of the density matrix $[\rho]$ are all equal to zero, except for one that is equal to unity. It follows from equation (107) that the entropy of a pure state is equal to zero.

It can be shown that any pure state may be described also by means of a wave function of quantum mechanics; and, conversely, states that can be described by wave functions correspond to zero entropy. In general, however, the entropy of a system is not equal to zero, and the state of the system cannot in general, therefore, be described by a wave function.

Stable equilibrium states. In the language of quantum thermodynamics, the criterion for stable equilibrium (see above *Stable equilibrium*) implies that the density matrix for a stable equilibrium state be such that the entropy (equation [107]) is at its maximum for given values of energy and numbers of particles. When this criterion is applied to a system of which the numbers of particles are known without uncertainty (the probability of the value for the number of particles of a given kind that is found by a measurement is unity), it yields the eigenvalues $x_1^\circ, x_2^\circ, \ldots, x_m^\circ, \ldots$ for the stable equilibrium states as functions of the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ of the Hamiltonian matrix of the system and the temperature of the stable equilibrium state in question. The various mathematical functions are as follows:

$$x_1^\circ = \frac{\exp(-E_1/kT)}{\sum_m \exp(-E_m/kT)}; \; x_2^\circ = \frac{\exp(-E_2/kT)}{\sum_m \exp(-E_m/kT)}; \ldots \tag{108}$$

$$T \equiv \left(\frac{\partial E}{\partial S}\right)_\beta, \tag{109}$$

$$E = \sum_m x_m^\circ E_m = \frac{\sum_m E_m \exp(-E_m/kT)}{\sum_m \exp(-E_m/kT)}, \tag{110}$$

and

$$S = -k \sum_m x_m^\circ \ln x_m^\circ = k \ln \left[\sum_m \exp(-E_m/kT)\right] + \frac{E}{T}. \tag{111}$$

Because the eigenvalues $x_1, x_2, \ldots, x_m, \ldots$ of the density matrix for any equilibrium state and, therefore, the eigenvalues $x_1^\circ, x_2^\circ, \ldots, x_m^\circ, \ldots$ of the density matrix for any stable equilibrium state represent probabilities that measurements of energy will yield eigenvalues $E_1, E_2, \ldots, E_m, \ldots$, respectively, equation (108) can be thought of as analogous to the canonical distribution postulated by Gibbs, provided that the two constants Θ and Ψ in equation (104) are expressed in terms of the temperature T and the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$. It can be shown that Θ and Ψ are given by the relations

$$\Theta = kT \tag{112}$$

and

$$\Psi = kT \ln \left[\sum_m \exp(-E_m/kT)\right]. \tag{113}$$

It can be readily verified from equations (111) and (113) that the function Ψ is equal to the Helmholtz free energy of the system; *i.e.*, equal to $E - TS$. Moreover, because the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ are in general functions of the values of the constraints, the Helmholtz free energy Ψ is a function of temperature and the constraints and, therefore, a characteristic function. This means that in quantum thermodynamics the problem of evaluating the properties of any system with numbers of particles that are known without uncertainty and in a stable equilibrium state reduces to the problem of evaluating the energy eigenvalues as functions of the constraints. The evaluation of the energy eigenvalues is a difficult mathematical task that has been carried out for only a very few systems. The difficulty, however, is in the calculation rather than in the conception of the evaluation.

The canonical partition function

The quantity Q_c, called the canonical partition function, is defined as the sum of $\exp(-E_1/kT)$, $\exp(-E_2/kT)$, $\exp(-E_3/kT)$, etc. It appears in the expressions for many properties of systems in stable equilibrium states. For example, because

$$Q_c \equiv \sum_m \exp(-E_m/kT), \tag{114}$$

it follows that the probability x_m° of observing an energy eigenvalue E_m is the quotient of $\exp(-E_m/kT)$ and Q_c, that the Helmholtz free energy per mole is the product of (kT) and the logarithm of Q_c, and that the entropy is the sum of the product $k \ln Q_c$ of k and logarithm of Q_c and the quotient E/T of the value of the energy and the temperature:

$$x_m^\circ = \frac{\exp(-E_m/kT)}{Q_c};$$

$$\Psi = kT \ln Q_c;$$

and

$$S = k \ln Q_c + \frac{E}{T}.$$

GRAND SYSTEMS

Stable equilibrium states. In many systems the numbers of particles may be uncertain either because the system is open to the transfer of rest mass or because particles can be created and annihilated within the system. The terminology of Gibbs suggests that such systems be called grand systems.

Uncertainty in the numbers of particles means that measurements of these numbers for a grand system in a given state yield different particle-number eigenvalues. This uncertainty is analogous to that associated in general with the energy. It follows that an expectation value rather than a dispersion-free value (that is, rather than a unique value that is observed as a result of every measurement) is assigned to the number of particles of each component of a state of a grand system. Without discussion of the matrix formalism for grand systems, some results applicable to stable equilibrium states will be given.

A stable equilibrium state of a grand system is fully described by the set of eigenvalues $x_1^\circ, x_2^\circ, \ldots, x_m^\circ, \ldots$ of the density matrix that maximizes the entropy of the system at given values of energy, numbers of particles of the components, and constraints. The mth eigenvalue x_m° is equal to the probability that a suitable measurement will yield the mth energy eigenvalue E_m and the mth number-of-particle eigenvalues $n_{1m}, n_{2m}, \ldots, n_{km}$ for the set of k components of the system. It can be expressed as a function of the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ of the Hamiltonian matrix of the system, the eigenvalues $n_{11}, n_{12}, \ldots, n_{1m}, \ldots$ of the number of particles of component number one, the eigenvalues $n_{21}, n_{22}, \ldots, n_{2m}, \ldots$ of the number of particles of component number two, ..., the total potentials $\mu_1, \mu_2, \ldots, \mu_k$ of the k components 1, 2, ... k, and the temperature T of the stable equilibrium state in question. It is given by the relation

$$x_m^\circ = \frac{\exp[(n_{1m}\mu_1 + n_{2m}\mu_2 + \ldots + n_{km}\mu_k - E_m)/kT]}{\sum_m \exp[(n_{1m}\mu_1 + n_{2m}\mu_2 + \ldots + n_{km}\mu_k - E_m)/kT]} \quad (115)$$

The sum in the denominator of (115) is called the grand partition function Q_g; *i.e.*,

$$Q_g \equiv \sum_m \exp[(n_{1m}\mu_1 + n_{2m}\mu_2 + \ldots + n_{km}\mu_k - E_m)/kT]. \quad (116)$$

The grand partition function

It appears in many relations between properties for grand systems in stable equilibrium states. For example, for a grand system with volume V as the only independent constraint, the equation of state is given by the relation

$$pV/kT = \ln Q_g. \quad (117)$$

Equation (117) applies to grand systems in gaseous, liquid, or solid forms.

The one-particle approximation for one-component systems. The energy eigenvalues of most systems can be computed only approximately. A class of approximations that consists in expressing each energy eigenvalue of the system as a sum of energy eigenvalues of suitably defined subsystems, each having one particle only, is called the one-particle approximation. It is valid for some crystals and for dilute gases at such low densities that short-range interparticle forces (forces that act between particles in close proximity) can be neglected, and long-range forces on each particle are independent of the positions of other particles. Some results of the analysis applicable to dilute gases will be given below.

In the context of the one-particle approximation, each of the energy eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ of a dilute gas having one component only (namely, consisting of a number of particles of a single type) is expressed as a sum of terms such that each term is a positive integer multiplied by an energy eigenvalue of a system that has one particle only and for which the eigenvalues can be evaluated. For example, if $\nu_{m1}, \nu_{m2}, \ldots, \nu_{mj}, \ldots$ denote the positive integers that appear in the sum for the mth eigenvalue E_m and $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_j, \ldots$, the energy eigenvalues of the system with the one particle, then E_m is given by the relation

$$E_m = \nu_{m1}\varepsilon_1 + \nu_{m2}\varepsilon_2 + \ldots + \nu_{mj}\varepsilon_j + \ldots = \sum_j \nu_{mj}\varepsilon_j \text{ for all values of } m. \quad (118)$$

Equation (118) is interpreted as meaning that of the n_m particles associated with the energy eigenvalue E_m, ν_{m1} have energy ε_1, ν_{m2} have energy $\varepsilon_2, \ldots$, ν_{mj} have energy $\varepsilon_j, \ldots$. From this interpretation it follows that the sum of all the positive integers $\nu_{m1}, \nu_{m2}, \ldots, \nu_{mj}, \ldots$ must be equal to n_m; *i.e.*,

$$\nu_{m1} + \nu_{m2} + \ldots + \nu_{mj} + \ldots = \sum_j \nu_{mj} = n_m. \quad (119)$$

The values that each integer ν_{mj} can assume are restricted by the nature of the particles in question. For certain particles, called fermions, each ν_{mj} may be either zero or unity for all values of the subscripts m and j; *i.e.*, for any energy eigenvalue E_m of the overall system and any energy eigenvalue ε_j of the auxiliary one-particle system. For example, because electrons are fermions a grand system consisting of electrons has, for a state with an energy eigenvalue E_m, at most one electron of one-particle energy eigenvalue ε_j. (This restriction is equivalent to the so-called exclusion principle of atomic physics, announced in 1925 by the Austrian physicist Wolfgang Pauli.) On the other hand, for certain particles called bosons, each of the integers ν_{mj} may have any positive integral value as well as the value zero. In a grand system consisting of photons—which are bosons—in a state with energy eigenvalue E_m, any number of photons from zero to n_m may have a particular energy ε_j.

Fermions and bosons

When the allowed numerical values of the integers ν_{mj} are considered, the properties of a dilute gas in a stable equilibrium state can be expressed as functions of the one-particle energy eigenvalues $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_j \ldots$ rather than the eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ of the overall system.

For example, the expectation or average value ν_j of the number of particles that can be thought of as having one-particle energy ε_j—namely, the expectation value ν_j of the integers $\nu_{1j}, \nu_{2j}, \ldots, \nu_{mj}, \ldots$—is defined as the sum of terms each being an integer ν_{mj} multiplied by the probability x_m° that a suitable measurement will yield the energy eigenvalue E_m.

It can be shown that, if μ denotes the total potential of the single component of the grand system, then ν_j is given by the relations

$$\nu_j = \sum_m x_m^\circ \nu_{jm} = \frac{1}{\exp[(\varepsilon_j - \mu)/kT] + 1} \text{ for fermions} \quad (120)$$

and

$$\nu_j = \sum_m x_m^\circ \nu_{jm} = \frac{1}{\exp[(\varepsilon_j - \mu)/kT] - 1} \text{ for bosons.} \quad (121)$$

Relation (120) is called the Fermi–Dirac factor, and the corresponding dilute gas is said to obey Fermi–Dirac statistics, formulated for this class of particles in 1926–27 by the physicists Enrico Fermi, then working in Italy, and Paul A.M. Dirac in England. Relation (121) is called the Bose–Einstein factor, and the corresponding dilute gas is said to obey Bose–Einstein statistics, introduced in 1924 by the Indian physicist Satyendra Nath Bose and subsequently extended by Einstein.

Again, for a system with volume V as the only constraint, it can be shown that the equation of state, (117), and the value n of the number of particles are given by the relations

$$\frac{pV}{kT} = \sum_j \ln\{1 \pm \exp[(\mu - \varepsilon_j)/kT]\}^{\pm 1} \quad (122)$$

and

$$n = \sum_j \{[\exp(\varepsilon_j - \mu)/kT] \pm 1\}^{-1}, \quad (123)$$

in which the plus sign in $\pm$ applies to fermions and the minus sign to bosons.

Fundamental equation for one-component simple systems. For a system for which both sets of eigenvalues $E_1, E_2, \ldots, E_m, \ldots$ and $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_j, \ldots$ are functions of volume V only, equations (122) and (123) indicate that p and n are functions of volume V, temperature T, and potential μ only. In principle, the p and n functions can be combined so as to eliminate volume V and obtain a fundamental equation that gives the total potential as a

function of n, p, and T. But because equations (122) and (123) are transcendental, the derivation of such a fundamental equation is a difficult mathematical task. Under certain conditions it can be done with the aid of some approximations that are additional to the one-particle approximation.

For example, for a dilute gas in which the molecules have three translational degrees of freedom and of which the temperature is sufficiently high and pressure sufficiently low, it can be shown that the potential μ can be approximated by the expression

$$\mu = kT\ln p - \frac{5}{2}kT\ln T - kT\ln q_s - kT\ln\frac{k(2\pi mk)^{3/2}}{\hbar^3}, \quad (124)$$

in which m denotes the mass of each particle of the system; $\hbar$, Planck's constant divided by 2π; and q_s, the partition function associated with the energy eigenvalues for the internal structure of each molecule:

$$q_s = \sum_i \exp(-\bar{\varepsilon}_i/kT).$$

Such a gas is called a semiperfect gas. Consistent with the relations found for a semiperfect gas above without reference to the detailed structure of the molecules of the system, its fundamental equation is independent of n. This result reflects conformity with the definition of a simple system, which excludes capillarity. In contrast with equation (68), equation (124) gives the chemical potential per particle instead of per mole. It includes, therefore, the Boltzmann constant k, which is related to a single molecule and which is equal to the universal gas constant R divided by the number of molecules contained in a mole.

Boltzmann constant

As indicated earlier, the heat capacities of a semiperfect gas are functions of temperature. From equation (124) may be found the following expressions for specific heats per molecule:

$$c_p = \frac{5}{2}k + 2kT\frac{\partial \ln q_s}{\partial T} + kT^2\frac{\partial^2 \ln q_s}{\partial T^2}$$

and

$$c_v = \frac{3}{2}k + 2kT\frac{\partial \ln q_s}{\partial T} + kT^2\frac{\partial^2 \ln q_s}{\partial T^2},$$

in which $\partial^2 \ln q_s/\partial T^2$ denotes the partial derivative of $\partial \ln q_s/\partial T$ with respect to T. Because q_s is a function of T, both specific heats are functions of T.

A particular semiperfect gas is one for which the heat capacities c_p and c_v are independent of temperature. As stated above, such a gas is called a perfect gas. A gas behaves as a perfect gas either when the molecules have no internal structure, so that q_s is unity, or when q_s can be approximated by the product $g\exp(-\bar{\varepsilon}_0/kT)$, in which g and $\bar{\varepsilon}_0$ are constants.

Electronegativity of atoms and molecules. An atom or a molecule may be regarded as a grand system with electrons as its only component particles because it can exchange energy and electrons while reacting chemically with other atoms and molecules.

An atom A of atomic number z contains z units of positive electric charge in addition to its electrons. It has all the energy eigenvalues of the neutral atom and of each of the multiply (positively) charged ionized atoms. In addition, it can be negatively charged. In this section, consideration will be limited to atoms having energy eigenvalues corresponding to a singly charged negative ion; *i.e.*, an ion with $z+1$ electrons.

The eigenvalues n_i of the number of electrons in atom A are such that

$$n_i = i = 0, 1, 2, \ldots, z, z+1;$$

that is, the atom can be fully ionized ($i=0$), partially ionized ($i<z$), neutral ($i=z$), or singly negatively charged ($i=z+1$).

For each n_i, one energy eigenvalue ($g_{i0}=1$) will have the minimum numerical value E_{i0}. Each eigenvalue E_{i0} represents the energy of the so-called ground state of A with exactly n_i electrons. Moreover, an infinite number of energy eigenvalues E_{ij} ($j=1, 2, \ldots$), each with a multiplicity or degeneracy g_{ij}, correspond to the excited states for each n_i.

For a stable equilibrium state at temperature T, the value n of the number of electrons of the atom is given in terms of the above notation by the relation

$$n = \frac{\sum_{i,j} n_i g_{ij}\exp[(n_i\mu - E_{ij})/kT]}{\sum_{i,j} g_{ij}\exp[(n_i\mu - E_{ij})/kT]}, \quad (125)$$

in which the symbol $\sum_{i,j}$ denotes a double summation, one over all values of i from zero to $z+1$ and the other over all values of j from zero to infinity. The number n may assume any value between 0 and $z+1$, although n_i can assume only integral values.

For given n and T values equation (125) can be solved for the value of the potential μ. Although the solution is numerically difficult, some general results are readily established: (1) For a fully ionized atom (that is, for the minimum value $n=0$) μ is minus infinity, and for a singly charged negative ion (that is, for the maximum value $n=z+1$) μ is plus infinity, both for all values of T. Such extreme values of μ are always obtained when the value of the number of particles of the grand system is either minimum or maximum. They are consistent with the interpretation of the potential μ as an escaping tendency. (2) For values of n in the range between z and $z+1$, the potential μ is positive. For all other values the potential μ is negative. (3) For a neutral atom (that is, for $n=z$), in the limit as T approaches zero, μ is equal to one-half the difference between the energy eigenvalues of the ground states of the singly charged negative ion and the singly charged positive ion. It can also be written in the form

$$\mu = -\frac{I_1 + A_1}{2}, \quad (126)$$

in which I_1 and A_1 are, respectively, the first ionization energy and the electron affinity of the atom. For example, for the hydrogen atom the first (and only) ionization energy is equal to 13.6, the electron affinity is 0.7, and, therefore, the potential μ is -7.15, all in electron-volt units.

Since μ is a measure of the escaping tendency of a species, $-\mu$ is a measure of a capturing tendency or power to attract. The power of an atom to attract electrons is called the electronegativity of the atom. The preceding analysis indicates that electronegativity can be identified with the potential $-\mu$ of electrons in an atom, and its value can be computed by means of quantum thermodynamics. Similar results can be obtained for molecules and for solid surfaces.

Summary

The concepts of a system and states of a system adopted throughout this article are more general than are usually adopted in the science of thermodynamics. In the first part of the article, in which the microscopic structure of the particles that constitute the system is ignored, the many relations for systems in stable equilibrium states that are well known to classical thermodynamics are derived. The method, however, lends itself well to the treatment of states other than stable equilibrium inasmuch as the values of entropy may be found for such states.

In the second part, the microscopic structure is brought into consideration but without loss of the concept of an unambiguous stable equilibrium state. This result is achieved through the quantum-mechanical interpretation of measurement as an operation that yields definite eigenvalues with certain probabilities. The results are, first, many relations familiar to statistical mechanics that permit evaluation of properties of a system from the known structure of the particles and, second, a means of applying the laws of thermodynamics to systems that are large or small, simple or complicated. The limitation of thermodynamics, frequently applied in the past, to macroscopic systems no longer applies. To illustrate this generality, thermodynamic ideas are applied above to a single atom in order to discover the meaning of the previously recognized quantity electronegativity.

Thomas Aquinas and Thomism

St. Thomas Aquinas (Italian San Tommaso d'Aquino) was a Christian philosopher who developed his own conclusions from Aristotelian premises, notably in the metaphysics of personality, creation, and Providence; a theologian responsible in his two masterpieces, the *Summa theologiae* and the *Summa contra gentiles,* for the classical systematization of Latin theology; and a poet who wrote some of the most gravely beautiful eucharistic hymns in the church's liturgy. Although many modern Roman Catholic theologians do not find him altogether congenial, he is recognized by the Roman Catholic Church as its foremost Western philosopher and theologian.

Thomism refers both to the doctrinal system of St. Thomas Aquinas and to the explanations and developments made by his followers. The main phases in the philosophical and theological tradition of the Thomistic school are the personal synthesis of St. Thomas, the work of the great commentators, and the modern revival.

LIFE AND WORKS

Early years. Thomas was born in 1224 or 1225, at Roccasecca, near Aquino, on the road from Rome to Naples, where his parents were in possession of a modest feudal domain on a boundary constantly disputed by the emperor and the pope. His father was of Lombard origin; his mother was of the later invading Norman strain. His people were distinguished in the service of Emperor Frederick II during the civil strife in southern Italy between the papal and imperial forces. Thomas was placed in the monastery of Monte Cassino near his home as an oblate (*i.e.,* offered as a prospective monk) when he was still a young boy; his family doubtless hoped that he would someday become abbot to their advantage. In 1239, after nine years in this sanctuary of spiritual and cultural life, young Thomas was forced to return to his family when the Emperor expelled the monks because they were too obedient to the Pope. He was then sent to the University of Naples, recently founded by the Emperor, where he first encountered the scientific and philosophical works that were being translated from the Greek and the Arabic. In this setting Thomas decided to join the Friars Preachers, or Dominicans, a new religious order founded 30 years earlier, which departed from the traditional paternalistic form of government for monks to the more democratic form of the mendicant friars (*i.e.,* religious orders whose corporate as well as personal poverty made it necessary for them to beg alms) and from the monastic life of prayer and manual labour to a more active life of preaching and teaching. By this move he took a liberating step beyond the feudal world into which he was born and the monastic spirituality in which he was reared. A dramatic episode marked the full significance of his decision. His parents had him abducted on the road to Paris, where his shrewd superiors had immediately assigned him so that he would be out of the reach of his family but also so that he could pursue his studies in the most prestigious and turbulent university of the time.

Entry into the Dominican order

Studies in Paris. Thomas held out stubbornly against his family despite a year of captivity. He was finally liberated and in the autumn of 1245 went to Paris to the convent of Saint-Jacques, the great university centre of the Dominicans; there he studied under Albertus Magnus, a tremendous scholar with a wide range of intellectual interests.

Escape from the feudal world, rapid commitment to the University of Paris, and religious vocation to one of the new mendicant orders all meant a great deal in a world in which faith in the traditional institutional and conceptual structure was being attacked. The encounter between the gospel and the culture of his time formed the nerve centre of Thomas' position and directed its development. Normally, his work is presented as the integration into Christian thought of the recently discovered Aristotelian philosophy, in competition with the integration of Pla-

"Apotheosis of St. Thomas Aquinas," altarpiece by Francesco Traini, 1363. In the Sta. Caterina, Pisa.
Alinari—Art Resource

tonic thought effected by the Fathers of the Church during the first 12 centuries of the Christian Era. This view is essentially correct; more radically, however, it should also be asserted that Thomas' work accomplished an evangelical awakening to the need for a cultural and spiritual renewal not only in the lives of individual men but also throughout the church. Thomas must be understood in his context as a mendicant religious, influenced both by the evangelism of St. Francis of Assisi, founder of the Franciscan order, and by the devotion to scholarship of St. Dominic, founder of the Dominican order.

Study of Aristotle's works

When Thomas Aquinas arrived at the University of Paris, the influx of Arabian–Aristotelian science was arousing a sharp reaction among believers; and several times the church authorities tried to block the naturalism and rationalism that were emanating from this philosophy and, according to many ecclesiastics, seducing the younger generations. Thomas did not fear these new ideas, but, like his master Albertus Magnus (and Roger Bacon, also lecturing at Paris), he studied the works of Aristotle and eventually lectured publicly on them.

For the first time in history, Christian believers and theologians were confronted with the rigorous demands of scientific rationalism. At the same time, technical progress was requiring men to move from the rudimentary economy of an agrarian society to an urban society with production organized in trade guilds, with a market economy, and with a profound feeling of community. New generations of men and women, including clerics, were reacting against the traditional notion of contempt for the world and were striving for mastery over the forces of nature through the use of their reason. The structure of Aristotle's philosophy emphasized the primacy of the intelligence. Technology itself became a means of access to truth; mechanical arts were powers for humanizing the cosmos. Thus, the dispute over the reality of universals—*i.e.*, the question about the relation between general words such as "red" and particulars such as "this red object"—which had dominated early Scholastic philosophy, was left behind; and a coherent metaphysics of knowledge and of the world was being developed.

During the summer of 1248, Aquinas left Paris with Albertus, who was to assume direction of the new faculty established by the Dominicans at the convent in Cologne. He remained there until 1252, when he returned to Paris to prepare for the degree of master of theology. After taking his bachelor's degree, he received the *licentia docendi* ("license to teach") at the beginning of 1256 and shortly afterward finished the training necessary for the title and privileges of master. Thus, in the year 1256 he began teaching theology in one of the two Dominican schools incorporated in the University of Paris.

Years at the papal Curia and return to Paris. In 1259 Thomas was appointed theological adviser and lecturer to the papal Curia, then the centre of Western humanism. He returned to Italy, where he spent two years at Anagni at the end of the reign of Alexander IV and four years at Orvieto with Urban IV. From 1265 to 1267 he taught at the convent of Santa Sabina in Rome and then, at the request of Clement IV, went to the papal Curia in Viterbo. Suddenly, in November 1268, he was sent to Paris, where he became involved in a sharp doctrinal polemic that had just been triggered off.

Opposition to the Averroists

The works of Averroës, the outstanding representative of Arabic philosophy in Spain, who was known as the great commentator and interpreter of Aristotle, were just becoming known to the Parisian masters. There seems to be no doubt about the Islāmic faith of the Cordovan philosopher; nevertheless, he asserted that the structure of religious knowledge was entirely heterogeneous to rational knowledge: two truths—one of faith, the other of reason—can, in the final analysis, be contradictory. This dualism was denied by Muslim orthodoxy and was still less acceptable to Christians. With the appearance of Siger of Brabant, however, and from 1266 on, the quality of Averroës' exegesis and the wholly rational bent of his thought began to attract disciples in the faculty of arts at the University of Paris. Thomas Aquinas rose in protest against his colleagues; nevertheless, the parties retained a mutual esteem. As soon as he returned from Italy, Thomas began to dispute with Siger, who, he claimed, was compromising not only orthodoxy but also the Christian interpretation of Aristotle. Aquinas found himself wedged in between the Augustinian tradition of thought, now more emphatic than ever in its criticism of Aristotle, and the Averroists. Radical Averroism was condemned in 1270, but at the same time Thomas, who sanctioned the autonomy of reason under faith, was discredited.

In the course of this dispute, the very method of theology was called into question. According to Aquinas, reason is able to operate within faith and yet according to its own laws. The mystery of God is expressed and incarnate in human language; it is thus able to become the object of an active, conscious, and organized elaboration in which the rules and structures of rational activity are integrated in the light of faith. In the Aristotelian sense of the word, then (although not in the modern sense), theology is a "science"; it is knowledge that is rationally derived from propositions that are accepted as certain because they are revealed by God. The theologian accepts authority and faith as his starting point and then proceeds to conclusions using reason; the philosopher, on the other hand, relies solely on the natural light of reason. Thomas was the first to view theology expressly in this way or at least to present it systematically, and in doing so he raised a storm of opposition in various quarters. Even today this opposition endures, especially among religious enthusiasts for whom reason remains an intruder in the realm of mystical communion, contemplation, and the sudden ecstasy of evangelical fervour.

Literary form of his works

The literary form of Aquinas' works must be appreciated in the context of his methodology. He organized his teaching in the form of "questions," in which critical research is presented by pro and con arguments, according to the pedagogical system then in use in the universities. Forms varied from simple commentaries on official texts to written accounts of the public disputations, which were significant events in medieval university life. Thomas' works are divided into three categories: 1) commentaries on such works as the Old and New Testaments, the *Sentences* of Peter Lombard (the official manual of theology in the universities), and the writings of Aristotle; 2) disputed questions, accounts of his teaching as a master in the disputations; 3) two *summae* or personal syntheses, the *Summa contra gentiles* and the *Summa theologiae,* which were presented as integral introductions for the use of beginners. Numerous *opuscula* ("little works"), which have great interest because of the particular circumstances that provoked them, must also be noted.

The logic of Aquinas' position regarding faith and reason required that the fundamental consistency of the realities of nature be recognized. A *physis* ("nature") has necessary laws; recognition of this fact permits the construction of a science according to a *logos* ("rational structure"). Thomas thus avoided the temptation to sacralize the forces of nature through a naïve recourse to the miraculous or the Providence of God. For him, a whole "supernatural" world that cast its shadow over things and men, in Romanesque art as in social customs, had blurred men's imaginations. Nature, discovered in its profane reality, should assume its proper religious value and lead to God by more rational ways, yet not simply as a shadow of the supernatural. This understanding is exemplified in the way that Francis of Assisi admired the birds, the plants, and the Sun.

The inclusion of Aristotle's *Physics* in university programs was not, therefore, just a matter of academic curiosity. Naturalism, however, as opposed to a sacral vision of the world, was penetrating all realms: spirituality, social customs, and political conduct. About 1270, Jean de Meun, a French poet of the new cities and Thomas' neighbour in the Rue Saint-Jacques in Paris, gave expression in his *Roman de la Rose* to the coarsest realism, not only in examining the physical universe but also in describing and judging the laws of procreation. Innumerable manuscripts of the Roman poet Ovid's *Ars amatoria* ("Art of Love") were in circulation; André le Chapelain, in his *De Deo amoris* ("On the God of Love") adapted a more refined version for the public. Courtly love in its more seductive forms became a more prevalent element in the culture of the 13th century.

At the same time, Roman law was undergoing a revival at the University of Bologna; this involved a rigorous analysis of the natural law and provided the jurists of Frederick II with a weapon against ecclesiastical theocracy. The traditional presentations of the role and duties of princes, in which biblical symbolism was used to outline beautiful pious images, were replaced by treatises that described experimental and rational attempts at government. Thomas had composed such a treatise—*De regimine principum* ("On the Government of Princes")—for the King of Cyprus in 1266. In the administration of justice, juridical investigations and procedures replaced fanatical recourse to ordeals and to judgments of God.

Resistance of traditional theologians

In the face of this movement, there was a fear on the part of many that the authentic values of nature would not be properly distinguished from the disorderly inclinations of mind and heart. Theologians of a traditional bent firmly resisted any form of a determinist philosophy which, they believed, would atrophy liberty, dissolve personal responsibility, destroy faith in Providence, and deny the notion of a gratuitous act of creation. Imbued with Augustine's doctrines, they asserted the necessity and power of grace for a nature torn asunder by sin. The optimism of the new theology concerning the religious value of nature scandalized them.

Although he was an Aristotelian, Thomas Aquinas was certain that he could defend himself against a heterodox interpretation of "the Philosopher," as Aristotle was known. Thomas held that human liberty could be defended as a rational thesis while admitting that determinations are found in nature. In his theology of Providence, he taught a continuous creation, in which the dependence of the created on the creative wisdom guarantees the reality of the order of nature. God moves sovereignly all that he creates; but the supreme government that he exercises over the universe is conformed to the laws of a creative Providence that wills each being to act according to its proper nature. This autonomy finds its highest realization in the rational creature: man is literally self-moving in his intellectual, volitional, and physical existence. Man's freedom, far from being destroyed by his relationship to God, finds its foundation in this very relationship. "To take something away from the perfection of the creature is to abstract from the perfection of the creative power itself." This metaphysical axiom, which is also a mystical principle, is the key to St. Thomas' spirituality.

Last years at Naples. At Easter time in 1272, Thomas returned to Italy to establish a Dominican house of studies at the University of Naples. This move was undoubtedly made in answer to a request made by King Charles of Anjou, who was anxious to revive the university. After participating in a general chapter, or meeting, of the Dominicans held in Florence during Pentecost week and, having settled some family affairs, Thomas resumed his university teaching at Naples in October and continued it until the end of the following year.

Although Thomas' argument with the Averroists had for years been matched by a controversy with the Christian masters who followed the traditional Augustinian conception of man as fallen, this latter dispute now became more pronounced. In a series of university conferences in 1273, Bonaventure, a Franciscan friar and a friendly colleague of Thomas at Paris, renewed his criticism of the Aristotelian current of thought, including the teachings of Thomas. He criticized the thesis that philosophy is distinct from theology, as well as the notion of a physical nature that has determined laws; he was especially critical of the theory that the soul is bound up with the body as the two necessary principles that make up the nature of man and also reacted strongly to the Aristotelians' denial of the Platonic–Augustinian theory of knowledge based upon exemplary Ideas or Forms.

The disagreement was profound. Certainly, all Christian philosophers taught the distinction between matter and spirit. This distinction, however, could be intelligently held only if the internal relationship between matter and spirit in individual human beings was sought. It was in the process of this explanation that differences of opinion arose—not only intellectual differences between idealist and realist philosophers but also emotional differences. Some viewed the material world merely as a physical and biological reality, a stage on which the history of spiritual persons is acted out, their culture developed, and their salvation or damnation determined. This stage itself remains detached from the spiritual event, and the history of nature is only by chance the setting for the spiritual history. The history of nature follows its own path imperturbably; in this history, man is a foreigner, playing a brief role only to escape as quickly as possible from the world into the realm of pure spirit, the realm of God.

Relationship of matter and spirit for Thomas

Thomas, on the contrary, noted the inclusion of the history of nature in the history of the spirit and at the same time noted the importance of the history of spirit for the history of nature. Man is situated ontologically (*i.e.*, by his very existence) at the juncture of two universes, "like a horizon of the corporeal and of the spiritual." In man there is not only a distinction between spirit and nature but there is also an intrinsic homogeneity of the two. Aristotle furnished Aquinas with the categories necessary for the expression of this concept: the soul is the "form" of the body. For Aristotle, form is that which makes a thing to be what it is; form and matter—that out of which a thing is made—are the two intrinsic causes that constitute every material thing. For Thomas, then, the body is the matter and the soul is the form of man. The objection was raised that he was not sufficiently safeguarding the transcendence of the spirit, the doctrine that the soul survives after the death of the body.

In January 1274 Thomas Aquinas was personally summoned by Gregory X to the second Council of Lyons, which was an attempt to repair the schism between the Latin and Greek churches. On his way he was stricken by illness; he stopped at the Cistercian abbey of Fossanova, where he died on March 7, 1274. In 1277 the masters of Paris, the highest theological jurisdiction in the church, condemned a series of 219 propositions; 12 of these propositions were theses of Thomas. This was the most serious condemnation possible in the Middle Ages; its repercussions were felt in the development of ideas. It produced for several centuries a certain unhealthy spiritualism that resisted the cosmic and anthropological realism of Aquinas.

Importance of the university environment

Assessment. The biography of Thomas Aquinas is one of extreme simplicity; it chronicles little but some modest travel during a career devoted entirely to university life: at Paris, the Roman Curia, Paris again, and Naples. It would be a mistake, however, to judge that his life was merely the quiet life of a professional teacher untouched

by the social and political affairs of his day. The drama that went on in his mind and in his religious life found its causes and produced its effects in the university. In the young universities all the ingredients of a rapidly developing civilization were massed together, and to these universities the Christian Church had deliberately and authoritatively committed its doctrine and its spirit. In this environment, Thomas found the technical conditions for elaborating his work—not only the polemic occasions for turning it out but also the enveloping and penetrating spiritual milieu needed for it. It is within the homogeneous contexts supplied by this environment that it is possible today to discover the historical intelligibility of his work, just as they supplied the climate for its fruitfulness at the time of its birth.

Thomas Aquinas was canonized a saint in 1323, officially named doctor of the church in 1567, and proclaimed the protagonist of orthodoxy during the modernist crisis at the end of the 19th century. This continuous commendation, however, cannot obliterate the historical difficulties in which he was embroiled in the 13th century during a radical theological renewal—a renewal that was contested at the time and yet was brought about by the social, cultural, and religious evolution of the West. Thomas was at the heart of the doctrinal crisis that confronted Christendom when the discovery of Greek science, culture, and thought seemed about to crush it. William of Tocco, Aquinas' first biographer, who had known him and was able to give evidence of the impression produced by his master's teaching, says:

> Brother Thomas raised new problems in his teaching, invented a new method, used new systems of proof. To hear him teach a new doctrine, with new arguments, one could not doubt that God, by the irradiation of this new light and by the novelty of this inspiration, gave him the power to teach, by the spoken and written word, new opinions and new knowledge.

THOMISM

Aquinas' position. Although making respectful use of Aristotle and the Platonists, Augustine and the Fathers, Thomas Aquinas developed a distinctive position. His originality was shown in treating existence (*esse*) as the supreme act or perfection of being in God as well as in created things, in reserving the creative act to God alone, in denying the presence of matter in angels, and thus in distinguishing between God and creatures by a real composition of existence and essence as principles in all created beings. Also characteristic was his teaching that the human soul is a unique subsistent form, substantially united with matter to constitute human nature. Aquinas maintained that the immortality of the human soul can be strictly demonstrated, that there is a real distinction of principles between the soul and its powers of knowing and willing, and that human knowledge is based upon sense experience leading to the mind's reflective activity. He held that both man and lower creatures have a natural tendency or love toward God, that supernatural grace perfects and elevates our natural abilities, and that blessedness consists formally in knowing God Himself, a knowledge accompanied by our full love of God.

This coherent but complex body of Thomistic doctrines was critically explained and developed during subsequent centuries. Views of St. Thomas on individuation and the localization of angels, man's nature and the unity of the world, appeared among the theses condemned in 1277 by Bishop Étienne Tempier at Paris and by Archbishop Robert Kilwardby at Oxford. At stake were the manner and extent of using Aristotle and his Arabian commentators in explaining Christian theology. The later 13th century was crowded with "correctorial" literature—treatises attacking and defending basic positions of St. Thomas, especially on the unicity of the human substantial form and the distinction of essence and existence. His precise meaning was lost even by some Thomists, who treated essence and existence as distinct things and overlooked the unifying relation between the substantial form and existence.

"Correctorial" literature

Commentators. Encouragement toward consulting Aquinas' own writings came with the adoption of his doctrine by the Dominican Order (1278, 1279, 1286), his canonization by Pope John XXII (1323), and the special place accorded to his works at the Council of Trent. The scientific task of analyzing his thought was executed by a line of devoted commentators during the period 1400–1650. The first was the Dominican Jean Capréolus (*c.* 1380–1444), called the Prince of the Thomists, who recognized the need to make a direct integral study of the texts of St. Thomas. In his *Four Books of Defenses of the Theology of St. Thomas Aquinas,* Capréolus made a systematic use of the sources against the Scotists and Ockhamists. Another major Dominican commentator was Tomaso de Vio, Cardinal Cajetan, who made elaborate expositions of St. Thomas' *Summa theologiae* and *On Being and Essence.* He made his own restatement of the Thomistic arguments and drew upon many other writings of St. Thomas. Cajetan's independence was displayed in his work *On the Analogy of Names,* where he proposed the influential division of kinds of analogy into inequality, attribution, and proportionality, as well as in his opinion that the human soul's immortality can be supported only by probable reasons.

The classical commentary on St. Thomas' *Summa contra gentiles* was done by the Dominican Francesco Sylvestri of Ferrara (*c.* 1474–1528), who showed the importance of this work for the relation of faith and philosophy, the meaning of person, and the desire of God. After the mid-16th century, the Thomistic commentators became involved in the intricate theological controversies on grace and premotion. Highly systematized presentations of opposing views were introduced into the commentaries on the *Summa theologiae* made by the Spanish Dominican theologian Domingo Bañez and the Spanish Jesuit authors Francis Toletus and Gabriel Vázquez. But the new Renaissance tendency to give separate treatment to philosophical and theological issues, as well as the pressures of seminary education, undermined the usefulness of the commentary form of approach to St. Thomas. A new trend is present in the Dominican John of St. Thomas (1589–1644), who issued a separate *Cursus Philosophicus* ("Course in Philosophy") and then a *Cursus Theologicus* ("Course in Theology") in Thomistic thought. Using the framework of logic, philosophy of nature, and metaphysics, John assembled the philosophical teachings of St. Thomas under these systematic headings and reformulated the material for students who would then study theology. There were original features in his logic, including the distinction between formal and objective concepts and the stress on intentional signs.

Studies by John of St. Thomas

Modern Thomism. Throughout the 17th and 18th centuries, Thomism continued to be presented in philosophy and theology courses or manuals, especially in the Dominican Order. Most Thomistic manuals of this period were watered with the opinions of other Schoolmen and remained remote from modern problems. In most Catholic seminaries and universities of the early 19th century, eclecticism was the rule and more attention was paid to Descartes, Locke, and Wolff than to Aquinas. The modern revival of authentic Thomism began at this time in Italy. Vincent Buzzetti (1777–1824) and the Jesuit teacher Serafino Sordi (1793–1865) were instrumental in urging a direct study of the text of Aristotle and Aquinas. The revolutions of 1848 had a decisive influence upon both the Holy See and the Society of Jesus toward finding sound principles on God, man, and society in the works of St. Thomas. In editions of their philosophy manuals appearing after 1850, this renewal of Thomistic thought was advocated by three influential Jesuit writers in Italy and Germany: Luigi Taparelli d'Azeglio, Matteo Liberatore, and Joseph Kleutgen. Their own positions in epistemology, metaphysics, and social theory remained eclectic, but they did give impetus to the work of studying St. Thomas and the other Schoolmen in the light of modern intellectual and social issues.

Decisive support for this movement came with Pope Leo XIII's encyclical *Aeterni Patris* (1879). It noted the importance of sound doctrine for meeting today's problems and called for a restoration of the Christian philosophy of the Fathers and medieval Doctors, augmented where

necessary by the reliable advances of modern research. Leo asked especially for a recovery of the wisdom of St. Thomas, whom he hailed as "the special bulwark and glory of the Catholic Faith." This program required an accurate historical study of St. Thomas himself and his major commentators, combined with a readiness to use the evidences and resources of modern learning and science. St. Thomas was declared the universal patron of Catholic schools, and a canon (1366, par. 2) in the new Code of Canon Law (1917) required philosophy and theology teachers to adhere to the method, doctrine, and principles of St. Thomas. This established the special authority of the Common Doctor in the church's teaching institutions, without impairing the recovery of all the other sources of Christian thought, the careful discussion of commonly recognized difficulties, and the effort to evaluate modern teachings.

Thomism in the 20th century

Thomists of the 20th century concentrated upon two major tasks: a historical investigation of St. Thomas' doctrine in its medieval context and a rethinking of that doctrine in reference to contemporary problems. Pioneer historians were Pierre Mandonnet and Martin Grabmann, who investigated the life of Aquinas, the canon of his writings, and his historical relationships. The setting of Thomistic doctrine in the wider medieval intellectual currents was described by Maurice de Wulf and Étienne Gilson. The latter also brought out the basic role of existence in Thomistic metaphysics, which he contrasted with other historical forms of metaphysics. Some general presentations of Thomistic thought were made by showing the development of the principles of act and potency in the major areas of philosophy. The Dominican R. Garrigou-Lagrange stressed the problem of God and providence; A. Sertillanges, another Dominican, made the act of creation central to his exposition; the Jesuit Martin D'Arcy brought out the dynamic and effective aspects in the mind of Aquinas.

At the University of Louvain, Désiré-Joseph Cardinal Mercier and his associates concentrated on the challenge of modern thought for Thomism. They treated the epistemological issue at the outset of philosophy, so that metaphysics might have the support of a well-founded realism. The aim of Joseph Maréchal was to reformulate the major thinkers, especially St. Thomas, in terms of the mind's dynamic affirmation of being and ultimate reference to the reality of God. Francesco Olgiati used a metaphysical realism of substance to establish the critical relevance of Thomism to Cartesian and empiricist thinkers. How to unite the various kinds of methods and knowledges in a human order was the main concern of Jacques Maritain, but he also applied the Thomistic concept of person and community to the problem of democracy.

After World War II, Thomists faced three major tasks: to develop an adequate philosophy of science, to take account of the phenomenological and psychiatric findings on man, and to evaluate the ontologies of existentialism and naturalism. (J.D.Co.)

MAJOR WORKS

THEOLOGICAL TREATISES: *Scriptum super IV libros Sententiarum* (1254–56); *De veritate* (1256–59); *Summa contra gentiles* (*c.* 1258–64; *On the Truth of the Catholic Faith,* 1955); *Summa theologiae* (1265 or 1266–73; incomplete); *De potentia Dei* (1259–68; *On the Power of God,* 1932–34); *De malo* (undated; *On Free Choice*); *De spiritualibus creaturis* (undated; *On Spiritual Creatures,* 1949); *De anima* (undated; *The Soul,* 1949); *De unione Verbi incarnati* (undated); *De virtutibus* (1269–72; *On the Virtues in General,* 1951).

BIBLICAL COMMENTARIES: *Expositio in Evangelium S. Matthaei* (1269–72); *Expositio in Job ad litteram* (1261–64); *Expositio in Evangelium Joannis* (1269–72); *Exposition in S. Pauli Apostoli epistolas* (undated; incomplete); *In psalmos Davidis expositio* (1272–73).

COMMENTARIES ON ARISTOTLE: *In octo libros Physicorum expositio* (1268–71; *Commentary on Aristotle's Physics,* 1963); *In tres libros De anima* (undated; *The Commentary of St. Thomas Aquinas on Aristotle's Treatise on the Soul,* 1946); *In librum De sensu et sensato expositio* (1270–71); *In decem libros Ethicorum expositio* (1271–72; *Commentary on the Nicomachean Ethics,* 1964); *In duodecim libros Metaphysicorum expositio* (*c.* 1272; *Commentary on the Metaphysics of Aristotle,* 1961); *In libros De caelo et mundo expositio* (1272–73); *In libros Posteriorum analyticorum expositio* (undated; probably late).

OTHER WORKS: (PHILOSOPHICAL TREATISES): *De ente et essentia* (before 1256; *On Being and Essence,* 1949); *Contra impugnantes Dei cultum et religionem* (1256; *An Apology for the Religious Orders,* 1902); *De regno (De regimine principum) ad regem Cypri* (1266; *On Kingship,* 1949); *De perfectione vitae spiritualis* (1269–70); *De unitate intellectus contra Averroistas* (1270; *The Unicity of the Intellect,* 1946); *De aeternitate mundi contra murmurantes* (1270–72); *De substantiis separatis, seu de angelorum natura* (undated; *Treatise on Separate Substances,* 1959). (HYMNS AND LITURGICAL COMPOSITIONS): "Pange, lingua, gloriosi" (1264); "Verbum supernum prodiens" (1264; "The Word of God Proceeding Forth"); office for the Feast of Corpus Christi (*c.* 1264), including the sequence "Lauda Sion Salvatorem" ("Praise, O Zion, thy Salvation").

BIBLIOGRAPHY. St. Thomas' first biography was that of his disciple, WILLIAM OF TOCCO, published in *Acta Sanctorum,* vol. 1, pp. 656–686 (March 1865); new ed., with other biographies, *Fontes vitae S. Thomas Aquinatis,* 6 fasc. (1912–37). See also ANGELUS M. WALZ, *Saint Thomas Aquinas: A Biographical Study* (1951; originally published in Italian, 1945).

Latin editions of the Opera omnia: Rome, 17 vol. (1570), called *Piana* because they were published under Pius V; new and rev. ed., 25 vol., Parma (1852–73, reprinted 1948–50); then in Paris, Vivès ed., 34 vol., (1871–80); and a critical edition, called *Leonina* because it was requested by Leo XIII, which began publication in 1882. Of all his works, the *Summa theologiae* has been the most frequently reedited. An excellent edition was published by the Institute of Medieval Studies in Montreal, 5 vol. (1941–45).

English translations: The two *Summae,* by the English Dominicans, 22 vol.(1911–34); selections, by THOMAS GILBY, *Philosophical Texts* (1951, reissued 1982), and *Theological Texts* (1955); and ANTON C. PEGIS, *Basic Writings of St. Thomas Aquinas,* 2 vol. (1945). TERRY L. MIETHE and VERNON J. BOURKE (eds.), *Thomistic Bibliography: 1940–1978* (1980), lists more than 4,000 books and articles by and about St. Thomas in European languages. It continues VERNON J. BOURKE, *Thomistic Bibliography: 1920–1940* (1945); and PIERRE MANDONNET and JEAN DESTREZ, *Bibliographie Thomiste,* 2nd rev. ed. (1960), covering items up to 1920.

BURRELL, *Aquinas: God and Action* (1979), an advanced linguistic discussion of St. Thomas' *Summa theologica*; and FERNAND VAN STEENBERGHEN, *Thomas Aquinas and Radical Aristotelianism* (1980), a study of major aspects of St. Thomas' thought.

Thought and Thought Processes

In everyday language the word thinking covers several distinct psychological activities. It is sometimes a synonym for "tending to believe," especially with less than full confidence. ("I think that it will rain, but I am not sure.") At other times it denotes attentiveness ("I did it without thinking"); or it denotes whatever is in consciousness, especially if it refers to something outside the immediate environment. ("It made me think of my old grandmother.") In the sense on which psychologists have concentrated, thinking is intellectual exertion aimed at finding an answer to a question or a means of achieving a desirable practical goal.

The psychology of thought processes concerns itself with activities similar to those usually attributed to the inventor, the mathematician, or the chess player; but psychologists have not reached agreement on any definition or characterization of thinking. For some it is a matter of modifying "cognitive structures" (*i.e.,* perceptual representations of the world or parts of the world). Others view thinking as internal problem-solving behaviour.

Perhaps the most satisfactory provisional conception of thinking is one that applies the term to any sequence of covert symbolic responses (*i.e.,* occurrences within the human organism that can serve to represent absent events). If such a sequence is aimed at the solution of a specific problem and fulfills the criteria for reasoning, it is called directed thinking. Reasoning, of which rudimentary forms can be inferred to occur in infrahuman mammals, is a process of piecing together the results of two or more distinct previous learning experiences to produce a new pattern of behaviour. Directed thinking contrasts with other symbolic sequences that have different functions; *e.g.,* the simple recall (mnemonic thinking) of a chain of past events.

In the past, psychologists and laymen often identified thinking with conscious experiences. But as the scientific study of behaviour came to be recognized generally as the task of psychology, the limitations of introspection as a source of data have become widely apparent. It thus has become more usual to treat thought processes as intervening variables or constructs with properties that must be inferred from relations between two sets of observable events. These empirically available events are inputs (stimuli, present and past) and outputs (responses, including bodily movements and speech). For many psychologists such intervening variables are of interest as aids in dealing with and in making sense of the immensely complicated network of associations between stimulus conditions and responses, the analysis of which otherwise would be prohibitively cumbersome. Others are concerned, rather, with identifying cognitive (or mental) structures that are held to underlie a human being's observable behaviour without his necessarily being aware of them.

General considerations

ELEMENTS OF THOUGHT

The prominent use of words in thinking ("silent speech") has encouraged the belief, especially among behaviourist and neobehaviourist psychologists, that to think is to string together linguistic elements subvocally. Early experiments (largely in the 1930s) by E. Jacobson and L.W. Max revealed that evidence of thinking commonly is accompanied by electrical activity in the muscles of the thinker's organs of articulation. This work later was extended with the help of more sophisticated electromyographic equipment, notably by A.N. Sokolov. It became apparent, however, that the muscular phenomena are not the actual vehicles of thinking but represent rather a means of facilitating the appropriate activities in the brain when an intellectual task is particularly exacting. The identification of thinking with speech was assailed by L.S. Vygotski and by J. Piaget, both of whom saw the origins of human reasoning in the ability of children to assemble nonverbal acts into effective and flexible combinations. These theorists insisted that thinking and speaking arise independently, although they acknowledged the profound interdependence of these functions, once they have reached fruition.

Following different approaches, a 19th-century Russian physiologist (I.M. Sechenov), the U.S. founder of the behaviourist school of psychology (J.B. Watson), and a 20th-century Swiss developmental psychologist (Piaget) all arrived at the conclusion that the activities that serve as elements of thinking are internalized or fractional versions of motor responses; that is, the elements are considered to be attenuated or curtailed variants of neuromuscular processes that, if they were not subjected to partial inhibition, would give rise to visible bodily movements.

Sensitive instruments can indeed detect faint activity in various parts of the body other than the organs of speech; *e.g.,* in a person's limbs when the movement is thought of or imagined without actually taking place. Such findings have prompted statements to the effect that we think with the whole body and not only with the brain, or that "thought is simply *behaviour*—verbal or nonverbal, covert or overt" (B.F. Skinner). The logical outcome of these and similar statements was the peripheralist view (Watson, C.L. Hull) that thinking depends on events in the musculature, feeding proprioceptive impulses back to influence subsequent events in the central nervous system, ultimately to interact with external stimuli in determining the selection of a course of overt action. There is, however, evidence that thinking is not precluded by administering drugs that suppress all muscular activity. Furthermore, it has been pointed out (*e.g.,* by K.S. Lashley) that thinking, like other more-or-less skilled activities, often proceeds so quickly that there is simply not enough time for impulses to be transmitted from the central nervous system to a peripheral organ and back again between consecutive steps. So the centralist view that thinking consists of events confined to the brain (though often accompanied by widespread activity in the rest of the body) was gaining ground in the third quarter of the 20th century. Nevertheless, each of these neural events can be regarded both as a response (to an external stimulus or to an earlier neurally mediated thought or combination of thoughts) and as a stimulus (evoking a subsequent thought or a motor response).

Thinking as a brain function

The elements of thinking are classifiable as "symbols" in accordance with the conception of the sign process ("semiotic") that has grown out of the work of some philosophers (*e.g.,* C.S. Peirce, C.K. Ogden, I.A. Richards, and C.R. Morris) and of psychologists specializing in learning (*e.g.,* C.L. Hull, N.E. Miller, O.H. Mowrer, and C.E. Osgood). The gist of this conception is that a stimulus event

x can be regarded as a sign representing (or "standing for") another event y if x evokes some part, but not all, of the behaviour (external and internal) that would have been evoked by y if it had been present. When a stimulus that qualifies as a sign results from the behaviour of an organism for which it acts as a sign, it is called a "symbol." The "stimulus-producing responses" that are said to make up thought processes (as when one thinks of something to eat) are prime examples.

This treatment, favoured by psychologists of the stimulus-response (S-R) or neo-associationist current, contrasts with that of the various cognitivist or neorationalist theories. Rather than regarding the components of thinking as derivatives of verbal or nonverbal motor acts (and thus subject to laws of learning and performance that apply to learned behaviour in general), adherents of such theories see them as unique central processes, governed by principles that are peculiar to them. These theorists attach overriding importance to the so-called structures in which "cognitive" elements are organized. Unlike the S-R theorists who feel compunction about invoking unobservable intermediaries between stimulus and response (except where there is clearly no other alternative), the cognitivists tend to see inferences, applications of rules, representations of external reality, and other ingredients of thinking at work in even the simplest forms of learned behaviour.

The Gestalt school of psychologists held the constituents of thinking to be of essentially the same nature as the perceptual patterns that the nervous system constructs out of sensory excitations. After mid-20th century, analogies with computer operations acquired great currency; in consequence, thinking frequently is described in terms of storage, retrieval, and transmission of items of information. The information in question is held to be freely translatable from one "coding" to another without impairing its functions. The physical clothing it assumes is regarded as being of minor importance. What matters in this approach is how events are combined and what other combinations might have occurred instead.

THE PROCESS OF THOUGHT

Laws of association: contiguity, similarity

According to the classical empiricist-associationist view, the succession of ideas or images in a train of thought is determined by the laws of association. Although additional associative laws were proposed from time to time, two invariably were recognized. The law of association by contiguity states that the sensation or idea of a particular object tends to evoke the idea of something that has often been encountered together with it. The law of association by similarity states that the sensation or idea of a particular object tends to evoke the idea of something that is similar to it. The early behaviourists, beginning with Watson, espoused essentially the same formulation but with some important modifications. The elements of the process were conceived not as conscious ideas but as fractional or incipient motor responses, each producing its proprioceptive stimulus. Association by contiguity and similarity were identified by these behaviourists with the Pavlovian principles of conditioning and generalization.

Külpe, Hull, and Selz

The Würzburg school, under the leadership of Külpe, saw the prototype of directed thinking in the "constrained-association" experiment, in which the subject has to supply a word bearing a specified relation to a stimulus word that is presented to him (*e.g.*, an opposite to an adjective, or the capital of a country). Their introspective researches led them to conclude that the emergence of the required element depends jointly on the immediately preceding element and on some kind of "determining tendency" such as *Aufgabe* ("awareness of task") or "representation of the goal." These latter factors were held to impart a direction to the thought process and to restrict its content to relevant material. Their role was analogous to that of motivational factors—"drive stimuli," "fractional anticipatory goal responses"—in the later neobehaviouristic accounts of reasoning (and of behaviour in general) produced by C.L. Hull and his followers.

Hull's theory resembled G.E. Müller's earlier "constellation theory" of constrained association. Hull held that one particular response will occur and overcome its competitors because it is associated both with the cue stimulus (which may be the immediately preceding thought process or an external event) and with the motivational condition (task, drive stimulus) and is thus evoked with more strength than are elements associated only with the one or the other. O. Selz pointed out that in many situations this kind of theory would imply the occurrence of errors as often as correct answers to questions. It thus was untenable. Selz contended that response selection depends rather on a process of "complex completion" that is set in motion by an "anticipatory schema," which includes a representation of both the cue stimulus and the relation that the element to be supplied must bear to the cue stimulus. The correct answer is associated with the schema as a whole and not with its components separately. Selz's complex completion resembles the "eduction of correlates" that C.E. Spearman saw as a primary constituent of intellectual functioning, its complement being "eduction of relations," that is, recognition of a relation when two elements are presented.

The determination of each thought element by the whole configuration of factors in the situation and by the network of relations linking them was stressed still more strongly in the 1920s and 1930s by the Gestalt psychologists on the basis of W. Köhler's experiments on "insightful" problem solving by chimpanzees, and on the basis of later experiments by M. Wertheimer and of K. Duncker on human thinking. They pointed out that the solution to a problem commonly requires an unprecedented response or pattern of responses that hardly could be attributed to simple associative reproduction of past behaviour or experiences. For them, the essence of thinking lay in sudden perceptual restructuring or reorganization, akin to the abrupt changes in appearance of an ambiguous visual figure.

Thinking as perceptual reorganization

The Gestalt theory has had a deep and far-reaching impact, especially in drawing attention to the ability of the thinker to discover creative, innovative ways of coping with situations that differ from any that have been encountered before. This theory, however, has been criticized for underestimating the contribution of prior learning and for not going beyond rudimentary attempts to classify and analyze the structures that it deems so important. Later discussions of the systems in which items of information and intellectual operations are organized have made fuller use of the resources of logic and mathematics. Merely to name them, they include the "psychologic" of Piaget, the simulation of human thinking with the help of computer programs using list-processing languages and tree structures (H.A. Simon and A. Newell), and extensions of Hull's notion of the "habit-family hierarchy" (I. Maltzman, D.E. Berlyne).

A further development of consequence is a growing recognition that the essential components of the thought process, the events that keep it moving in fruitful directions, are not words, images, or other symbols representing stimulus situations; rather, they are the operations that cause each of these representations to be succeeded by the next, in conformity with restrictions imposed by the problem or aim of the moment. In other words, directed thinking can reach a solution only by going through a properly ordered succession of "legitimate steps." These steps might be representations of realizable physicochemical changes, modifications of logical or mathematical formulas that are permitted by rules of inference, or legal moves in a game of chess. This conception of the train of thinking as a sequence of rigorously controlled transformations is buttressed by the theoretical arguments of Sechenov and of Piaget, the results of the Würzburg experiments, and the lessons of computer simulation.

Implicit trial and error

Early in the 20th century both E. Claparède and John Dewey suggested that directed thinking proceeds by "implicit trial-and-error." That is to say, it resembles the process whereby laboratory animals confronted with a novel problem situation try out one response after another until they sooner or later hit upon a response that leads to success. In thinking, however, the trials were said to take the form of internal responses (imagined or conceptualized courses of action, directions of symbolic search); once attained, a train of thinking that constitutes a solution often can be recognized as such without the

necessity of implementation through action, followed by sampling of external consequences. This kind of theory, popular among behaviourists and neobehaviourists, was stoutly opposed by the Gestalt school whose insight theory stressed discovery of a solution as a whole and in a flash.

The divergence between these theories appears, however, to represent a false dichotomy. The protocols of Köhler's chimpanzee experiments and of the rather similar experiments performed later under Pavlov's auspices show that insight typically is preceded by a period of groping and of misguided attempts at solution that soon are abandoned. On the other hand, even the trial-and-error behaviour of an animal in a simple selective-learning situation does not consist of a completely blind and random sampling of the behaviour of which the learner is capable. Rather, it consists of responses that very well might have succeeded if the circumstances had been slightly different.

Heuristic (probabilistic) thinking; computer simulation

A. Newell, J.C. Shaw, and H.A. Simon pointed out the indispensability in creative human thinking, as in its computer simulations, of what they call "heuristics." A large number of possibilities may have to be examined, but the search is organized heuristically in such a way that the directions most likely to lead to success are explored first. Means of ensuring that a solution will occur within a reasonable time, certainly much faster than by random hunting, include adoption of successive subgoals and working backward from the final goal (the formula to be proved, the state of affairs to be brought about).

MOTIVATIONAL ASPECTS OF THINKING

The problem to be taken up and the point at which the search for a solution will begin are customarily prescribed by the investigator for a subject participating in an experiment on thinking (or by the programmer for a computer). Thus, prevailing techniques of inquiry in the psychology of thinking have invited neglect of the motivational aspects of thinking. The conditions that determine when the person will begin to think in preference to some other activity, what he will think about, what direction his thinking will take, and when he will regard his search for a solution as successfully terminated (or abandon it as not worth pursuing further) barely are beginning to attract investigation. Although much thinking is aimed at practical ends, special motivational problems are raised by "disinterested" thinking, in which the discovery of an answer to a question is a source of satisfaction in itself.

In the views of the Gestalt school and of F.C. Bartlett, the initiation and direction of thinking are governed by recognition of a "disequilibrium" or "gap" in an intellectual structure. Similarly, Piaget's notion of "equilibration" as a process impelling advance from less equilibrated structures, fraught with uncertainty and inconsistency, toward better equilibrated structures that overcome these imperfections, was introduced to explain the child's progressive intellectual development in general. Piaget's approach may also be applicable to specific episodes of thinking. For computer specialists, the detection of a mismatch between the formula that the program so far has produced and some formula or set of requirements that define a solution is what impels continuation of the search and determines the direction it will follow.

Neobehaviourists (like psychoanalysts) have made much of secondary reward value and stimulus generalization; *i.e.*, the tendency of a stimulus pattern to become a source of satisfaction if it resembles or has frequently accompanied some form of biological gratification. The insufficiency of this kind of explanation becomes apparent, however, when the importance of novelty, surprise, complexity, incongruity, ambiguity, and uncertainty is considered. Inconsistency between beliefs, between items of incoming sensory information, or between one's belief and an item of sensory information evidently can be a source of discomfort impelling a search for resolution through reorganization of belief systems or through selective acquisition of new information.

Novelty, incongruity, uncertainty

The motivational effects of such factors have been receiving more attention since the middle of the 20th century, mainly because of the pervasive role they have been found to play in exploratory behaviour, play, and aesthetics. But their role in all forms of thinking also began to be appreciated and studied in relation to curiosity, conflict, and uncertainty. As evidence accumulates about the brain processes that underlie fluctuations in motivational state, and as psychophysiological equipment with which such fluctuations can be monitored comes in for increasing use, future advances in the theory of thinking are likely to correct the present imbalance and give due prominence to motivational questions. (D.E.B.)

Types of thinking

Expressive and disciplined thinking

The spectrum or range of thinking reflects the relative intensity of intrinsic and extrinsic influences. When intrinsic processes operate strongly and are relatively free of environmental constraints, a person thinks expressively: he imagines, fantasizes, dreams, hallucinates, or has delusions. As his thinking becomes dominated by external stimuli, he tends to become more logical, directed, disciplined; the process then is identified by such terms as judging, conceptualizing, and problem solving.

Sigmund Freud recognized this distinction between expressive and disciplined function in contrasting what he called primary and secondary process thinking. Freud held that one's impulses and wishes arise from unconscious sources and determine primary process thinking, while the pursuit of exterior objects and goals determines secondary process thinking, which he associated with planning, rational control, and continuous organization. These two aspects of thinking also can be called, respectively, autistic (determined by subjective emotional-motivational activities) and realistic (oriented toward the external environment). The terms are not mutually exclusive but rather correspond to relative degrees of influence of different conditions that enter into thinking.

In a broad sense, then, activities called thinking are internally adaptive responses to intrinsic and extrinsic stimuli; not only do they express inner impulses but they also serve to generate environmentally effective, goal-seeking behaviour.

REALISTIC THINKING

Convergent thought processes. It has been proposed that certain forms of thinking call on one's abilities to assemble and organize information. The result of such thinking satisfies a defined goal in the achievement of an effective solution to a problem. These forms are called convergent thinking and become apparent when situations arise in which one's ability to cope with a task demands resources beyond the explicit stimuli presented; *i.e.*, converges the components of one's past and present experience in organizing or directing one's response.

Experimental approaches. In studying thinking experimentally, investigators often use standardized tasks that have measurable outcomes; for example, a human subject (say, a young child) may be shown three levers—one black, the other two white. Initially, the standard task may be for the child to discover that for pulling the black lever he will receive some reward (perhaps something good to eat) but that for pulling either white lever he will get no reward at all. Orderly procedures are established under which experimental changes can be introduced to observe their effects on the thinker's performance. The results are compared with those obtained under a standard control condition without the changes.

Among the variables that can be manipulated are the amount of information available to the individual (*e.g.*, the black lever may also be illuminated); the kind or degree of incentives under which he works (*e.g.*, a larger or better tasting reward); the order or arrangement of objects (*e.g.*, black lever in the middle or on the right); the instructions provided; the subject's familiarity or degree of prior experience with the task; and the stress under which he functions, such as punishment for mistakes or the threat of failure. The thinker's personality characteristics provide another set of variables for study; for example, subjects who typically exhibit high levels of anxiety can be compared in their task performance with those who ordinarily show little anxiety; or the performance of a

person who shows a compelling need to achieve success can be compared with that of a person who exhibits strong fears of failure.

Conditions that affect realistic thinking

Research results indicate that any condition that increases the complexity of a task requiring convergent thinking tends to make the solution more difficult and time-consuming. The more multiple choices (*e.g.,* ten levers instead of three) a thinker is offered, the more difficult the solution of the task is likely to be. Irrelevant items of information, such as the illumination of all levers, may complicate a problem; and as irrelevant data become more numerous or as relevant information becomes less accessible to or discoverable by the thinker, the solution becomes more difficult.

Finding a solution is helped by providing the thinker with cues, guidelines, rules, or other appropriate ways of orienting himself toward the problem (*e.g.,* he may be pointed toward the right lever). Performance is uncertain to the degree that the individual must discover these directions by his own efforts. When separate cues must be combined (*e.g.,* the colour of the lever and the presence or absence of illumination), the more suitable they are for the required relationship, the more efficient the process of solution tends to be.

Individual traits and factors. Conditions that increase the thinker's motivation, such as incentives and special instructions, tend to improve performance. A person's response to these conditions, however, depends on his personality characteristics; very anxious people typically show particularly impaired performance when the task is difficult or stressful. An important consideration is the set (or expectation) of the person; a person's tendency toward rigidity—inability to adapt readily to changing conditions of the task—is likely to have adverse effects on his performance. Instruction or special training that aids one in overcoming his prior sets fosters his ability to achieve correct solution.

Realistic thinking may be aided or hindered by the individual's strategies and cognitive or perceptual style. Such characteristics include the way a person attends to and uses sensory information; he may, for example, focus on inessentials, may fail to observe details accurately, or may be disturbed by complexities in the task stimuli. Also important to convergent thinking are the individual's abilities to analyze and to synthesize sensory information.

Realistic thinking tends to be elicited when the individual perceives no obvious or immediate path to a desired goal. It is likely to begin with his recognition of a problem—otherwise, his behaviour would simply indicate the operation of habits or the automatic production of responses. Realistic thinking continues with one's consideration of alternatives, each marked by some uncertainty or risk. He next begins processing information (including pertinent past experience) by analyzing, combining, and organizing available and potential resources for reaching his goal. In the final phase of the process he produces a response; it may be a wrong solution, a partial solution, or a correct solution. Recycling of these phases (recognition, considering alternatives, processing data, and responding) may continue in a complex way until the goal finally is reached or until the process ends in failure.

Phases of realistic thinking

The explicitness of these phases varies with the complexity of the task, as well as with the problem-solving skills of the individual. In this connection, the individual may show evidence of "learning how to learn"; that is, he may exhibit a progressive increase in skill as he encounters a series of similar problems.

Judgment. A simple form of realistic thinking that lends itself well to controlled experimentation is inferred from one's ability to discriminate discrete objects or items of information (*e.g.,* distinguishing a lion from a tiger). The outcome is a judgment, and the process may be called decision making. The availability of information, the rate at which it is presented, the set (expectancy) of the judge, and the number of alternatives available to him influence the efficiency of his judgment. Redundancy (or surplus) of information facilitates judgment; for example, the lion may be discriminated on the basis of a number of different sensory cues: he is tan or brown, he lacks stripes, he has a mane, and so on. Within what is called the general theory of adaptation level, the decision-making response is considered to be a weighted average of various stimuli: focal (the specific sensory properties of the lion and tiger), contextual (the background in which they are observed), and residual (such intrinsic or experiential factors as memory for other brown or striped objects). Variations in one or more of these three types of stimuli shift the judge's decision in one direction or another in relation to his immediately preceding judgment.

Concept attainment. A more complex form of realistic thinking is inferred when an individual is asked to identify or use a *class* of items, as in selecting several different kinds of triangle from an array of other geometric figures. The individual may proceed to link together in his thinking a newly experienced group of objects according to one or more of their common properties. He thus may be able to give them a general name, as in first learning the meaning of the term triangle, or he may determine whether a newly given object fits a category he already knows. Physical objects are multidimensional; that is, they may vary in shape, size, colour, their location in relation to other objects, their emotional significance, or their connotative meaning. How a person identifies such dimensions, develops hypotheses (or tentative conclusions) about which of the specific dimensions define a class, arrives at the rules of class membership, and how he tests various hypotheses all reflect his ability to grasp concepts. Successful performance in all these processes leads to his formulation of pertinent rules based on his ability to classify specific items (see LEARNING AND COGNITION: *Concept formation*).

Linking by common properties

Problem solving. Still more complex forms of realistic thinking seem to occur when tasks are presented in which the goal is impossible (or very difficult) to achieve directly. In such situations, people commonly appear to pass through intermediate stages of exploring and organizing their resources; indeed, one may first need to exert himself in understanding the problem itself before he can begin to seek possible directions toward a solution. Familiar examples of problem-solving tasks include anagrams (*e.g.,* rearrange "lpepa" to spell "apple"); mathematical problems; mechanical puzzles; verbal "brain teasers" (*e.g.,* Is it legal for a man to marry his widow's sister?); and, in a more practical sense, design and construction problems. Also of interest are issues of human relations, games, and questions pertinent to economics and politics.

Trial and error. Problem-solving activity falls broadly into two categories: one emphasizes simple trial and error; the other requires some degree of insight. In trial and error, the individual proceeds mainly by exploring and manipulating elements of the problem situation in an effort to sort out possibilities and to run across steps that might carry him closer to the goal. This behaviour is most likely to be observed when the problem solver lacks advance knowledge about the character of the solution, or when no single rule seems to underlie the solution. Trial-and-error activity is not necessarily overt (as in one's observable attempts to fit together the pieces of a mechanical puzzle); it may be implicit or vicarious as well, the individual reflecting on the task and symbolically testing possibilities by thinking about them.

Solutions through insight. In striving toward insight, a person tends to exhibit a strong orientation toward understanding *principles* that might bear on the solution sought. The person actively considers what is required by the problem, noting how its elements seem to be interrelated, and seeks some rule that might lead directly to the goal. The insightful thinker is likely to centre on the problem to understand what is needed, to take the time to organize his resources, and to recentre on the problem (reinterpret the situation) in applying any principle that seems to hold promise.

Understanding, organizing, and applying principle

Direction and flexibility characterize insightful problem solving. The thinker directs or guides his steps toward solution according to some plan; he exhibits flexibility in his ability to modify or to adapt procedures as required by his plan and in altering the plan itself. Both characteristics are influenced by the thinker's attitudes and by environmental conditions. If, for example, the task is to empty

a length of glass tubing of water (without breaking it) by removing wax plugs about a half-inch up the tube from each end, and the only potential tools are a few objects ordinarily found on a desk top, the usual appearance and functions of such common objects may make it difficult for the problem solver to see how they can be adapted to fit task requirements. If a paper clip is perceived as holding a sheaf of papers in the usual way, such perception would tend to interfere with the individual's ability to employ the principle that the clip's shape could be changed: straightened out for use in poking a hole in the wax.

Formal, logical processes. A special form of problem solving employs formal, systematic, logical thinking. The thinker develops a series of propositions, often as postulates; *e.g.,* the shortest distance between two points is a straight line. He builds a structure of arguments in which statements are consistent with each other in reaching some goal, such as defining the area of a triangle. This kind of logical, mathematical reasoning applies formal rules in supporting the validity of successive propositions.

Inductive and deductive thinking

Both inductive and deductive processes may be used by a problem solver. In inductive thinking one considers a number of particular or specific items of information to develop more inclusive (or general) conceptions. After aspirin was synthesized, for example, some people who swallowed the substance reported that it relieved their *particular* headaches. Through induction, the reports of these *specific* individuals were the basis for developing a more inclusive notion: aspirin may be helpful in relieving headaches in general.

Deduction is reasoning from general propositions—or hypotheses—to more specific instances or statements. Thus, after the general hypothesis about the effectiveness of aspirin had been put forward, physicians began to apply it to specific, newly encountered headache cases. The deduction was that, if aspirin is *generally* useful in managing pains in the head, it might also be helpful in easing pains elsewhere in the body. Although a person may deliberately choose to use induction or deduction, people typically shift from one to the other, depending on the exigencies of the reasoning process.

Students of problem solving almost invariably have endorsed some variety of mediation theory in their efforts to understand realistic thinking. The assumptions in that kind of theory are that implicit (internal) representations of experience are stored in and elicited from memory and are linked together during the period between the presentation of a stimulus and the implementation of a response. Those theorists who prefer to avoid the use of unobservable "entities" (*e.g.,* "mind") increasingly have been invoking the nervous system (particularly the brain) as the structure that mediates such functions.

Creative thinking. Divergent (or creative) thinking has been defined as an activity that leads to new information, or previously undiscovered solutions, rather than to a predetermined, correct solution (as in convergent thinking). Some tasks call for flexibility, originality, fluency, and inventiveness, especially for problems in which the individual must supply his own, unique solution. The "problem" might be a personal, emotional difficulty that needs resolution or expression.

Four progressive stages. A number of processes or phases have been identified as typical of creative thinking. In what logically would be the first phase (*i.e.,* preparation), the thinker assembles and explores his resources and perhaps makes preliminary decisions about their value in solving the problem at hand. Incubation represents the next period, in which he mulls over possibilities and shifts about from one to another relatively free of any rigid rational or logical preconceptions and constraints. Incubation seems to be at least partly unconscious, proceeding without the individual's full awareness. Illumination occurs when resources fall into place, and a definite decision is reached about the result or solution. Verification (refinement or polishing), the process of making relatively minor modifications in committing ideas to final form, follows. Often enough, objective standards for judging creative activity (*e.g.,* musical composition) are lacking; an important criterion is the emotional satisfaction of the creator.

Preparation, incubation, illumination, verification

Although the four phases have been ordered in a logical sequence, they often vary widely and proceed in different orders from one person to the next. Many creative people attain their goals by special strategies that are not neatly describable.

The phases of preparation, incubation, illumination, and verification are characteristic of creative thinkers generally but do not guarantee that a worthwhile product will ensue. Results also depend on whether an individual has the necessary personality characteristics and abilities; in addition, the quality of creative thinking stems from the training of the creator. The artist who produces oil paintings needs to learn the brushing techniques basic to the task; the scientist who creates a new theory does so against a background of previous learning. Further, creativity intimately blends realistic (objective) and autistic (subjective) processes; the successful creator learns how to release and to express his feelings and insights.

Creative thinking is a matter of using intrinsic resources to produce tangible results. This process is markedly influenced by early experience and training. School situations, for example, that encourage individual expression and that tolerate idiosyncratic or unorthodox thinking seem to foster the development of creativity.

Artistic versus scientific creativity. While the processes of creative thinking in artistic and scientific pursuits have much in common, there are also distinctive differences. The artist places more importance on feeling and individual expression, often going to extremes to divorce himself from environmental constraints. The scientist relies more on disciplined, logical thinking to lead him in new directions. Artistic endeavour is dominantly expressive (although clearly oriented toward a goal), while scientific inventiveness is dominantly disciplined (although flexibly receptive to feelings and to imaginative experiences).

Thinking in groups. It might be supposed that greater efficiency should be achieved if several people collaborate to solve a problem than if only one individual works on it. Such results are by no means invariable.

Although groups often may increase the motivation of their members to deal with problems, there is a counterbalancing need to contend with conflicts arising among members of a group and with efforts to give it coherent direction. Problem solving is facilitated by the presence of an effective leader who not only provides direction but permits the orderly, constructive expression of a variety of opinions; much of the leader's effort may be devoted to resolving differences. Success in problem solving also depends on the distribution of ability within a group. Solutions simply may reflect the presence of an outstanding individual who might perform even better by himself.

Although groups may reach a greater number of correct solutions, or may require less time to discover an answer, their net man-hour efficiency is typically lower than that achieved by skilled individuals working alone.

Brainstorming for new solutions

A process called brainstorming has been offered as a method of facilitating the production of new solutions to problems. In brainstorming, a problem is presented to a group of people who then proceed to offer whatever they can think of, regardless of quality and with as few inhibitions as can be managed. Theoretically these unrestricted suggestions increase the probability that at least some superior solutions will emerge. Nevertheless, studies show that when individuals work alone under similar conditions, performance tends to proceed more efficiently than it does in groups.

Under special circumstances, however, a group may solve problems more effectively than does a reasonably competent individual. Group members may contribute different (and essential) resources to a solution that no individual can readily achieve alone; such pooling of information and skills can make group achievements superior in dealing with selected problems. Sometimes social demands may require group agreement on a single alternative, as in formulating national economic or military policies under democratic governments. When only one among several alternative solutions is correct, even if a group requires more time, it has a higher probabil-

ity of identifying the right one than does an individual alone.

One difference between problem solving by a group and by an individual is the relative importance of covert or vicarious processes. The group depends heavily on verbal communication, while the individual, in considerable degree, attacks the problem through implicit, subjective, silent activity.

AUTISTIC THINKING

When the intensity of extrinsic (or environmental) influence is greatly reduced and intrinsic (or internal) influences dominate, thought processes tend to become autistic, or especially responsive to emotional and motivational impulses; autistic thought processes include so-called free association, fantasy (and reverie), dreaming, and pathological thinking. Often seeming to arise from wishes or needs, autistic thinking may represent an activity through which the individual symbolically gains gratification that the environment does not provide. For instance, one's wishes may be fulfilled only in dreaming. According to Freud, autistic thinking is especially influenced by unconscious tendencies that otherwise might find no expression.

Free association. A person freely associates by responding verbally when the usual constraints of logic, goal orientation, or controlled sequence of thinking are removed or reduced. His responses are likely to reflect aroused emotional activity or impulses; for example, during free association, ordinarily forgotten and repressed past experiences seem to be more readily remembered. What is actually produced in free association (as in other forms of autistic thinking) may not always seem to be particularly coherent or meaningful. Some theorists suggest that such responses are likely to symbolize rather than to state an impulse directly. Thus a psychoanalytic theorist might imagine that a young woman's verbal associations about being run over by a beer truck symbolically disguise a socially unacceptable wish to be seduced in some illicit romantic encounter.

One technique that is claimed to be helpful in uncovering an individual's latent or repressed tendencies is the word-association test, devised by Carl Jung, a Swiss psychiatrist. The test taker is presented with a list of words, to each of which he is supposed to respond by saying whatever he thinks of first. It is theorized that especially significant responses may be identified by such clues as the person's delay in responding, by his use of words that indicate strong emotion, or by unusual or bizarre responses. The word chair for example, prompts many people to say table; the analyst is likely to be alerted if the response is *criminal* or *blood.*

Fantasy. Fantasizing is definable as comparatively well organized sequences of thinking in which sensory imagery prevails. When a person who is otherwise awake tends to lose contact with the environment and his thinking proceeds with little or no concern for logical considerations, conditions become favourable for fantasizing. The activity may also take on a problem-solving character, especially when the thinker periodically monitors the process to evaluate the degree to which he may have progressed toward a solution. Fantasy tends to be highly egocentric, dramatic, pleasurable, and free flowing; it may range from vaguely conscious reverie to vivid, almost hallucinatory visual, auditory, or tactual daydreams.

Rorschach and other projective tests

Psychologists have tried to infer the details of such covert processes by asking people to respond to ambiguous stimuli in whatever way they wish, and by so doing to project their inner experiences. Well-known projective methods include the Rorschach Test, in which inkblots in black and white and colour are used as stimuli; and the so-called Thematic Apperception Test (TAT), in which pictures (of people, for example) are shown, about which the subject is asked to make up stories. The Rorschach Test is believed by some to provide evidence of a person's originality, of the balance he maintains between emotional and logical thinking, and of typical ways in which he perceives the environment; some psychologists assert that the TAT may yield clues to a person's motivational characteristics, his inner conflicts, and his attitudes toward other people. Others hold that those projective methods are most untrustworthy and that their use can lead to dangerously misleading conclusions (as in mistakenly committing people to psychiatric hospitals).

Certain marginal states of consciousness seem especially favourable for autistic thinking. An example is the drowsy (hypnagogic) period experienced just before falling asleep; at such times, images and apparently random thinking may well up and "float" freely. Similar (hypnopompic) experiences that emerge on awakening also have been reported. Roughly equivalent activities may occur even when one seems fully awake, but when autistic processes hover between full fantasy and conscious orientation to the environment.

Drugs may induce a variety of alterations in thinking; there may be heightened sensitivity to sensory stimuli and responsiveness to inner states through enhanced imagery and unusual ideational activity. Dosed with some drugs, people seem completely to withdraw from the environment and may show evidence of hallucinatory and delusional experiences.

Dreaming. Autistic thinking during sleep is called dreaming. Reduction in external stimulation while one is asleep permits intrinsic activities to exert a strong influence on thought processes. Some psychoanalytic theorists interpret dreaming as a mechanism for maintaining sleep and fulfilling wishes. Freud held that impulses may be expressed in disguised form when one dreams, particularly if their frank expression would be in conflict with the dreamer's moral and social standards. Freud wrote that the original wish that prompts dreaming corresponds to the dream's latent content. Such latent content is to be inferred from the dream as it is directly experienced (the manifest content). The meaning of any dream, according to Freud, lies in its latent content; to the extent that the latent wish is unacceptable to or threatens the dreamer, he is said to employ mechanisms of symbolic imagery, condensation, displacement, and secondary elaboration to disguise it. Condensation refers to the combining of elements; by itself, a knife may suggest a hostile weapon, but dreamed of in combination with other eating utensils it appears innocuous. In displacement the dreamer shifts an impulse from one object to another; he may dream of slicing a melon (manifest) rather than an enemy (latent). Secondary elaboration is the process of imposing structure to increase the coherence and logic of the dream.

Freud's theories of dreams

Other theorists suggest that in many instances dreams do not hold the latent or hidden significance that Freud assigned them. These critics indicate that dreams may simply be the result of random remembering or of imagery that wells up during sleep. In such dreaming, the sequence of dream elements would represent little more than transient associations (see SLEEP AND DREAMS).

In their efforts to study dreaming in terms of more objective evidence, some investigators record electrical activity generated by the brains of sleeping people. People are most likely to say they have been dreaming if they are awakened during a period of so-called rapid eye movement, at which times distinctive changes in brain activity are observable. When people are chronically wakened whenever such signs of dreaming appear, they tend to develop symptoms of psychological disturbance (*e.g.,* hallucinatory activity) during daylight hours. When later permitted to sleep without interruption, they give evidence of dreaming intensively, as if to compensate for previous deprivation. It would appear that dreaming may meet some fundamental physiological need.

Physiological studies of dreaming

Although dreaming largely seems to express intrinsic activity, it can be influenced by external stimuli and is likely to include experiences that symbolize such stimuli. A light tap on the foot of a sleeper, for example, might prompt him to dream of buying a new pair of shoes.

Pathological thinking. One popular system for classifying disturbances in personality is based on general patterns or categories of activity called behaviour disorder, neurosis, and psychosis.

Behaviour disorders. Individuals who are judged to show difficulty in self-control, in ability to withstand stress, or who hold unorthodox moral and social standards are

likely to be labelled as exhibiting behaviour disorders. The thinking of such people appears to be essentially "normal" in that they show efficient awareness of the environment. Behaviour disorder is displayed mainly in antisocial acts, stemming from what many observers consider to be the individual's deviant evaluation of what is "right" or "wrong," or of what is socially acceptable.

Neurosis. According to some theories, persons classified as neurotic are thought to suffer deep-lying conflicts, controlled in varying degrees by repression. Their tensions are held to produce feelings of anxiety and guilt and to lead to emotion-laden thinking (or worrying). Such theories also posit the operation of so-called ego-defense mechanisms, or activities believed to allow the individual to keep his distressing, repressed impulses from his own awareness. Thus his reasoning may be altered, as in dreaming. Defense mechanisms include rationalization, which justifies actions on a false basis, as when a soldier who enjoys killing feels he does so through patriotism; projection, which attributes to others one's own impulses, as when a hater feels hated; denial, or refusal to admit unacceptable or embarrassing aspects of experience; reaction formation, in which one acts contrary to his repressed impulses, as when he drowns his lecherous tendencies in excessive piety; and rigidity, or excessively careful, fixed thinking (see also MENTAL DISORDERS: *Psychoneuroses*).

Psychosis. When one's thinking seems grossly disturbed over an appreciable period, he is usually classified by psychiatrists as psychotic. Severe personality disorders of this sort may result from environmental stress, bodily disease, chemical or toxic factors, or any number of experiential influences (*e.g.,* combat experiences, loss of loved ones). The relation between thinking and environmental constraints seems grossly distorted in some forms of psychosis; the effect may be disorientation in time, in space, or in personal identity. In significant degree, the psychotic's emotional and cognitive processes appear to the observer to be independent of what is happening in the surrounding environment.

Bizarre symptoms of psychosis

Some ideational symptoms observed among psychotics are bizarre hallucinatory activities such as those reflected in vivid visual or auditory experiences (*e.g.,* hearing "voices") perceived by the individual as coming from the environment; delusions, ostensibly false beliefs that dominate thinking, such as notions of being persecuted or of having a special identity or a mission (as of being appointed to destroy the world); stereotyped, repetitive ideation or actions, such as the incessant recurrence of silly, emotionless "laughter" or detailed rituals resembling peculiar kinds of calisthenics.

Psychotic persons also may show signs of amnesia, inability to understand what others are saying, failures of attention, disorganization of thinking as expressed in meaningless or incoherent speaking or writing. Among psychotics who are likely to be identified as schizophrenics, speech tends to become odd, fragmented, and difficult to follow rationally; their idiosyncratic use of words is common, along with apparently meaningless phrases and sometimes disregard for sentence structure. Instances of what some claim to be "second sight," divine inspiration, possession by spirits, or extreme detachment from ordinary concerns all are likely, in psychiatric settings, to be interpreted as temporary psychotic episodes.

Thought processes cover a remarkably wide range of types; many are poorly understood or may not even be known to professional psychologists. It seems clear, however, that any kind of thinking mediates between intrinsic (bodily) activities and extrinsic (external) sources of stimulation, each type of thought process representing a resultant of autistic and environmental influences. Tientsin

Tientsin (Wade-Giles romanization T'ien-ching, Pinyin romanization Tianjin), the third largest municipality of the People's Republic of China after Shanghai and Peking, is located to the east of Hopeh Province at the northeastern extremity of the North China Plain. Central Tientsin (the municipality's urban core) lies about 60 miles (96 kilometres) southeast of central Peking and about 35 miles inland from the Po Hai (Po Gulf), a shallow inlet of the Yellow Sea. Tientsin Municipality, like Peking and Shanghai, is under direct control of the State Council and covers an area of about 4,365 square miles (11,305 square kilometres). Tientsin (meaning literally Heavenly Ford) has been an important transport and trading centre since the Yüan (Mongol) dynasty (1206–1368). It is China's second largest manufacturing centre after Shanghai and the leading port in North China.

Tientsin was famous as a cosmopolitan centre long before the arrival of the European trading community in the 19th century. Its maritime orientation and its role as the commercial gateway to Peking fostered the growth of an ethnically diverse and commercially innovative population. The city is noted for its woven handicraft products, terra-cotta figurines, hand-painted woodblock prints, and extensive seafood cuisine.

Physical and human geography

THE LANDSCAPE

The city site. Central Tientsin is located at the point where the Tzu-ya and the Hsin-k'ai rivers, and the north and south sections of the Grand Canal (Pei Yün-ho and Nan Yün-ho, respectively) converge before merging into the Hai Ho (Hai River), which then flows eastward into the Po Hai. The city stands at an elevation of less than 15 feet (five metres) above sea level on a level alluvial plain. Some low-lying areas east of the city are only about six feet above sea level, and the majority of the built-up area is below 12 feet.

The municipality borders on the Po Hai to the east, Peking Municipality to the northwest, and Hopeh Province to the north, west, and south. Between 1955 and 1967 Tientsin was a subprovince-level city, which served as the capital of Hopeh Province. Its jurisdiction extended over the built-up urban core and eastward along the Hai Ho to include the port at T'ang-ku. At that time, Tientsin city was administratively separate from the Tientsin Special District, which had its seat at Yang-liu-ch'ing, southwest of central Tientsin.

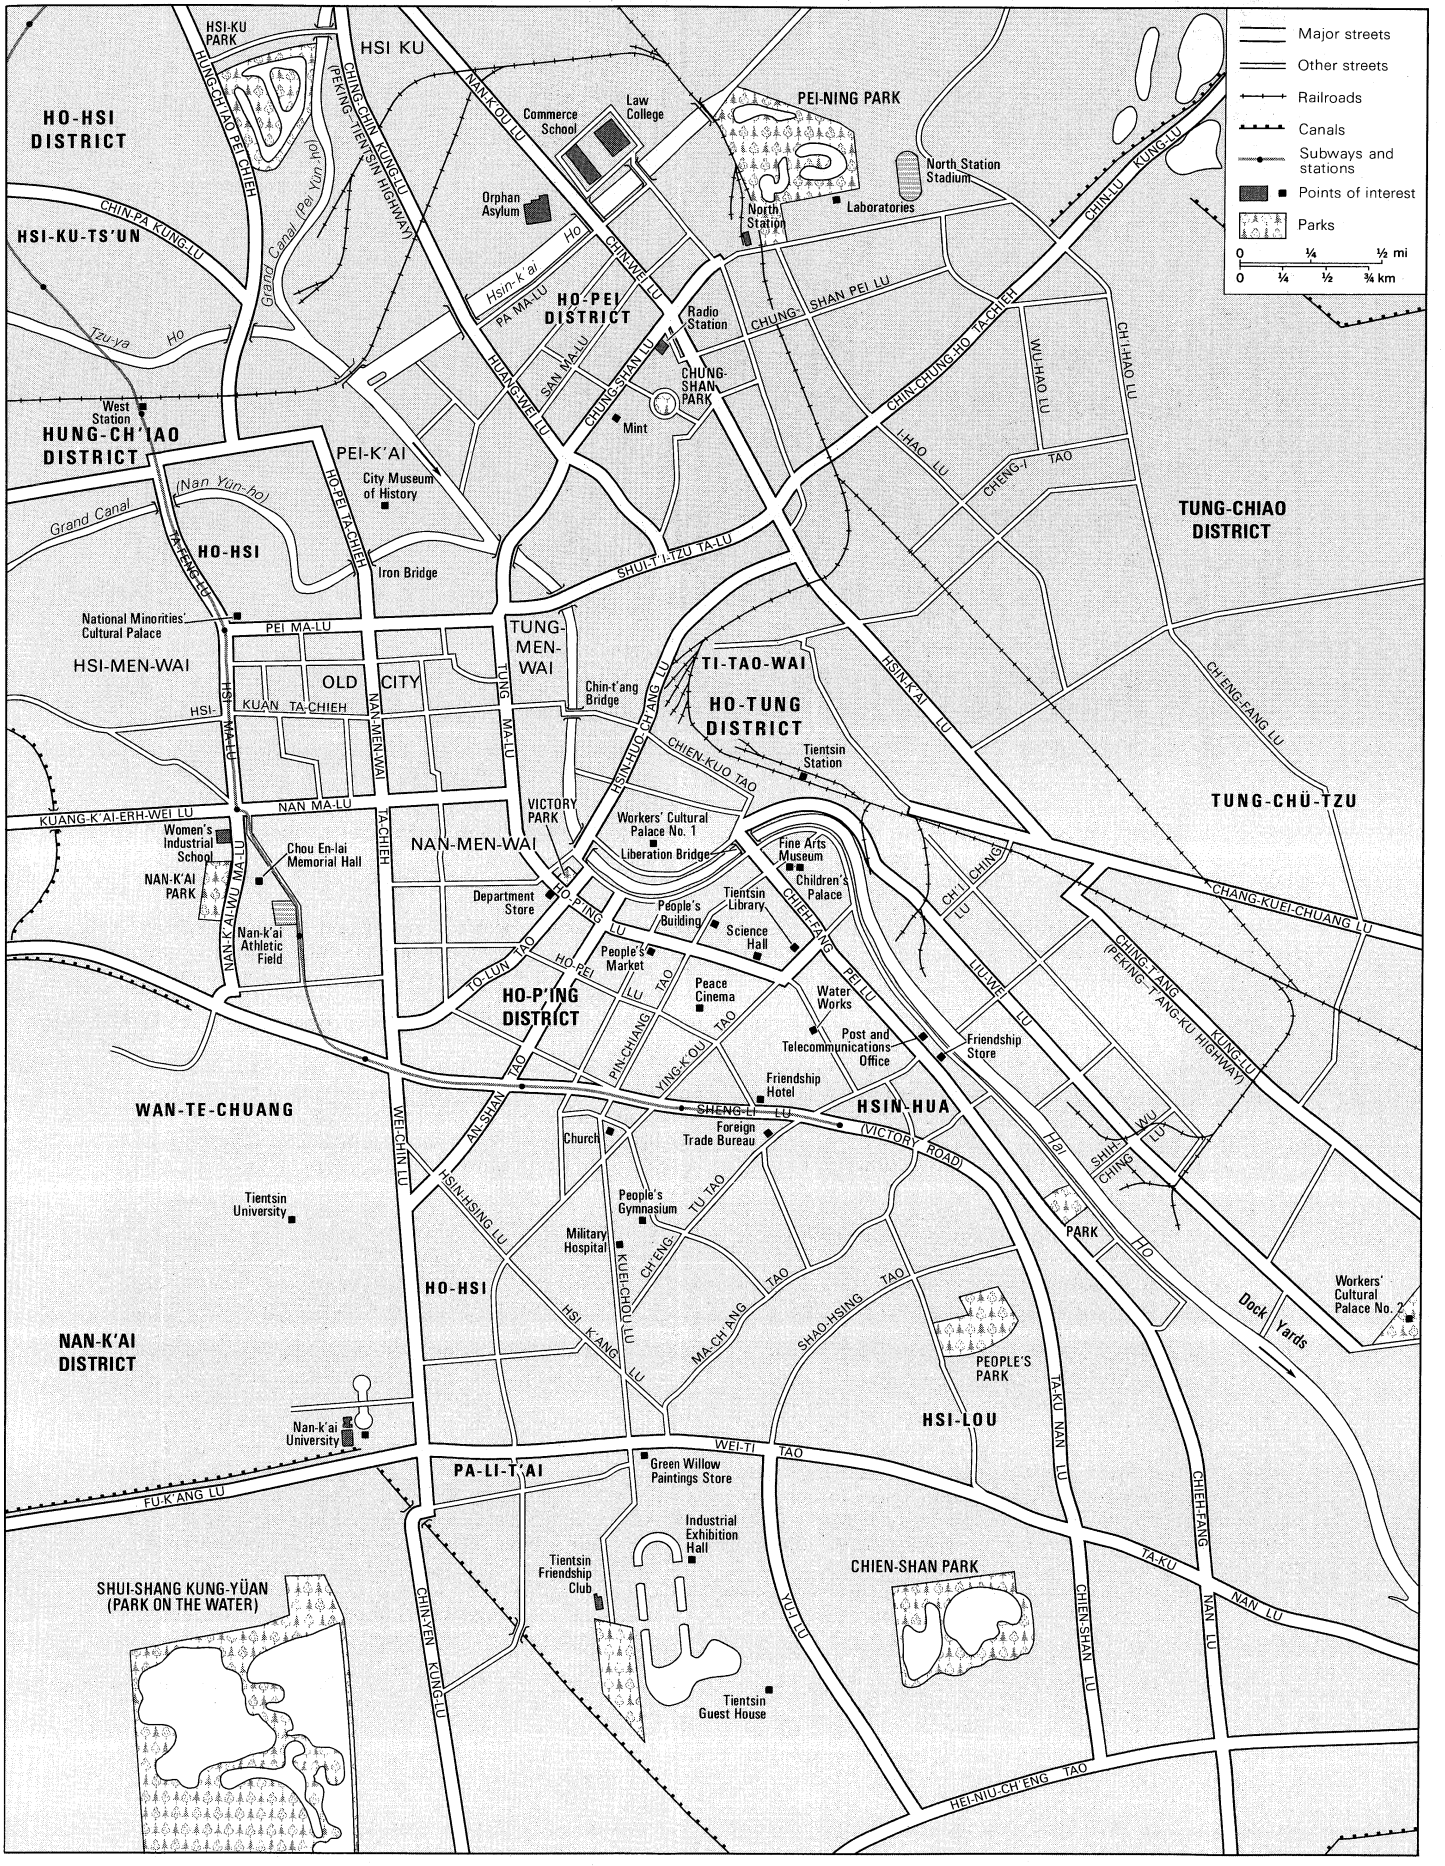
In 1967 Tientsin Municipality was made a first-order, province-level administrative unit, and the area under its immediate control was expanded to include counties (*hsien*) formerly under the special district. The city simultaneously became the special district seat but lost its position as provincial capital. In the early 1980s Tientsin Municipality was composed of 13 urban and suburban districts (*ch'u*) and five rural counties. The municipality was under direct jurisdiction of the central government in Peking.

Climate. Despite Tientsin's proximity to the sea, it has a distinctly continental climate with sharp daily and seasonal temperature fluctuations. It is subject to the full effects of the cool, dry Siberian high-pressure system during the winter (October to April), while in the summer (May to September), the high pressure system over the North Pacific Ocean brings hot and rainy weather. Winter precipitation is minimal, and the air is dry, with relative humidity averaging 50 percent. In summer, moist, rain-bearing southerly winds prevail, and the average relative humidity exceeds 70 percent. The average annual temperature is 56° F (13° C), with a January average of 39° F (4° C) and a July average of 84° F (29° C). Severe winter storms are common, but typhoons seldom occur.

Flood-control measures

Drainage. The Hai Ho was long subject to frequent flooding. As the main outlet for the rivers of the North China Plain, it frequently became heavily silted during the spring and summer months; during the winter season its water level was often too low for navigation. Extensive water conservation began in 1897. The river was straightened to facilitate tidal action and to shorten the distance to the sea. Locks were constructed to regulate the flow of water from the river into its many canals, the river and the sand bars at its mouth were dredged, and silt-laden water was diverted into settling basins.

Since 1949 multipurpose flood-control, irrigation, and navigation improvements have been made. Construction of the Kuang-ting Reservoir on the Yung-ting Ho near Peking has helped alleviate flood damage within metropolitan Tientsin. New diversion channels have also been built to control the floodwaters of the Ta-ch'ing and Tzu-ya rivers to the southwest.



Plant and animal life. The marshy lakes and floodplains around Tientsin abound with numerous varieties of reeds, bulrushes, and shrubs, such as tamarisk. Closer to the seashore, Russian thistle, glasswort, and artemisia can be found. Freshwater fish (including silver and golden carp) are raised in ponds and marshy depressions.

The city layout. The urban core of Tientsin extends for about seven miles from east to west and about nine miles from north to south. Ho-p'ing, the central district, is located on the west bank of the Hai Ho, just below the large bend of the Hai Ho. It is the main commercial and financial centre, and its two main streets of Ho-p'ing Lu (Ho-p'ing Road) and Chieh-fang Lu have several large department stores, restaurants, and hotels.

The central district

The old "Chinese" city is situated immediately to the northwest of Ho-p'ing Lu. It is bounded by the four wide boulevards of Tung, Hsi, Pei, and Nan Ma-lu that follow the course of the old rectangular wall. The street pattern in the old city is winding and irregular, in contrast to the more regular gridded pattern in the foreign-developed zones to the south and west. The old city is subdivided into four smaller sections, each of which in traditional times had special marketing and commercial functions.

North and west of the old city and continuing across the Nan Yün-ho is the mixed residential and industrial Hung-ch'iao District. It extends to the confluence of the Tzu-ya Ho, Pei Yün-ho, and Hai Ho. The northern outskirts

The city of Tientsin.

The telecommunications building in Tientsin.
Li Changyuan—New China Pictures Co./Eastfoto

contain workers' housing developments, and the area is best known for its domestic handicrafts.

The southern and western neighbourhoods of Hsin-hua and Ho-hsi and the Nan-k'ai District were built on what (until it was drained) was marshy, low-lying land. Hsin-hua, at the bend of the Hai Ho well south of the central district, is the main trading, shipping, and administrative area. It has extensive shipping facilities and is the site of the customs office, the central post office, the harbour bureau, and the central police headquarters. Residential sections have been built in the southern part of this neighbourhood. Ho-hsi neighbourhood and Nan-k'ai District in the west and southwest are given primarily to residential and recreational use, and Nan-k'ai is also a major university centre.

The eastern districts of Ho-pei and Ho-tung, east of the Hai Ho, centre on industry and transport. Ho-pei has a few technical and vocational educational institutions in addition to its residential quarters, while Ho-tung is mainly industrial.

Housing and architecture. The provision of housing for Tientsin's work force has been a major concern of the municipal authorities. The emphasis since 1949 has been on suburban development, although residential areas in the urban core have also been rehabilitated. Major new residential and commercial construction was undertaken in the early 1980s in central Tientsin as a result of damage incurred in the T'angshan earthquake of 1976. Before World War II many of the suburban residential areas were built on marshy, poorly drained land subject to flooding, and sanitary conditions were especially bad. Most of the modern complexes have been constructed near industrial zones on the outskirts of the city.

Many of the large commercial and administrative buildings in the central city were built by foreign concessionaires. They are typical of European and Japanese colonial architecture of the 1920s and 1930s, with buildings of contrasting architectural styles juxtaposed helter-skelter, without any plan. Some of the public buildings dating from the 1950s were built in imitation of the Soviet monolithic style, and housing complexes are usually standard multistory rectangular blocks. More recent commercial and residential construction follows modern design, with individual balconies and multicoloured facades.

THE PEOPLE

The majority of the population lives in the central city, where densities are probably in the range of 15,000 to 75,000 persons per square mile (6,000 to 29,000 persons per square kilometre).

Before 1949 most people were engaged in commercial or service occupations. Since then the occupational structure of the city has changed, and about half the population is employed by industry and only about one-fifth in commerce. The remainder are employed primarily in public services.

Ethnic minorities compose a small proportion of the population; the largest groups are Tungans, Koreans, Manchus, and Uighurs. Most of them live in the central city in areas that have special historical associations. The largest single community of Tungans is in the northern suburb of T'ien-mu-ts'un.

THE ECONOMY

Industry. Since 1949 heavy industry has been developed and the existing industrial base consolidated for greater productivity. Major activities are the production of heavy machinery, chemicals, and iron and steel and shipbuilding and repair. The Tientsin Heavy Machine-building plant is one of China's largest manufacturers of mining equipment. Other products include machinery for textile mills and agriculture, machine tools, electrical equipment, bicycles, tractors, elevators, precision instruments, trucks, and watches.

The chemical complex at Ta-ku, T'ang-ku, and also at Han-ku (north of T'ang-ku on the rail line to T'ang-shan) produces agricultural fertilizers and pesticides, pharmaceuticals, chemicals and petrochemical products, plastics, artificial fibres, dyestuffs, and paints. The Yung-li alkali products plant at T'ang-ku accounts for much of China's total output of purified soda, some of which is exported to Japan.

Tientsin's light industries

Textiles are the chief light industry. Other such products include processed foods, hides, rubber goods, and paper. Tientsin's industry is largely under the jurisdiction of the municipality and is subject to local price setting, planning, and raw-material allocation.

Finance. Financial services include branches of the Bank of China, the Agricultural Bank of China, and The People's Insurance Company of China. Retail and whole-

sale trade is managed by commerce bureaus that are responsible to municipal and provincial authorities. Pricing and personnel matters are managed locally, while the distribution of commodities, long-range planning, and high-level financial management are handled by provincial-level bureaus responsible to Peking. A municipality-run General Trade Corporation formed in the early 1980s helps coordinate and improve the efficiency of domestic and foreign trade by assuming functions previously performed by central government agencies.

Railway services

Transportation. Tientsin is North China's leading transport centre. The Ching-p'u railway runs south from Tientsin to Shanghai via Chi-nan, Shantung Province, and Süchow, Kiangsu Province. The Ching-shan railway runs north from Peking through Tientsin and Shan-hai-kuan on the Hopeh–Liaoning border to Shenyang, Liaoning Province. The lines are served in Tientsin by three railway stations, classification yards, and extensive maintenance and repair facilities.

Heavily traversed inland waterways radiate to the south and southwest along the Grand Canal and Tzu-ya and Ta-ch'ing rivers; they connect the city with Pao-ting, Ts'ang-chou, and Heng-shui in southern Hopeh Province. The Ching-T'ang Kung-lu highway from Peking through Tientsin to T'ang-ku is the main all-weather freight road to the sea. Other main roads extend southward along the Ching-p'u railway into Shantung Province, westward to Shansi Province, and northward to Ch'in-huang-tao, northeastern Hopeh, and the Northeast (formerly Manchuria).

Intraurban and suburban transport is extensive. Several dozen intraurban trolley, electric-trolleybus, and motor bus routes connect the city's railway stations and serve the near suburban districts. The first 7.5 miles (12 kilometres) of Central Tientsin's subway line was in operation by mid-1983. In addition, about two dozen long-distance motor bus routes connect the urban core with more distant rural areas.

Tientsin is the main collection point and transshipment centre in North China for goods manufactured for export and is the chief port of entry for heavy machinery and other capital-intensive imports. Much of China's total foreign trade by value is handled through Tientsin's outport and fishing port of T'ang-ku.

ADMINISTRATIVE AND SOCIAL CONDITIONS

The People's Congress

Government. The Tientsin People's Congress is the city's chief administrative body. It's predecessor, the Municipal Revolutionary Committee, was established in 1967 during the political disruption of the Great Proletarian Cultural Revolution (1966–69). Prior to 1967 responsibility for the management of the city's affairs was shared by a number of bureaus under both party and governmental control.

The Tientsin Municipal Planning Commission plays a key role in managing industry and commerce. It controls the supply and distribution of industrial raw materials, sets production levels, allocates funds for capital investments, determines manpower needs, supervises product research and development, and coordinates transportation, public works, and environmental policy.

Public utilities. Major public works projects since 1949 have helped alleviate chronic flood damage and have improved the city's water supply and sewage disposal systems. Marshy, low-lying lands have been drained and converted to agricultural and recreational use, new roads have been constructed, and streetlights have been installed.

The city's water supply

The supply of fresh water has always been a problem because of the city's location near the sea at low elevation. Severe water shortages developed in the early 1980s because of industrialization, population growth, and drought that cut off the water supply from Miyun Reservoir northeast of Peking. These shortages were temporarily alleviated by diverting water from the Huang Ho, to the south, but construction was also undertaken to divert water from the Luan Ho, to the northeast. The project began in late 1981, and its initial stage was completed in late 1983. Swampy lowlands to the southwest have been drained; one of the most extensive was converted into the large recreational area of the Shui-shang Kung-yüan (Park on the Water).

Electricity is generated by thermal power plants (fuelled with coal), and the city is connected by a power grid with Peking and T'ang-shan, Hopeh.

Health. Tientsin has many Western-style and Chinese hospitals, with separate facilities for children, workers, and members of ethnic minorities. After the Cultural Revolution,Tientsin also developed one of China's earliest and most effective urban planned birth programs. In 1973 an Office of Planned Births was established by the municipality and was granted status and authority equal to the Department of Public Health.

Education. Before the Cultural Revolution about one-sixth of Tientsin's population was enrolled in educational institutions. During the late 1960s and early 1970s, enrollments fell. By the late 1970s, to support China's modernization program, considerable investments had been made to improve and expand scientific and technical institutions, especially those supportive of petrochemical, iron and steel, and marine services and engineering industries. The general universities of Nan-k'ai and Tientsin are located in Nan-k'ai District, on the southwestern periphery of the city. Other higher educational institutions include the Polytechnic Institute, the Central Conservatory of art and music, a medical school, and a teacher training school. Work-study schools attached to factories supplement formal educational programs.

CULTURAL LIFE

The city has several museums and a major library. The Fine Arts Museum is noted for its collection of Yüan, Ming, and Ch'ing dynasty paintings, while the City Museum of History and the Tientsin Science Hall have more contemporary displays. The Tientsin Library is the municipality's largest library.

Special exhibits are held at the Industrial Exhibition Hall and the National Minorities' Cultural Palace, and the People's Festival Hall is used for operas, plays, and concerts. The largest movie house is the Peace Cinema. There is also an astronomical observatory.

Recreational facilities

There are several dozen parks and recreation centres. Victory Park and the Children's Park are in the centre of the city, and the Hsi-ku, Nan-k'ai, People's, Chien-shan, Shui-shang, and Pei-ning parks are in the urbanized area. Recreational clubs have also been built for industrial workers, and there are four stadiums.

History

EVOLUTION OF THE CITY

Origins of the city

The marshy, poorly drained area surrounding contemporary Tientsin was sparsely populated until the Sung dynasty (960–1126), when the settlement of San Ch'a K'ou was built on the west bank of the Hai Ho. The original settlement was later joined by the larger town of Chih-ku, built on high ground at the confluence of the Tzu-ya and Hai rivers. Chih-ku grew rapidly as a port and commercial centre, and it became the chief storage, transfer, and distribution point for grain and other foodstuffs from central and southern China.

In recognition of the importance of Chih-ku (then called Hai-chin) as a shipping centre, the Yüan (Mongol) government (1206–1368) established offices for the regulation of navigation and customs and expanded the town's warehouse and harbour facilities. The city also became a major salt producer when salterns were constructed along the Hai Ho.

The development of modern Tientsin began during the Ming dynasty (1368–1644), when the national capital was shifted from Nanking to Peking. In 1368 the settlement became a garrison town and was named T'ien-chin-wei (Defense of the Heavenly Ford). A large military base was built and a rectangular wall constructed in 1425. The town prospered as it became the main gateway to Peking, and its population was swelled by immigrants from Shantung, Kiangsu, and Fukien provinces.

By the beginning of the Ch'ing (Manchu) dynasty (1644–1911/12), Tientsin had become the leading economic centre of North China because of its location at the northern terminus of the Grand Canal (Ta Yün-ho). As better inland waterway connections were established, there was a steady

increase in the city's volume of trade. Members of the first Dutch diplomatic mission to China in the mid-17th century commented favourably on the well-constructed 25-foot- (7.6-metre-) high wall surrounding the city and noted the many temples and the large commercial and marketing area.

The period of foreign control

Economic prosperity declined temporarily during the mid-19th century when the European nations trading with China unremittingly pressed their demands for commercial and diplomatic privileges. The treaties of Tientsin, during the second Opium War (1856–60) against China, were signed by the British, French, and Chinese in 1858. Among their provisions, they authorized the establishment of British and French concessions in Tientsin. Between 1895 and 1902 concessions were given to Japan, Germany, Russia, Austria-Hungary, Italy, and Belgium. Hostilities were resumed in Tientsin in 1860, and the city was shelled by the British and French; the Convention of Peking then declared Tientsin an open trading port. Ten years later, a violent expression of Chinese antiforeign feeling erupted in the city when the French Catholic orphanage and cathedral were attacked. In 1900 renewed anti-foreign demonstrations led to the shelling and occupation of the city by Allied (Western) forces and the destruction of the old city wall.

By the end of the 19th century, Tientsin had grown to more than 200,000 people, with about half the population residing within the old "Chinese" city. Living conditions for the Chinese were in sharp contrast to those in the spacious, well-tended European quarters that were distributed to the southeast and along the riverbanks.

Tientsin became an important ocean shipping centre by 1900. The Huang Ho shifted its course, and the Grand Canal became silted up in the early 1850s, thereby restricting inland waterway traffic through the city, and shipping operations were shifted eastward along the banks of the Hai Ho. Facilities were also built at Ta-ku and T'ang-ku at the mouth of the Hai Ho.

THE 20TH CENTURY

The Chinese Republic period

Under the Republic of China (1911–49), Tientsin became a special municipality (*shih*) under the direct administration of the National government. In 1935 the Japanese attempted to extend their control over North China by establishing an autonomous area in eastern Hopeh Province, which was to be administered by Japanese military authorities in Tientsin. One year later, the Japanese presented demands to the Chinese authorities that were designed to weaken Chinese control over the area. With the opening of the Sino-Japanese War (1937–45), Tientsin was occupied by the Japanese, and in 1939 the Japanese blockaded the British and French concessions in response to anti-Japanese demonstrations.

During the Communist Revolution (1945–49), Tientsin remained under Nationalist control until mid-January 1949, when the city was captured by the Communists. Since then, Tientsin's growth as a trading and manufacturing centre has been responsive to internal development needs. Despite its proximity to Peking, the city retains a distinctive character, attributable to its functional and utilitarian origins.

BIBLIOGRAPHY. KENNETH G. LIEBERTHAL, *Revolution and Tradition in Tientsin, 1949–52* (1980), examines interrelations among economic development, administrative organization, and mass mobilization strategies during the early years of Communist control. KATHERINE CH'U LYLE, "Report from China, Planned Birth in Tianjin," *China Quarterly*, 85:551–67 (1980), documents family planning programs in the late 1970s.

Time

One facet of human consciousness is the awareness of time. Humans feel the passage of time in their personal experience and observe it in their environment. Time, as experienced, is a one-way flow at a pace that is slow enough to be perceptible. (Actually, only material fluids flow; but, like psychic experiences in general, that of time can be described only in the language of material phenomena.) People feel, think, and act in the time flow. (A.J.T.)

Time and its role in the history of thought and action

NATURE AND DEFINITION OF TIME

Time appears to be more puzzling than space because it seems to flow or pass or else people seem to advance through it. But the passage or advance seems to be unintelligible. The question of how many seconds per second time flows (or one advances through it) is obviously an absurd one, for it suggests that the flow or advance comprises a rate of change with respect to something else—to a sort of hypertime. But if this hypertime itself flows, then a hyper-hypertime is required, and so on, ad infinitum.

Again, if the world is thought of as spread out in space–time, it might be asked whether human consciousness advances up a timelike direction of this world and, if so, how fast; whether future events pop into existence as the "now" reaches them or are there all along; and how such changes in space–time can be represented, since time is already within the picture. (Ordinary change can, of course, be represented in a space–time picture: for example, a particle at rest is represented by a straight line and an oscillating particle by a wavy line.)

Process philosophers versus philosophers of the manifold

In the face of these difficulties, philosophers tend to divide into two sorts: the "process philosophers" and the "philosophers of the manifold," respectively. Process philosophers—such as Alfred North Whitehead, an Anglo-American metaphysician who died in 1947—hold that the flow of time (or human advance through it) is an important metaphysical fact. Like the French intuitionist Henri Bergson, they may hold that this flow can be grasped only by nonrational intuition. Bergson even held that the scientific concept of time as a dimension actually misrepresents reality.

Philosophers of the manifold hold that the flow of time or human advance through time is an illusion. They argue, for example, that words such as past, future, and now, as well as the tenses of verbs, are indexical expressions that refer to the act of their own utterance. Hence, the alleged change of an event from being future to being past is an illusion. To say that the event is future is to assert that it is later than this utterance; then later yet, when one says that it is in the past, he or she asserts that it is earlier than that other utterance. *Past* and *future* are not real predicates of events in this view; and change in respect of them is not a genuine change.

Again, although process philosophers think of the future as somehow open or indeterminate, whereas the past is unchangeable, fixed, determinate, philosophers of the manifold hold that it is as much nonsense to talk of changing the future as it is to talk of changing the past. If a person decides to point left rather than to point right, then pointing left *is* what the future was. Moreover, this thesis of the determinateness of the future, they argue, must not be confused with determinism, the theory that there are laws whereby later states of the universe may be deduced from earlier states (or vice versa). The philosophy of the manifold is neutral about this issue. Future events may well exist and yet not be connected in a sufficiently lawlike way with earlier ones.

One of the features of time that puzzled the Platonist Augustine, in the 5th century AD, was the difficulty of defining it. In contemporary philosophy of language, however (influenced by Ludwig Wittgenstein, a Cambridge philosopher), no mystery is seen in this task. Learning to handle the word *time* involves a multiplicity of verbal skills, including the ability to handle such connected words as *earlier, later, now, second,* and *hour.* These verbal skills have to be picked up in very complex ways (partly by ostension), and it is not surprising that the meaning of the word *time* cannot be distilled into a neat verbal definition. (It is not, for example, an abbreviating word like *bachelor.*)

The philosophy of time bears powerfully on human emotions. Not only do individuals regret the past, they also fear the future, not least because the alleged flow of time seems to be sweeping them toward their deaths, as swimmers are swept toward a waterfall. (J.J.C.S.)

PRESCIENTIFIC CONCEPTIONS OF TIME AND THEIR INFLUENCE

Temporal existence, death, and survival

The individual's experience and observation of time. The irreversibility and inexorability of the passage of time is borne in on human beings by the fact of death. Unlike other living creatures, they know that their lives may be cut short at any moment and that, even if they attain the full expectation of human life, their growth is bound to be followed by eventual decay and, in due time, death (see also PERCEPTION, HUMAN: *Time perception*).

Although there is no generally accepted evidence that death is not the conclusive end of life, it is a tenet of some religions (*e.g.,* of Zoroastrianism, Judaism, Christianity, and Islām) that death is followed by everlasting life elsewhere—in *sheol,* hell, or heaven—and that eventually there will be a universal physical resurrection. Others (*e.g.,* Buddhists, Orphics, Pythagoreans, and Plato) have held that people are reborn in the time flow of life on Earth and that the notion that a human being has only one life on Earth is the illusion of a lost memory. The Buddha claimed to recollect all of his previous lives. The Greek philosophers Pythagoras and Empedocles, of the 6th and early 5th centuries BC, whose lives probably overlapped that of the Buddha, likewise claimed to recollect some of their previous lives. Such rebirths, they held, would continue to recur any number of times unless a person should succeed in breaking the vicious circle (releasing himself from the "sorrowful wheel") by strenuous ascetic performances.

The belief that a person's life in time on Earth is repetitive may have been an inference from the observed repetitiveness of phenomena in the environment. The day-and-night cycle and the annual cycle of the seasons dominated the conduct of human life until the recent harnessing of inanimate physical forces in the Industrial Revolution made it possible for work to be carried on for 24 hours a day throughout the year—under cover, by artificial light, and at a controlled temperature. There is also the generation cycle, which the Industrial Revolution has not suppressed: the generations still replace each other, in spite of the lengthening of life expectancies. In some societies it has been customary to give a man's son a different name but to give his grandson the same name. To name father and son differently is an admission that generations change; but to name grandfather and grandson the same is perhaps an intimation that the grandson is the grandfather reincarnate.

Thus, though every human being has the experience of irreversible change in his own life, he also observes cyclic change in his environment; hence the adherents of some religions and philosophies have inferred that, despite appearances, time flows cyclically for the individual human being, too.

Interpretations of time in different ages and lands

The human experience and observation of time has been variously interpreted. Parmenides, an Italiote Greek (Eleatic) philosopher (6th–5th century BC) and Zeno, his fellow townsman and disciple, held that change is logically inconceivable and that logic is a surer indicator of reality than experience; thus, despite appearances, reality is unitary and motionless. In this view, time is an illusion. The illusoriness of the world that "flows" in time is also to be found in some Indian philosophy. The Buddha and, among the Greeks, Plato and Plotinus, all held that life in the time flow, though not wholly illusory, is at best a low-grade condition by comparison, respectively, with the Buddhist Nirvāṇa (in which desires are extinguished) and with the Platonic world of Ideas; *i.e.,* of incorporeal timeless exemplars, of which phenomena in the time flow are imperfect and ephemeral copies.

It has been held, however—*e.g.,* by disciples of the Greek philosopher Heracleitus—that the time flow is of the essence of reality. Others have held that life in the time flow, though it may be wretched, is nevertheless momentous; for it is here that a person decides his destiny. In the Buddhist view, a person's conduct in any one of his successive lives on Earth will increase or diminish his prospects of eventually breaking out of the cycle of recurrent births. For those who believe in only one earthly life, however, the momentousness of life in the time flow is still greater because this life will be followed by an everlasting life at a destination decided by conduct in this brief and painful testing time. The view that life in time on Earth is a probation for weal or woe in an everlasting future has often been associated—as it was by the Iranian prophet Zoroaster (*c.* 600 BC)—with a belief in a general judgment of all who have ever lived to be held on a common judgment day, which will be the end of time. The belief in an immediate individual judgment was also held in pharaonic Egypt. Both of these beliefs have been adopted by Jews, Christians, and Muslims.

Cyclic view of time in the philosophy of history. The foregoing diverse interpretations of the nature and significance of the individual human being's experience and ob-

servation of time differ sharply from each other, and they have led to equally sharp differences in views of human history and of ultimate reality and in prescriptions for the conduct, both collective and individual, of human life. Thinkers have been divided between holders of the cyclic view and holders of the one-way view of time and between believers in the different prescriptions for the conduct of life that these differing views have suggested. Variations in the two basic views of time and in the corresponding codes of conduct have been among the salient characteristics distinguishing the principal civilizations and philosophies and higher religions that have appeared in history to date.

Environmental recurrences and religion. The cyclic theory of time has been held in regard to the three fields of religion, of history (both human and cosmic), and of personal life. That this view arose from the observation of recurrences in the environment is most conspicuously seen in the field of religion. The observation of the generation cycle has been reflected in the cult of ancestors, important in Chinese religion and also in older civilizations and in precivilizational societies. The observation of the annual cycle of the seasons and its crucial effect on agriculture is reflected in a ceremony in which the emperor of China used to plow the first furrow of the current year; in the ceremonial opening of a breach in the dike of the Nile to let the annual floodwaters irrigate the land; and in the annual "sacred marriage," performed by a priest and priestess representing a god and goddess, which was deemed to ensure the continuing fertility of Babylonia. A cycle longer than that of the seasons is represented by the recurrent *avatāra*s (epiphanies, incarnate, on Earth) of the Hindu god Vishnu (Viṣṇu) and in the corresponding series of buddhas and *bodhisattva*s (potential buddhas). Although the only historical Buddha was Siddhārtha Gautama (6th–5th century BC), in the mythology of the northern school of Buddhism (the Mahāyāna), the identity of the historical Buddha has been almost effaced by a long vista of putative buddhas extending through previous and future times.

Seasons, generations, eons

In contrast to northern Buddhism and to Vaiṣṇava Hinduism, Christianity holds that the incarnation of God in Jesus was a unique event; yet the rite of the Eucharist, in which Christ's self-sacrifice is held by Catholic and Eastern Orthodox Christians to be reperformed, is celebrated every day by thousands of priests, and the nature of this rite has suggested to some scholars that it originated in an annual festival at the culmination of the agricultural year. In this interpretation, the bread that is Christ's body and the wine that is his blood associate him with the annually dying gods Adonis, Osiris, and Attis—the divinities, inherent in the vital and vitalizing power of the crops, who die in order that people may eat and drink and live. "Unless a grain of wheat falls into the earth and dies, it remains alone; but, if it dies, it bears much fruit" (John 12:24).

The cyclic view in various cultures. The cyclic view of history, both cosmic and human, has been prevalent among the Hindus and the pre-Christian Greeks, the Chinese, and the Aztecs; and it has reappeared in modern Western society, although this civilization was originally Christian—that is, was nurtured on a religion that sees time as a one-way flow and not as a cyclic one.

The Chinese, Hindus, and Greeks saw cosmic time as moving in an alternating rhythm, classically expressed in the Chinese concept of the alternation between Yin, the passive female principle, and Yang, the dynamic male principle. When either Yin or Yang goes to extremes, it overlaps the other principle, which is its correlative and complement in consequence of being its opposite. In the philosophy of Empedocles, an early Greek thinker, the equivalents of Yin and Yang were Love and Strife. Empedocles revolted against the denial of the reality of motion and plurality that was made by his Eleatic predecessors on the strength of mere logic. He broke up the Eleatics' motionless, and therefore timeless, unitary reality into a movement of four elements that were alternately harmonized by Love and set at variance by Strife. Empedocles' Love and Strife, like Yin and Yang, each overlapped the other when they had gone to extremes.

Yin-Yang, Love-Strife, kalpas

Plato translated Empedocles' concept from psychological into theistic terms. At the outset, in his view, the gods guide the cosmos, and they then leave it to its own devices. But when the cosmos, thus left to itself, has brought itself to the brink of disaster, the gods resume control at the 11th hour—and these two phases of its condition alternate with each other endlessly. The recurrence of alternating phases in which, at the darkest hour, catastrophe is averted by divine intervention is similarly an article of Vaiṣṇava Hindu faith. In guessing the lengths of the recurrent eons (kalpas), the Hindus arrived, intuitively, at figures of the magnitude of those reached by modern astronomers through meticulous observations and calculations. Similarly, the Aztecs of Meso-America rivaled modern Westerners and the Hindus in the scale on which they envisaged the flow of time, and they kept an astonishingly accurate time count by inventing a set of interlocking cycles of different wavelengths.

Plato and Aristotle took it for granted that human society, as well as the cosmos, has been, and will continue to be, wrecked and rehabilitated any number of times. This rhythm can be discerned, as a matter of historical fact, in the histories of the pharaonic Egyptian and of the Chinese civilizations during the three millennia that elapsed, in each of them, between its first political unification and its final disintegration. The prosperity that had been conferred on a peasant society by political unity and peace turned into adversity when the cost of large-scale administration and defense became too heavy for an unmechanized economy to bear. In each instance, the unified state then broke up—only to be reunited for the starting of another similar cycle. The Muslim historian Ibn Khaldūn, writing in the 14th century AD, observed the same cyclic rhythm in the histories of the successive conquests of sedentary populations by pastoral nomads.

In the modern West, an Italian philosopher of history, Giambattista Vico, observed that the phases through which Western civilization had passed had counterparts in the history of the antecedent Greco-Roman civilization. Thanks to a subsequent increase in the number of civilizations known to Western students of cultural morphology, Oswald Spengler, a German philosopher of history, was able, in the early 20th century, to make a comparative study of civilizations over a much broader spectrum than that of Vico. The comparison of different civilizations or of successive periods of order and disorder in Chinese or in pharaonic Egyptian history implied, of course, that, in human affairs, recurrence is a reality.

Cultural morphology in Vico and Spengler

The application of the cyclic view to the life of a human being in the hypothesis of rebirth was mentioned earlier. This hypothesis relaxes the anxiety about being annihilated through death by replacing it with a no less agonizing anxiety about being condemned to a potentially endless series of rebirths. The strength of the reincarnationists' anxiety can be gauged by the severity of the self-mortification to which they resort to liberate themselves from the "sorrowful wheel." Among the peoples who have not believed in rebirth, the pharaonic Egyptians have taken the offensive against death and decay with the greatest determination: they embalmed corpses; they built colossal tombs; and, in the Book of the Dead, they provided instructions and spells for ensuring for that portion of the soul that did not hover around the sarcophagus an acquittal in the postmortem judgment and an entry into a blissful life in another world. No other human society has succeeded in achieving this degree of indestructibility despite the ravages of time.

One-way view of time in the philosophy of history. When the flow of time is held to be not recurrent but one-way, it can be conceived of as having a beginning and perhaps an end. Some thinkers have felt that such limits can be imagined only if there is some timeless power that has set time going and intends or is set to stop it. A god who creates and then annihilates time, if he is held to be omnipotent, is often credited with having done this with a benevolent purpose that is being carried out according to plan. The omnipotent god's plan, in this view, governs the time flow and is made manifest to humans in progressive revelations through the prophets—from Abraham, by way of Moses, Isaiah, and Jesus, to the Prophet Muḥammad (as Muslims believe).

Salvation history and the "axis age"

This belief in *Heilsgeschichte* (salvational history) has been derived by Islām and Christianity from Judaism and Zoroastrianism. Late in the 12th century, the Christian seer Joachim of Fiore saw this divinely ordained spiritual progress in the time flow as unfolding in a series of three ages—those of the Father, the Son, and the Spirit. Karl Jaspers, a 20th-century Western philosopher, has discerned an "axis age"—*i.e.,* a turning point in human history—in the 6th century BC, when Confucius, the Buddha, Zoroaster, Deutero-Isaiah, and Pythagoras were alive contemporaneously. If the "axis age" is extended backward in time to the original Isaiah's generation and forward to Muḥammad's, it may perhaps be recognized as the age in which humans first sought to make direct contact with the ultimate spiritual reality behind phenomena instead of making such communication only indirectly through their nonhuman and social environments.

The belief in an omnipotent creator god, however, has been challenged. The creation of time, or of anything else, out of nothing is difficult to imagine; and, if God is not a creator but is merely a shaper, his power is limited by the intractability of the independent material with which he has had to work. Plato, in the *Timaeus,* conceived of God as being a nonomnipotent shaper and thus accounted for the manifest element of evil in phenomena. Marcion, a 2nd-century Christian heretic, inferred from the evil in phenomena that the creator was bad and held that a "stranger god" had come to redeem the bad creator's work at the benevolent stranger's cost. Zoroaster saw the phenomenal world as a battlefield between a bad god and a good one and saw time as the duration of this battle. Though he held that the good god was destined to be the victor, a god who needs to fight and win is not omnipotent. In an attenuated form, this evil adversary appears in the three Judaic religions as Satan.

Evolutionary and dialectical views

Observation of historical phenomena suggests that, in spite of the manifestness of evil, there has been progress in the history of life on this planet, culminating in the emergence of humans who know themselves to be sinners yet feel themselves to be something better than inanimate matter. Charles Darwin, in his theory of the selection of mutations by the environment, sought to vindicate apparent progress in the organic realm without recourse to an extraneous god. In the history of Greek thought, the counterpart of such mutations was the swerving of atoms. After Empedocles had broken up the indivisible, motionless, and timeless reality of Parmenides and Zeno into four elements played upon alternately by Love and Strife, it was a short step for the Atomists of the 5th century BC, Leucippus and Democritus, to break up reality still further into an innumerable host of minute atoms moving in time through a vacuum. Granting that one single atom had once made a single slight swerve, the build-up of observed phenomena could be accounted for on Darwinian lines. Democritus' account of evolution survives in the fifth book of *De rerum natura,* written by a 1st-century-BC Roman poet, Lucretius. The credibility of both Democritus' and Darwin's accounts of evolution depends on the assumption that time is real and that its flow has been extraordinarily long.

Heracleitus had seen in phenomena a harmony of opposites in tension with each other and had concluded that War (*i.e.,* Empedocles' Strife and the Chinese Yang) "is father of all and king of all." This vision of Strife as being the dominant and creative force is grimmer than that of Strife alternating on equal terms with Love and Yang with Yin. In the 19th-century West, Heracleitus' vision has been revived in the view of G.W.F. Hegel, a German Idealist, that progress occurs through a synthesis resulting from an encounter between a thesis and an antithesis. In political terms, Heracleitus' vision has reappeared in Karl Marx's concept of an encounter between the bourgeoisie and the proletariat and the emergence of a classless society without a government.

Apocalyptic views

In the Zoroastrian and Jewish-Christian-Islāmic vision of the time flow, time is destined to be consummated—as depicted luridly in the Revelation to John—in a terrifying climax. It has become apparent that history has been accelerating, and accumulated knowledge of the past has revealed, in retrospect, that the acceleration began about 30,000 years ago, with the transition from the Lower to the Upper Paleolithic Period, and that it has taken successive "great leaps forward" with the invention of agriculture, with the dawn of civilization, and with the progressive harnessing—within the last two centuries—of the titanic physical forces of inanimate nature. The approach of the climax foreseen intuitively by the prophets is being felt, and feared, as a coming event. Its imminence is, today, not an article of faith but a datum of observation and experience. (A.J.T.)

EARLY MODERN AND 19TH-CENTURY SCIENTIFIC PHILOSOPHIES OF TIME

Isaac Newton distinguished absolute time from "relative, apparent, and common time" as measured by the apparent motions of the fixed stars, as well as by terrestrial clocks. His absolute time was an ideal scale of time that made the laws of mechanics simpler, and its discrepancy with apparent time was attributed to such things as irregularities in the motion of the Earth. Insofar as these motions were explained by Newton's mechanics (or at least could not be shown to be inexplicable), the procedure was vindicated. Similarly, in his notion of absolute space, Newton was really getting at the concept of an inertial system. Nevertheless, the notion of space and time as absolute metaphysical entities was encouraged by Newton's views and formed an important part of the philosophy of Immanuel Kant, a German critical philosopher, for whom space and time were "phenomenally real" (part of the world as described by science) but "noumenally unreal" (not a part of the unknowable world of things in themselves). Kant argued for the noumenal unreality of space and time on the basis of certain antinomies that he claimed to find in these notions—that the universe had a beginning, for example, and yet (by another argument) could not have had a beginning. In a letter dated 1798, he wrote that the antinomies had been instrumental in arousing him from his "dogmatic slumber" (pre-critical philosophy). Modern advances in logic and mathematics, however, have convinced most philosophers that the antinomies contain fallacies.

Static versus dynamic systems

Newtonian mechanics, as studied in the 18th century, was mostly concerned with periodic systems that, on a large scale, remain constant throughout time. Particularly notable was the proof of the stability of the solar system that was formulated by Pierre-Simon, marquis de Laplace, a mathematical astronomer. Interest in systems that develop through time came about in the 19th century as a result of the theories of the British geologist Sir Charles Lyell, and others, and the Darwinian theory of evolution. These theories led to a number of biologically inspired metaphysical systems, which were often—as with Henri Bergson and Alfred North Whitehead—rather romantic and contrary to the essentially mechanistic spirit of Darwin himself (and also of present-day molecular biology).

Contemporary philosophies of time

TIME IN 20TH-CENTURY PHILOSOPHY OF PHYSICS

Minkowski space–time and Lorentz transformations

Time in the special theory of relativity. Since the classic interpretation of Einstein's special theory of relativity by Hermann Minkowski, a Lithuanian-German mathematician, it has been clear that physics has to do not with two entities, space and time, taken separately, but with a unitary entity space–time, in which, however, timelike and spacelike directions can be distinguished. The Lorentz transformations, which in special relativity define shifts in velocity perspectives, were shown by Minkowski to be simply rotations of space–time axes. The Lorentz contraction of moving rods and the time dilatation of moving clocks turns out to be analogous to the fact that different-sized slices of a sausage are obtained by altering the direction of the slice: just as there is still the objective (absolute) sausage, so also Minkowski restores the absolute to relativity in the form of the invariant four-dimensional object, and the invariance (under the Lorentz transformation) of the space–time interval and of certain fundamental physical quantities such as action (which has the dimensions of

energy times time, even though neither energy nor time is separately invariant).

Process philosophers charge the Minkowski universe with being a static one. The philosopher of the manifold denies this charge, saying that a static universe would be one in which all temporal cross sections were exactly similar to one another and in which all particles (considered as four-dimensional objects) lay along parallel lines. The actual universe is not like this, and that it is not static is shown in the Minkowski picture by the dissimilarity of temporal cross sections and the nonparallelism of the world lines of particles. The process philosopher may say that change, as thus portrayed in the Minkowski picture (*e.g.,* with the world lines of particles at varying distances from one another), is not true Bergsonian change, so that something has been left out. But if time advances up the manifold, this would seem to be an advance with respect to a hypertime, perhaps a new time direction orthogonal to the old one. Perhaps it could be a fifth dimension, as has been used in describing the de Sitter universe as a four-dimensional hypersurface in a five-dimensional space. The question may be asked, however, what advantage such a hypertime could have for the process philosopher and whether there is process through hypertime. If there is, one would seem to need a hyper-hypertime, and so on to infinity. (The infinity of hypertimes was indeed postulated by John William Dunne, a British inventor and philosopher, but the remedy seems to be a desperate one.) And if no such regress into hypertimes is postulated, it may be asked whether the process philosopher would not find the five-dimensional universe as static as the four-dimensional one. The process philosopher may therefore adopt the expedient of Henri Bergson, saying that temporal process (the extra something that makes the difference between a static and a dynamic universe) just cannot be pictured spatially (whether one supposes four, five, or more dimensions). According to Bergson, it is something that just has to be intuited and cannot be grasped by discursive reason. The philosopher of the manifold will find this unintelligible and will in any case deny that anything dynamic *has* been left out of his world picture. This sort of impasse between process philosophers and philosophers of the manifold seems to be characteristic of the present-day state of philosophy.

Possible fifth-dimensional hypertime

The theory of relativity implies that simultaneity is relative to a frame of axes. If one frame of axes is moving relative to another, then events that are simultaneous relative to the first are not simultaneous relative to the second, and vice versa. This paradox leads to another difficulty for process philosophy over and above those noted earlier. Those who think that there is a continual coming into existence of events (as the present rushes onward into the future) can be asked "Which present?" It therefore seems difficult to make a distinction between a real present (and perhaps past) as against an as-yet-unreal future. Philosophers of the manifold also urge that to talk of events becoming (coming into existence) is not easily intelligible. Enduring things and processes, in this view, can come into existence; but this simply means that as four-dimensional solids they have an earliest temporal cross section or time slice.

When talking in the fashion of Minkowski, it is advisable, according to philosophers of the manifold, to use tenseless verbs (such as the "equals" in "2 + 2 equals 4"). One can say that all parts of the four-dimensional world exist (in this tenseless sense). This is not, therefore, to say that they all exist *now,* nor does it mean that Minkowski events are "timeless." The tenseless verb merely refrains from dating events in relation to its own utterance.

The clock paradox

The power of the Minkowski representation is illustrated by its manner in dealing with the so-called clock paradox, which deals with two twins, Peter and Paul. Peter remains on Earth (regarded as at rest in an inertial system) while Paul is shot off in a rocket at half the velocity of light, rapidly decelerated at Alpha Centauri (about four light-years away), and shot back to Earth again at the same speed. Assuming that the period of turnabout is negligible compared with those of uniform velocity, Paul, as a four-dimensional object, lies along the sides AC and CB of a space–time triangle, in which A and B are the points of his departure and return and C that of his turnaround. Peter, as a four-dimensional object, lies along AB. Now, special relativity implies that on his return Paul will be rather more than two years younger than Peter. This is a matter of two sides of a triangle not being equal to the third side: AC + CB < AB. The "less than"—symbolized < — arises from the semi-Euclidean character of Minkowski space–time, which calls for minus signs in its metric (or expression for the interval between two events, which is

$$ds = \sqrt{c^2dt^2 - dx^2 - dy^2 - dz^2}\,).$$

The paradox has been held to result from the fact that, from Paul's point of view, it is Peter who has gone off and returned; and so the situation is symmetrical, and Peter and Paul should each be younger than the other—which is impossible. This is to forget, however, the asymmetry reflected in the fact that Peter has been in only one inertial system throughout, and Paul has not; Paul lies along a bent line, Peter along a straight one.

Time in general relativity and cosmology. In general relativity, which, though less firmly established than the special theory, is intended to explain gravitational phenomena, a more complicated metric of variable curvature is employed, which approximates to the Minkowski metric in empty space far from material bodies. Cosmologists who have based their theories on general relativity have sometimes postulated a finite but unbounded space–time (analogous, in four dimensions, to the surface of a sphere) as far as spacelike directions are concerned, but practically all cosmologists have assumed that space–time is infinite in its timelike directions. Kurt Gödel, a contemporary mathematical logician, however, has proposed solutions to the equations of general relativity whereby timelike world lines can bend back on themselves. Unless one accepts a process philosophy and thinks of the flow of time as going around and around such closed timelike world lines, it is not necessary to think that Gödel's idea implies eternal recurrence. Events can be arranged in a circle and still occur only once.

Dilatation of time in gravitational fields and black holes

The general theory of relativity predicts a time dilatation in a gravitational field, so that, relative to someone outside of the field, clocks (or atomic processes) go slowly. This retardation is a consequence of the curvature of space–time with which the theory identifies the gravitational field. As a very rough analogy, a road may be considered that, after crossing a plain, goes over a mountain. Clearly, one mile as measured on the humpbacked surface of the mountain is less than one mile as measured horizontally. Similarly—if "less" is replaced by "more" because of the negative signs in the expression for the metric of space–time—one second as measured in the curved region of space–time is more than one second as measured in a flat region. Strange things can happen if the gravitational field is very intense. It has been deduced that so-called black holes in space may occur in places where extraordinarily massive or dense aggregates of matter exist, as in the gravitational collapse of a star. Nothing, not even radiation, can emerge from such a black hole. A critical point is the so-called Schwarzschild radius measured outward from the centre of the collapsed star—a distance, perhaps, of the order of 10 kilometres. Something falling into the hole would take an infinite time to reach this critical radius, according to the space–time frame of reference of a distant observer, but only a finite time in the frame of reference of the falling body itself. From the outside standpoint the fall has become frozen. But from the point of view of the frame of the falling object, the fall continues to zero radius in a very short time indeed—of the order of only 10 or 100 microseconds. Within the black hole spacelike and timelike directions change over, so that to escape again from the black hole is impossible for reasons analogous to those that, in ordinary space–time, make it impossible to travel faster than light. (To travel faster than light a body would have to lie—as a four-dimensional object—in a spacelike direction instead of a timelike one.)

Time beyond infinite time

As a rough analogy two country roads may be considered, both of which go at first in a northerly direction. But road A bends round asymptotically toward the east;

i.e., it approaches ever closer to a line of latitude. Soon road B crosses this latitude and is thus to the north of all parts of road A. Disregarding the Earth's curvature, it takes infinite space for road A to get as far north as that latitude on road B; *i.e.*, near that latitude an infinite number of "road A northerly units" (say, miles) correspond to a finite number of road B units. Soon road B gets "beyond infinity" in road A units, though it need be only a finite road.

Rather similarly, if a body should fall into a black hole, it would fall for only a finite time, even though it were "beyond infinite" time by external standards. This analogy does not do justice, however, to the real situation in the black hole—the fact that the curvature becomes infinite as the star collapses toward a point. It should, however, help to alleviate the mystery of how a finite time in one reference frame can go "beyond infinity" in another frame.

Expanding universe; creation; τ time

Most cosmological theories imply that the universe is expanding, with the galaxies receding from one another (as is made plausible by observations of the red shifts of their spectra), and that the universe as it is known originated in a primeval explosion at a date of the order of 15×10^9 years ago. Though this date is often loosely called "the creation of the universe," there is no reason to deny that the universe (in the philosophical sense of "everything that there is") existed at an earlier time, even though it may be impossible to know anything of what happened then. (There have been cosmologies, however, that suggest an oscillating universe, with explosion, expansion, contraction, explosion, etc., ad infinitum.) And *a fortiori*, there is no need to say—as Augustine did in his *Confessions* as early as the 5th century AD—that time itself was created along with the creation of the universe, though it should not too hastily be assumed that this would lead to absurdity, because common sense could well be misleading at this point.

A British cosmologist, E.A. Milne, however, proposed a theory according to which time in a sense could not extend backward beyond the creation time. According to him there are two scales of time, "τ time" and "t time." The former is a time scale within which the laws of mechanics and gravitation are invariant, and the latter is a scale within which those of electromagnetic and atomic phenomena are invariant. According to Milne τ is proportional to the logarithm of t (taking the zero of t to be the creation time); thus, by τ time the creation is infinitely far in the past. The logarithmic relationship implies that the constant of gravitation G would increase throughout cosmic history. (This increase might have been expected to show up in certain geological data, but apparently the evidence is against it.)

Time in microphysics. Special problems arise in considering time in quantum mechanics and in particle interactions.

Quantum-mechanical aspects of time. In quantum mechanics it is usual to represent measurable quantities by operators in an abstract many-dimensional (often infinite-dimensional) so-called Hilbert space. Nevertheless, this space is an abstract mathematical tool for calculating the evolution in time of the energy levels of systems—and this evolution occurs in ordinary space-time. For example, in the formula $AH - HA = i\hbar(dA/dt)$, in which i is $\sqrt{-1}$ and $\hbar$ is $1/2\pi$ times Planck's constant, h, the A and H are operators, but the t is a perfectly ordinary time variable. There may be something unusual, however, about the concept of the time at which quantum-mechanical events occur, because according to the Copenhagen interpretation of quantum mechanics the state of a microsystem is relative to an experimental arrangement. Thus energy and time are conjugate: no experimental arrangement can determine both simultaneously, for the energy is relative to one experimental arrangement, and the time is relative to another. (Thus, a more relational sense of "time" is suggested.) The states of the experimental arrangement cannot be merely relative to other experimental arrangements, on pain of infinite regress; and so these have to be described by classical physics. (This parasitism on classical physics is a possible weakness in quantum mechanics over which there is much controversy.)

Conjugate relation of energy and time

The relation between time uncertainty and energy uncertainty, in which their product is equal to or greater than $h/4\pi$, $\Delta E \Delta t \geq h/4\pi$, has led to estimates of the theoretical minimum measurable span of time, which comes to something of the order of 10^{-24} second and hence to speculations that time may be made up of discrete intervals (chronons). These suggestions are open to a very serious objection, viz., that the mathematics of quantum mechanics makes use of continuous space and time (for example, it contains differential equations). It is not easy to see how it could possibly be recast so as to postulate only a discrete space–time (or even a merely dense one). For a set of instants to be dense, there must be an instant between any two instants. For it to be a continuum, however, something more is required, viz., that every set of instants earlier (later) than any given one should have an upper (lower) bound. It is continuity that enables modern mathematics to surmount the paradox of extension framed by the Pre-Socratic Eleatic Zeno—a paradox comprising the question of how a finite interval can be made up of dimensionless points or instants.

Time in particle interactions. Until recently it was thought that the fundamental laws of nature are time symmetrical. It is true that the second law of thermodynamics, according to which randomness always increases, is time asymmetrical; but this law is not strictly true (for example, the phenomenon of Brownian motion contravenes it), and it is now regarded as a statistical derivative of the fundamental laws together with certain boundary conditions. The fundamental laws of physics were long thought also to be charge symmetrical (for example, an antiproton together with a positron behave like a proton and electron) and to be symmetrical with respect to parity (reflection in space, as in a mirror). The experimental evidence now suggests that all three symmetries are not quite exact but that the laws of nature are symmetrical if all three reflections are combined: charge, parity, and time reflections forming what can be called (after the initials of the three parameters) a CPT mirror. The time asymmetry was shown in certain abstruse experiments concerning the decay of K mesons that have a short time decay into two pions and a long time decay into three pions.

Charge–parity–time symmetry

Time in molar physics. The above-mentioned violations of temporal symmetry in the fundamental laws of nature are such out-of-the-way ones, however, that it seems unlikely that they are responsible for the gross violations of temporal symmetry that are apparent in the visible world. An obvious asymmetry is that there are traces of the past (footprints, fossils, tape recordings, memories) and not of the future. There are mixing processes but no comparable unmixing process: milk and tea easily combine to give a whitish brown liquid, but it requires ingenuity and energy and complicated apparatus to separate the two liquids. A cold saucepan of water on a hot brick will soon become a tepid saucepan on a tepid brick; but the heat energy of the tepid saucepan never goes into the tepid brick to produce a cold saucepan and a hot brick. Even though the laws of nature are assumed to be time symmetrical, it is possible to explain these asymmetries by means of suitable assumptions about boundary conditions. Much discussion of this problem has stemmed from the work of Ludwig Boltzmann, an Austrian physicist, who showed that the concept of the thermodynamic quantity entropy could be reduced to that of randomness or disorder. Among 20th-century philosophers in this tradition may be mentioned Hans Reichenbach, a German-U.S. Positivist, Adolf Grünbaum, a U.S. philosopher, and Olivier Costa de Beauregard, a French philosopher-physicist. There have also been many relevant papers of high mathematical sophistication scattered through the literature of mathematical physics. Reichenbach (and Grünbaum, who improved on Reichenbach in some respects) explained a trace as being a branch system; *i.e.*, a relatively isolated system, the entropy of which is less than would be expected if one compared it with that of the surrounding region. For example, a footprint on the beach has sand particles compressed together below a volume containing air only, instead of being quite evenly (randomly) spread over the volume occupied by the compressed and empty parts.

Statistics, causality, and the molar clock

Another striking temporal asymmetry on the macro level, viz., that spherical waves are often observed being emitted from a source but never contracting to a sink, has been stressed by Sir Karl Popper, a 20th-century Austrian and British philosopher of science. By considering radiation as having a particle aspect (*i.e.*, as consisting of photons), Costa de Beauregard has argued that this "principle of retarded waves" can be reduced to the statistical Boltzmann principle of increasing entropy and so is not really different from the previously discussed asymmetry. These considerations also provide some justification for the common-sense idea that the cause–effect relation is a temporally unidirectional one, even though the laws of nature themselves allow for retrodiction no less than for prediction.

A third striking asymmetry on the macro level is that of the apparent mutual recession of the galaxies, which can plausibly be deduced from the red shifts observed in their spectra. It is still not clear whether or how far this asymmetry can be reduced to the two asymmetries already discussed, though interesting suggestions have been made.

The statistical considerations that explain temporal asymmetry apply only to large assemblages of particles. Hence, any device that records time intervals will have to be macroscopic and to make use somewhere of statistically irreversible processes. Even if one were to count the swings of a frictionless pendulum, this counting would require memory traces in the brain, which would function as a temporally irreversible recording device.

TIME IN 20TH-CENTURY PHILOSOPHY OF BIOLOGY AND PHILOSOPHY OF MIND

Biological rhythms

Organisms often have some sort of internal clock that regulates their behaviour. There is a tendency, for example, for leaves of leguminous plants to alter their position so that they lie in one position by day and in another position by night. This tendency persists if the plant is in artificial light that is kept constant, though it can be modified to other periodicities (*e.g.*, to a six-hour instead of a 24-hour rhythm) by suitably regulating the periods of artificial light and darkness. In animals, similar daily rhythms are usually acquired, but in experimental conditions animals nevertheless tend to adapt better to a 24-hour rhythm than to any other. Sea anemones expand and contract to the rhythm of the tides, and this periodic behaviour will persist for some time even when the sea anemone is placed in a tank. Bees can be trained to come for food at fixed periods (*e.g.*, every 21 hours), and this demonstrates that they possess some sort of internal clock. Similarly, humans themselves have some power to estimate time in the absence of clocks and other sensory cues. This fact refutes the contention of the 17th-century English philosopher John Locke (and of other philosophers in the Empiricist tradition) that time is perceived only as a relation between successive sensations. The U.S. mathematician Norbert Wiener has speculated on the possibility that the human time sense depends on the α-rhythm of electrical oscillation in the brain.

Temporal rhythms in both plants and animals (including humans) are dependent on temperature, and experiments on human subjects have shown that, if their temperature is raised, they underestimate the time between events.

Despite these facts, the Lockean notion that the estimation of time depends on the succession of sensations is still to some degree true. People who take the drugs hashish and mescaline, for example, may feel their sensations following one another much more rapidly. Because there are so many more sensations than normal in a given interval of time, time seems to drag, so that a minute may feel like an hour. Similar illusions about the spans of time occur in dreams.

It is unclear whether most discussions of so-called biological and psychological time have much significance for metaphysics. As far as the distorted experiences of time that arise through drugs (and in schizophrenia) are concerned, it can be argued that there is nothing surprising in the fact that pathological states can make people misestimate periods of time, and so it can be claimed that facts of this sort do not shed any more light on the philosophy of time than facts about mountains looking near after rainstorms and looking far after duststorms shed on the philosophy of space.

The idea that psychological studies of temporal experience are philosophically important is probably connected with the sort of Empiricism that was characteristic of Locke and still more of the Empiricists George Berkeley and David Hume and their successors. The idea of time had somehow to be constructed out of the primitive experience of ideas succeeding one another. Nowadays, concept formation is thought of as more of a social phenomenon involved in the "picking up" of a language; thus, contemporary philosophers have tended to see the problem differently: humans do not have to construct their concepts from their own immediate sensations. Even so, the learning of temporal concepts surely does at least involve an immediate apprehension of the relation of "earlier" and "later." A mere succession of sensations, however, will go no way toward yielding the idea of time: if one sensation has vanished entirely before the other is in consciousness, one cannot be immediately aware of the succession of sensations. What Empiricism needs, therefore, as a basis for constructing the idea of time is an experience of succession as opposed to a succession of experiences. Hence, two or more ideas that are related by "earlier than" must be experienced in one single act of awareness. William James, a U.S. Pragmatist philosopher and also a pioneer psychologist, popularized the term *specious present* for the span of time covered by a single act of awareness. His idea was that at a given moment of time a person is aware of events a short time before that time. (Sometimes he spoke of the specious present as a saddleback looking slightly into the future as well as slightly into the past, but this was inconsistent with his idea that the specious present depended on lingering short-term memory processes in the brain.) He referred to experiments by the German psychologist Wilhelm Wundt that showed that the longest group of arbitrary sounds that a person could identify without error lasted about six seconds. Other criteria perhaps involving other sense modalities might lead to slightly different spans of time, but the interesting point is that, if there is such a specious present, it cannot be explained solely by ordinary memory traces: if one hears a "ticktock" of a clock, the "tick" is not remembered in the way in which a "ticktock" 10 minutes ago is remembered. The specious present is perhaps not really specious: the idea that it was specious depended on an idea that the real (nonspecious) present had to be instantaneous. If perception is considered as a certain reliable way of being caused to have true beliefs about the environment by sensory stimulation, there is no need to suppose that these true beliefs have to be about an instantaneous state of the world. It can therefore be questioned whether the term *specious* is a happy one.

Time-consciousness

Two matters discussed earlier in connection with the philosophy of physics have implications for the philosophy of mind: (1) the integration of space and time in the theory of relativity makes it harder to conceive of immaterial minds that exist in time but are not even localizable in space; (2) the statistical explanation of temporal asymmetry explains why the brain has memory traces of the past but not of the future and, hence, helps to explain the unidirectional nature of temporal consciousness. It also gives reasons for skepticism about the claims of parapsychologists to have experimental evidence for precognition; or it shows, at least, that if these phenomena do exist they are not able to be fitted into a cosmology based on physics as it exists today. (J.J.C.S.)

Time as systematized in modern scientific society

TIME MEASUREMENT: GENERAL CONCEPTS

Accuracy in specifying time is needed for civil, industrial, and scientific purposes. Although defining time presents difficulties, measuring it does not; it is the most accurately measured physical quantity. A time measurement assigns a unique number to either an epoch, which specifies the moment when an instantaneous event occurs, in the sense

of time of day, or a time interval, which is the duration of a continued event. The progress of any phenomenon that undergoes regular changes may be used to measure time. Such phenomena make up much of the subject matter of astronomy, physics, chemistry, geology, and biology. The following sections of this article treat time measurements based on manifestations of gravitation, electromagnetism, rotational inertia, and radioactivity.

Fundamental time scales

Series of events can be referred to a time scale, which is an ordered set of times derived from observations of some phenomenon. Two independent, fundamental time scales are those called dynamical—based on the regularity of the motions of celestial bodies fixed in their orbits by gravitation—and atomic—based on the characteristic frequency of electromagnetic radiation emitted or absorbed in quantum transitions between internal energy states of atoms or molecules.

Two time scales that have no relative secular acceleration are called equivalent. That is, a clock displaying the time according to one of these scales would not—over an extended interval—show a change in its rate relative to that of a clock displaying time according to the other scale. It is not certain whether the dynamical and atomic scales are equivalent, but present definitions treat them as being so.

The Earth's daily rotation about its own axis provides a time scale, but one that is not equivalent to the fundamental scales because tidal friction inexorably decreases the Earth's rotational speed (symbolized by the Greek letter omega, ω). There are also other sources of variation. Rotational time is needed for civil purposes, celestial navigation, and tracking of space vehicles.

The decay of radioactive elements is a random, rather than a repetitive, process, but the statistical reliability of the time required for the disappearance of any given fraction of a particular element can be used for measuring long time intervals.

Principal scales. Numerous time scales have been formed; several important ones are described in detail in subsequent sections of this article. The abbreviations given here are derived from English or French terms. Universal Time (UT; the mean solar time of the meridian of Greenwich, England), Coordinated Universal Time (UTC; the basis of legal, civil time), and leap seconds are treated under the heading *Rotational time.* Ephemeris Time (ET; the first correct dynamical time scale) is treated in the section *Dynamical time,* as are Barycentric Dynamical Time (TDB) and Terrestrial Dynamical Time (TDT), which are more accurate than Ephemeris Time because they take relativity into account. International Atomic Time (TAI; introduced in 1955) is covered in the section *Atomic time.*

Relativistic effects. Accuracies of atomic clocks and modern observational techniques are so high that the small differences between classical mechanics (as developed by Newton in the 17th century) and relativistic mechanics (according to the special and general theories of relativity proposed by Einstein in the early 20th century) must be taken into account. The equations of motion that define TDB include relativistic terms. The atomic clocks that form TAI, however, are corrected only for height above sea level, not for periodic relativistic variations, because all fixed terrestrial clocks are affected identically. TAI and TDT differ from TDB by calculable periodic variations.

Apparent positions of celestial objects, as tabulated in ephemerides, are corrected for the Sun's gravitational deflection of light rays.

Clocks. The atomic clock is the only object that both generates a precise time scale and tells time. It has made possible new, highly accurate techniques for measuring time and distance. These techniques, involving radar, lasers, spacecraft, radio telescopes, and pulsars, have been applied to the study of problems in celestial mechanics, astrophysics, relativity, and cosmogony.

Atomic clocks serve as the basis of scientific and legal clock times. A single clock, atomic or quartz-crystal, synchronized with either TAI or UTC provides the SI second (that is, the second as defined in the International System of Units), TAI, UTC, and TDT immediately with high accuracy.

Time units and calendar divisions. The familiar subdivision of the day into 24 hours, the hour into 60 minutes, and the minute into 60 seconds is of ancient origins but has come into general use since about AD 1600. When the increasing accuracy of clocks led to the adoption of the mean solar day, which contained 86,400 seconds, this mean solar second became the basic unit of time. The adoption of the SI second, defined on the basis of atomic phenomena, as the fundamental time unit has necessitated some changes in the definitions of other terms.

In this article, unless otherwise indicated, second (symbolized s) means the SI second; a minute (m or min) is 60 s; an hour (h) is 60 m or 3,600 s. An astronomical day (d) equals 86,400 s. An ordinary calendar day equals 86,400 s, and a leap-second calendar day equals 86,401 s. A common year contains 365 calendar days and a leap year, 366.

The system of consecutively numbering the years of the Christian Era was devised by Dionysius Exiguus in about 525; it included the reckoning of dates as either AD or BC (the year before AD 1 was 1 BC). The Julian calendar, introduced by Julius Caesar in the 1st century BC, was then in use, and any year whose number was exactly divisible by four was designated a leap year. In the Gregorian calendar, introduced in 1582 and now in general use, the centurial years are common years unless their numbers are exactly divisible by 400; thus, 1600 was a leap year, but 1700 was not.

Leap years

Lengths of years and months. The tropical year, whose period is that of the seasons, is the interval between successive passages of the Sun through the vernal equinox. Because the Earth's motion is perturbed by the gravitational attraction of the other planets and because of an acceleration in precession, the tropical year decreases slowly, as shown by comparing its length at the end of the 19th century (365.242196 d) with that at the end of the 20th (365.242190 d). The accuracy of the Gregorian calendar results from the close agreement between the length of its average year, 365.2425 calendar days, and that of the tropical year.

A calendar month may contain 28 to 31 calendar days; the average is 30.437. The synodic month, the interval from New Moon to New Moon, averages 29.531 d.

Astronomical years and dates. In the Julian calendar, a year contains either 365 or 366 days, and the average is 365.25 calendar days. Astronomers have adopted the term *Julian year* to denote an interval of 365.25 d, or 31,557,600 s. The corresponding Julian century equals 36,525 d. For convenience in specifying events separated by long intervals, astronomers use *Julian dates* (JD) in accordance with a system proposed in 1583 by the French classical scholar Joseph Scaliger and named in honour of his father, Julius Caesar Scaliger. In this system days are numbered consecutively from 0.0, which is identified as Greenwich mean noon of the day assigned the date Jan. 1, 4713 BC, by reckoning back according to the Julian calendar. The *modified Julian date* (MJD), defined by the equation MJD = JD − 2,400,000.5, begins at midnight rather than noon and, for the 20th and 21st centuries, is expressed by a number with fewer digits. For example, Greenwich mean noon of Nov. 14, 1981 (Gregorian calendar date), corresponds to JD 2,444,923.0; the preceding midnight occurred at JD 2,444,922.5 and MJD 44,922.0.

Historical details of the week, month, year, and various calendars are treated in the article CALENDAR.

ROTATIONAL TIME

The Earth's rotation causes the stars and the Sun to appear to rise each day in the east and set in the west. The apparent solar day is measured by the interval of time between two successive passages of the Sun across the observer's celestial meridian, the visible half of the great circle that passes through the zenith and the celestial poles. One sidereal day (very nearly) is measured by the interval of time between two similar passages of a star. Fuller treatments of astronomical reference points and planes are given in the articles STARS AND STAR CLUSTERS: *Astronomical maps;* and MECHANICS: *Celestial mechanics.*

The plane in which the Earth revolves about the Sun is called the ecliptic. As seen from the Earth, the Sun moves

eastward on the ecliptic 360° per year, almost one degree per day. As a result, an apparent solar day is nearly four minutes longer, on the average, than a sidereal day. The difference varies, however, from 3 minutes 35 seconds to 4 minutes 26 seconds during the year because of the ellipticity of the Earth's orbit, in which at different times of the year it moves at slightly different rates, and because of the 23½° inclination of the ecliptic to the Equator. In consequence, apparent solar time is nonuniform with respect to dynamical time. A sundial indicates apparent solar time.

The introduction of clocks and watches during the 17th century made apparent solar time unsuitable for civil use. Therefore, mean solar time was introduced; it is defined below. The difference between apparent solar time and mean solar time, called the equation of time, varies from zero to about 16 minutes.

The measures of sidereal, apparent solar, and mean solar time are defined by the hour angles of certain points, real or fictitious, in the sky. Hour angle is the angle, taken to be positive to the west, measured along the celestial equator between an observer's meridian and the hour circle (a great circle passing through the poles) on which some celestial point or object lies. Hour angles are measured from zero through 24 hours.

Sidereal time is the hour angle of the vernal equinox, a reference point that is one of the two intersections of the celestial equator and the ecliptic. Because of a small periodic oscillation, or wobble, of the Earth's axis, called nutation, there is a distinction between the true and mean equinoxes. The difference between true and mean sidereal times, defined by the two equinoxes, varies from zero to about one second.

Mean solar time

Apparent solar time is the hour angle of the centre of the true Sun plus 12 hours. Mean solar time is 12 hours plus the hour angle of the centre of the fictitious mean Sun. This is a point that moves along the celestial equator with constant speed and that coincides with the true Sun on the average. In practice, mean solar time is not obtained from observations of the Sun. Instead, sidereal time is determined from observations of the transit across the meridian of stars, and the result is transformed by means of a quadratic formula to obtain mean solar time.

Standard time. Local mean solar time depends upon longitude; it is advanced by four minutes per degree eastward. In 1869 Charles F. Dowd, principal of a school in Saratoga Springs, N.Y., proposed the use of time zones, within which all localities would keep the same time. Others, including Sir Sandford Fleming, a Canadian civil engineer, strongly advocated this idea. Time zones were adopted by U.S. and Canadian railroads in 1883.

In October 1884 an international conference held in Washington, D.C., adopted the meridian of the transit instrument at the Royal Observatory, Greenwich, as the prime, or zero, meridian. This led to the adoption of 24 standard time zones; the boundaries are determined by local authorities and in many places deviate considerably from the 15° intervals of longitude implicit in the original idea. The times in different zones differ by an integral number of hours; minutes and seconds are the same.

The International Date Line is a zigzag line in the mid-Pacific Ocean near 180° longitude. When one travels across it westward a calendar day is added; one day is dropped in passing eastward.

During World War I, daylight-saving time was adopted in various countries; clocks were advanced one hour to save fuel by reducing the need for artificial light in evening hours. During World War II, all clocks in the United States were kept one hour ahead of standard time for the interval Feb. 9, 1942–Sept. 30, 1945, with no changes made in summer. Beginning in 1967, by act of Congress, the United States has observed daylight-saving time in summer, though state legislatures retain the power to pass exempting laws, and a few have done so.

Reckoning of days and hours. The day begins at midnight and runs through 24 hours. In the 24-hour system of reckoning, used in Europe and by military agencies of the United States, the hours and minutes are given as a four-digit number. Thus 0028 means 28 minutes past midnight, and 1240 means 40 minutes past noon. Also, 2400 of May 15 is the same as 0000 of May 16. This system allows no uncertainty as to the epoch designated.

In the 12-hour system there are two sets of 12 hours; those from midnight to noon are designated AM (ante meridiem, "before noon"), and those from noon to midnight are designated PM (post meridiem, "after noon"). The use of AM and PM to designate either noon or midnight can cause ambiguity. To designate noon, either the word noon or 1200 or 12 M should be used. To designate midnight without causing ambiguity, the two dates between which it falls should be given unless the 24-hour notation is used. Thus, midnight may be written: May 15–16 or 2400 May 15 or 0000 May 16.

Universal Time. Until 1928 the standard time of the zero meridian was called Greenwich Mean Time (GMT), and in accord with astronomical tradition the epoch 0000 GMT occurred at noon. In 1925 the numbering system was changed so that the day began at midnight, as does the civil day. To alleviate the resulting confusion, in 1928 the International Astronomical Union (IAU) adopted the term Universal Time (UT).

In 1955 the IAU defined several kinds of UT. The initial values of Universal Time obtained at various observatories, denoted UT0, differ slightly because of polar motion. A correction is added for each observatory to convert UT0 into UT1. An empirical correction to take account of annual changes in the speed of rotation is then added to convert UT1 to UT2. UT2 has since been superseded by atomic time.

Precise values of UT1, which give the Earth's rotational position in space, are derived by the Bureau International de l'Heure (BIH) from values determined at about 75 observatories.

Variations in the Earth's rotation rate. The Earth does not rotate with perfect uniformity, and the variations have been classified as (1) secular, resulting from tidal friction, (2) irregular, ascribed to motions of the Earth's core, and (3) periodic, caused by seasonal meteorological phenomena.

Separating the first two categories is very difficult. Observations made since 1621, after the introduction of the telescope, show irregular fluctuations about a decade in duration and a long one that began about 1650 and is not yet complete. The large amplitude of this effect makes it impossible to determine the secular variation from data accumulated during an interval of only about four centuries. The record is supplemented, however, by reports—not always reliable—of eclipses that occurred tens of centuries ago. From this extended set of information it is found that, relative to dynamical time, the length of the mean solar day increases secularly about 1.6 milliseconds per century, the rate of the Earth's rotation decreases about one part per million in 5,000 years, and rotational time loses about 30 seconds per century squared.

Changing length of the day

The annual seasonal term, nearly periodic, has a coefficient of about 25 milliseconds.

Coordinated Universal Time; leap seconds. The time and frequency broadcasts of the United Kingdom and the United States were coordinated (synchronized) in 1960. As required, adjustments were made in frequency, relative to atomic time, and in epoch to keep the broadcast signals close to the UT scale. This program expanded in 1964 under the auspices of the IAU into a worldwide system called Coordinated Universal Time (UTC).

Since Jan. 1, 1972, the UTC frequency has been the TAI frequency, the difference between TAI and UTC has been kept at some integral number of seconds, and the difference between UT1 and UTC has been kept within 0.9 second by inserting a leap second into UTC as needed. This is done by making the last minute of a month, preferably June or December, contain 61 seconds.

About one leap second per year has been inserted since 1972. Estimates of the loss per year of UT1 relative to TAI due to tidal friction range from 0.7 second in 1900 to 1.3 seconds in 2000. Irregular fluctuations cause unpredictable gains or losses; these have not exceeded 0.3 second per year.

Time determination. The classical, astrometric methods of obtaining UT0 are, in essence, determinations of the

instant at which a star crosses the local celestial meridian. Instruments used include the transit, the photographic zenith tube, and the prismatic astrolabe.

The transit is a small telescope that can be moved only in the plane of the meridian. The observer generates a signal at the instant that the image of the star is seen to cross a very thin cross hair aligned in the meridian plane. The signal is recorded on a chronograph that simultaneously displays the readings of the clock that is being checked.

The photographic zenith tube (PZT) is a telescope permanently mounted in a precisely vertical position. The light from a star passing almost directly overhead is refracted by the lens, reflected from the perfectly horizontal surface of a pool of mercury, and brought to a focus just beneath the lens. A photographic plate records the images of the star at clock times close to that at which it crosses the meridian. The vertical alignment of the PZT minimizes the effects of atmospheric refraction. From the positions of the images on the plate, the time at which the star transits the meridian can be accurately compared with the clock time. The distance of the star from the zenith (north or south) also can be ascertained. This distance varies slightly from year to year and is a measure of the latitude variation caused by the slight movement of the Earth's axis of rotation relative to its crust.

The prismatic astrolabe is a refinement of the instrument used since antiquity for measuring the altitude of a star above the horizon. The modern device consists of a horizontal telescope into which the light from the star is reflected from two surfaces of a prism that has three faces at 60° angles. The light reaches one of these faces directly from the star; it reaches the other after reflection from the surface of a pool of mercury. The light traversing the separate paths is focused to form two images of the star that coincide when the star reaches the altitude of 60°. This instant is automatically recorded and compared with the reading of a clock. Like the PZT, the prismatic astrolabe detects the variation in the latitude of the observatory.

DYNAMICAL TIME

Dynamical time is defined descriptively as the independent variable, T, in the differential equations of motion of celestial bodies. The gravitational ephemeris of a planet tabulates its orbital position for values of T. Observation of the position of the planet makes it possible to consult the ephemeris and find the corresponding dynamical time.

The Moon as a timekeeper

The most sensitive index of dynamical time is the position of the Moon because of the rapid motion of that body across the sky. The equations that would exactly describe the motion of the Moon in the absence of tidal friction, however, must be slightly modified to account for the deceleration that this friction produces. The correction is made by adding an empirical term, aT^2, to the longitude, λ, given by gravitational theory. The need for this adjustment was not recognized for a long time.

The U.S. astronomer Simon Newcomb noted in 1878 that fluctuations in λ that he had found could be due to fluctuations in rotational time; he compiled a table of Δt, its difference from the time scale based on uniform rotation of the Earth. Realizing that nonuniform rotation of the Earth should also cause apparent fluctuations in the motion of Mercury, Newcomb searched for these in 1882 and 1896, but the observational errors were so large that he could not confirm his theory.

A large fluctuation in the Earth's rotational speed, ω, began about 1896, and its effects on the apparent motions of both the Moon and Mercury were described by the Scottish-born astronomer Robert T.A. Innes in 1925. Innes proposed a time scale based on the motion of the Moon, and his scale of Δt from 1677 to 1924, based on observations of Mercury, was the first true dynamical scale, later called Ephemeris Time.

Ephemeris Time. Further studies by the Dutch astronomer Willem de Sitter in 1927 and by Harold Spencer Jones (later Sir Harold, Astronomer Royal of England) in 1939 confirmed that ω had secular and irregular variations. Using their results, the U.S. astronomer Gerald M. Clemence in 1948 derived the equations needed to define a dynamical scale numerically and to convert measurements of the Moon's position into time values. The fundamental definition was based on the Earth's orbital motion as given by Newcomb's tables of the Sun of 1898. The IAU adopted the dynamical scale in 1952 and called it Ephemeris Time (ET). Clemence's equations were used to revise the lunar ephemeris published in 1919 by the U.S. mathematician Ernest W. Brown to form the *Improved Lunar Ephemeris* (ILE) of 1954.

Ephemeris second. The IAU in 1958 defined the second of Ephemeris Time as 1/31,556,925.9747 of the tropical year that began at the instant specified, in astronomers' terms, as 1900 January $0^d\ 12^h$, "the instant, near the beginning of the calendar year AD 1900, when the geocentric mean longitude of the Sun was 279° 41′ 48″.04," that is, Greenwich noon on Dec. 31, 1899. In 1960 the General Conference of Weights and Measures (CGPM) adopted the same definition for the SI second.

Definition of the second

Since, however, 1900 was past, this definition could not be used to obtain the ET or SI second. It was obtained in practice from lunar observations and the ILE and was the basis of the redefinition, in 1967, of the SI second on the atomic time scale. The present SI second thus depends directly on the ILE.

The ET second defined by the ILE is based in a complex manner on observations made up to 1938 of the Sun, the Moon, Mercury, and Venus, referred to the variable, mean solar time. Observations show that the ET second equals the average mean solar second from 1750 to 1903.

TDB and TDT. In 1976 the IAU defined two scales for dynamical theories and ephemerides to be used in almanacs beginning in 1984.

Barycentric Dynamical Time (TDB) is the independent variable in the equations, including terms for relativity, of motion of the celestial bodies. The solution of these equations gives the rectangular coordinates of those bodies relative to the barycentre (centre of mass) of the solar system. (The barycentre does not coincide with the centre of the Sun but is displaced to a point near its surface in the direction of Jupiter.) Which theory of general relativity to use was not specified, so a family of TDB scales could be formed, but the differences in coordinates would be small.

Terrestrial Dynamical Time (TDT) is an auxiliary scale defined by the equation TDT = TAI + 32.184 s. Its unit is the SI second. The constant difference between TDT and TAI makes TDT continuous with ET for periods before TAI was defined (mid-1955). TDT is the time entry in apparent geocentric ephemerides.

The definitions adopted require that $\mathrm{TDT} = \mathrm{TDB} - R$, where R is the sum of the periodic, relativistic terms not included in TAI. Both the above equations for TDT can be valid only if dynamical and atomic times are equivalent (see below *Atomic time: SI second*).

Almanacs

For use in almanacs the barycentric coordinates of the Earth and a body at epoch TDB are transformed into the coordinates of the body as viewed from the centre of the Earth at the epoch TDT when a light ray from the body would arrive there. Almanacs tabulate these geocentric coordinates for equal intervals of TDT; since TDT is available immediately from TAI, comparisons between computed and observed positions are readily made.

Since Jan. 1, 1984, the principal ephemerides in *The Astronomical Almanac,* published jointly by the Royal Greenwich Observatory and the U.S. Naval Observatory, have been based on a highly accurate ephemeris compiled by the Jet Propulsion Laboratory, Pasadena, Calif., in cooperation with the Naval Observatory. This task involved the simultaneous numerical integration of the equations of motion of the Sun, the Moon, and the planets. The coordinates and velocities at a known time were based on very accurate distance measurements (made with the aid of radar, laser beams, and spacecraft), optical angular observations, and atomic clocks.

ATOMIC TIME

Basic principles. The German physicist Max Planck postulated in 1900 that the energy of an atomic oscillator is quantized; that is, it equals $h\nu$, where h is a constant (now called Planck's constant) and ν is the frequency. Einstein extended this concept in 1905, stating that elec-

tromagnetic radiation is localized in packets, later called photons, of frequency ν and energy $E = h\nu$. Niels Bohr of Denmark postulated in 1913 that atoms exist in states of discrete energy and that a transition between two states differing in energy by the amount ΔE is accompanied by absorption or emission of a photon that has a frequency $\nu = \Delta E/h$. For detailed information concerning the phenomena on which atomic time is based, see ELECTROMAGNETIC RADIATION; ATOMS: *Major ideas and discoveries;* MECHANICS: *Quantum mechanics.*

Atomic transitions

In an unperturbed atom, not affected by neighbouring atoms or external fields, the energies of the various states depend only upon intrinsic features of atomic structure, which are postulated not to vary. A transition between a pair of these states involves absorption or emission of a photon with a frequency ν_0, designated the fundamental frequency associated with that particular transition.

Atomic clocks. Transitions in many atoms and molecules involve sharply defined frequencies in the vicinity of 10^{10} hertz, and, after dependable methods of generating such frequencies were developed during World War II for microwave radar, they were applied to problems of timekeeping. In 1946 principles of the use of atomic and molecular transitions for regulating the frequency of electronic oscillators were described, and in 1947 an oscillator controlled by a quantum transition of the ammonia molecule was constructed. An ammonia-controlled clock was built in 1949 at the National Bureau of Standards, Washington, D.C.; in this clock the frequency did not vary by more than one part in 10^8. In 1954 an ammonia-regulated oscillator of even higher precision—the first maser—was constructed.

Cesium clocks. In 1938 the so-called resonance technique of manipulating a beam of atoms or molecules was introduced. This technique was adopted in several attempts to construct a cesium-beam atomic clock, and in 1955 the first such clock was placed in operation at the National Physical Laboratory, Teddington, Eng.

In practice, the most accurate control of frequency is achieved by detecting the interaction of radiation with atoms that can undergo some selected transition. From a beam of cesium vapour, a magnetic field first isolates a stream of atoms that can absorb microwaves of the fundamental frequency ν_0. Upon traversing the microwave field, some—not all—of these atoms do absorb energy, and a second magnetic field isolates these and steers them to a detector. The number of atoms reaching the detector is greatest when the microwave frequency exactly matches ν_0, and the detector response is used to regulate the microwave frequency. The frequency of the cesium clock is $\nu_t = \nu_0 + \Delta\nu$, where $\Delta\nu$ is the frequency shift caused by slight instrumental perturbations of the energy levels. This frequency shift can be determined accurately, and the circuitry of the clock is arranged so that ν_t is corrected to generate an operational frequency $\nu_0 + \varepsilon$, where ε is the error in the correction. The measure of the accuracy of the frequency-control system is the fractional error ε/ν_0, which is symbolized γ. Small, commercially built cesium clocks attain values of γ of ± 1 or 2×10^{-12}; in a large, laboratory-constructed clock, whose operation can be varied to allow experiments on factors that can affect the frequency, γ can be reduced to $\pm 5 \times 10^{-14}$.

Accuracy of atomic clocks

Between 1955 and 1958 the National Physical Laboratory and the U.S. Naval Observatory conducted a joint experiment to determine the frequency maintained by the cesium-beam clock at Teddington in terms of the ephemeris second, as established by precise observations of the Moon from Washington, D.C. The radiation associated with the particular transition of the cesium-133 atom was found to have the fundamental frequency ν_0 of 9,192,631,770 cycles per second of Ephemeris Time.

The merits of the cesium-beam atomic clock are that (1) the fundamental frequency that governs its operation is invariant; (2) its fractional error is extremely small; and (3) it is convenient to use. Several thousand commercially built cesium clocks, weighing about 70 pounds (32 kilograms) each, have been placed in operation. A few laboratories have built large cesium-beam oscillators and clocks to serve as primary standards of frequency.

Other atomic clocks. Clocks regulated by hydrogen masers have been developed at Harvard University. The frequency of some masers has been kept stable within about one part in 10^{14} for intervals of a few hours. The uncertainty in the fundamental frequency, however, is greater than the stability of the clock; this frequency is approximately 1,420,405,751.77 Hz. Atomic-beam clocks controlled by a transition of the rubidium atom have been developed, but the operational frequency depends on details of the structure of the clock, so that it does not have the absolute precision of the cesium-beam clock.

SI second. The CGPM redefined the second in 1967 to equal 9,192,631,770 periods of the radiation emitted or absorbed in the hyperfine transition of the cesium-133 atom; that is, the transition selected for control of the cesium-beam clock developed at the National Physical Laboratory. The definition implies that the atom should be in the unperturbed state at sea level. It makes the SI second equal to the ET second, determined from measurements of the position of the Moon, within the errors of observation. The definition will not be changed by any additional astronomical determinations.

Atomic time scales. An atomic time scale designated A.1, based on the cesium frequency discussed above, had been formed in 1958 at the U.S. Naval Observatory. Other local scales were formed, and about 1960 the BIH formed a scale based on these. In 1971 the CGPM designated the BIH scale as International Atomic Time (TAI).

The long-term frequency of TAI is based on about six cesium standards, operated continuously or periodically. About 175 commercially made cesium clocks are used also to form the day-to-day TAI scale. These clocks and standards are located at about 30 laboratories and observatories. It is estimated that the second of TAI reproduces the SI second, as defined, within about one part in 10^{13}. Two clocks that differ in rate by this amount would change in epoch by three milliseconds in 1,000 years.

Time and frequency dissemination. Precise time and frequency are broadcast by radio in many countries. Transmissions of time signals began as an aid to navigation in 1904; they are now widely used for many scientific and technical purposes. The seconds pulses are emitted on Coordinated Universal Time, and the frequency of the carrier wave is maintained at some known multiple of the cesium frequency.

Radio time signals

The accuracy of the signals varies from about one millisecond for high-frequency broadcasts to one microsecond for the precisely timed pulses transmitted by the stations of the navigation system loran-C. Trigger pulses of television broadcasts provide accurate synchronization for some areas. When precise synchronization is available a quartz-crystal clock suffices to maintain TAI accurately.

Cesium clocks carried aboard aircraft are used to synchronize clocks around the world within about 0.5 microsecond. Since 1962 artificial satellites have been used similarly for widely separated clocks.

Relativistic effects. A clock displaying TAI on Earth will have periodic, relativistic deviations from the dynamical scale TDB and from a pulsar time scale PS (see below *Pulsar time*). These variations, denoted R above, were demonstrated in 1982–84 by measurements of the pulsar PSR 1937+21.

The main contributions to R result from the continuous changes in the Earth's speed and distance from the Sun. These cause variations in the transverse Doppler effect and in the red shift due to the Sun's gravitational potential. The frequency of TAI is higher at aphelion (about July 3) than at perihelion (about January 4) by about 6.6 parts in 10^{10}, and TAI is more advanced in epoch by about 3.3 milliseconds on October 1 than on April 1.

By Einstein's theory of general relativity a photon produced near the Earth's surface should be higher in frequency by 1.09 parts in 10^{16} for each metre above sea level. In 1960 the U.S. physicists Robert V. Pound and Glen A. Rebka measured the difference between the frequencies of photons produced at different elevations and found that it agreed very closely with what was predicted. The primary standards used to form the frequency of TAI are corrected for height above sea level.

Two-way, round-the-world flights of atomic clocks in 1971 produced changes in clock epochs that agreed well with the predictions of special and general relativity. The results have been cited as proof that the gravitational red shift in the frequency of a photon is produced when the photon is formed, as predicted by Einstein, and not later, as the photon moves in a gravitational field. In effect, gravitational potential is a perturbation that lowers the energy of a quantum state.

PULSAR TIME

A pulsar is believed to be a rapidly rotating neutron star whose magnetic and rotational axes do not coincide. Such bodies emit sharp pulses of radiation, at a short period P, detectable by radio telescopes. The emission of radiation and energetic subatomic particles causes the spin rate to decrease and the period to increase. $\dot{P}$, the rate of increase in P, is essentially constant, but sudden changes in the period of some pulsars have been observed.

Although pulsars are sometimes called clocks, they do not tell time. The times at which their pulses reach a radio telescope are measured relative to TAI, and values of P and $\dot{P}$ are derived from these times. A time scale formed directly from the arrival times would have a secular deceleration with respect to TAI, but if P for an initial TAI and $\dot{P}$ (assumed constant) are obtained from a set of observations, then a pulsar time scale, PS, can be formed such that δ, the difference between TAI and PS, contains only periodic and irregular variations. PS remains valid as long as no sudden change in P occurs.

It is the variations in δ, allowing comparisons of time scales based on very different processes at widely separated locations, that make pulsars extremely valuable. The chief variations are periodic, caused by motions of the Earth. These motions bring about (1) relativistic variations in TAI and (2) variations in distance, and therefore pulse travel time, from pulsar to telescope. Observations of the pulsar PSR 1937+21, corrected for the second effect, confirmed the existence of the first. Residuals (unexplained variations) in δ averaged one microsecond for 30 minutes of observation. This pulsar has the highest rotational speed of any known pulsar, 642 rotations per second. Its period P is 1.55 milliseconds, increasing at the rate $\dot{P}$ of 3.3×10^{-12} second per year; the speed decreases by one part per million in 500 years.

Continued observations of such fast pulsars should make it possible to determine the orbital position of the Earth more accurately. These results would provide more accurate data concerning the perturbations of the Earth's motion by the major planets; these in turn would permit closer estimates of the masses of those planets. Residual periodic variations in δ, not due to the sources already mentioned, might indicate gravitational waves. Irregular variations could provide data on starquakes and inhomogeneities in the interstellar medium.

RADIOMETRIC TIME

Atomic nuclei of a radioactive element decay spontaneously, producing other elements and isotopes until a stable species is formed. The life span of a single atom may have any value, but a statistical quantity, the half-life of a macroscopic sample, can be measured; this is the time in which one-half of the sample disintegrates. The age of a rock, for example, can be determined by measuring ratios of the parent element and its decay products.

Half-life

The decay of uranium to lead was first used to measure long intervals, but the decays of potassium to argon and of rubidium to strontium are more frequently used now. Ages of the oldest rocks found on the Earth are about 3.5×10^9 years. Those of lunar rocks and meteorites are about 4.5×10^9 years, a value believed to be near the age of the Earth.

Radiocarbon dating provides ages of formerly living matter within a range of 500 to 50,000 years. While an organism is living, its body contains about one atom of radioactive carbon-14, formed in the atmosphere by the action of cosmic rays, for every 10^{12} atoms of stable carbon-12. When the organism dies, it stops exchanging carbon with the atmosphere, and the ratio of carbon-14 to carbon-12 begins to decrease with the half-life of 5,730 years. Measurement of this ratio determines the age of the specimen.

For an extended discussion of the principles of radiometric dating, including sources of error, see GEOCHRONOLOGY: *Relative and absolute dating.*

PROBLEMS OF COSMOLOGY AND UNIFORM TIME

It has been suggested—by the English scientists E.A. Milne, Paul A.M. Dirac, and others—that the coefficient G in Newton's equation for the gravitational force might not be constant. Searches for a secular change in G have been made by studying accelerations of the Moon and reflections of radar signals from Mercury, Venus, and Mars. The effects sought are small compared to observational errors, however, and it is not certain whether G is changing or whether dynamical and atomic times have a relative secular acceleration.

A goal in timekeeping has been to obtain a scale of uniform time, but forming one presents problems. If, for example, dynamical and atomic time should have a relative secular acceleration, then which one (if either) could be considered uniform?

By postulates, atomic time is the uniform time of electromagnetism. Leaving aside relativistic and operational effects, are SI seconds formed at different times truly equal? This question cannot be answered without an invariable time standard for reference, but none exists. The conclusion is that no time scale can be proved to be uniform by measurement. This is of no practical consequence, however, because tests have shown that the atomic clock provides a time scale of very high accuracy. (W.Ma.)

Tissue Culture

Tissue culture involves removing fragments of cell-containing material from a plant or animal and placing them in an artificial environment in which they can continue to function biologically. A tissue in culture may consist of a single cell, a population of cells, or, as in organ culture, all or part of an organ, in which different cell types interact in specific ways. The complex plants and animals contain many different kinds of specialized cells whose activities are interdependent and coordinated. Cells in culture may multiply; they may exhibit specialized activity (*i.e.*, locomotion); they may change size, form, and state of differentiation (*i.e.*, the kinds of different structures and functions they display); and they may interact in other complex ways. Thus, cultures of heart cells may display typical rhythmical beating, cells from the pancreas may produce the hormone insulin, and cells from the plant known as the deadly nightshade (*Atropa belladonna*) may produce the alkaloid compound atropine.

Bibliography 668

Uses of tissue culture

Cultures of cells and organs have been used to study cell composition and form; cellular, genetic, biochemical, and reproductive activity; the nature of specialized cell functions (*i.e.*, differentiation); the effects of physical, chemical, and biological agents—for example, drugs, hormones, or viruses; and structural and behavioral differences between abnormal cells, such as cancers, and their normal counterparts.

One of the traditional uses of tissue culture has been as an aid in the diagnosis of disease. A physician may, for example, culture a tissue sample to identify a simple bacterial or parasitic infection. Other diagnostic applications of tissue culture include the classification of brain tumours, identification of enzyme deficiencies in metabolic diseases, and identification of chromosomal abnormalities. Tissue culture is also used in the formulation and testing of new drugs and vaccines. The demonstration in 1949 that the causative virus of poliomyelitis would grow in cultures of human cells resulted in the preparation of vaccines that provide immunity against several viral diseases, including influenza, measles, and mumps.

The results of experiments in cell growth and differentiation have also added considerably to the body of scientific knowledge about basic biological and biochemical processes. Cell and organ culture techniques made possible an understanding of the nutrition and metabolism of many kinds of cells.

Most recently, however, the use of tissue culture methodology in the discipline of somatic cell genetics has opened new areas of investigation in the study of mammalian, and particularly human, genetics. One great advantage of tissue culture as a research tool is that it permits control of the cellular environment in a fashion and to a degree not possible inside the body, allowing the behaviour of cells to be both explored and manipulated. Some applications of somatic cell genetics are discussed below.

GENERAL BACKGROUND AND DEFINITIONS

The cell consists of a central nucleus, the cytoplasm, which surrounds the nucleus and contains the bulk of the cellular chemical machinery, and the cell membrane, which mediates all interaction between the cell and its environment. Within the nucleus are the chromosomes, bodies on which

the genes are carried in linear order. The totality of a cell's genes and chromosomes is called its genome.

Genes are molecules of deoxyribonucleic acid, or DNA, each of which specifies the structure of a particular protein. The proteins constitute the basic chemically mediating molecules of the cell (enzymes) and also form important parts of its structure. All cells may be classified as either germ cells or somatic cells. Germ cells consist of sperm and egg cells whose mating constitutes the act of conception and leads to reproduction of a new individual. Somatic cells are body cells not connected with this reproductive process.

A tissue is a structural and functional aggregation of similar cells and their associated materials; *e.g.,* connective and vascular tissues in animals and sclerenchyma and xylem in plants are tissues that perform similar functions, namely those of support and internal transport. An organ such as the lung, liver, or brain is a complex structural unit composed of several tissues. A clone is a population of cells derived from a single cell by asexual reproduction; it represents the most uniform possible biological population. The nutrient medium is the material in which tissue culture cells are placed and from which the cells derive the molecules necessary for their reproduction and other functions.

ORIGINS AND METHODS OF TISSUE CULTURE

Tissue culture is a relatively recent development. The first attempt to grow cells from higher plants and animals in nutrient media was made at the turn of the 20th century. In 1907 the U.S. zoologist Ross G. Harrison successfully demonstrated the growth of frog nerve cell processes in a medium of clotted lymph. Thereafter a number of experimenters succeeded in cultivating animal cells, using as culture media a variety of biological fluids, such as lymph, blood serum, plasma, and tissue extracts to support cell growth and functions that could not be maintained in synthetically processed media.

Techniques for examining cells

Cells in culture can be examined directly by light microscopy or by the techniques of photomicrography and cinephotomicrography; in the latter, time-lapse motion pictures are taken through the microscope, permitting visualization of the movements of cells and their component parts. Cells in culture can also be fixed, *i.e.,* treated with agents that kill the cells but preserve many of their structural features. The cells can then be studied by selective staining of specific structures, or they can be sliced into very thin sections, allowing otherwise hidden structural details to be revealed by the light microscope or the electron microscope. Finally, cells in culture can be examined by the techniques of biochemistry and immunology, such as analysis of protein composition, enzyme activity, and antigenic reactivity.

Cells can be cultivated in many ways—as layers or sheets, on glass or plastic surfaces, or as suspensions in liquid or semisolid media. In general, only cancer cells multiply readily in suspension. While some kinds of cells, including many cancer cells, apparently can be perpetuated forever in tissue culture, most normal somatic cells can be cultivated only for approximately 50 or 100 generations, after which time their rate of multiplication slows markedly. The cause of this "aging" is not yet understood, but the phenomenon itself does not impose severe limitations on the culture of normal cells since even before the growth process begins to decline, many billions of cell progeny can be produced in the test tube, furnishing an enormous supply of cells for experimental studies. Furthermore, cells can be stored in viable condition at extremely low temperatures and can be reinitiated into active growth after many years without apparent change in structure or behaviour. Mixtures of synthetic materials supplemented with small amounts of blood serum or its macromolecular components are now readily available for use as nutrient media in which cells can be grown at rapid rates for long periods of time. It is necessary, of course, to maintain sterile conditions so as to prevent contamination of either cells or culture media by microorganisms such as bacteria and fungi. A typical photomicrograph of a cell culture growing as a sheet one cell thick is shown in Figure 1.

Cultures may be initiated from tiny samples of an extremely large variety of tissues. The tissue may be minced with scissors or dispersed by means of an appropriate enzyme, which digests the intercellular cementing substances, leaving single cells or small clumps. This material, called the inoculum, is then deposited in dishes containing nutrient medium. The cells usually attach to the dish and grow out from the initial inoculum. In order to maintain a suspension culture, the liquid medium may be continuously agitated, or its viscosity may be increased by the addition of materials such as agar. Cultures generally are incubated at a temperature close to that of the normal environment in which the cells originated.

TISSUE CULTURE AND SOMATIC CELL GENETICS

The limitations of classical genetics. One of the most important applications of modern tissue culture has been in the area of genetics and molecular biology of humans and other complex organisms. Classical genetics of humans and other higher organisms involves the mating of many pairs of selected individuals and the subsequent study of the distribution of particular characteristics among the offspring. The germ, or sex, cells carry out the reproduction process and eventually yield a complete new organism. Systematic study of characteristics passed down through such matings was initiated in the 19th century by the Austrian monk Gregor Mendel, who experimented with plant breeding. It was Mendel who founded the discipline known as classical genetics, which has yielded important information about hereditary processes in plants, insects such as the fruit fly (*Drosophila*), and, somewhat less ef-

Study of heredity

fectively, certain mammals, such as the mouse and the guinea pig. This experimental approach, however, has been far less successful in human research for two reasons. First, the time required for normal human reproduction is much greater than that required for, to cite a common example, the fruit fly, in which thousands of new offspring can be produced in a matter of days. Further, it is not possible to use human subjects to carry out the particular matings that would answer specific genetic questions. Consequently, as late as 1956, human genetics was still a primitive and incomplete discipline.

Origins of somatic cell genetics. Tissue culture made possible a new approach to the genetics of man and other complex organisms. The concept of somatic cell genetics, developed by Theodore T. Puck and his co-workers at the Eleanor Roosevelt Institute for Cancer Research and the Florence R. Sabin Laboratories of the University of Colorado School of Medicine, Denver, involves study of the genetics of the mammalian somatic, or body, cells rather than of the germ cells. Since each somatic cell contains a nucleus and its component chromosomes and genes, it appeared to these researchers that the necessity for human mating could be bypassed, and the much shorter reproductive cycle of cells substituted for the long time period necessary for reproduction of the entire organism.

This concept required adaptation and application of the basic methodologies of bacteriology to genetic and genetic biochemical analysis of the somatic cells of complex organisms. It also necessitated a series of new laboratory techniques. The first of these was the development of a simple, reliable procedure for taking tissue samples from any individual and culturing the resulting cells for long periods under conditions such that integrity of the chromosomal structure could be maintained. Also necessary was a technique whereby single cells could be grown into discrete colonies, visible to the unaided eye, in a simple operation applicable to thousands of cells simultaneously and under conditions such that every viable cell would produce a colony. It had been shown earlier by Katherine Sanford and her colleagues at the National Institutes of Health (NIH) that occasional single cells, when sealed in capillary tubes under stringently controlled conditions, could be made to grow into large populations. Subsequently, the single-cell plating technique was developed by which a similar result could be achieved for many thousands of single cells simultaneously in a simple, quantitative, reproducible, and routine operation (see Figure 2).

Next, means were devised by which mutant colonies can be recognized and cultured in new populations. These populations can then be used in genetic experiments in which a particular mutation is used as a genetic marker to trace the operation of hereditary mechanisms. Finally, it became necessary to identify each of the human chromosomes and to be able to analyze the chromosomal constitution of any cell culture. The first complete identification of each of the human chromosomes was carried out in Denver, and in 1959 the first human chromosome study group assembled there and devised the classification presently in use for the human chromosomes (see Figure 3). By the 1960s all of the essential elements for the new discipline of somatic cell genetics had been achieved, and a new means for study of the genetics of man and other mammals, based on cell growth in tissue culture, became available.

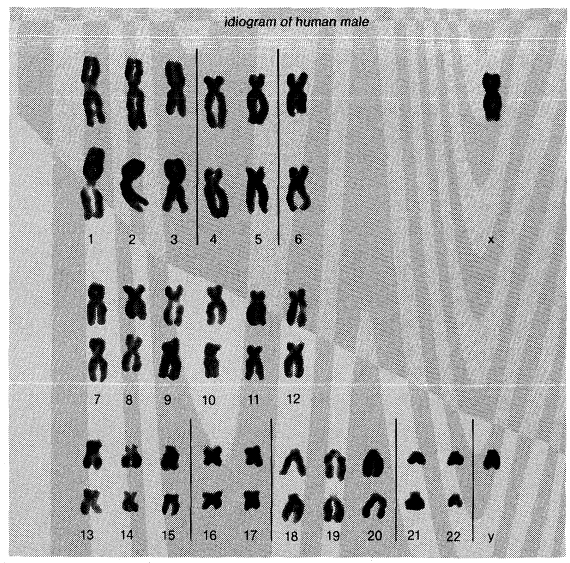

Figure 3: Classification of the normal human male chromosomes according to the internationally accepted system established in 1959.

APPLICATIONS OF TISSUE CULTURE

These developments in somatic cell genetics have made possible enormous gains in the understanding of genetic processes and structures in man and other higher organisms and have permitted application of the techniques of molecular biology to higher organisms in a fashion not previously possible. Clonal cell cultures can now be readily prepared from any individual, and single-gene mutants of cell cultures can be produced and developed into new clonal stocks. The effects of mutagens on mammalian and other kinds of cells has been studied; mutation analysis has made possible the delineation of the genetic–biochemical pathways underlying various metabolic processes; and

an impressive number of previously enigmatic human diseases have now been identified as being caused by changes in the number or structure of the chromosomes. Finally, prenatal diagnosis of such chromosomal diseases, as well as of a number of diseases due to single-gene mutations, is now possible.

Production of hybrid cells. Using tissue culture, researchers have developed a simple and convenient method for causing coalescence or fusion of cells, so that chromosomes from one cell can be added to those of another. This important technique made possible the creation of many kinds of hybrid cells. The process of introducing chromosomes from one cell into another constitutes a new kind of cell mating and has enabled the production of large numbers of different cell hybrids. Classical genetics permits mating and production of hybrids only between members of the same species. Hybridization in tissue culture permits hybrid formation between individual cells of widely different species and growth of large cultures of these new interspecies hybrids. Thus, one of the great barriers that sharply restricted the scope of classical genetic science has been eliminated. In one very important series of hybrid cells, single human chromosomes were incorporated into Chinese hamster (*Cricetulus griseus*) cells, allowing the functions of individual human chromosomes to be separately studied and defined (see Figure 4).

Hybrid cells

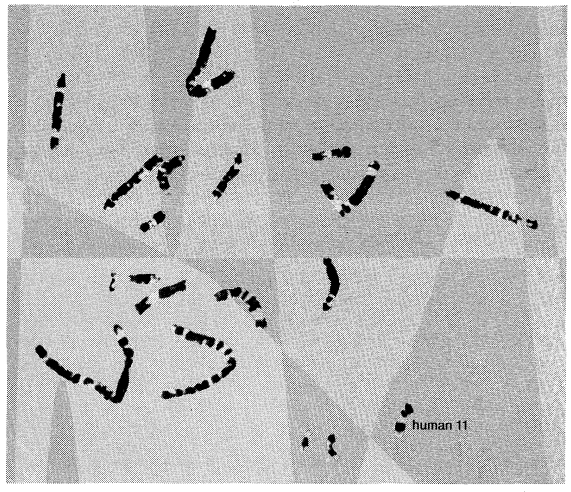

Figure 4: Chromosomes of a hybrid cell obtained by fusion of a Chinese hamster (*Cricetulus griseus*) ovary cell with a human cell to produce a new cell containing all of the chromosomes of the former and the single human chromosome 11.

Translating the genetic code. By means of somatic cell genetic studies in tissue culture great advances have been made in identifying specific human genes; examining their biochemical actions in normal and diseased developmental processes; determining their association with particular chromosomes; and mapping their positions on the chromosome with great precision. Such studies are making it possible for researchers to isolate particular human DNA fragments that carry the genetic code for specific proteins and to introduce these fragments into bacteria. In this way large numbers of such particular DNA fragments can be produced. The DNA segments are radioactively labelled and used as probes to diagnose the presence of genetic diseases, study gene regulatory phenomena, and facilitate identification of new protein molecules important to human health. Moreover, such proteins can then be synthesized cheaply and on a large scale by bacteria into whose genomes the critical DNA regions have been inserted. A new industry for fermentative synthesis of important biological molecules has been created as a result of these activities.

Tissue culture studies have also shown the existence of a considerable amount of DNA in the mammalian genome consisting of highly repetitive sequences that do not code for protein and whose function is unknown. Moreover, it has been demonstrated that the coding sequences in the mammalian cell are interrupted by noncoding DNA intervals, called introns, whose function remains to be elucidated. Studies in tissue culture have demonstrated the critical role of cell surface receptors, which act as targets in specific cells for different hormones, drugs, and other active molecules. These receptors mediate the characteristic actions of these all-important molecules on cell chemistry. Studies of cells in culture have revealed the specific molecular requirements for growth and other functions and demonstrated that different states of cellular differentiation have characteristic nutritional requirements. Specific cell membrane structures have been defined, and detailed biochemical and immunological properties of cell membrane elements have been demonstrated.

Research into cell structure, mutations, and cancer. Tissue culture studies have demonstrated the existence within mammalian cells of a universal cellular structure called the cytoskeleton; it consists of an integrated network of different kinds of fibres, some of which are rigid and some of which are contractile. This cytoskeletal system, which corresponds in some degree to the skeletal and muscular system of the body, gives the cells of each tissue their characteristic shape and is of critical importance in cell locomotion and ingestion of particles from surrounding fluid. In addition, however, the cytoskeleton regulates a variety of the cell's biochemical activities, including aspects of growth control that differentiate normal cells from some kinds of cancer.

The cytoskeletal system

In addition to the examination of normal cells, tissue culture has been used to study a variety of cell mutants produced artificially or obtained from patients with various genetic diseases; the nature of specific mutations responsible for particular diseases has thus been elucidated. Furthermore, methods for detection of environmental mutagens and carcinogens and for identification of cell mechanisms that repair genetic damage have been developed. These investigations promise important contributions to preventive medicine: identification of substances that may result in cancer and genetic disease is a necessary step in preventing exposure to such hazards.

Knowledge of the molecular biology of mammalian viruses has made major advances through the techniques of tissue culture. A crucial discovery has been the identification of a set of viral genes that play a critical role in cancer. Such genes, called oncogenes, are also present in normal cells but usually in inactive form; they can be activated under certain circumstances to produce cancer. In addition, specific chromosomal aberrations have been identified as being associated with various human cancers, among them a specific deletion in the short arm of chromosome 3 accompanying small-cell carcinoma of the lung, a deletion in chromosome 11 that is a frequent concomitant of Wilms' tumour of the kidney, and a deletion in chromosome 13 associated with a cancer of the retina. These examples illustrate how developments in tissue culture are uncovering basic phenomena at the cellular and molecular levels that promise dramatic advances in the understanding of body functions in health and disease.

Oncogenes

Contributions to immunological research. In the field of immunology, tissue culture studies have illuminated the extremely complex ways in which the two different subpopulations of the white cells of the blood, the so-called T cells and B cells, interact with foreign molecules and with each other. These cells produce the soluble antibodies responsible for protection against such infectious agents as viruses and bacteria and form the phagocytic cells that normally rid the body of pathologic cells. Production and identification of monoclonal antibodies; *i.e.*, antibodies consisting of a single molecular species that interact with a single molecular grouping, has been one of the great triumphs of tissue culture and somatic cell genetic methodologies. Another crucial insight into the immunological response resulting from the techniques for manipulating DNA is an explanation of how the body is able to produce a sufficient diversity of antibodies to confer protection against almost any kind of foreign protein (antigen). Experiments have demonstrated that genes specifying the code for that part of the antibody molecule that combines specifically with different antigens have huge potential for genetic recombination. Thus millions

of different gene combinations are possible, each of which can code for a different antibody. Each antibody is then capable of combining structurally with a different antigenic substance.

Use of single-cell survival curves. The development of single-cell survival curves, used to measure the doses of physical, chemical, or biological agents required to kill or alter mammalian cells, is another application of modern tissue culture techniques. The procedure involves placing measured numbers of single cells into a series of dishes in the same nutrient medium and exposing each dish to a different graded dose of the agent under investigation. The dishes are incubated at 99° F (37° C) and removed from the incubator after several days, and the number of colonies that have developed from each cell are counted. When the number of surviving colonies is plotted against the dose, as shown in Figure 5, a highly reproducible curve is obtained for each agent, from which the mean

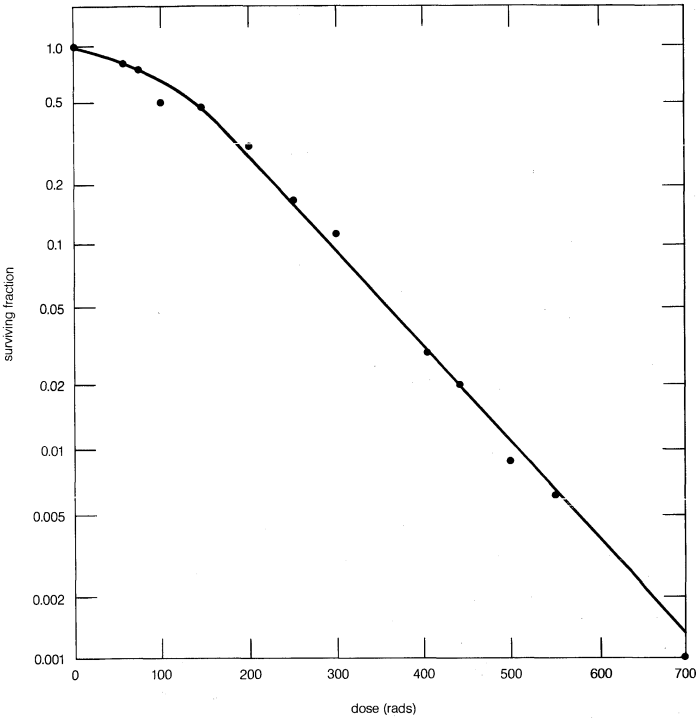

Figure 5: Single-cell survival curve showing the fraction of cells that retain the ability to form colonies after various doses of X-radiation. Survival curves of this kind offer a simple and reliable means for measuring the action of physical, chemical, and biological agents on the reproduction of mammalian cells.

lethal dose of the agent for that particular cell can be determined. This method made possible the first accurate measurements of lethal doses of different agents at the cellular level. Figure 5 represents the survival curve for human cells treated with X-radiation in tissue culture; this curve revealed that the previously accepted value for the cellular lethal dose of X-rays was more than 500 times too high. The development of these standards of measurement ushered in the era of quantitative mammalian cell radiobiology and made possible much more effective use of radiotherapy in medicine. Similiar curves have been plotted to demonstrate and analyze radiation repair processes at the cellular level; to establish mechanisms of action of chemicals, drugs, viruses, and antibodies; and to study cellular defenses against such toxins.

One noteworthy medical application of survival curves has been developed by Sidney Salmon at the University of Arizona (Tucson). In the treatment of cancer the physician often faces the dilemma of choosing the most effective chemotherapeutic agent for a particular patient. When single cells derived from a small sample of the tumour are grown in tissue culture, varying concentrations of different chemotherapeutic agents can be added to the cultured populations, and single-cell survival curves can be constructed for each agent under consideration. The physician can then select the therapeutic agent that produces the best specific response.

Future experimentation. A significant aspect of modern tissue culture developments is the possibility that these may resolve at least some of the ethical problems connected with the question of human experimentation in medicine. The availability of large numbers of new drugs and treatments and the necessity of monitoring toxic environmental agents make it mandatory that careful tests be devised for definitive evaluation of benefits and risks to man. The use of animal models is far from adequate in assessing human conditions. It now appears possible that animal testing for toxicity of biological agents and for other biological modes of action can be supplemented with tissue culture studies on human cells to produce far more definitive results with less human cost.

Application to plant cells

While tissue culture has been practiced for more than 50 years, the concepts and methods of somatic cell genetics—first developed in connection with mammalian cells—are now being vigorously applied to plant cells. Specifically, the concepts of new gene and chromosome insertions are being studied in an effort to improve nutritional properties of crops and to confer greater resistance to deleterious agents. Cereal crops, particularly rice and corn—upon which most of the human inhabitants of the planet depend—are relatively deficient in certain amino acids needed for human nutrition. It seems feasible, therefore, that the techniques of somatic cell genetics may be applied to the development of new strains, in which these deficiences can be corrected by incorporation of new genes into the basic plant genome. Such approaches appear promising and could materially affect the food problems of the world.

Tissues and Fluids

By definition, a tissue is a collection of cells having similar structures and performing special, as well as similar, functions. Those tissues, such as muscle, that consist almost entirely of cells devoted to a single purpose are known as simple tissues. Other tissues, such as those lining the alimentary canal (digestive tract) of higher animals, may serve a variety of functions; therefore, they are called composite tissues. Within the tissues and within their cellular components, circulating body fluids maintain the homeostasis of the organism. This article treats the nature, formation, and function of tissues and fluids in both animal and plant bodies. For a depiction of some of the tissues of the human body, shown in relation to each other, see the colour Trans-Vision in the *Propædia*: Part Four, Section 421.

The article is divided into the following sections:

The tissues and fluids of animals 669
- Classification of tissues 669
  - Tissues for assimilation, storage, transport, and excretion 670
  - Tissues for coordination 672
  - Tissues for support and movement 674
  - Other tissues and tissue fluids 675
- Blood and lymph 677
  - Definitions and origin 677
  - Plasma 677

THE TISSUES AND FLUIDS OF ANIMALS

Very early in the evolution of animals, different tissues tended to become aggregated into organs, and the organs themselves divided into specialized parts. The simple pouchlike outgrowth of glandular cells from the side of the alimentary canal of amphioxus, a primitive chordate animal, for example, is now represented in complex vertebrates by a separate liver, pancreas, and gallbladder. Thus, an animal can be considered as a collection of tissues that are often, but not always, united into organs and organ systems. The fluids that are produced by tissues and in which they are bathed usually are considered as tissues only when they have a definite and continuing cell content.

Classification of tissues

Anatomical classification. The classification of tissues has always been determined by the methods available for their study. Hence, because early investigators were accustomed to dividing an animal body into its organ systems, tissues were first classified anatomically according to the organ system from which they came—*i.e.,* nervous tissues, digestive tissues, reproductive tissues, and so on. This system proved inadequate, however, when it became obvious that there were more tissues than could be accounted for by the few types that were peculiar to a specific organ system. This realization led to an attempt to classify tissues according to the cell types of which they are composed: tissues composed of epithelial cells covered the outside of organs; those composed of endothelial cells lined the inside of organs; and those consisting of stroma cells were thought to serve as a functionless matrix in which other functional cells were embedded. Tissues that did not have an obvious function were collectively called connective tissue because it was thought that their sole purpose was to connect one type of cell to another. This category included the elastic tissue of tendons, the cartilage of joints, the main skeletal elements, and even blood, although there appears to be no logical connection in structure or function between blood and bone. Despite such seeming inconsistencies, however, this method of classification was useful in drawing attention to the similarities that occur throughout the animal body. A particular type of epithelial cell, for example, may be found in many different locations and in many kinds of organs.

Inadequacies of classification systems

Embryological classification. The great surge in structural embryology (the study of the formation and development of the embryo in plants and animals) that occurred when tissues were being classified according to cell types led to a system of tissue classification based on embryological origin. In the course of embryological development in most animals, it is fairly easy to recognize those cells that originate on the outside of the embryo (ectodermal cells), those that originate on the inside of the embryo (endodermal cells), and those that lie between the inside and outside of the embryo (mesodermal cells). This classification, although valuable for the information it reveals concerning evolution, is of far less value when applied to specific tissues. The epidermal and mesodermal elements of skin, for example, are confused; how far back the mouth ectoderm goes by infolding before true endoderm starts has been the subject of endless semantic arguments.

Functional classification. The most useful of all systems is to classify tissues according to the functions that they perform. On this basis tissues can be divided into three distinctive classes and a miscellaneous class. One of the distinctive classes contains those tissues that are used for assimilation, storage, transport, and excretion of food or waste products—*i.e.,* those tissues that serve an animal's needs for growth, repair, and energy. Involved in assimilation are the alimentary tissues, which not only break down food products to derive energy but also transform energy into utilizable sources that can be stored and released as required (see DIGESTION AND DIGESTIVE SYSTEMS). In any but the smallest animals the products secured by the alimentary tissues or liberated from the storage tissues are transported to other areas of the body, a function that is performed by blood and lymph. The role of tissues such as those in the lung and kidney is to excrete waste products from the body.

Figure 1: Photomicrographs of epithelial cells.
(Left) Simple columnar epithelium of small intestine showing striated (grooved) border. (Centre) Stratified squamous epithelium of the skin of the fingertip. (Right) Ciliated epithelium from the alimentary tract of a mussel.
Don W. Fawcett, M.D.

Another group of tissues classified according to function contains those used for coordination. This group includes those tissues that coordinate the organism in relation to its external environment as well as those that coordinate the parts of the organism internally. External coordination is performed by the central nervous system (brain and spinal cord) and its associated sense organs; internal coordination, though aided by the sense organs, is largely the responsibility of the chemical secretions (hormones) of specialized endocrine glands.

The third distinctive group of tissues according to the functional classification contains those required for support and movement, the skeletal and muscular tissues. The fourth group includes tissues used for reproduction; the hemopoietic tissues, which are concerned with the production of blood cells; and tissue fluids.

TISSUES FOR ASSIMILATION, STORAGE, TRANSPORT, AND EXCRETION

Alimentary tissues. The principal tissues involved in assimilation lie along the alimentary canal, the anterior end of which is the mouth. Lining the mouth is a simple form of covering tissue, or epithelium, known as squamous (scaly) epithelium because it consists of flattened, overlapping cells. It is also called stratified epithelium because there are several layers of cells. In such an arrangement, which is necessary in an area of rough usage like the mouth, cells that are detached from the surface can be replaced quickly by those underneath. Because they are in direct contact with the air, these tissues must be kept moist. Interspersed among the epithelial cells, therefore, are numerous cells that secrete a slimy fluid called mucus. In many animals these cells are aggregated into small glands. Surface tissues (epithelia) containing mucous cells are called mucous membranes; irrespective of the type of epithelium involved, such membranes line the entire alimentary canal.

Tongue and salivary glands

The mouth of terrestrial animals also contains the tongue, which is the main food-gathering organ of many amphibians, some reptiles, and even a few mammals. Regardless of the organism, the interior of the tongue invariably consists of a mass of well-vascularized (blood-filled), interlacing muscle fibres; the tissues covering the surface of the tongue, on the other hand, differ from one group of animals to another. The squamous epithelium on the upper surface of most, if not all, animals is cornified epithelium; it is capable of producing keratin, the tough material that comprises horns, hooves, and nails. The surface of the mammalian tongue contains pits that extend down to the underlying mucus-producing tissues, from which arise pillars of various shapes. With this arrangement, sensory nerve endings in the pits can be kept constantly moist; yet, the organ itself is so tough on the surface that it can be used for scraping or rasping.

Mammals require such large quantities of mucus to moisten food and to protect oral membranes that they have developed specialized glands, the salivary glands, with ducts leading into the mouth. Anatomically, these glands are botryoidal; physiologically, they are merocrine; and biochemically, they are mixed. These terms also apply to many other glands. A botryoidal gland is one with many branching ducts, each of which finally terminates in a hollow spherical gland, thus giving the appearance of a bunch of grapes. A merocrine gland is one in which no part of the cytoplasm (the part of a cell exclusive of the nucleus) of the secreting cell is lost; all the granules of the secreted product pass through the cell membrane and into the lumen (cavity) of a duct, in which they are dissolved and distributed. A mixed gland is one that produces a number of products; thus, the salivary glands yield a serous fluid called mucus, which is a dispersion of a protein in water, and small quantities of the digestive enzymes ptyalin and maltase. (Enzymes are proteins that control chemical reactions in living matter.) The total of all these secretions is saliva, the importance of which is indicated by the fact that its daily output in man exceeds that of urine.

Esophagus and stomach

After leaving the mouth, food passes down the esophagus, a muscular tube that histologically—*i.e.*, in terms of its tissue structure—is little more than an extension of the mouth. Internally, the esophagus is lined with a thick coat of the same type of stratified squamous epithelium as is found in the mouth. There is a longitudinal layer of striated muscle (muscle in which the bands, or striations, represent areas of different composition), the contractions of which control swallowing, and a thin circular layer of nonstriated muscle that is separated from the epithelium-lined lumen by a cushion of connective tissues. The esophagus enters the stomach, an organ of variable tissue construction in different animals; it is primarily a sack, or a series of sacks, that holds, churns, and partially digests the contents. In the human stomach the entire inner surface is covered with a simple columnar-shaped epithelium from which thousands of pits, or gastric glands, descend into the underlying layer of connective tissue. In the stomachs of some animals the glands are confined to small areas, and much of the inner stomach wall is composed of stratified squamous, and even occasionally keratinized, epithelium. The outer stomach wall consists of three layers of nonstri-

ated muscle fibres that run longitudinally, circularly, and diagonally.

Interesting tissues in the stomach are the gastric glands, which are simple in structure but complex in cellular makeup and function. In most organisms the glands are S-shaped tubular structures, but sometimes they are branched. The cells forming the glands are of four types. In the gastric pit, the part of the gland that opens into the stomach, the cells resemble the general epithelial lining and are active secretors of mucus. Just below the pit is the isthmus, a section of the gland containing a few mucus-producing cells and many hydrochloric-acid-secreting ones; the acid is necessary in the digestive process. Between the isthmus and the base of the gland is the neck, which contains additional mucus cells and a few that produce hydrochloric acid. The base of the gland consists mostly of cells that secrete an enzyme that catalyzes the breakdown of proteins in the stomach; the base also includes several of another type of cell, the exact function of which is still in doubt.

Small intestine

After partial digestion in the stomach, from which only a very few simple substances are absorbed, the food passes to the small intestine. In higher vertebrates all the tissues and structures of the small intestine are modified for the sole purpose of absorption, which is a direct function of surface area. The inner wall of the small intestine consists of a series of connecting ridges. Arising from the ridges are millions of finger-like projections called villi, the centre of each of which contains blood vessels that remove absorbed materials. The tightly packed epithelial cells covering the villi are themselves covered with even smaller projections (microvilli). This combination of villi and microvilli results in a total absorptive surface of the small intestine that is approximately 10,000 times greater than that of a smooth tube. The tissues of the remaining length of the alimentary canal are primarily devoted to the recycling of water. They do not have villi and are usually covered with a simple epithelium containing numerous mucus-secreting cells.

In lower vertebrates the glands that produce the enzymes necessary to convert food substances into absorbable molecules are found along the entire length of the small intestine. In all higher forms, however, the larger surface area creates a greater demand for enzymes. As a result, the glands are located in a completely separate organ, the pancreas, which, in tissue structure and secretory function, closely resembles a salivary gland.

Digested food materials of all types, as well as undigested droplets of fat, are picked up by the blood from the small intestine and transported to other parts of the body either for storage or for immediate use. Fat is stored in fat cells, which develop from undifferentiated cells in connective tissue. At an early stage of their development, the undifferentiated cells become filled with small fat droplets; later, these coalesce into a large single fat droplet. In some lower vertebrates, particularly amphibians, fat cells are localized, forming fat bodies that are distinct from the surrounding tissue. In most higher forms, however, fatty (adipose) tissue is dispersed throughout the body, although fat cells do tend to aggregate into fat masses in certain areas, particularly in the layers beneath the surface of the skin.

Fatty tissue

Liver tissues. The bulk of nutrient-bearing blood goes to the liver, which is probably the most important single tissue in the maintenance of the mammalian body. The evolutionary mechanism by which the liver reached this important function is not entirely clear. Many invertebrates and such lower vertebrates as amphioxus have outgrowths from the anterior region of the alimentary canal, apparently for the purpose of increasing the secretory area. In the cyclostomes (*e.g.,* lamprey, hagfish) the lumen of a much-branched outgrowth remains open; hence, the liver in these animals is a series of intercoiled tubes. In higher forms, however, there is no lumen; instead, the liver consists essentially of many-sided (polygonal) cells so closely pressed together that all trace of a tubular origin is lost. The cells cluster about much-branched blood vessels, from which phagocytes (cells that ingest and destroy foreign materials) migrate and become interspersed among the liver cells. There is also a network of branching ducts, originating as intercellular spaces, that collect bile (a fluid secreted by the liver that aids in digestion) and form the bile duct, which leads to the gallbladder. Despite the fact that they perform a multiplicity of functions, all liver cells appear to be of the same type.

When blood reaches the liver from the small intestine, its carbohydrate content is adjusted either by the removal of excess sugars and their conversion to glycogen particles that are stored in the liver or by the addition of sugar through the breakdown of previously stored glycogen. Poisonous substances carried by the blood are either detoxified, if possible, or removed from the blood and stored. Partially broken down erythrocytes (red blood cells), arriving from the spleen at the rate of about 3,000,000 per second, are picked up by the phagocytes and broken down further; the breakdown products are either recycled or, as in the case of excess pigments, excreted through the bile. Liver cells also control the synthesis and distribution of fat in the form of large molecules composed of both lipid and protein (lipoprotein); the synthesis of all proteins in blood plasma; and the synthesis of urea, a nitrogenous waste that is subsequently excreted by the kidney.

Blood and lymph. To refer to blood as a tissue is a semantic, not a scholarly, definition, because in some invertebrates (*e.g.,* annelids) the blood is almost acellular (lacking in cells), and in the great majority of invertebrates it contains at the most only a few leukocytes (white blood cells). Only at the vertebrate level do the oxygen-carrying pigments of the blood become localized in specific blood cells, and only at the mammalian level do they lose their nuclei. The acellular portion of blood is called plasma when it is in a blood vessel and lymph when it passes out through the walls of capillaries (tiny blood vessels) to bathe the cells in surrounding tissues (see below *Blood and lymph*).

Respiratory pigments

The most important function of blood is to carry oxygen, which is transported by a respiratory pigment; the best known pigments are the hemoglobins. These compounds, which contain iron, are found in all vertebrates and also in many annelids, insects, and a few mollusks. Other respiratory pigments include the hemocyanins, which contain copper, and the hemovanadins, which contain vanadium. All of these pigments function in much the same manner: they pick up oxygen from the air and transport it to the cells, where it is released. The blood of most animals also contains leukocytes of various forms and functions.

Blood plasma contains approximately 7 percent dissolved proteins, including the globulin fraction, which is of great immunological importance; other constituents include nutrients and hormones. The most important function of plasma is to maintain a proper fluid balance among the various tissues of the body. The lymph that passes through the walls of capillaries and bathes the tissues collects in lymph vessels and is recycled back into the bloodstream.

Kidney tissues. The original function of the vertebrate kidney was to remove water from the body cavity (coelom) of aquatic animals. The primitive kidney consisted of little more than a longitudinal duct opening at its posterior end into the cloaca (a passage into which waste products are discharged) and contained at its anterior end a series of funnels with cilia (lashing hairlike projections) to remove the excess fluid. This type of kidney is found in the larvae (*e.g.,* tadpoles) of many vertebrate animals. Early in the evolutionary history of aquatic vertebrates a tissue was developed that permitted excess blood fluids to be removed by a similar mechanism: a small, tangled mass of capillaries (the glomerulus) entered a pouch in the side of the longitudinal coelomic duct. With the adaptation of early vertebrates to terrestrial life, however, it was necessary that water be conserved; the coelomic funnel disappeared, and the glomerulus with its pouch (Bowman's capsule) no longer led directly into the excretory duct but into a highly complex series of tubules designed to concentrate and recycle water while permitting the removal of some water-soluble wastes.

Adult vertebrates known as the anamniota (fishes and amphibians) have a kidney structure very much like that of the embryo; the adult kidney of amniotes (reptiles, birds, and mammals), however, is derived from the pos-

terior end of the embryonic kidney (see EXCRETION AND EXCRETORY SYSTEMS). In the anamniotic kidney, venous blood goes directly into a large sinus (a cavity or hollow space within a structure of the body). Located in this sinus are branched, tangled tubules, each of which terminates in a Bowman's capsule containing arterial blood that comes directly from the heart through a series of branches of the main artery in the body. After its passage through the glomerulus, the arterial blood empties into the sinus, which, at its anterior end, drains into a large vein.

Embryonic amniotes have a very similar structure, but a pouched outgrowth from the posterior end of the collecting tubule develops completely new units around it. This outgrowth becomes the ureter (the duct that carries urine from the kidney to the urinary bladder), and the pouch becomes the renal pelvis (a saclike cavity at which the ureter is attached to the kidney). The excretory units (nephrons), each of which consists of a Bowman's capsule, glomerulus, and tubule, then develop in the surrounding tissue and become attached through one or more branches to the renal pelvis. Arterial blood enters the kidney through the renal artery directly from the dorsal aorta (the main posterior artery from the heart). It then passes through arterioles (tiny arteries) to the glomerulus in the Bowman's capsule; a great deal of water and all but the largest molecules in the blood are forced through the walls of the glomerulus by the high pressure of the blood. (The human kidney excretes about 7.5 litres [two gallons] of water an hour through the glomeruli; of course, most of this is subsequently reabsorbed.) Blood leaves the glomerulus through another set of arterioles that form a network of capillaries around the coils of the kidney tubules; it then returns to the heart through the venous system.

Nephrons

Histologically, the kidney tubule is divided into three parts: a thick proximal section that is adjacent to the Bowman's capsule and consists of columnar or cubical epithelial cells with large numbers of microvilli on their surface; a distal portion of very similar structure that leads to the collecting duct; and, between the two, a long, but variable, length of thin-walled tubule. The proximal portion of the tubule has the dual function of reabsorbing materials to be recycled—*e.g.*, water, glucose, amino acids, ascorbic acid, sodium, chlorides, and bicarbonates—and of removing from the blood in the arterioles surrounding the tubule those substances that do not pass through the walls of the glomerulus. The thin-walled portion of the tubule further concentrates the urine, and in the final convoluted section the water, sodium, and phosphate contents of the urine are adjusted to the requirements of the body.

Apart from the capillaries and tubule cells described, there are a few specialized tissues in the kidney. Located around the neck of each arteriole, where it enters the glomerulus, is a cuff of juxtaglomerular cells; these are thought both to control the flow of blood into the glomerulus and to secrete an enzyme. Another interesting cellular adaptation is the presence of podocytes in the walls of the Bowman's capsule. As the name podocytes indicates, these are "footed" cells that protrude from the wall of the capsule and press against the glomerulus, thereby improving fluid flow by maintaining a clear space between the blood vessels of the glomerulus and the wall of the capsule.

Lung tissues. Animal tissues to secure oxygen and excrete carbon dioxide are extremely variable (see RESPIRATION AND RESPIRATORY SYSTEMS). In many small invertebrates, gas exchange takes place directly through the body wall or through external gills, which are thin, often tufted extensions of the body wall through which the blood circulates. The protected gill first appears in the pelecypod mollusks (*e.g.*, clam, oyster, scallop); it is a folded sheet of parallel anastomosing (connecting) blood vessels that are covered first by the mantle (the tissue covering the soft body organs of a mollusk) and then the shell. Adaptation for life on land, however, required the development of the lung, an internal sac with a heavily vascularized wall into which air could be drawn and from which waste gases could be expelled by the expansion and contraction of adjacent structures. The first such organ appears in the gastropod mollusks (*e.g.*, snail, slug, whelk); an analogous structure, in the form of an outgrowth from the anterior end of the alimentary canal, was developed by the lungfish and persists in most adult amphibians, in which the walls of the sac begin to show folding. The increased demand for oxygen occasioned by rapid movement on land resulted in the evolution of multilobed, heavily vascularized lungs in reptiles, birds, and mammals. Gases were inhaled and exhaled first by the simple contraction of the thoracic (chest) walls and later with the assistance of the diaphragm (a muscular partition that separates the thoracic cavity from the abdominal cavity).

Respiratory structures in animals

Two other mechanisms for gas exchange were developed by the arthropods (*e.g.*, insects, spiders, crustaceans). In scorpions the interior surface of a series of four pairs of ventral pouches is folded into a number of lamellae (thin plates). Because of the pagelike appearance of this arrangement, it is called a book lung. In insects and a few other groups (*e.g.*, onycophorans and centipedes), thin-walled ducts, supported by rings of chitin (a horny substance), conduct atmospheric gases to small pouches that are in direct contact with tissues. That this system is extremely efficient in small animals is indicated by its ability to meet the extraordinary oxygen demands of, for example, the flight muscles of many insects. But because it cannot be adapted to large organisms, terrestrial arthropods that use this system have never reached the sizes attained by those animals that have lungs.

TISSUES FOR COORDINATION

None of the tissues so far described would be able to function satisfactorily were they not coordinated in relation to both the external and the internal environment of the animal. Coordinating tissues are broadly classified into those that are physical (nervous and sensory tissues) and those that are chemical (endocrine tissues).

Physical coordinators. It may be stated as a broad generalization that both physical and chemical coordination in invertebrates are performed by the same tissues, because the nervous tissues of many invertebrates also serve as hormone sources. (Hormones, chemical substances secreted into the bloodstream by endocrine glands, have specific effects on other organs.) In vertebrates most endocrine functions are isolated in specialized glands, several of which, such as the pineal and hypophysis in the brain, are derived from nervous tissue. The basic unit of all nervous tissue is the neuron, which, with few exceptions, consists of a cell body from which protrude numerous branching cytoplasmic processes (dendrites) and one long fibre (the axon). The dendritic fibres act as interconnections between neurons; the axon either transmits impulses to an organ (efferent axon) or collects impulses from sensory organs (afferent axon; see NERVES AND NERVOUS SYSTEMS). Internally, the cell body of the neuron contains considerable quantities of what were once called Nissl bodies, which consist of stacks of rough-surfaced endoplasmic reticulum (a convoluted membranous network in cells) with large numbers of ribosomes (granular structures consisting of protein and ribonucleic acid—RNA) sandwiched between them. The presence and structure of the Nissl bodies indicate that RNA plays a major role in the functioning of the nerve cell and is probably responsible for the storage of information (memory). Aggregations of neurons are known as ganglia.

The neuron

In addition to neurons, and also associated with the central nervous system, ganglia, and the axon itself is a tissue that may be either in the form of glia cells or Schwann cells. The former, which are also known as neuroglia cells, constitute a special type of connective tissue that is interspersed among nerve cells and fibres. The Schwann cells are large, flattened cells that are wrapped in such a tight spiral around the axon that most of their cytoplasm has been squeezed out through their membrane. In effect, the axon is wrapped in many layers of membrane with only a little cytoplasm on the inner and outer surfaces. Membranes have a central lipid (fatty) layer; the nerve, therefore, is covered by an insulating layer of lipids that is commonly known as the myelin sheath.

There are three principal types of neuroglia cells: astrocytes, which, as the name indicates, are star-shaped cells with numerous branches at their ends; oligoglia (also

Types of neuroglia cells

called oligodendroglia or oligodendrocytes), which have fewer but thicker branches than astrocytes and are generally smaller; and microglia, which are the smallest of the three. It was once thought that these cells serve merely as connective tissue to support neurons. Evidence is accumulating, however, that they may play a more active role not only in transmitting nutrients and forming enzymes but also in the conduction of neural impulses. Because the short ends of some oligoglia are wrapped tightly around the capillaries in the brain, they could form a direct conducting path for hormones. The astrocytes become active principally when there is neural damage, at which time they assume a phagocytic function.

A slice across the brain or spinal cord shows it to be divided into two regions, descriptively called gray matter and white matter. The former, which is on the outside of the brain and on the inside of the spinal cord, contains the neurons; the white matter owes its appearance to the lipid content of the myelin sheaths around the nerves of which it is largely composed. A typical neuron has about 100 dendritic branches; these may form junctions (synapses) either with dendritic branches from other cells (axodendritic synapses) or with the surface of another neuron (axosomatic synapses). Impulses originating in one neuron may or may not be transmitted through the synapses to other neurons; the mechanism of such selective transmission, on which depend thought, reason, and memory, is not at present fully understood.

A neuron not only receives and transmits impulses to other dendrites but it may also receive an impulse from a sense organ in an outlying part of the body or transmit an impulse to an outlying muscle. The bundles of axons through which these impulses are carried are called nerves. At the terminal end of a transmitting axon in, for example, a muscle, there is a short spray of branches known as axonal telodendria, each of which terminates in a structure called a bouton. When an impulse reaches the boutons, they secrete the chemical acetylcholine, which, because the boutons are in molecular contact with the membrane of the muscle, causes the muscle to contract. Although the nerves leading to the abdominal muscles of the viscera are structurally similar, they operate by a different method. Because visceral muscles are not anchored to joints or bones, they are in a constant state of partial contraction, and movement is produced either by increasing (exciting) or decreasing (depressing) this state. The excitatory nerves mediate their action through the release of acetylcholine; the depressant nerves, through the release of adrenaline or noradrenaline.

There are a few specialized types of neurons in the central nervous system. In many invertebrates and vertebrate larvae, giant neurons carry impulses directly across areas at which they would otherwise be interrupted. Another highly specialized type of giant neuron, the Purkinje cell, lies at the junction of the cerebral cortex and the medulla of the cerebellum, an area in the brain that coordinates locomotor functions and is most highly developed in birds and mammals. Each Purkinje cell has many dendritic branches that ramify through the whole of the outer (molecular) layer of the cerebral cortex. The only afferent nerves leaving the cerebral cortex are those that are made up of the axons of Purkinje cells. In the inner (granule) layer of the cerebellar cortex are large numbers of small granular cells, the dendritic branches of which receive impulses from the axons of incoming (afferent) nerves. Each granular cell has a single axon that rises vertically through the molecular layer and then divides into two branches that run in opposite directions and synapse with the dendrites of some of the Purkinje cells. The union of all the Purkinje cells with the granular cells, which has been likened to a telephone distribution system, is the mechanism for the transmission of the extremely complex nervous impulses required for the locomotor responses of mammals and birds.

Afferent nerves (those that conduct impulses toward the brain and spinal cord) reaching other areas of the central nervous system come from sense organs (receptors) that receive either internal or external stimuli. For higher animals the most important of these are the photoreceptors, the light-sensitive nerve endings located in the rods and cones of the retina of the eye (see SENSORY RECEPTION: *Photoreception*). Chemoreceptors, or taste buds, usually consist of two types of cell pressed together into a small, pear-shaped Y. The receptor cells, which are elongated into an apical process that is in contact with the medium to be tasted, are heavily innervated by terminal buds of the afferent nerves; they are separated from each other by the sustentacular (supporting) cells that lie beneath the surface and are not innervated. There is considerable argument as to whether the human perception of sweet, sour, salty, metallic, and bitter are sensed by the same nerve endings or by different ones; there is still more argument as to which of these senses are present in lower vertebrates. Catfish have "taste buds" in slender projections on their lips, called barbels, and insects have very similar structures both in their antennae and, in the case of butterflies, in their feet (see SENSORY RECEPTION: *Chemoreception*).

Chemoreceptors

The vibroreceptors (those sensitive to mechanical vibrations) apparently are present in relatively few animals. Except for the ear, the most developed of such organs are located in the fish, in which they extend in lines along the length of the body (see SENSORY RECEPTION: *Mechanoreception*). Although the function of sensory structures in animals other than man is difficult to determine, it appears that most organisms possess heat and cold receptors, which are different organs; each apparently consists of a single cell permeated by a terminal treelike branching of a nerve. Pressure sensors, on the other hand, usually consist of a fluid-filled cavity and several cells bunched around the end of a nerve. In man these receptors, called Pacinian corpuscles, are very large (up to four millimetres, or 0.2 inch); they are found in the deeper layers of the skin and throughout the body, at points at which pressure sensation is necessary—*e.g.*, joints, tendons, ligaments.

Chemical coordinators. In many invertebrates chemical stimulators are secreted by the neurons themselves and then move to their place of action along the axon. Such is the case with the hormone in crustaceans that controls the lightening or darkening of the body in response to the environment. The hormonal activities of neurons, however, are nowhere better shown than in the insects, the principal endocrine glands of which are the corpora allata (wing-shaped bodies) and the corpora cardiaca (heart-shaped bodies) that lie alongside the brain. Neurons in the brain secrete large colloidal (jellylike) granules that pass beyond the axon to the heart-shaped bodies and then to the wing-shaped bodies. Some evidence indicates that these colloid granules are also liberated directly into the hemolymph (the fluid in invertebrate tissues and body cavities).

The principal endocrine tissues of the higher vertebrates are the thyroid gland, parathyroid glands, endocrine constituents of the pancreas, interrenal chromaffin tissues of the adrenal gland, and the pituitary gland (see ENDOCRINE SYSTEMS). Of these the thyroid gland presents the clearest evolutionary and histological picture. In mammals this gland secretes not only the hormone thyroxine (tetraiodothyronine) but also smaller quantities of another hormone, triiodothyronine; both have a powerful effect on both rate of maturation and general metabolism. A similar product (monoiodotyrosine) is synthesized by many algae, and both monoiodotyrosine and diiodotyrosine are found in all invertebrates, in many of which the synthesis is apparently centred in the pharyngeal region (the portion of the digestive tract lying between the mouth and the esophagus and forming the respiratory organs of aquatic vertebrates). In the most primitive vertebrates (the cyclostomes) there appears, as an outgrowth of the pharyngeal region, an exocrine gland (one that secretes through a duct, as for example, the digestive glands) that is not unlike a salivary gland in structure. In all higher forms, embryological development of the thyroid gland begins with a duct connected to the pharynx, just as in the lower vertebrates. Ultimately, however, it becomes a ductless (endocrine) gland that is divided into lobes and lobules, which are small, spherical collecting pouches surrounded by cells that secrete the hormone into the lumen of the pouch. Blood vessels in the organ pick up the thyroxine and transport it around the body. The thyroid

Endocrine glands

is chemically linked to the pituitary gland by a system of negative feedback; that is, as the secretory activity of one increases, that of the other decreases.

The parathyroids are also pharyngeal derivatives that are represented in most teleost (bony) fishes by structures called ultimobranchial bodies and in higher forms by four small endocrine glands imbedded in the back part of the thyroid, two on each side. These glands, which have completely lost their lobular structure, consist of a tangled mass of cellular cords, the secretory products of which pass directly to capillaries. The secretions appear to have their principal effect on the calcium–phosphorus ratio in blood.

The endocrine portions of the pancreas (a large gland located behind the stomach that secretes digestive enzymes as well as hormones) are called the islets of Langerhans. In some lower vertebrates, however, the islets are individual glands, completely separated from the pancreas. Like the parathyroids, the islets also consist of tangled cords; they contain four kinds of cells that are designated by the first four letters of the Greek alphabet—alpha, beta, gamma, and delta. The alpha cells are filled with dense masses of granules that yield the hormone glucagon, which, because it is antagonistic to the hormone insulin, prevents the synthesis of glycogen, protein, and fat. The beta cells, which are the most numerous cells in the islets, also consist of large masses of granules that produce insulin, a hormone that controls the sugar (glucose) content of the blood. The function of the gamma and delta cells is not yet known.

Although in mammals interrenal and chromaffin cells are combined into the adrenal gland, the former being the cortex (outside) and the latter the medulla (inside), both tissues are quite distinct. (There are two adrenal glands in mammals, one associated with each kidney.) The interrenal tissues, which exist as separate glands in all vertebrates except birds and mammals, secrete hormones, of which cortisone is a typical example. The cells of these tissues are usually distinguished by the presence in their cytoplasm of large vesicular mitochondria (granular or rodlike bodies, which, in this case, contain fluid-filled cavities). Chromaffin cells, which occur in most animals as scattered clumps, secrete the hormones adrenaline and noradrenaline. The cells are large and ovoid, resembling neurons in all but their lack of axons and dendrites.

The pituitary, which has a dual origin and a dual function, is the most important endocrine gland of the body. It originates from two separate locations: one part, the adenohypophysis, develops as an upgrowth from the roof of the mouth; the other part, the neurohypophysis, develops as a downgrowth from the floor of the brain. The adenohypophysis is divided into three regions, the anterior lobe, the intermediate lobe, and a third lobe that connects to the neurohypophysis. Like most endocrine glands, the anterior lobe consists of tangled masses of cords with numerous types of secreting cells. The hormones secreted by this region mostly interact with the secretions from other endocrine glands to control the internal environment of the body. The neurohypophysis not only has direct axonic connections with the brain but also contains numerous neurosecretory cells (neurons that produce one or more hormones). The products of these cells pass directly to the anterior lobe, the activities of which they control. Thus, through the neurohypophysis the brain can control the secretions of the anterior lobe and thereby adjust the internal environment to the external environment, conditions of which are communicated to the brain by the sense organs. A typical example of such control is found in birds. When the brain becomes aware of increasing day length through impulses from the eye, it stimulates the neurohypophysis to secrete neurohormones. These, in turn, stimulate the anterior lobe to release hormones that cause the rapid development of the gonads, thus assuring that the bird will be in condition to breed in the spring.

Neurohormones

TISSUES FOR SUPPORT AND MOVEMENT

Connective tissues. Connective tissues hold the body together. Most such tissue is of the white fibrous type, which is divided into two kinds, loose and dense, although the two actually grade imperceptibly into each other. White fibrous connective tissue has several roles—it envelops and often penetrates organs to hold them together, encloses muscles, and forms a considerable proportion of the spongy layers of the skin. It is composed of a loose meshwork of a relatively inelastic fibrous protein (collagen), the fibres of which are interspersed in a gelatinous matrix that contains numerous leukocytes derived from the blood. When glandular organs contain considerable quantities of connective tissue—as do, for example, the spleen and thymus—the leukocytes increase in number and become star-shaped cells, the terminal processes of which anastomose to form a loose three-dimensional network. This is best seen in such invertebrates as flatworms, in which a stellate reticulum (a network of star-shaped cells) fills all the space not occupied by discrete internal organs. Mucoid connective tissue, which contains much more gelatinous substance than connective tissue, is found in all embryos as the initial stage in the development of connective tissue; and though rare in adult animals, it does form in the main bulk of such outgrowths as cockscombs and turkey wattles.

Connective tissue of great structural strength consists of almost pure collagen fibres arranged in parallel layers, as in tendons. In ligaments, fibres of elastin, a fibrous protein that is brownish in colour, are mixed with collagen fibres, in which case the tissue is often called yellow elastic connective tissue.

Cartilage. Although usually classified as connective tissues, cartilage and bone are better regarded as supportive in function. Cartilage is the product of cells known as chondrocytes, which secrete around themselves a clear, jellylike mass of a sugar-like substance containing sulfur (chondroitin sulfate). Cartilage of this type, which is found in the adult skeletons of cyclostomes as well as in small sharks and rays, is called hyaline cartilage. In larger sharks the deposition of calcium salts modifies the hyaline cartilage into calcified cartilage, which, because it resembles bone in composition but not in structure, must be clearly differentiated from bone. Another modified form of cartilage is fibrous cartilage, which grades almost imperceptibly into fibrous connective tissue at, for example, the junction of tendons with bone or cartilaginous joints. Elastic cartilage (Figure 2) contains yellow elastic fibres; one of the places at which this type of cartilage appears as a supporting structure is in the outer ears of mammals.

Chondrocytes

Cartilage is also found in some invertebrates, such as in the cranial capsule (head covering) of cephalod mollusks (*e.g.,* squid, octopus), but the principal skeletal substance of invertebrates is chitin—a hard, waterproof, inelastic nitrogenous polysaccharide. Among the animals in which it is found are cnidarians (*e.g.,* hydroids, corals, sea anemones), mollusks, bryozoans ("moss animals"), nematodes (roundworms), and acanthocephalians (spiny-headed worms) as well as the better known arthropods (see SUPPORTIVE AND CONNECTIVE TISSUES: *Varieties of invertebrate skeletons*).

Chitin

Bone. Bone is derived from cells called osteoblasts, which lay down crystals of calcium phosphate known as apatite, in bone. When calcium phosphate is deposited in connective tissue, the resulting structure is called direct bone; when it is deposited as a replacement for cartilage, the resulting structure is called indirect bone. Because the osteoblasts move into a thick, fibrous sheet of white connective tissue during direct bone formation, the somewhat misleading term of membrane bone is often used. At the beginning of direct bone formation, the osteoblasts produce columnar structures (trabeculae) arranged so as to provide the maximum support for the bone that forms on both sides. The space between the trabeculae is filled with red bone marrow. As the osteoblasts become encased in bone, they turn into stellate cells known as osteocytes, which maintain contact with each other through long, branching surface projections. Because the osteocytes cluster around blood vessels, a cross section through a bone appears as a series of concentric rings with a small opening in the centre, called the haversian canal; this opening is actually the space occupied by the blood vessel. Membrane bones, such as those of the growing skull, frequently change their shape with the aid of cells known as osteoclasts. Osteoclasts break down the existing bone

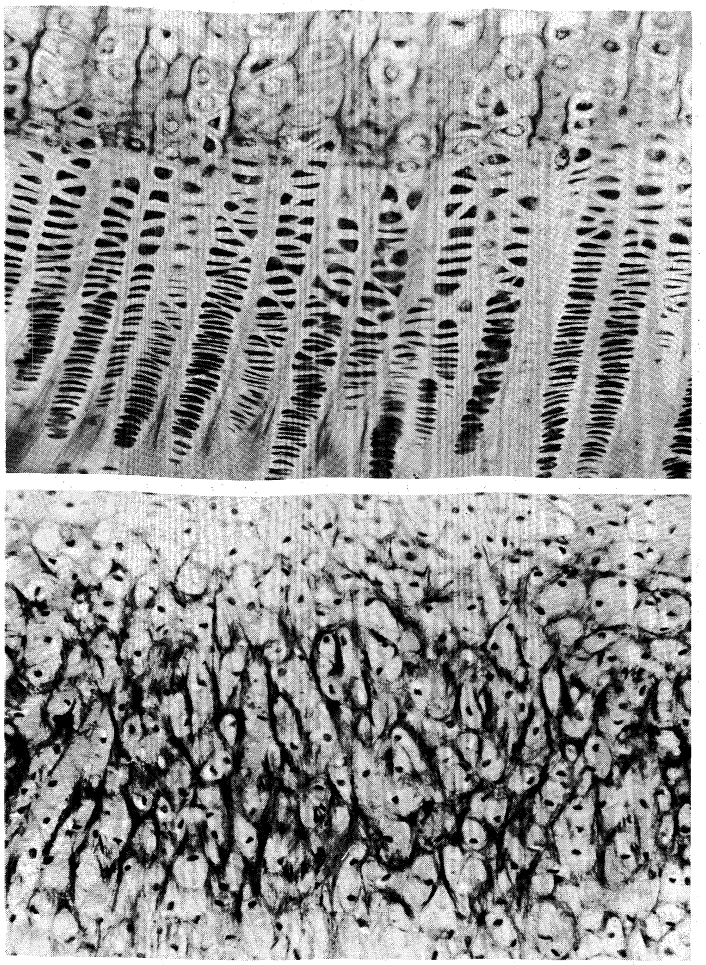

Figure 2: *Photomicrographs of cartilage.*

(Bottom) Elastic cartilage.
Don W. Fawcett, M.D.

into material that can be redistributed to new positions by osteoblasts.

Indirect bone formation, in which bone replaces cartilage (Figure 2), occurs in the shaft bones (those of the arms and legs) of all animals and in the jawbones of most of them. A cell known as chondroclast dissolves the chondroitin sulfate, leaving a soft mucus-like material into which the osteoblasts move. As in the case of direct bone formation, the osteoblasts first build internal trabeculae and then encase them with solid bone. On the shank of bones (the long portion between the ends) there is always a lamellar layer of bony plates wrapped around the outside.

Muscle. Muscle, a relatively simple tissue of complex function, has primarily two kinds of cells. One cell type, found in smooth muscle, contains one nucleus; it is controlled by the autonomic nervous system (the nerves outside the central nervous system that control involuntary body functions, such as breathing and digestion) and is concerned with the maintenance of the body's interior environment. The other cell type makes up striated (striped) muscle, which is also known as skeletal muscle; it is a multinucleate cell (cell with many nuclei) innervated by the central nervous system. Because the latter is under voluntary control, it can coordinate the organism with its external environment. Although cardiac (heart) muscle consists of striated cells (fibres) that are branched and interlocking, this type of muscle is under autonomic nervous control and has a unique system for the conduction of nerve impulses (see MUSCLES AND MUSCLE SYSTEMS).

Smooth muscle tissue generally occurs in simple sheets that are wrapped around, or run along, internal organs. At points at which the cell membranes are fused, the individual cells are interconnected by projections (called nexuses) that run from one cell into the other. Only a relatively few cells contain nerve endings, the impulses being transmitted from cell to cell through the nexuses. This arrangement can readily result in such rhythmic movements as the peristalsis (wavelike muscle contractions) of the intestine.

The striated cells that make up skeletal muscles are very different from those of smooth muscle cells. Each cell consists of numerous long, minute, threadlike structures (myofibrils) that are of two kinds: large fibrils composed of the protein myosin give rise to dark-banded striations; thin fibrils composed of the protein actin give rise to light-banded striations. The myosin bands are designated as the A bands and the actin bands as the I bands after the manner in which they refract (bend) light. When a muscle cell contracts, the thin actin fibres slip in between or coil around the thick myosin fibres; even when fully stretched, the actin fibres still slightly overlap the myosin fibres. This system permits a large degree of extension and contraction without breaking cytoplasmic continuity. Myofibrils

Because striated muscle cells have several nuclei, it is customary to refer to them as muscle fibres rather than cells. These fibres are grouped together into strands, each surrounded by a thin layer of connective tissue. The strands, in turn, are gathered into bundles that are connected by a thicker layer of connective tissue, and the bundles are held together as a muscle. At each end of a muscle the tissue is infiltrated by white fibrous connective tissue, which itself becomes a ligament for attachment. Unlike smooth muscle, in which only a few cells contain nerve endings, each fibre of a striated muscle is in contact with the terminal of an afferent nerve.

The muscles of the heart were, until very recently, regarded as a single large syncytium (a multinucleate mass of cytoplasm resulting from a fusion of cells). It now appears, however, that fine divisions do exist between the fibres. The muscle fibres in this organ branch and are interlaced; they continue to contract rhythmically long after all connections to the nervous system have been severed.

OTHER TISSUES AND TISSUE FLUIDS

Reproductive tissues. The most important of the reproductive tissues, the gonads (ovaries and testes), produce the gametes (eggs and sperm, respectively). These organs are simplest in the teleost fishes, in which each gonad consists of a simple closed sac, the anterior wall of which carries the spermatogonia (the precursors of mature sperm) in the male and the oogonia (the precursors of mature eggs) in the female. These gamete-producing cells are inactive except during the breeding season, when they proliferate so rapidly that the distended sac often occupies 60 percent of the total body space.

In all other vertebrates the testes develop as an independent body of tubules surrounding a lumen. The distal end of the tubules contains spermatogonia, and the resulting sperm accumulate in many different forms in a central area in the testes. The network of tubules leads to a duct that may, in some forms, have both a spermatheca (a small bulbous sac) for the accumulation of sperm and an ejaculatory pouch for the expulsion of seminal fluid (the sperm and the liquid secretions in which they are carried). In addition to the seminiferous tubules (those in which the sperm are formed), the testes of vertebrates contain interstitial cells (undifferentiated connective tissue cells lying between the testicular tubules) that secrete male hormones (Figure 3). In vertebrates the sperm duct (vas deferens) joins with the kidney duct (ureter) just before leaving the body. In some invertebrates, notably flatworms, the testes are diffuse structures, actually clumps of spermatogonia scattered throughout the body with ducts leading to a short vas deferens. Although many annelids (*e.g.,* earthworms) contain two or more pairs of segmentally arranged tests, the sperm still leaves the organism by a single duct. Male reproductive tissues

The principal features of the male reproductive system—testes and sperm duct—are common throughout the animal kingdom, but in all groups there are many accessory sexual glands, some of unknown function. In mammals the main accessory glands are the prostate and Cowper's gland. In the former, which is a mass of branched tubules embedded in a matrix of fibrous connective tissue, the secreting tubules open by numerous ducts into the urethra

(Top) Don W. Fawcett, M.D., (bottom) L. Zamboni

(the duct that conducts urine from the urinary bladder to the exterior); it is the excretion of the prostate that forms the main mass of seminal fluid. Cowper's glands also lead into the urethra; they consist of branched tubules that secrete a thick, viscous substance for which no useful function has yet been found in most mammals. In rodents, however, the substance forms a vaginal plug that apparently helps to keep the sperm in the vagina of the female.

Female reproductive tissues

In many animals in which fertilization occurs outside the body, the female reproductive system consists of an egg-producing gland (the ovary) and a tube (the oviduct) to convey the eggs to the exterior. In all vertebrates except bony fishes, no direct connection exists between the ovary and the oviduct; the latter terminates internally as an open funnel that is pressed against the ovary only at the time of ovulation (release of the egg from the ovary). In both oviparous and viviparous forms, the tissues of the oviducts are divided into specific areas for specific functions. In oviparous vertebrates (those that lay eggs) the upper portion of the duct is lined with a mucous epithelium containing simple tubular glands that secrete a dense albuminous fluid, a protein that constitutes egg white. As the egg twists in its passage through this region, each of the ends of the thick albumin is twisted into a chalaza, one of the two spiral cords for holding the egg in the centre of the shell. The next region of the oviduct contains two types of tubular glands that are sometimes branched. One set of these glands secretes additional albumin; the other set of glands secretes a substance that constitutes the liquid portion of the egg white. The next oviduct region lays down a coat of keratin as the base over which the next section deposits the calcareous shell.

In viviparous mammals (those who bear live young) the term oviduct is usually applied only to the region that lies between the internal funnel and the uterus (the organ in which the embryo and fetus develop). The tissues of this oviduct are quite simple, consisting of ciliated epithelium, with a few mucus-secreting cells, thrown into longitudinal folds that fill most of the lumen. At the time of ovulation the blood vessels in the oviduct become engorged with blood, and a circular band of smooth muscle contracts rhythmically so that the lip of the open funnel strokes the ovary and thus secures the egg. The epithelium of the uterus is also deeply folded and contains numerous blood vessels and mucus-secreting glands. The vagina is a simple tubular structure that, in virgins, is coated with ciliated epithelium; ultimately, this is replaced at its distal end with stratified epithelium that becomes cornified in some mammals.

The ovarian tissue is one of the most complex in the body. It consists essentially of a surface epithelium in which the oogonia are developed and a central matrix composed largely of collagen fibres and fibroblasts (cells in the connective tissue that form and maintain the fibres in such tissue). Oocytes (cells derived from mature oogonia that eventually become eggs) are budded into the matrix, in which each is surrounded by a flattened layer of what are called nurse cells. As the egg matures, it becomes surrounded by a membrane and lies within a small cavity (follicle) filled with a fluid secreted by the nurse cells. When the egg is fully mature (Figure 3), the follicle moves to the surface of the ovary and ruptures, after which the egg is taken up by the oviduct. The cleft in the follicle then closes, and because it becomes filled with yellow pigmented cells, it is known as the corpus luteum, or yellow body. The luteal cells secrete a hormone that both inhibits further egg production and assists in preparing the uterus for implantation of the egg. In such animals as the frog, in which large quantities of eggs are produced at the same time, no corpora lutea are formed; instead, the remnants of the ovary survive as a shrivelled body that does not commence egg production again until the next breeding season. In forms having heavily yolked eggs, such as birds, a dense mesh of blood vessels surrounds the follicle; yolk is transferred to the egg through the nurse cells, which remain in contact with the outer surface of the egg.

Hemopoietic tissues. Hemopoietic tissues, which produce the cellular components of blood, have an interesting evolutionary history. In the cyclostomes they appear in scattered masses throughout the intestinal wall, but by the time the level of lungfish is reached, the tissues have become aggregated into a rather well-defined mass in the wall of the stomach. In amphibians and reptiles the hemopoietic tissues are segregated as a distinct organ, the spleen; it is filled with a red pulp consisting primarily of large cells (hemocytoblasts) from which are differentiated all the various types of blood cells. The spleen in these organisms is permeated by arteries that divide into extremely thin-walled arterioles through which the white cells enter the blood; there is still some argument, however, concerning the manner in which the red cells get into the blood.

Production and destruction of blood cells

In mammals the spleen has lost entirely its hemopoietic function; its sole concern is to sort out and destroy erythrocytes that are no longer useful. The production of the cellular constituents of blood has been transferred to the red bone marrow, which fills the spaces in trabecular, or spongy, bone. Here are produced large cells called myeloblasts, which, as the need develops, differentiate into three types of leukocytes; into erythroblasts, from which the erythrocytes are formed; or into multinucleate megakaryocytes, which ultimately produce the blood platelets (minute granular bodies that function in blood clotting). In a normal human, erythrocytes are produced at the rate of about 3,000,000 per second, a figure that may double following serious injury and blood loss. Simultaneous with production, 3,000,000 erythrocytes per second are broken up in the spleen and the pieces passed to the liver, where they are broken down further. Excess pigments are excreted as bile pigments; the remainder are recycled.

Tissue fluids. The most important tissue fluid is lymph, which, as mentioned previously, is a colourless substance derived from blood that filters through the walls of capillaries to bathe the cells in all the tissues of the body (for a detailed discussion, see below *Blood and lymph*).

Another blood fluid of great importance but of little-known function is cerebrospinal fluid. This colourless watery substance, which fills the cavities of the brain and spinal cord, is, to all intents and purposes, identical with

the aqueous fluid that fills the eye. Cerebrospinal fluid is a specialized form of lymph; as such, it contains a few lymphocytes, a type of white blood cell that is formed in lymphoid tissues found in such organs as the spleen, tonsils, and lymph nodes. The fluid reaches the cavities of the central nervous system through a complex of tangled capillaries known as the choroid plexus, which is located in the roof of one of the brain cavities (for a detailed discussion, see below *Cerebrospinal fluid*).

Milk

A third body fluid of immense importance is that secreted by the milk-producing glands located in the breasts of female mammals. These are actually greatly enlarged sebaceous glands (saclike structures, usually opening into hair follicles, which secrete an oily fluid that lubricates the skin and hair); it is the large fat drops secreted by these glands into the fluid of the breasts that produces the familiar white emulsion known as milk. In most mammals the glands are activated by a hormone contained in the placenta (the vascular organ that connects the fetus with the maternal uterus), which is eaten by the mother shortly after the birth of its young. Hormones from the corpus luteum of the ovary also enter into the mechanism for initiating milk production. In primitive mammals, such as the duck-billed platypus, milk is not elaborated; instead, the secretion of slightly enlarged sebaceous glands is licked from the surface of the skin by the newborn, which, unlike other mammals, are hatched from eggs. Some birds also produce "milk," so called because of its opaque white appearance; female pigeons, for example, grind grain in the gizzard (a muscular enlargement of the alimentary canal), predigest it to a milky substance, and then regurgitate it for the young. (Pe.G.)

Blood and lymph

Blood is a cell-containing fluid that transports oxygen, water, carbon dioxide, products of metabolism, and internal secretions (*e.g.,* hormones). Blood is also defined as a tissue, constantly circulating throughout animals; it is a means by which the constancy of the internal environment is maintained, and it is also the route by which the defenses against injury and disease may be quickly mobilized. Lymph is a fluid that is derived from the tissues of animal bodies and conveyed to the blood stream by lymphatic vessels. The circulatory system, which contains blood and lymph, is an important connecting pathway; it permits a continuous integration among various tissues and organs of animals and facilitates contact with the environment outside the body.

This section compares blood and lymph in a number of living systems. For more specific information about human blood, see BLOOD. The human lymphatic system is treated in the article CIRCULATION AND CIRCULATORY SYSTEMS.

DEFINITIONS AND ORIGIN

Definitions. Blood in mammals may be defined as the red fluid that is pumped by the heart into arteries and returns to the heart in veins, following a complex but completely closed circular path. The red colour of mammalian blood is caused by hemoglobin, an oxygen-carrying protein in red cells (erythrocytes). Mature red blood cells of mammals, which contain no nuclear component, are disk shaped and float in a nearly colourless liquid called plasma. Plasma also contains white cells (leukocytes) and tiny bodies called platelets, which seal wounds. The grainy cytoplasmic component of one type of white cell, called granulocytes, constantly changes shape, engulfing and destroying unwanted particles. A nongranular type of white cell (lymphocytes) originates in mammalian lymphoid tissue (*e.g.,* spleen, lymph nodes) and has important immunological functions. Lymph, a rather colourless, sometimes milky liquid, drains from the tissues into lymph vessels, which converge into a thoracic duct, which empties into the blood. The above definitions of blood and lymph also apply (with modifications) to vertebrates other than mammals; *i.e.,* the red cells of other vertebrates contain nuclei but are red, except in the icefish, which has colourless blood. White cells vary in shape not only among vertebrates but even among mammals. The platelets of mammals resemble tiny disks of cytoplasm, but those of other vertebrates have nuclei.

Invertebrate animals have a great variety of liquids, cells, and modes of circulation. In insects, a heart pumps fluid, called hemolymph, through an open system to the tissues. In some worm species the fluid contains pigmented cells, but the fluid, called coelomatous fluid, does not circulate; in others the fluid circulates, but the cells may contain no pigment.

Perhaps blood should be defined by its functions, rather than by its appearance—when passing through skin, gills, or lungs, blood picks up oxygen from outside the body and loses carbon dioxide that was picked up in the metabolizing tissues; when passing through tissues, blood does the reverse and also picks up metabolized food, which maintains the cells of the body, and passes poisonous molecules and excess water to the kidneys for excretion.

Origin. How did the need for blood and lymph arise? Life probably originated in the oceans from molecules that accidentally developed an ability to reproduce, to form cells, and to evolve by reproducing many of the accidental changes (mutations) that occurred in their hereditary material. Most of the early cells must have developed certain deficiencies, and many survived only if they also developed the ability to depend on other cells, either as food sources or for transporting food, oxygen, and waste products.

Eventually, aggregations of specialized cells became organized into bodies whose inner cells lost contact with the outer world and with each other. An electronic system (the nervous system) and liquid systems of blood and lymph developed to provide communication among specialized body regions. In addition, as organs became complicated, both structurally and functionally, they developed a mechanism (hormones) for transmitting, receiving, and integrating information. A hormone is formed in one organ and transported in the blood to another site, where its major effect is exerted. An increase in blood sugar, for example, causes an increase in synthesis (in the pancreas) of the hormone insulin, which causes a decrease in blood sugar; an increase in the activity of the pituitary gland, in the brain, causes an increase in the activity of the adrenal glands, near the kidneys; and adrenal secretions in turn cause a decrease in pituitary activity. Mechanisms such as those provided by hormones enable a multicellular organism to outlive the individual cells comprising it; the removal of dead cells and of other particles too large to be transported by the blood to the kidneys for excretion is carried out by white cells.

Hormones

The blood has a mechanism that prevents its being emptied through wounds. Platelets in mammals and cells called thrombocytes in other vertebrates aggregate at a wound site, and, in the plasma near them, a clot, composed of a protein called fibrin, forms. Invertebrates may rely on the motion of cells to plug their wounds.

In the brief discussion of blood and lymph that follows, it may seem as if in species most alien to man the least sophisticated fluids exist; *i.e.,* fewer and less specialized proteins occur, as well as more primitive, all-purpose cells, but this may reflect limitations of knowledge.

PLASMA

Small molecules and the regulation of water content. Water molecules, which are the main component of body fluids, probably form clusters that break up rapidly except at water-repellent surfaces (*e.g.,* as provided by fats), where the clusters are more stable and icelike. The complex mixture of fatty and nonfatty structures in cell membranes, therefore, profoundly affects the behaviour of water and the substances dissolved in it. Although water itself and certain small molecules and ions (charged particles) pass through the membranes of all active cells, certain other molecules cannot; urea, an organic compound larger than most ions, however, apparently passes into cells by disrupting water clusters.

When two solutions containing different quantities of a substance are separated by a membrane that allows only water to pass (a semipermeable membrane), water flows through the membrane to the solution containing the

most substance, in an attempt to equalize the concentrations on both sides of the membrane. When a cell is placed in water, therefore, it swells, because water passes into the cell through the membrane in response to the dissolved molecules and ions inside the cell; these particles are said to exert an internal pressure, called osmotic pressure, which may cause the cell to burst, or lyse (or, in the case of blood cells, hemolyse). If a cell is placed in a solution containing a higher concentration of a substance than that found in the cell, water leaves the cell through the membrane, and the cell assumes a wrinkled, or crenated, appearance. Living cells, including the blood cells in plasma, must expend metabolic energy to maintain an osmotic equilibrium.

Cell lysis

The salt concentrations in present-day seas are higher than those within cells. Invertebrate animals capable of regulating the water content of their circulating body fluids usually lower it to about two-thirds that of the surrounding ocean; aquatic mammals also are able to perform this physiological regulation. Other animals apparently need no such regulation. The body fluids of echinoderms, for example, resemble seawater; among crustaceans, the shore crab (*Carcinus*) regulates its water content, but the spider crab (*Maia*) does not. *Rhithropanopeus* is able to swell when it must molt; its eyestalks produce a hormone that prevents water inflow at other times. Animals that cannot regulate their water content and thus tolerate only a narrow range of salt concentrations (stenohaline animals) probably are restricted to oceanic life; animals that are able to regulate their water content (euryhaline animals) are free of this restriction. Mechanisms other than those involving a circulating body fluid, however, enable certain animals to regulate their water content; *e.g.*, some coelenterates and flatworms (Platyhelminthes), which live in freshwater, utilize a diffusely branched system to remove water.

Some cyclostomes (hagfish and lampreys), among the most primitive fishes, live in the ocean, are permeable to water, and regulate their osmotic pressure. Elasmobranch fishes (sharks and rays) maintain a blood osmotic pressure above that of seawater by retaining urea, which is excreted rapidly in other vertebrates by the kidneys. The advantages to marine animals of maintaining specific osmotic pressures are not well known. Saltwater fishes lose some regulatory ability in the cold; as a result, the concentration of salts in the plasma increases, so that it acts as an "antifreeze." Fishes in freshwater also may be affected by cold, but their plasma loses ions, which means that it freezes more easily.

The ability of an animal to retain salts when moving to freshwater may have been a prerequisite to the evolution of animals capable of retaining both salts and water on land. The urine of freshwater fishes contains a low concentration of salts. Amphibians and many crabs return to water when some as yet unknown mechanism senses the need for water to dilute body fluids. A specific region in the brain of amphibians produces a hormone similar to the antidiuretic hormone of man, which regulates water retention. Among reptiles, the evolutionary success of crocodiles over dinosaurs may be attributable to the development in crocodiles of a skin more impermeable to water; certain crocodiles, however, when dehydrated, return to the water, taking in more water through the skin than by drinking.

Although a sense of thirst is necessary in all animals living on land, the composition of their internal fluids may vary. Most of the osmotic pressure in the plasma of water-dwelling crustaceans, for example, is provided by salts; half of that in land-dwelling insects is provided by organic compounds called amino acids.

Regulation of ion content in man

The regulation of the content of ions in the plasma of vertebrates, especially mammals, appears increasingly complex at higher evolutionary levels; but perhaps man seems most complex because he has been studied most. The plasma concentrations of ions such as sodium, potassium, and calcium are regulated by hormones; but human emotional stress increases the activity of the adrenal glands, whose secretions affect the transport of sodium and potassium ions across cell membranes.

Glucose has relatively little effect on the osmotic pressure of plasma, but it is an important source of energy in cells; it must be available at all times, therefore, within controlled levels. Blood-glucose levels in vertebrates are regulated by two hormones formed in the pancreas, insulin and glucagon. Insulin, synthesized when plasma-glucose concentration increases, stimulates the liver to convert excess glucose into a storage compound, glycogen. Glucagon acts in the opposite way; *i.e.*, it increases abnormally low levels of plasma glucose. Among vertebrates, either hormone may dominate in maintaining the proper levels of plasma glucose, whose concentration is profoundly affected by feeding and by stress.

Because fatlike substances do not dissolve in water and force a specific arrangement of water molecules around them, they usually circulate surrounded by protein molecules, so that their water-hating (hydrophobic) areas do not come in contact with water in the plasma.

Proteins and their various roles. There are about 20 kinds of amino acids that link together in a specific order to form protein molecules. Each amino-acid sequence is determined by heredity; in turn, the sequence of amino acids determines the shape of each protein. A mosaic-like arrangement of amino acids with positive and negative charges may comprise most of the exposed parts of a protein molecule; other amino acids, which are hydrophobic, are found inside the coil-shaped molecule and thus do not come in contact with water surrounding it. The function of a protein molecule depends on its shape.

During evolution, a chance mutation may result in the replacement of one amino acid in a specific protein molecule by another. If the newly inserted amino acid destroys the function of the protein, an organism may die; on the other hand, the loss of a protein function by mutation may be compensated for by another mutation, either in the protein molecule itself or in some other one. If an animal survives a partial loss of function, the loss may be discovered if the animal becomes ill. Many proteins function as enzymes (biological catalysts); some enzymes (*e.g.*, several blood-clotting factors) have been shown to exist only because people born without them develop specific symptoms. Mutations that do not affect function can be discovered only by analyzing proteins whose sequences of amino acids have been established. The insulin of vertebrates, whose amino-acid sequence has been established, functions only if the two functional chains comprising the molecule are not altered; a mutation in the nonfunctional section that connects the chains does not inactivate the molecule.

Since an enzyme catalyzes a reaction involving a specific compound, it can be identified. An enzyme whose shape must change before it becomes active or a protein involved in the structure of an organism usually can be distinguished only by crude tests. Many active enzymes function efficiently only with molecules prepared from the same species. Although others (*e.g.*, insulin, blood-clotting Factor VIII) derived from one mammalian species will function if injected into another species, they act as antigens; *i.e.*, they stimulate formation of proteins called antibodies in the injected species. These enzymes, therefore, are recognized in the injected animal as foreign in composition, if not in function. The specificity of proteins for their own hosts has limited the understanding of their functions in species remote from man. Crude separation of plasma proteins carried out in mammals other than man show that proteins such as albumin and alpha, beta, and gamma globulins occur in them.

Species-specific enzymes

Albumin, a rather small protein that dissolves in water, comprises more than half the total proteins found in mammalian plasma, contributes to the blood osmotic pressure, and transports certain ions and fatty acids. Yet, humans born without it appear normal. The second most abundant protein in mammalian blood is a long, large molecule called fibrinogen. When blood clots, a series of enzyme interactions converts an inactive plasma enzyme (prothrombin) into an active enzyme (thrombin) that removes two pairs of amino-acid groups from each fibrinogen molecule to convert it into a molecule called a fibrin monomer. Molecules of the fibrin monomer then

link together to form strands of fibrin, the visible clot. The remaining liquid, plasma lacking fibrinogen, is called serum. Fibrinogen, prothrombin, and many other proteins are formed in the liver. In animals other than mammals, some clotting enzymes, as well as the events that trigger their interactions, may be restricted to the cytoplasmic component of specific sensitive cells (see below *Thrombocytes and platelets*).

Gamma globulins are produced by plasma cells and lymphocytes that probably occur only in vertebrates. Some other globulins carry specific metal ions, which colour them—*e.g.,* mammalian transferrin, which carries iron, is brown, and ceruloplasmin, which carries copper, is blue. The most deeply coloured globulins have a specific slot in which they carry a flat molecule (heme) containing iron. In vertebrates, four globulin-heme moieties form one hemoglobin molecule in the red cells, where it remains until the cells die. Many polychaete worms have developed a similar protein; slight difference in the structure of its heme, however, makes it green in colour. A variety of polychaete blood proteins exists. The noncirculating coelomic fluid of some polychaetes contains hemoglobin; other polychaetes have two hemoglobins—one in the plasma and another in coelomic cells. Hemoglobin predominates in young *Serpula* polychaetes, green pigment (chlorocruorin) in older ones, and another polychaete, *Arenicola,* has a very large hemoglobin molecule. Hemocyanin, a large protein molecule that contains copper and turns blue when it takes up oxygen, occurs in many mollusks, where it may be the main plasma protein. All the pigment types mentioned pick up oxygen molecules easily and release them where they are needed. A change of shape in each hemoglobin subunit accompanies oxygen uptake or release and is transmitted to the other units in a way that facilitates the process (see COLORATION).

Hemoglobin

FORMED ELEMENTS

Red cells (erythrocytes). The hemoglobin in the plasma of some worms allows them to carry about ten times more oxygen than can an equal volume of seawater. The localization of hemoglobin in red cells increases this capacity another four times. The evolution of cells with such a singular function is traceable by arranging species in order of the increasing oxygen-carrying efficiency of their red cells. The mature red cells of mammals lack nuclei. Not only does a nucleus take space; it also requires oxygen; mammals, therefore, have the most efficient red cells, at least so far as oxygen-carrying ability is concerned. It thus is tempting to presume that, if no further evolutionary progress occurs, even though mutations continue, a maximum efficiency has been attained. Indeed, one can say that in the following aspects, evolution of red cells apparently stopped long ago: the total volume of red cells in proportion to the total volume of blood varies relatively little among mammalian species; in addition, all normal red cells have about the same high concentration of hemoglobin, above which the molecules would soon interfere with each other or even form crystals. On the other hand, the diameter of red cells varies greatly, ranging from less than 3 to more than 9 micrometres, or microns (1 micrometre is 0.001 millimetre). Both Indian and African elephants have large red cells (9.2 micrometres in diameter), but no clear relationship between red-cell size and total body size exists among other species. Red cells apparently became smaller as life on land developed or evolution in general progressed, but the relationship between red-cell size and evolutionary advancement is not clear. The supposedly primitive hagfish, for example, has red cells 26.4 micrometres long; those of the related lamprey are only 14.3 micrometres. The red cells of many sharks, about as large as those of some amphibians, are larger than those of many other fishes.

Evolution and red-cell size

The disk-shaped mature erythrocytes of most mammals have thick, rounded edges and lack nuclei. When such a cell is cut in half, both halves may assume a disk shape and resemble small red cells. Certain membrane components in the smallest red cells (two to four micrometres in diameter), which occur in ruminants such as cows, occur in a proportion different from that in other mammalian red cells. The fact that red cells are thin in the centre may increase their efficiency in gas transport. The efficiency of gas exchange and transport may be increased also by the fact that the shape of red cells can be distorted into cones, clubs, and dumbbells as they pass through the extremely narrow blood capillaries.

Perhaps red and white blood cells originate in the same cells in bone marrow. The need for red cells is conveyed in mammals by a protein (erythropoietin). The protein is formed by the action of a substance (erythrogenin), synthesized by the kidneys when they lack oxygen, on another molecule (erythropoietinogen), which is synthesized in the liver. A severe loss of red cells and the subsequent decrease in available oxygen is normally followed by a flood of young red cells, which still have nuclear material. The mature red cells of mammals contain many enzymes important for their maintenance and partly responsible for their death when they fail; the oldest cells, therefore, should die first, and they do in some mammals (*e.g.,* mouse, dog, and man); in other species, however, red-cell death may occur at any age in an apparently random manner. Although it has been suggested that red cells must pump out sodium ions and retain potassium ions to survive, dogs and some other mammals have about the same proportions of sodium and potassium ions in both red cells and surrounding plasma; yet their cells live no longer than do those of man. On the other hand, the less heat a vertebrate species produces, the longer its red cells live: turtle erythrocytes, for example, live longer than those of man; red cells of birds and mice have a shorter existence.

Extreme differences between sodium- and potassium-ion concentrations in erythrocytes exist in various species (see Table 1) and even within breeds in one species.

Table 1: Concentration of Potassium and Sodium Ions in Plasma and Red Cells of Certain Vertebrates

	potassium ions*		sodium ions*		percentage of red cells replaced per day
	red cells	plasma	red cells	plasma	
Man	95	4	19	138	1
Dog	8	4	97	143	1
Chicken	119	6	18	154	3

*Milli-equivalents per 1,000 millilitres.

White cells. All poorly pigmented cells normally found floating in blood, hemolymph, or coelomic fluid may be called leukocytes, although those in the hemolymph and coelomic fluid of invertebrates are often called hemocytes and coelomocytes, respectively. White cells in hemolymph and coelomic fluid include cells that eat (phagocytize) foreign particles, as do the granulocytes of mammals; cells that recognize and chemically attack only specific foreign matter, as do the lymphocytes and plasma cells of mammals; and cells that clump together when disturbed, as do the thrombocytes. The distinctions among functions and blood-cell types of animals other than man, however, have not yet been clearly established.

A superficial resemblance exists among some mammalian blood cells and those of other animals. Some white cells of sea cucumbers (Holothuroidea), for example, resemble mammalian white blood cells called basophils; gastropod mollusks have cells that resemble lymphocytes and granular amoebocytes that resemble certain granulocytes of man (eosinophils); crustaceans have coelomocytes that clump around foreign cells and eat them; and insects have a multitude of hemocytes some of which resemble human white cells while others do not. The evolution of insects and other arthopods diverged from that of man and other chordates so long ago that the blood cells of these two animal groups do not provide any evidence of a common ancestry. The most active white cells in insects, called plasmatocytes, can spread either over surfaces of parasites forming membranous capsules or over foreign particles; often they become granular. Hemocytes, most abundant in the last immature stage (larval instar) of insects, decrease in numbers during the nonfeeding stage called pupation, after which, in certain insects, new cells are formed. When a pupa is injured, hemocytes appear to seal the wound; ac-

Plasmatocytes

tual clotting in insects, however, is initiated by cells called cystocytes (coagulocytes). When hemolymph flows from a wound, cystocytes enlarge, break down, and either turn the plasma around them cloudy or form threads around which the plasma jells. Other insect hemocytes show no identifiable activity.

Echinoderms and worms also contain blood cells very different from those of man. Echinoderm groups differ in their types of blood cells; all, however, have phagocytes to eat foreign particles, and other hemocytes to repair damage and to seal wounds. Echinoderm blood cells probably form from stem cells (so-called lymphocytes); active movement of cells within the heartless hemal system may transport food throughout the body. Hemoglobin-containing cells occur in some burrowing echinoderms. The variety of cells in hemal and coelomic fluids among echinoderms and even within various areas of one individual possibly reflects a range of requirements totally different from those of man, so that there are no blood kinships between man and echinoderms. Among vertebrates, relationships are clearer; *e.g.,* fishes and amphibians have granulocytes, lymphocytes, and, probably, a type of white cell present in human blood and referred to as a monocyte.

Thrombocytes and platelets. The thrombocytes of fishes, amphibians, reptiles, and birds resemble the cells that aggregate at wounds in invertebrates; in vertebrates, however, the plasma apparently has more responsibility in the clotting process. Since no thrombin (an enzyme involved in clotting) forms when thrombocytes are removed from the plasma of fishes, these cells, which break down on contact with a wound, must liberate substances that convert plasma prothrombin (an enzyme precursor) to thrombin, which then converts plasma fibrinogen into fibrin strands (a clot). In contrast to other vertebrates, the plasma of mammals contains an inactive enzyme, Factor XII, also called the Hageman factor. Mammalian Factor XII, upon contact with some hard foreign substance, becomes an active enzyme that initiates clotting. The contact-sensitive thrombocytes of other vertebrates are analogous to small disks of cytoplasm (platelets) in mammals. Platelets are derived from large bone-marrow cells (megakaryocytes). Although platelets aggregate in plasma under a variety of conditions, which also cause the aggregation of thrombocytes, and their clumping, or sticking, is accompanied by the liberation of several important substances, they contribute to the clotting of plasma only by making available a chemical component of their membranes (phospholipids). Platelets, however, are essential for sealing wounds in mammals.

Factor XII

Lymphocytes and lymph. Animals must recognize their own cells, so that they do not eat them. The system by which vertebrates protect themselves (*i.e.,* development of specific immunities), however, has not yet been found in the invertebrates. Hagfish appear to be the most primitive animals to have lymphocytes, form antibodies, and reject tissue grafts. From the higher fishes to man, lymphocytes and plasma cells become progressively more abundant, antibodies more specific, and tissue grafts less successful.

As blood flows through the capillaries, dissolved substances pass between the blood and the surrounding tissues. Most of these substances pass readily through the capillary walls, but a small amount of protein, once forced from the plasma, cannot return because the protein molecules are too large. This protein and waste fluids pass from the cells into the lymph vessels, which have much more permeable walls and within which the pressure is much lower than that in the capillaries. The fluids are pushed through the vessels by the motion of organs and muscles, their flow directed by valves along the way; in fishes, amphibians, reptiles, and some birds, a heartlike organ (the lymph heart) helps the circulation. As it flows, the lymph passes through many glandlike masses of tissue, called lymph nodes, and through the thymus, a glandular body present in all vertebrates. Birds have an extra lymphatic organ, the bursa of Fabricius. In all vertebrates, the lymph vessels combine, finally reaching a duct (*e.g.,* the thoracic duct in mammals) from which the lymph enters the venous bloodstream.

In very young animals, lymphocytes are formed in the thymus; later they form from cells in the bone marrow and are transported, and deposited at, certain nodes or organs. The fate of each lymphocyte depends on the information or stimulation it receives at its point of deposition. The lymphocytes in gut-associated lymph tissues or those in the bursa of birds, for example, are apparently prepared to form antibodies if they are needed. In mammals, a lymphocyte at a lymph gland may be stimulated by a molecule (antigen) to form a specific antibody. Certain lymphocytes first form a globulin known as immunoglobulin M (IgM); then the lymphocytes divide, and each daughter cell receives some IgM. If stimulated again by more antigen molecules, the lymphocytes again divide, liberating their IgM and transforming into plasma cells that form a smaller globulin (IgG). Some antigen molecules probably remain with certain cells in the lymph node and eventually stimulate new lymphocytes passing the lymph node. Speed, intensity, and complexity of these reactions apparently increase from cyclostomes through elasmobranchs to bony fishes. Most of their globulins of fishes probably resemble human IgM. Amphibians, however, may be more advanced; bullfrogs may form IgM, then IgG, or IgG first, depending on the type of antigen molecule injected. The antibodies formed by a bullfrog injected with serum of one mammalian species react with the serums of other mammals; the antibodies of mammals, however, are more specific. The serum of a rabbit immunized to serum of one fish species, for example, reacts less with serums of other fishes; in fact, the extent of interaction of the serums serves as a measure of evolutionary relationships among species.

Fate of lymphocytes

The vertebrate thymus plays a role in determining which lymphocytes survive, apparently stimulating their division and then destroying undesired ones. Lymphocytes may spend only a few hours at a time in the blood and many months elsewhere. The variety of lymphatic systems among vertebrate species probably has some relationship to the immunological functions required for each. The ability of man's immunological system to distinguish differences in blood-group substances means that there are many blood incompatibilities; *i.e.,* few humans, unless they are twins, have completely identical sets of blood groups. Perhaps the thymus destroys cells that know too much; *i.e.,* cells that would form antibodies against substances or tissues that are useful (see IMMUNITY). (L.V.)

Cerebrospinal fluid

In the vertebrate embryo the central nervous system is formed as a hollow tube with a canal extending its entire length. In later life the canal remains open in the brain stem but narrows considerably in the spinal cord. In each of the two cerebral hemispheres of the brain the canal widens into cavities called ventricles. The cerebrospinal fluid (CSF) fills these ventricles and the canal within the brainstem. It also surrounds and bathes the spinal cord and the brain, acting as a lubricant and a mechanical barrier against shock. The fluid flows slowly from the ventricles, the principal site of formation; down through the canal of the brainstem; and ultimately out into the tissue spaces surrounding the central nervous system.

Distribution

It is a clear and colourless liquid of low specific gravity. Like the blood it is slightly alkaline in reaction, having a pH of 7.3–7.4. It is about 99 percent water and has an average freezing point of 0.57° C (33°F). The fluid normally has less than five leukocytes (mononuclears or possibly lymphocytes) per cubic millimetre and no red blood cells. The relationship of the various chemical constituents of the cerebrospinal fluid to that of blood plasma is shown (Table 2).

FUNCTIONS OF CEREBROSPINAL FLUID

The cerebrospinal fluid's many functions are chiefly mechanical. It bathes brain and spinal cord and helps to bear the weight of the brain. It lubricates the surfaces between the meninges covering the brain and spinal cord, on the one hand, and those covering the bones that encase them, on the other. The fluid is a buffer that distributes the force of a blow on the head. It helps to keep intracranial

Table 2: Comparison of Normal Cerebrospinal Fluid and Blood Plasma Average Values

	cerebrospinal fluid	blood plasma
Calcium	2.4 mEq/l	5.2 mEq/l
Carbon dioxide tension	46 mm Hg	40 mm Hg
Chloride	124 mEq/l	100 mEq/l
Bicarbonate	22 mEq/l	22 mEq/l
Glucose	50–80 mg/100 ml	70–110 mg/100 ml
Lactate	1.7 mEq/l	1.7 mEq/l
Lipids, total	1.25 mg/100 ml	876 mg/100 ml
Cholesterol	0.4 mg/100 ml	180 mg/100 ml
Cholesterol esters	0.3 mg/100 ml	126 mg/100 ml
Magnesium	2.6 mEq/l	1.8 mEq/l
Nonprotein nitrogen	19 mg/100 ml	27 mg/100 ml
Ammonia	6 μg/100 ml	56 μg/100 ml
Creatinine	1.1 mg/100 ml	1.6 mg/100 ml
Urea	14 mg/100 ml	14 mg/100 ml
Uric acid	0.24 mg/100 ml	4 mg/100 ml
Phosphorus	1.6 mg/100 ml	4 mg/100 ml
Potassium	3 mEq/l	4.5 mEq/l
Protein, total	15–45 mg/100 ml	7,000 mg/100 ml
Prealbumin	5%	0 (?)
Albumin	50%	56%
Globulin, total	45%	44%
Alpha globulin	15%	14.5%
Beta globulin	19%	12%
Gamma globulin	11%	17.5%
Sodium	142 mEq/l	137 mEq/l

pressures relatively constant; its volume decreases to compensate for increased arterial pulsations or greater volume of blood or brain tissue and increases to compensate for a decrease in these factors, as in degeneration or atrophy of the brain. By means of the cerebrospinal fluid, substances are removed from the tissues of brain and spinal cord and carried into the blood stream, and the fluid may possibly act also in the reverse direction. Materials carried away by the fluid include metabolic waste products, antibodies, abnormal chemical constituents, and pathologic products of disease. It helps to circulate drugs administered in therapy. It does not carry enough nutritional substances to be of much help in the normal metabolism of nervous tissue.

During certain diseases that affect the meninges or the central nervous system or both, the cerebrospinal fluid may change significantly in physical characteristics, cytological constituents, and chemical contents; and there may be microbiologic and serologic alterations in the fluid. Careful examination of the cerebrospinal fluid in such a situation may be very useful in differential diagnosis. Table 3 illustrates the changes in the profile of the cerebrospinal fluid in the differentiation of certain diseases of the meninges and the central nervous system.

FORMATION, REABSORPTION, AND FLOW

Mechanisms of formation

Although there are still differing views concerning the mechanisms of the formation of cerebrospinal fluid, the general belief is that the fluid originates largely by filtration across the membranes that line the spaces containing the fluid (the ependyma of both the choroid plexuses and the ventricles, as well as the arachnoid) but also by active secretion of substances such as protein and sodium.

From the cerebrospinal spaces the fluid enters into the venous system. It was formerly held that the greater part of the fluid is absorbed through the arachnoid villi or pacchionian granulations and passes into the dural sinuses and thence into the venous blood. Probably, however, much of the fluid is absorbed into the veins from the spaces around the spinal roots and cranial nerves and from the perivenous spaces. Some may also be absorbed

Table 3: Cerebrospinal Fluid in Differential Diagnosis

condition or disease	initial pressure (mm CSF)	spinal subarachnoid block	appearance	cells (per mm³)	protein (mg/100 ml)	glucose (mg/100 ml)	chlorides as NaCl (mg/100 ml)	colloidal gold curve	comments
Normal	70–150	absent	clear colourless	0–5 mononuclear	15–45	50–80	700–750	00000000	
Infections on the central nervous system and meninges									
Acute purulent meningitis	200–600	absent	cloudy to purulent	500–20,000 mainly polymorphonuclear	100–1,000	10–20 mg or less	575–700	variable	organisms may be found by direct stain or culture
Tuberculous meningitis	200–500	absent	opalescent to faint yellow	100–500 mainly lymphocytes	60–700	15 mg or less	525–675	variable	tubercle bacilli may be found by stain or guinea pig inoculation
Cryptococcus meningitis	200–400	absent	slightly opalescent	100–500 mainly lymphocytes	50–300	30–40 mg or less	normal or slightly decreased	variable	yeasts may be found with India ink stain or special culture
Syphilitic meningitis	150–300	absent	clear to slightly opalescent	300–2,000 mononuclear	50–400	normal or slightly decreased	normal or slightly decreased	first or midzone	serologic tests usually positive
Parenchymatous central nervous system syphilis	normal	absent	clear	10–50 mononuclear	50–100	normal	normal	first or midzone	serologic tests usually positive except in late treated tabes
Viral meningitis and encephalitis	100–250	absent	clear	25–250 polymorphonuclear early; later lymphocytes	40–80	normal (occasionally more)	normal	normal or nonspecific	occasionally virus may be found
Acute anterior poliomyelitis	normal	absent	clear	50–250 mainly mononuclear	40–100	normal	650–750	variable	polymorphonuclear cells may be found in preparalytic stage; gradual rise in protein
Brain abscess	200–800	absent	clear colourless	30–100 mainly mononuclear	40–200	normal	normal	variable	polymorphonuclear cells present early, before encapsulation
Miscellaneous meningeal and nervous system diseases									
Carcinomatous meningitis	150–400	absent	clear to opalescent	100–500 mainly mononuclear	40–200	moderately decreased	normal	variable	cancer cells may be found in stained sediment
Brain tumour	150–500	absent	clear to yellow	usually normal, may be up to 50–100	20–150	normal	normal	variable	pleocytosis usually indicates tumour near ventricles or meninges
Spinal cord tumour	normal or decreased	partial or complete	clear to yellow	usually normal	50–5,000	normal	normal	first or midzone	with complete block may be marked increase in protein
"Guillain-Barre syndrome"	normal	absent	clear to yellow	normal	50–1,000	normal	normal	variable	often marked increase in protein without associated pleocytosis
Subarachnoid or ventricular hemorrhage	150–400	absent	bloody yellow	crenated red blood cells	50–500	normal	normal	variable	fluid grossly bloody; supernatant yellow
Multiple sclerosis	normal	absent	clear colourless	5-50 mononuclear	40–70	normal	normal	first zone in 20%; variable in 40%	

through the ventricular ependyma and, in a reverse direction, through the choroid plexus and some, by osmosis, directly into the pial veins on the brain surface and into the capillaries of the pia arachnoid.

Unlike the blood, the cerebrospinal fluid is not given energy for circulation by an organ like the heart; but there is a definite movement of the fluid from the lateral ventricles down into the third and fourth ventricles, the basal cisterns, and the subarachnoid space; and there is constant circulation in the sense that the fluid is being continuously secreted and absorbed. There is clinical evidence that obstruction of one opening, the foramen of Monro, between one lateral ventricle and the third ventricle will cause hydrocephalus on one side, with enlargement of that ventricle, and that obstruction of the Sylvian aqueduct will cause hydrocephalus on both sides, involving the third and both lateral ventricles. The forces that bring about the flow of the cerebrospinal fluid and affect its rate include the arterial pulsations within the choroid plexus, respiration, the increase in venous pressure brought about by thoracic and abdominal movements, movements of the head and body and changes in their position, and filtration and secretion pressures.

The normal adult has from about 100 to 150 millilitres of cerebrospinal fluid. This fluid is replaced every six to eight hours or three or four times a day. Abnormally large volume is caused either by excessive formation or deficient absorption.

USE IN DIAGNOSIS: LUMBAR PUNCTURE

In lumbar puncture a needle is inserted into the subarachnoid space in the lumbar region, and a little cerebrospinal fluid is withdrawn for use in diagnosis. In most cases the cerebrospinal fluid pressure is also measured and the flow of the fluid investigated. The interspace between the third and fourth lumbar vertebrae is chosen for the site of the puncture because at this level the spinous processes are farthest apart and because, in the adult, this point is below the level of the lower end of the spinal cord.

After clear fluid has been obtained, the pressure is determined, ordinarily by means of the Ayer water manometer. Pressures from 70 to 150 millimetres (of cerebrospinal fluid) are normal. If the pressure is within the normal range and there is no other contra-indication, such as suspected intracranial disease, the Queckenstedt test is done. This is a test of the response of spinal fluid pressure to constriction of the jugular veins in the neck and release of the constriction. Normally the pressure rises rapidly and falls with equal rapidity. A slow, incomplete rise and fall or no response whatever is a positive Queckenstedt reaction and indicates a partial or complete spinal subarachnoid block. The Ayala index, computed by dividing the final pressure by the initial pressure and multiplying by the amount of fluid removed (at least ten millilitres must be removed if the test is to be reliable), helps in differentiating between an expanding intracranial lesion and other causes of pressure within the cranium. A quotient of 5.5 to 6.5 is normal. A swift drop in pressure and a quotient of less than 5 are indications of a small fluid reservoir and point to the possible presence of brain tumour or abscess, obstructive hydrocephalus, or a spinal subarachnoid block. A large reservoir is indicated by a value of more than 7, and nonobstructive hydrocephalus or cerebral atrophy is suspected.

Contra-indications against lumbar puncture

Lumbar puncture is contra-indicated by infections in or near the puncture site, by systemic infections (except when meningitis is suspected), and by symptoms or signs of increased intracranial pressure (unless diagnostic gains outweigh potential dangers). If the contra-indications mentioned are taken into account aftereffects of lumbar puncture are usually negligible. Postpuncture headache, the most frequent sequel, occurs in 15–30 percent of patients. It usually is mild and lasts only a day or two. The occasional severe headache may incapacitate for a week or longer; it is often accompanied by neck stiffness, is aggravated by movement, and is lessened or relieved by lying down. Current studies tend to indicate that postpuncture headache may occur less frequently if a needle of very narrow gauge is used.

(R.N.DeJ.)

Fluid and electrolyte balance

The chemical events by which body tissues are built and maintained and by which energy is provided for bodily activity can take place only in a watery solution in which the hydrogen ions and electrolytes are kept within relatively narrow limits. Disturbances of water, electrolyte, and acid–base balance impair the functioning of many organs, especially those concerned with contractility and nerve conduction.

THE NORMAL FUNCTION OF WATER AND ELECTROLYTES IN THE BODY

The fluids and electrolytes of the body are the water that pervades it and the ions formed from the acids, alkalis, and salts that are dissolved in it. Ions are atoms or groups of atoms that bear positive or negative electrical charges. Those bearing positive charges are called cations; those bearing negative charges are anions. The ions are called electrolytes because the solution that contains them is able to transmit an electrical current.

The fluids in the body may be classified into two main divisions: the fluid within the cells and the fluid outside (extracellular fluid). The extracellular fluid can be further divided into the fluid within blood vessels (intravascular fluid) and the fluid around the tissues.

Electrolytes. The electrolytes and their concentrations are shown in Table 4. They are not dispersed evenly throughout the fluids of the body. Sodium and chloride are confined mainly to the extracellular fluids; potassium, magnesium, phosphate, and organic acids are present in highest concentration inside the cells. Bicarbonate is found in the extracellular fluid at a little more than twice its concentration in the tissue cells, while the concentration of free hydrogen ions is twice as great within the cells as outside them. This difference with respect to hydrogen ions means that most tissue cells are slightly more acidic than the fluid that bathes them.

Table 4: Normal Distribution of Ions in Intracellular (Muscle) and Extracellular Fluids in Man

	intracellular (mEq/kg) H_2O	extracellular (mEq/kg) H_2O
Cations		
Sodium (Na^+)	10	145
Potassium (K^+)	150	5
Calcium (Ca^{++})	2	3
Magnesium (Mg^{++})	15	2
Total	177	155
Anions		
Chloride (Cl^-)	5	105
Bicarbonate (HCO_3^-)	10	25
Organic acids	120	6
Phosphate ($PO_4^{\equiv}$)		2
Proteins	42	17
Total	177	155

Because of the permeability of the walls of the capillaries (the smallest of the blood vessels), the concentrations of electrolytes in the plasma (the blood apart from its cells) and in the extracellular fluid outside the blood vessels is similar. Interchange between these two extracellular compartments is limited, however, in respect to protein molecules, the concentrations of which, except in the fluid bathing the cells in the liver, is much greater in the plasma.

Hydrostatic and osmotic pressures

Thus, the plasma volume is largely the result of two opposing forces—the hydrostatic pressure, which tends to force water outward, and the osmotic pressure of the plasma proteins, which attracts water into the network of vessels. In spite of the differences in the pattern of ions in the cells and in the extracellular fluid, their osmotic pressure under normal conditions is identical. Hydrostatic pressure, in this context, is the pressure in the body fluids as a result of the mechanical forces exerted upon them. These forces include that resulting from the contractions of the heart. Osmotic pressure comes into play when two solutions of differing concentrations are separated by

a semipermeable membrane. The solvent—*e.g.*, water—tends to move through the membrane into the more concentrated solution.

Hydrogen-ion concentration. Life is possible only if the blood is kept within a narrow range of alkalinity. The normal range, in terms of hydrogen-ion concentration (pH), is from 7.35 to 7.45. This range is close to neutrality, represented by a pH of 7; a pH of less than 7 represents acidity.

The blood contains the bases bicarbonate, proteins, and phosphate, and the weak acid, carbonic acid. The degree of alkalinity of the blood depends principally on the ratio of the concentrations of carbonic acid (H_2CO_3) and of the base bicarbonate (HCO_3^-).

In the pulmonary alveoli—the small air-filled spaces in the lungs from which oxygen is removed and into which carbon dioxide from the blood diffuses—the partial pressure of carbon dioxide is about 40 millimetres of mercury; in a mixture of gases the partial pressure of each gas is the proportion of the total gaseous pressure contributed by that particular gas. This alveolar carbon dioxide pressure gives rise to a concentration of carbonic acid in the blood plasma of about one milliequivalent per litre. (A milliequivalent [mEq] is the number of grams of a substance dissolved in one millilitre of normal solution.) The alveolar pressure of carbon dioxide is kept steady by the equal rate at which carbon dioxide is produced by the tissues and eliminated by respiratory ventilation.

Bicarbonate concentration, on the other hand, is regulated in the kidneys by the tubules. These are the long, fine tubes of the kidney's functional units, the nephrons. In health the bicarbonate concentration is kept at about 22 to 24 milliequivalents per litre of plasma. When the plasma bicarbonate falls below 24 milliequivalents, the amount filtered out of the blood in the kidneys is entirely reabsorbed by the tubules until the concentration is raised to this level; when the concentration rises above 24 mEq per litre, all the bicarbonate filtered out is excreted in the urine.

Water. The body of a normal man weighing 65 kilograms (about 145 pounds) contains approximately 40 litres (about 42 quarts) of water; of this about 28 litres (30 quarts) are inside the cells of the body and 12 litres are outside. Of the 12 extracellular litres, about 2–3 litres are in the blood plasma—and the rest are around the tissues outside the blood vessels.

Water passes rapidly through almost all cell membranes and readily enters and leaves almost all the bodily spaces normally containing fluid. Its final distribution is determined by osmotic and hydrostatic pressures.

The volume of bodily water normally remains constant because the amounts ingested and eliminated are equal. Physiologically, thirst and satiety are influenced by a group of nerve cells in the hypothalamus, at the base of the brain.

Imperceptible loss of water

At rest, and in temperate climates, there is an imperceptible loss of water from the surface of the body and in the air breathed out. This loss amounts to about 800 millilitres in 24 hours. It is increased when the surrounding temperature is elevated or when atmospheric humidity is low. Losses in this range become perceptible in other circumstances and form the cloud of moisture in one's breath on a winter day or the moisture that condenses on the inner side of a waterproof garment. Greater losses of water occur, of course, during vigorous exercise in the heat, and the losses from the bodily surfaces are then perceptible as sweat. The amount of water lost in the urine amounts to from one to two litres in 24 hours.

THE DEPLETION OF WATER AND SALTS IN THE BODY

Sodium depletion. In health the equality between the amount of sodium excreted and the amount ingested depends largely on normal kidney function. In temperate climates negligible amounts of sodium are lost in the stools and from the skin, and the power of the normal kidneys to conserve sodium in the face of reduced intake is virtually absolute. Salt depletion is usually the result of excessive loss of salt through faulty kidney function, rather than of inadequate intake.

Loss of sodium is usually accompanied by a reduction in body water. Pure sodium depletion unaccompanied by water loss, although uncommon, may arise when the response to abnormal losses of salt and water is unrestricted water intake, as, for example, when excessive sweating occurs in unfavourable environments and when the fluid loss is replenished by salt-free liquids. In these circumstances, the change in total body water may be negligible, in spite of considerable salt deficiency.

Causes. Failure of the kidney to conserve salt may occur because of kidney disease or because of inadequate hormonal control. Thus, a chronic infection of the urinary tract, acute ischemic renal failure (failure of the kidney to function normally because of inadequate blood supply), or insufficient adrenocortical hormones—hormones from the outer substance of the adrenal gland—may be responsible.

Sodium loss during diabetes

Excessive loss of salt and water in the urine also occurs during the excessive secretion of urine that is induced by high levels of blood sugar in the disease diabetes mellitus. If the diabetes causes acidosis, which is a decreased alkalinity of the blood and tissue fluids, the process by which sodium is returned to the blood from the tubular filtrate in return for hydrogen ions is upset. Salt depletion may also be induced by the excessive or prolonged use of diuretics, substances that induce increased excretion of urine. Salt depletion also results from diarrhea, vomiting, and other situations involving external loss of salt-containing fluids.

Consequences. Because sodium is predominantly extracellular, salt depletion leads quickly to a fall in the volume of extracellular fluid. Water tends to be excreted to balance intracellular and extracellular osmotic pressures. This volume decrease is responsible for such effects as loss of elasticity of the skin, diminution of the pressure within the eyeballs, and dryness of the tongue. Thirst may be prominent, but tends to be less severe when the sodium levels in the blood are low. The fall in blood volume causes fainting, low blood pressure, a reduced rate of glomerular filtration in the kidney, and a reduced volume of urine. (The glomeruli are clusters of minute blood vessels, capillaries, through the walls of which fluid is filtered from the blood into the nephrons, in the first stage of the production of urine.) The capacity of the body to rid itself of wastes decreases, and kidney failure develops. The pulse rate rises. Constriction of blood vessels diminishes the circulation through the skin so that the skin and the hands and feet become cold.

Treatment. Persons with mild degrees of sodium depletion, whose blood pressure is normal, usually need merely to drink salted water to recover a normal sodium level. In more severe cases, or when there is vomiting, the physician injects isotonic salt solution into a vein. (An isotonic salt solution is of the same osmotic pressure as the plasma; it contains about 0.9 percent sodium chloride.) When there is severe sodium depletion there often are losses of other electrolytes, which must also be restored.

Water depletion. The reduced water intake that is most often responsible for water depletion may result either from difficulties in drinking, as when there are sores in the mouth and throat, or from circumstances that cut off access to fresh water—for example, shipwreck, or becoming lost in the desert.

Excessive loss of water in the urine because of disease that interferes with the kidney's ability to concentrate the urine is a less common cause of water depletion.

As water is lost from the blood, the plasma concentration of sodium rises. Water is drawn from the cells, and intracellular dehydration occurs. The body loss of water is thus shared both by the extracellular and the intracellular fluids. For this reason, the clinical features of dehydration are not as obvious as those of salt depletion. Thirst, the result of stimulation of a thirst centre in the hypothalamus, is usual unless the person is senile, confused, or unconscious. The migration of water from the intracellular fluid to the extracellular helps to maintain the volume of the latter for a time, so that the blood pressure remains unaltered until considerable water depletion has occurred. The affected person then often shows mental confusion or complains of dizziness and difficulty in swallowing. Ultimately, flow of blood to the kidneys is reduced, and blood levels of urea and other wastes become abnormally high. The water

depletion is treated by giving liquids; these should be salt-free unless salt loss is also present.

Potassium depletion. Potassium depletion occurs in a wide variety of disorders. The healthy person eliminates about one-quarter of his daily intake of potassium in the stools and three-quarters in the urine. The bulk of urinary potassium is delivered into the channel of the nephron tubule by the cells lining the far end of the tubule (the distal tubule); these cells excrete potassium or sodium ions and, in exchange, take sodium ions from the liquid filtered out of the blood and into the tubule from the glomerulus.

Two types of potassium loss

Causes. Potassium depletion results from excessive loss of potassium from the intestinal tract or in the urine. Gastrointestinal losses are caused by severe acute or chronic diarrhea and by loss of intestinal fluid from vomiting, drainage through a gap in the intestinal wall (a fistula), or by aspiration—withdrawal of intestinal contents by suction in the course of medical treatment.

Loss of potassium in the urine is more subtle in its development. It occurs when the excretion of potassium ions in exchange for sodium ions is increased in the renal tubules. This increased excretion may result from administration of large amounts of sodium-containing fluids or from the use of diuretics, or it may occur as one feature of disorders such as Cushing's syndrome (a symptom complex resulting from overproduction of adrenocorticotropic hormone by the pituitary) or aldosteronism (the overproduction of the hormone aldosterone by the adrenals).

Excessive loss of potassium also results from diseases or drugs that suppress tubular secretion of hydrogen ions; with fewer hydrogen ions to exchange for sodium, more potassium will be lost in the exchange process.

Conditions that interfere with the activity of the cells in the maintenance of their concentration of potassium and in excluding or eliminating sodium (the process called the sodium pump) also lead to potassium depletion and increased loss of potassium in the urine. These conditions include a deficiency of oxygen; impaired carbohydrate metabolism, as seen in starvation or diabetes; dehydration; and acidosis.

Consequences and treatment. Because most of the body's potassium is inside the cells, severe depletion of potassium may occur without alteration in the potassium level of the plasma, and identification of the disorder is made difficult by the inaccessibility of the intracellular fluid to analysis.

Effects of potassium deficiency

A person whose potassium is depleted tends to be apathetic and physically weak; he is mentally confused, and his abdomen is distended. Potassium deficiency, sufficiently severe to cause a fall in plasma-potassium levels, is characterized by generalized muscular weakness with some degree of paralysis. Sensations of pins and needles in the skin are common. The electrocardiogram—tracings reflecting heart activity—shows characteristic changes. Severe potassium depletion may lead to death if it remains uncorrected.

The condition is treated by administration of potassium salts orally or by injection into a vein. Oral administration is more commonly used and is less dangerous.

THE ABNORMAL ACCUMULATION OF WATER AND SALTS IN THE BODY

Potassium intoxication. A rise in plasma-potassium levels above normal usually occurs only when the kidney fails to function normally and there is a resultant reduction in the amount of urine excreted.

Persons with this disorder are dull, lethargic, and confused. The condition of weakness and paralysis of muscles is indistinguishable from that seen in persons with low blood levels of potassium. The pulse becomes irregular, and some degree of heart block develops. (In heart block, the upper and lower chambers of the heart tend to beat independently, which interferes with the heart's efficiency as a pump.) If the plasma-potassium level rises above eight milliequivalents per litre, there is danger that the heart will stop beating.

Measures taken to correct the high plasma levels of potassium include avoidance of fruits and fruit juices that are rich in potassium, avoidance of protein, and taking of substances such as sodium- or calcium-ion-exchange resins, which absorb potassium from the blood and from the intestinal secretions.

Magnesium deficiency and intoxication. The adult body contains about 25 grams (0.9 ounce) of magnesium, 60 percent of which is in the bones. The most frequent cause of deficiency of magnesium is replacement of fluids lost during prolonged diarrhea or vomiting with fluids containing electrolytes, but without magnesium supplements. Depletion also may result from prolonged use of diuretics, chronic diarrhea, severe malnutrition, and alcoholism. In addition, excessive secretion of the hormone aldosterone or of parathyroid hormone may lead to magnesium deficiency. Magnesium chloride and magnesium hydroxide are given to correct the condition.

Magnesium intoxication occurs in kidney failure and causes symptoms related to the central nervous system. When the kidney recovers normal function, the abnormal levels of magnesium disappear without special treatment.

Water intoxication. When healthy persons drink large volumes of water, they can respond to this with corresponding increases in the amounts of urine excreted. The capacity of the body to excrete water depends upon many factors, which include the rate of glomerular filtration and the power of the distal tubules of the kidneys to produce a dilute urine; this ability in turn depends upon the presence of sodium in the distal renal tubules and the capacity of the nephron to reabsorb the sodium without reabsorbing water. (Each distal tubule is that portion of the nephron tubule that is furthest from the portion of the nephron that encloses the glomerulus.) Many persons who are ill have a restricted ability to dilute the urine when given large amounts of water, including persons suffering from acute and chronic kidney disease, severe heart failure, disease of the adrenal glands, and cirrhosis of the liver (a disease involving destruction of liver cells and formation of scar tissue). Occasionally, tumours of the ovaries or lungs secrete a substance with antidiuretic properties that lead to water intoxication. After surgery some people may be incapable of diluting the urine because of the liberation of vasopressin by the stress of the operation. Vasopressin is a hormone released by the hypothalamus; its many functions include contraction of small blood vessels and suppression of urine excretion.

Effects of vasopressin

In all the circumstances mentioned, even a modest water intake reduces the level of sodium ions in the plasma and may produce disordered cerebral function, dizziness, headache, nausea, mental confusion, convulsions, coma, and death.

Treatment consists of restricting water intake. In severe cases salt solution is injected into a vein.

Water and salt retention (edema). Abnormal accumulation of water and salt in the body has fascinated physiologists and clinicians for several centuries, and before the discovery of modern diuretic drugs gross edema was a common complication of a variety of diseases, the victim being drowned, as it were, in the high tide of his own body fluids. Death from edema was well known to the ancients, who often made a series of superficial cuts in the limbs in an attempt to release the fluid from the distended tissues as a remedy of the last resort.

Causes. The fundamental cause of edema is a fault in the physiological mechanisms that control the volume of the extracellular fluids. Figure 4 illustrates how a healthy individual undergoes slight fluctuations in the water and salt content even when consuming a diet fixed in calories, nitrogen, water, and salt. These natural ripples on the surface of the body fluids, which ebb and flow over periods of several days, are due to the operation of a hunting, or servo-feedback, mechanism for the control of body fluid volume. Such a mechanism must involve (1) a detector that identifies lack of stability in the system, (2) an integrator that analyzes the information, and (3) an effector organ that adjusts the rate of excretion of water and salt according to need. Whatever its clinical cause, edema represents a vast tidal wave upon the extracellular sea and arises from a breakdown in the system responsible for volume control. Little is known about the first two components of the volume-control system, but the kidney

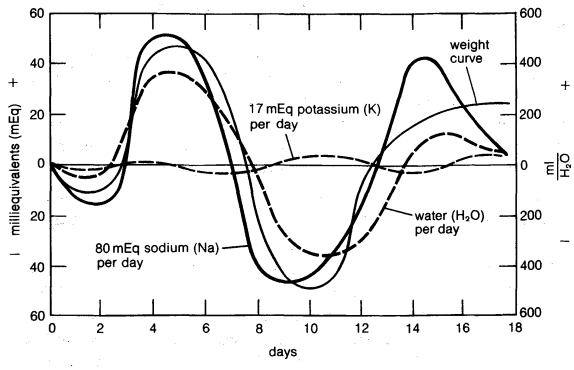

Figure 4: Cumulative sodium (Na^+), potassium (K^+), and water (H_2O) balance in subject on a constant diet at rest.

is certainly the effector organ, and edema arises when the kidney fails to meet its biological commitment.

The common primary event responsible for all types of generalized edema is an inadequate blood volume induced either by loss of plasma proteins or by inadequate cardiac output. The first condition may arise because of excessive loss of protein in the urine or from the gastrointestinal tract, failure of protein synthesis by the liver, or as a result of gastrointestinal malabsorption or of malnutrition; inadequate filling of the arterial circulation occurs in heart failure.

A fall in the concentration of plasma proteins disturbs the balance of factors that influences the exchange of fluid between the vascular and extravascular compartments. As a result, fluid moves from the blood into the tissues, where it accumulates. The resulting fall in blood volume activates the volume-control system and stimulates the kidney to conserve water and salt in an attempt to repair the deficit; as a result, the accumulation of edema fluid is merely aggravated. The physiological link between low blood volume and reduced arterial-filling pressure, on the one hand, and renal water and salt retention by the kidney, on the other, is far from clear, but probably includes the operation of pressure-sensitive areas in the thyrocarotid and renal arteries, the atria (upper chambers) of the heart, the juxtaglomerular apparatus in the kidney, and the adrenal cortex (Figure 5). The thyrocarotid pressure-sensitive area is also called the carotid sinus; it is located at the point where the common carotid arteries, the principal arteries to the head, divide to form the internal and external carotids. The renal arteries, the arteries to the kidneys, are branches of the abdominal portion of the aorta. The juxtaglomerular apparatus is made up of specialized cells in the middle coat of the arterioles (small arteries) that bring blood to the glomeruli. As a consequence, both the rate of secretion of aldosterone and vasopressin (ADH) is increased, and water and salt conservation is promoted. In addition, hemodynamic effects on the renal circulation and the influence of other hormonal agents (as yet inadquately defined), which may act principally on the reabsorption of sodium in the proximal convoluted tubule of the kidney, may contribute.

Pressure-sensitive areas

Consequences. The effects of generalized edema vary with its severity and with the part of the body predominantly affected. All tissues are involved to some extent, but swelling of the legs is almost universal and is partly the result of the hydrostatic effect of the upright posture. In the nephrotic syndrome, in which the urinary loss of protein is caused by glomerular disease, the edema is generalized; in heart failure it tends to accumulate either in the pulmonary circulation (pulmonary edema) or in the systemic circulation—*i.e.*, in the legs and the abdominal cavity; in liver disease caused by local factors within the liver and disturbance in the portal circulation, the peritoneal cavity (the space that in disease develops between the membrane lining the abdomen and the membrane covering the abdominal organs) is the most commonly involved. Edema in this region is called ascites. Localized edema may arise in a limb or other single part from venous or lymphatic obstruction; even localized edema activates the volume-control system, since the edema fluid is derived from the body fluids as a whole. The detector mechanism is stimulated, and water and salt retention encouraged. When the water and salt content of the rest of the body then remains within normal limits, the swelling of the affected part continues.

Treatment. The treatment of edema is the correction of the underlying cause of the disturbance; this correction involves appropriate therapy for kidney, heart, and liver disease, and measures aimed at ameliorating absolute and conditional undernutrition. If, as is often the case, this is not possible, the kidneys may be induced to excrete water and salt by the administration of diuretics that specifically inhibit sodium transport somewhere in the nephron; a large number of these agents are available and are remarkably successful.

DISTURBANCES IN ACID–BASE BALANCE AND MINERAL METABOLISM

Disturbances in acid–base balance. Fluctuations in hydrogen-ion concentration arise in many circumstances in health and disease. Four primary types of disorder are recognized: metabolic acidosis and alkalosis, and respiratory acidosis and alkalosis. The first two of these involve increased or decreased alkalinity of the blood plasma because of some change in the metabolic process; the second two arise from disorders in the carbon dioxide exchange in the lungs.

Metabolic acidosis. Metabolic acidosis arises from three main causes: (1) there may be an increased formation of acids during the metabolic process, as occurs, for example, in diabetes or starvation, during exercise, or as a result of reduced levels of oxygen in the tissues (acetoacetic and lactic acids are especially important in these contexts); (2) there may be diminished excretion of hydrogen ions, as occurs in several situations, including kidney failure; (3) there may be increased loss of base such as bicarbonate ions, as occurs in diarrhea and as a result of fistulas (openings) in the walls of the intestines.

The increased concentration of hydrogen ions in the plasma interferes with the reversible process by which carbon dioxide combines with water to form carbonic acid, and by which carbonic acid in turn becomes ionized into hydrogen ions and bicarbonate ions. Because of the high hydrogen-ion concentration, the production of bicarbonate falls and carbonic-acid levels rise.

The increase in hydrogen ions also stimulates the respira-

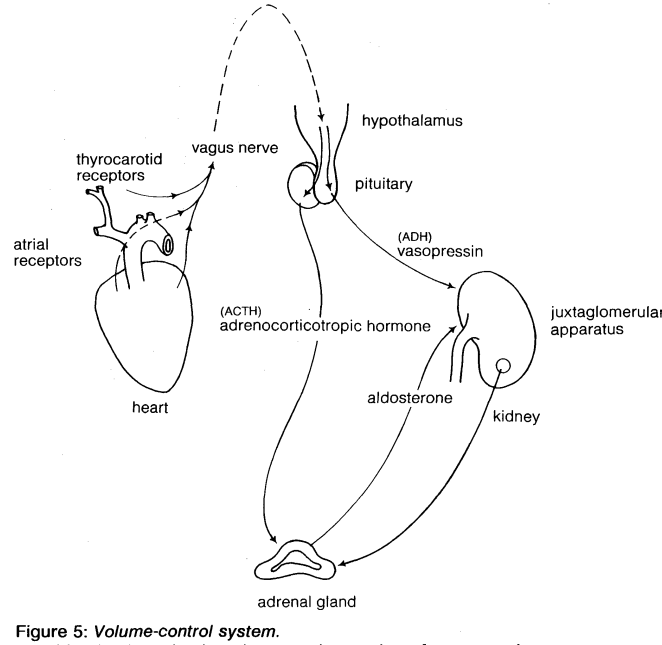

Figure 5: *Volume-control system.*
Low blood volume leads to increased secretion of vasopressin (also called antidiuretic hormone, ADH), adrenocorticotropic hormone (ACTH), and aldosterone, leading to conservation of salt and water and consequent increase in the volume of the blood.

tory centres in the brain to increase the rate and depth of breathing. Increased amounts of carbon dioxide are, thus, eliminated by the lungs, and the carbon dioxide pressure in the blood plasma falls below normal levels. This decrease reduces the formation of carbonic acid and lessens the tendency of the blood to become less alkaline.

Recovery of the normal alkalinity depends on the regeneration of bicarbonate by the cells of the kidney tubules during the process of hydrogen-ion excretion in exchange for sodium ions. In severe cases, this process is assisted by administration of sodium bicarbonate.

Causes of respiratory acidosis

Respiratory acidosis. If the ability of the lungs to expel carbon dioxide is impaired—for example, by depression of the respiratory centre, as occurs in barbiturate or morphine poisoning, or because of paralysis of respiratory muscles, as in poliomyelitis—carbon dioxide is retained in the body and the plasma-carbon dioxide pressure rises above its normal value of 40 millimetres of mercury. As a result, levels of carbonic acid and of hydrogen ions rise in the tissues and blood. This situation is mitigated by the acceptance of hydrogen ions by substances such as proteins, with the resultant generation of bicarbonate ions. The kidneys also respond to the elevated carbon dioxide pressure by reabsorbing bicarbonate ions and forming new bicarbonate ions.

Respiratory acidosis is dealt with by treatment of the underlying disease. Occasionally assisted or artificial respiration is needed.

Metabolic alkalosis. During digestion of a large meal the secretion of hydrochloric acid (HCl) by the stomach involves the withdrawal of hydrogen ions from the blood. If vomiting occurs, the hydrogen ions are lost from the body along with chloride ions, and the blood-hydrogen-ion concentration falls, increasing the alkalinity of the blood plasma. At the same time, the plasma levels of bicarbonate ions rise.

The fall in hydrogen-ion concentration reduces the stimulus to respiration. Carbon dioxide elimination by the lungs is reduced, and the pressure of carbon dioxide in the plasma rises, causing increased formation of carbonic acid and reducing the excess alkalinity.

Chronic metabolic alkalosis, induced by the taking of large amounts of sodium bicarbonate over long periods, especially when there is a high intake of calcium in the diet, may lead to deposition of calcium in the kidneys.

Severe potassium depletion also causes metabolic alkalosis, and depletion of chloride ions sometimes contributes to the condition. In the maintenance of sodium balance, sodium cations filtered into the nephron tubules from the glomeruli are reabsorbed in conjunction with chloride anions and also by the exchange process involving hydrogen or potassium ions. When the body is deficient in chloride, as may occur as a result of prolonged vomiting, the conservation of sodium by the nephron tubules is achieved by employment of hydrogen and potassium exchange for sodium ions to a greater extent than normal. This conservation leads to excessive loss of hydrogen and potassium ions and, thus, to metabolic alkalosis.

The electrolyte disorders may be corrected by intravenous administration of an isotonic solution containing sodium, ammonium, and potassium chloride.

Causes of respiratory alkalosis

Respiratory alkalosis. When one climbs a mountain of about 3,650 metres (12,000 feet), oxygen lack becomes a significant stimulus to respiration, and carbon dioxide is eliminated in larger amounts than occurs at sea level. As the carbon dioxide pressure falls, the plasma-hydrogen-ion concentration is reduced; but the extent of the reduction is lessened by the release of hydrogen ions by nonbicarbonate buffers such as proteins and by a compensatory kidney excretion of bicarbonate ions. A similar response occurs in hysterical overbreathing, in salicylate poisoning, after head injury, and in severe liver failure.

When respiratory alkalosis is the result of hysterical overbreathing, breathing into and out of a paper bag is often helpful.

Disturbance in calcium metabolism. Calcium is an essential component of bone, being present in the hydroxyapatite crystals of the intercellular substance (hydroxyapatite is a calcium phosphate). The adult human skeleton contains about 1.2 kilograms (2.6 pounds) of calcium. Because the skeleton takes about 20 years to be formed, the growing child must retain from his diet an average of 160 milligrams (0.005 ounce) of calcium a day. There is a continuing turnover of skeletal calcium, about 500 milligrams (0.02 ounce) being reabsorbed from the bone and replaced daily. The surfaces of the hydroxyapatite crystals have a layer of ions and water, and it is around this layer that exchange of calcium and other ions takes place.

Among the many factors that affect calcium-plasma levels are the two hormones thyrocalcitonin and parathyroid hormone, vitamin D levels, and the hydrogen-ion concentration of the plasma.

High levels of parathyroid hormone tend to raise plasma levels of calcium, and vitamin D causes absorption of calcium from the intestine. Thyrocalcitonin depresses the plasma-calcium levels.

Common causes of calcium disorders

Disorders of calcium metabolism are most commonly the result of endocrine abnormalities or of nutritional deficiency. Thus oversecretion and undersecretion of parathyroid hormone cause elevated and depressed levels of calcium in the plasma, respectively. Increased secretion of thyrocalcitonin is extremely rare, but may result from a tumour of the thyroid cells that secrete the hormone.

In kidney failure, high levels of urea in the blood appear to increase resistance to the action of parathyroid hormone and of vitamin D: this increased resistance causes a depressed level of calcium in the plasma, which, in turn, leads to secondary enlargement of the parathyroid glands.

Low levels of plasma calcium are also found in rickets and osteomalacia. These two related diseases, occurring in children and adults, respectively, involve inadequate deposition of calcium and phosphorus in the bones; a principal cause is insufficient intake of vitamin D. In another disease, osteoporosis, characterized by light, brittle bones, the plasma levels of calcium are normal or only slightly reduced, and no benefit is derived from taking increased amounts of vitamin D.

Disturbances in phosphorus metabolism. The human body contains about 700 grams (1.5 pounds) of phosphorus; of this about 80 percent is in the bones. Phosphorus deficiency is known to occur in cattle that graze on poor land and has been held responsible for stunting of growth and weakness. The existence of a primary phosphate deficiency in man is not yet established. It may occur in persons who take large doses of nonabsorbable antacids such as aluminum and magnesium hydroxide, which interfere with the intestinal absorption of phosphate.

(J.S.Ro.)

THE TISSUES AND FLUIDS OF PLANTS

The plant body, like the animal body, is constructed of various types of cells usually organized to form tissues. Tissues have been classified on the basis of their position in the plant, the types of cells they contain, and the function of these cells. No single criterion, however, adequately expresses the complex interaction of cells and their association in the form of specific tissues.

Tissues with cells that continuously divide to produce new cells are termed meristematic tissues. They give rise to the mature tissue systems of the plant of which three can be distinguished: (1) the dermal tissue system, which makes up the outer layers or protective tissue of the plant; (2) the vascular tissue system, which includes the water- and food-conducting tissues, xylem and phloem, respectively; and (3) the fundamental or ground tissue system, which includes all other tissues exclusive of dermal and vascular. Although mature tissues may consist of one cell type (simple tissues), they more often are made up of a variety of cell types (complex tissues).

Classification of plant tissues

MERISTEMATIC TISSUES

All tissues of the plant are derived from cell-producing tissues called primary tissue meristems, which begin to form early in embryonic development. The primary tissue meristems are designated protoderm, procambium, and ground meristem. Protoderm functions to produce the dermal or "skin" tissue system of the plant; procambium gives rise to the vascular or conducting tissue system; and ground meristem is the precursor of the fundamental or ground tissue system.

As the young embryo develops, protoderm tissue, which forms from the peripheral cells, is clearly delimited from the other tissues as the embryo elongates and becomes bilaterally symmetrical—that is, with mirror-image halves. At this stage procambium is also evident. The ground meristem originates from the embryonic tissue situated between protoderm and procambium.

Root and shoot systems

The cotyledons or first leaves (seed leaves) are the first organs formed. Soon after they begin to develop, the shoot apical meristem forms between them. At the end of the embryo opposite the cotyledons, the root apical meristem forms. The root and shoot apical meristems continuously contribute cells to the primary tissue meristems, which, following differentiation and maturation, give rise to the primary tissues and the primary plant body. The primary tissues include primary xylem, primary phloem, cortex, pith, and epidermis. In young stems the arrangement of tissues as seen in cross section is as follows: outermost tissue, the epidermis; cortex; primary phloem; and primary xylem. The pith occupies the centre of the stem (see Figure 6).

In many plants vegetative development is essentially complete when the primary tissues have matured. This is true in many lower vascular plants such as club mosses, horsetails, and some ferns; in monocotyledons (flowering plants with parallel-veined leaves, such as grasses, orchids, and palms); and in some nonwoody dicotyledons (flowering plants with net-veined leaves, such as violets and poppies). In other herbaceous dicotyledons, however, and in woody plants, formation of new tissues continues after primary growth is complete. The production of these tissues and the continuation of growth in such plants are attributable to the lateral meristems, regions of cell division that contribute to growth in stem thickness. These meristems, called the vascular cambium and the cork cambium, are responsible for producing the secondary tissues—secondary xylem, secondary phloem, and periderm—that form the secondary plant body (see Figure 6). The vascular cambium is chiefly responsible for increasing the diameter of the plant.

Lateral meristems

Apical meristems. The cells of the shoot and root apical meristem are organized in precise patterns that are characteristic of various plant groups. Knowledge of the arrangement and organization of cells at the apex is useful for descriptive purposes and for making structural comparisons between plants. Apical organization, however, is known to vary during normal development and is often influenced by seasonal changes.

Various regions of the apex can be distinguished from each other by examination of such features as cell and nucleus size, frequency and planes of cell division, and wall thickness. At the summit of the shoot apex a group of meristematic cells constitutes a so-called initiation zone, which gives rise to cells of the surface layer and a region below, the zone of central mother cells, which divide infrequently. Surrounding the latter zone is the peripheral zone, within which most of the apical activity takes place—cell divisions are frequent and leaf primordia and procambium cells are initiated. Below the central mother cell zone lies a zone termed the rib meristem, whose cells are arranged in radial, regular, longitudinal rows and divide transversely; much of the fundamental tissue system is derived from the rib meristem. Various kinds of mature tissues are produced in the plant body because the cells of the shoot apex divide at different rates and in different planes. Although in some plants, apical meristems lack distinguishable zones, the cells of the shoot apex retain the ability to divide at different rates and in different planes.

Despite the structural differences in apical meristems of various groups of plants, they function in similar ways. All apical meristems (1) produce cells that differentiate into primary-tissue meristems, which in turn produce the primary tissues of the plant; (2) initiate organs, primarily leaves and branches, in a coordinated manner and in a genetically determined pattern; and (3) contribute to the increase in length of the plant.

Function of apical meristems

Lateral meristems. The vascular cambium, which produces xylem and phloem cells, originates from procambium that has not completely differentiated during the formation of primary xylem and primary phloem. The cambium is thought to be a single row of cells that produces new cells: externally, the secondary phloem, and internally, the secondary xylem. Because it is not possible to distinguish the cambium from its immediate cellular derivatives, which also divide and contribute to the formation of secondary tissues, the cambium and its immediate derivatives are usually referred to as the cambial zone.

Unlike the apical meristems, which consist of a population of similar cells, the cambium consists of two different cell types; the fusiform initials and the ray initials (see Figure 7). The fusiform initials are elongated tapering cells that give rise to all cells of the vertical system of the secondary phloem and xylem. The ray initials are isodiametric cells—about equal in all dimensions—and they produce the vascular rays, which constitute the horizontal system of secondary tissues. The fusiform and ray initials of the cambium divide in a tangential plane (*i.e.*, parallel to the stem surface) generating xylem mother cells toward the inside and phloem mother cells toward the outside. These cells in turn continue to divide tangentially, producing new cells that add to the xylem and to the phloem. Divisions of the cambium cells and xylem and phloem mother cells do not result in the production of equal amounts of secondary xylem and secondary phloem; because the cambium produces more cells internally than externally, more secondary xylem is produced than secondary phloem. Because divisions in the fusiform and ray

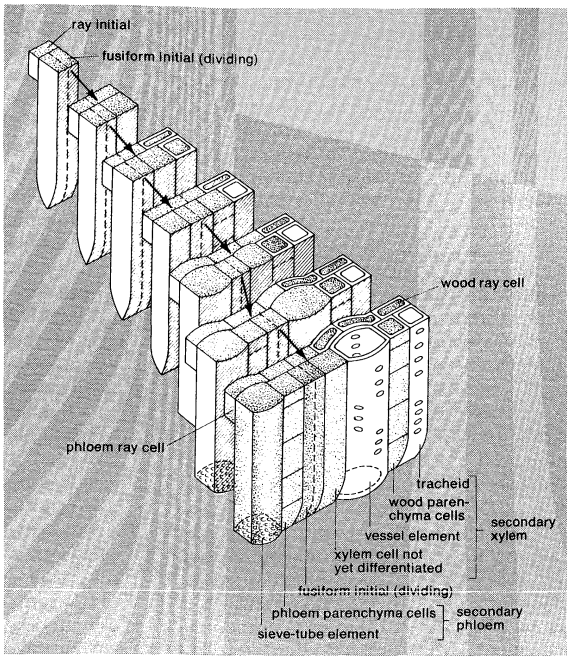

Figure 7: Production of secondary xylem and phloem cells by cambial initials.

initials are primarily tangential, new cells are regularly arranged in well-defined radial rows, a characteristic pattern for secondary vascular tissues.

Divisions in the cambium not only produce secondary vascular tissues but also increase the circumference of the cambium. As new cells are continuously added to the inside of the cambium, the cambium increases laterally (in circumference) to keep pace with the growth of the stem. In some plants this is accomplished simply by radial division of the fusiform and ray initials. In other plants, the mechanism for increasing cambial diameter or increasing the number of cambial cells is more complex. If cambial activity is extensive, the primary tissues lying outside the cambium, such as primary phloem, cortex, and epidermis, may be crushed by the pressure of new secondary tissue growth or become torn and obliterated because they cannot accommodate to the rapidly increasing diameter of the plant.

As growth proceeds the cork cambium forms in living cells of the epidermis, cortex, or, in some plants, phloem and produces a secondary protective tissue, the periderm. The cork cambium is, like the vascular cambium, a lateral meristem that produces cells internally and externally by tangential divisions. Unlike the cambium, the cork cambium consists of one cell type.

Intercalary meristems. Another type of meristem active in certain plants, especially horsetails and grasses, is the intercalary meristem. These cells possess the ability to divide and produce new cells, as do apical and lateral meristems. They differ, however, in being situated between regions of mature tissue, such as at the base of grass leaves, which are themselves located on mature stem tissue. In many instances intercalary meristems function for only a short time and eventually completely differentiate into mature tissues. Intercalary meristems are usually located at positions on the stem where leaves have emerged (nodes) and are largely responsible for elongation in grass shoots and leaves.

MATURE TISSUES

Dermal (protective) tissues. *Epidermis.* The epidermis, or surface cell layer, which covers all organs of the plant including stem and root, leaf, flower, fruit, and seed, functions in a variety of ways. It limits transpiration—evaporation of water from the surface of the plant, especially the leaf. Specialized cells facilitate gaseous exchange between the outside air and internal tissues. The epidermis also serves as a protective barrier, restricting insect and bacterial invasion of the underlying cells. In view of the many functions of this tissue, it is not surprising that it is also structurally variable. The epidermis may consist of either one cell layer or several.

Function of epidermis

The epidermis forms from protoderm, one of the primary tissue meristems. In addition to cellulose, the main carbohydrate component of wood, epidermal cells produce a fatty substance, cutin, which permeates the cell wall, eventually forming an outer layer, the cuticle. Although a cuticle covers the epidermis of all higher plants, the extent to which it develops depends on the plant species and the environment in which it grows. The cuticle is responsible for the protective functions of the epidermis. In some plants wax is also deposited on the cuticle and within the matrix of the cell wall. Waxy deposits may occur as thin layers or as thick layers such as those seen on leaves of the Brazilian wax palm, *Copernicia cerifera,* from which the commercially important carnauba wax is collected. The wax covering further serves to control water loss. Other substances, such as lignin, crystals, and mucilage, occur in epidermal cell walls of certain plants.

The epidermis is not continuous over the surface of the plant but is interrupted by pores that serve as channels to the interior tissues. The pores are bordered by specialized, often kidney-shaped epidermal cells, called guard cells. The combination of pore and guard cells is referred to as the stoma. Two to several epidermal cells, called accessory cells, may be adjacent to the guard cells and participate in stomatal opening and closing. The accessory cells and the stoma constitute the stomatal apparatus. There is considerable variation in the development, structure, and distribution of the stomatal apparatus in plant species. The size, shape, and wall thickenings of the guard cells are important in stomatal function and gaseous exchange.

Another important group of structurally modified epidermal cells includes hairs (trichomes) which occur as outgrowths of epidermal cells and, when present, are usually characteristic of the particular plant. Trichomes may be either glandular, consisting of a stalk terminating in a globular head, or nonglandular, consisting simply of elongated, often tapering structures. Both types may be single celled or multicellular. The glandular trichomes usually produce and secrete volatile and nonvolatile substances, such as volatile oils, mucilages, and resins. In addition, trichomes on many carnivorous plants produce digestive enzymes (biological catalysts). Nonglandular trichomes, which may function in reducing transpiration and excessive water loss, are variable in structure and occasionally provide commercially important products, such as cotton and kapok.

Root hairs

Hairs are found on the surfaces of roots. Root hair cells are initiated behind the meristematic zone of the root apex and continue to elongate as the distance of the epidermal cells from the meristem increases. Root hairs usually live and function only for a few days; the sequential nature of the production near the root apex, however, insures a continuous supply. Root hairs increase the water absorbing ability of the plant.

Periderm. In plants in which substantial secondary growth—increase in stem thickness—occurs, a protective tissue, the periderm, forms. It arises from the activity of a cork cambium and is a complex tissue consisting largely of cork cells. Periderm serves the secondary plant body in much the same way as the epidermis serves the primary plant body, restricting water loss from the tissues within, protecting against attack by organisms—particularly after tissue damage—and preventing mechanical injury to the underlying tissues. The protective nature of periderm results largely from the properties of cork cells, many layers of which form on the outer side of the cork cambium. Cork cells produce a fatty substance known as suberin, which is deposited over the primary cellulose walls; in addition, some wax may also be deposited. The combination of wax and suberin makes the cork relatively impermeable to the passage of water and gases. In certain plants some cork cells remain thin walled and alternate with thick-walled cells. Neither cell type is alive when mature. At maturity all cork cells become filled with air or, in some

instances, with resins or tannins that produce the dark pigmentation characteristic of certain types of cork and may have a protective function.

As secondary growth continues, the outer periderm layers crack and peel, and new layers of periderm form in tissues underlying the older periderm. In certain parts of the periderm, loosely arranged groups of cells often project above the other cells, forming prominent markings on the outer surface of the plant. These groups of cells, called lenticels, are similar to stomata in that they provide for passage of air to the interior tissues. The term bark is a nontechnical one usually referring to all tissues outside the vascular cambium. It may include parts of the phloem, cortex, and epidermis as well as periderm.

Vascular (conducting) tissues. All vascular plants, such as ferns, gymnosperms, and angiosperms, possess a well-developed vascular system that conducts water and food materials through the plant axis to the various organs; it usually also functions in support. The vascular system consists basically of two complex tissues, the xylem and phloem. The two tissues are distinctive, each being made up of several different cell types and each functioning in its own way. Movement of water and dissolved salts from the root system to other parts of the plant takes place through the xylem. Transfer of food materials produced in photosynthetic tissue or accumulated in storage organs occurs through the phloem (The structure and function of these tissues is described in detail below.)

Xylem and phloem

Fundamental (ground) tissues. The axis of most plants is composed of relatively large amounts of fundamental, or ground, tissues. The most common are parenchyma, collenchyma, and sclerenchyma (see Figure 8). These are simple tissues, but parenchyma and sclerenchyma are often found as components of complex tissues.

Parenchyma. Parenchyma is made up of thin-walled, commonly polyhedral (many-sided) living cells. The most common tissue in vascular plants and perhaps the most primitive, parenchyma is the chief constituent of the cortex and pith, the photosynthetic tissue of leaves, the pulp of fruits, and the endosperm (starchy nutrient tissue for the developing embryo) of many seeds. It is also found associated with the primary and secondary xylem and phloem. Although structurally simple, parenchyma cells may be highly specialized in a physiological sense. Some cells, especially those of the leaf and cortex, contain chloroplasts, which are small membrane-enclosed pigment bodies active in photosynthesis. Parenchyma containing chloroplasts is known as chlorenchyma. Other parenchyma cells may function in the production and storage of food substances necessary for maintenance of the plant. Parenchyma cells containing starch, lipid (fats), or protein are common in fruits, seeds, and especially in storage organs, such as rhizomes (creeping horizontal stem structures), bulbs, and tubers (underground storage stems, such as potatoes). Some parenchyma cells synthesize and accumulate other products such as crystals of calcium oxalate, tannins, mucilages, and resins. In addition, water, pigments, and soluble salts are found within parenchyma cells. Parenchyma tissue is therefore of primary importance to the plant.

Collenchyma. Collenchyma is basically a supporting tissue that provides structural rigidity for many plant organs. It is found chiefly in the cortex of stems and in leaves. For many herbaceous plants it is the chief supporting tissue, especially during early stages of development. In plants in which secondary growth occurs, the collenchyma tissue is only temporarily functional and becomes crushed as woody tissue develops. Collenchyma is located along the periphery of stems beneath the epidermal tissue. It may form a complete cylinder or occur as discrete strands that constitute the ridges and angles of stems and other supporting structures of the plant.

Collenchyma cells, polygonal in cross section, are much longer than parenchyma cells. The strength of the tissue results from the unevenly thickened cell walls and the longitudinal overlapping and interlocking of the cells. The cells have protoplasts, often containing chloroplasts, and they produce a thick cellulose wall. The wall is not uniformly thick in all cells, and thickening may occur predominately in longitudinal strips at the corners of the cell, on the tangential (*i.e.,* outer, toward the stem exterior) surface of the cell, or around the spaces between adjacent cells. Pits are present in the cell wall and provide a mechanism for intercellular communication. An important feature of collenchyma is that it is extremely plastic—the cells can extend and thus adjust to increase in growth of the organ.

Location of collenchyma wall thickenings

Sclerenchyma. The major function of sclerenchyma is support. Unlike collenchyma, mature cells of this tissue are generally nonliving and have heavily thickened walls containing lignin. The size, shape, and structure of sclerenchyma cells are not uniform. Two distinct types of cells occur: those that are greatly elongated are termed sclerenchyma fibres; those that are essentially uniform in diameter are called sclereids (see Figure 8). The division is arbitrary, and intermediate and overlapping types of sclerenchyma cells commonly occur, even within one plant organ.

Fibres may occur singly or in groups of few to many cells with their long, tapering ends interlocked, thus providing maximum support. They may be found almost anywhere

From T. Weier, C. Stocking, and M. Barbour, *Botany* (1970); John Wiley & Sons

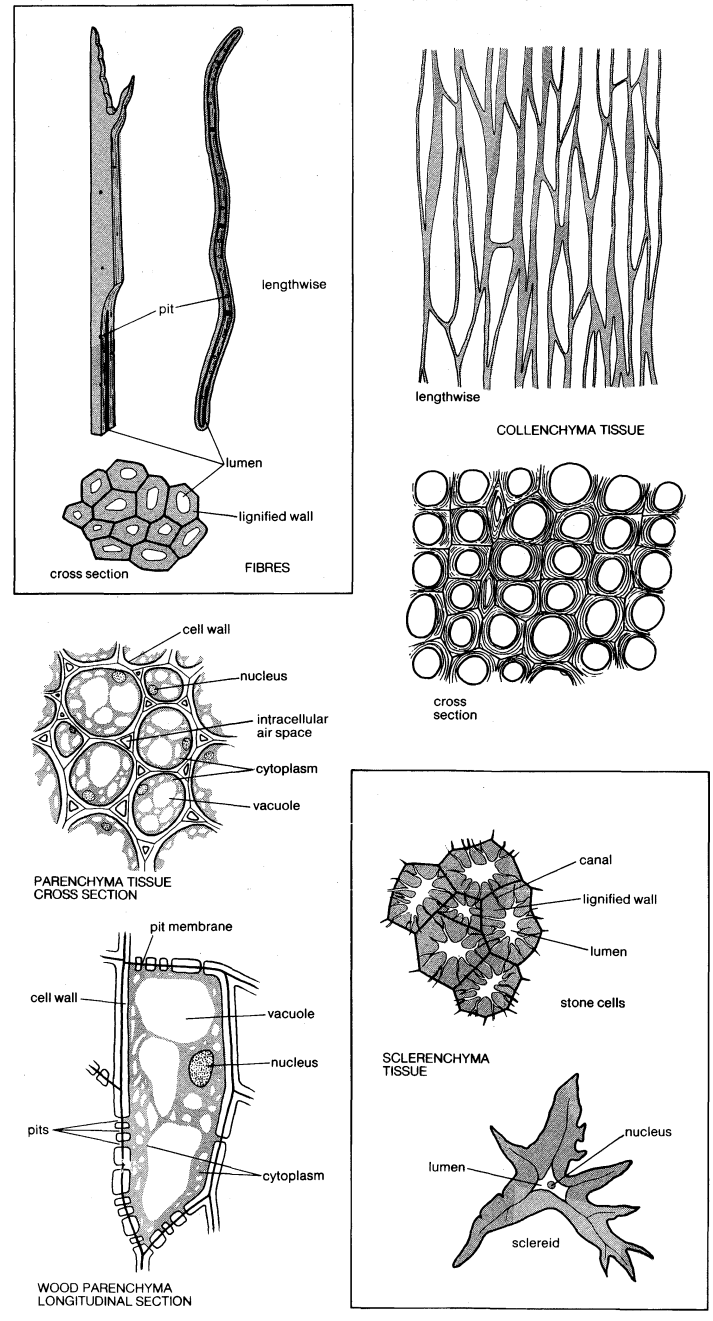

Figure 8: Cell types and tissues.

in the plant body and are classified according to position. Cortical fibres and phloem fibres are characteristic of the stems and roots of many plants. Fibres also partially or completely surround vascular bundles in leaves and in the plant axis. Most fibres have extremely thick cell walls containing pits, and the cell lumen is very narrow or completely obscured.

Sclereids occur singly or in groups and are present in various tissues of the plant such as periderm, cortex, pith, xylem, and phloem. They also occur in leaves and fruits and constitute the hard shell of nuts and the outer hard coat of many seeds. Sclereid walls are commonly pitted, and the pits may be extensively branched. Sclereids are extremely variable in form and are classified according to shape. Brachysclereids or stone cells are isodiametric; macrosclereids are rod shaped; osteosclereids are bone shaped; that is, elongated with enlarged ends; and asterosclereids are star shaped or otherwise branched. The utility of this classification is limited by the occurrence of sclereids that do not fit into any of the categories.

Endodermis. The endodermis, another kind of ground tissue, usually consists of a layer of cells surrounding the vascular system and separating it from the cortex. The endodermis is a prominent feature of the roots in most vascular plants and of shoots of many lower vascular plants. The endodermal cells have distinctive wall markings caused by the deposition of suberin in a strip along the transverse and radial walls (*i.e.,* on all walls except the inner and outer ones that are parallel to the root surface) of the cells; it is known as the Casparian strip. The Casparian strip is often impregnated with lignin. The combination of suberin and lignin in the cellulose matrix of the wall restricts the passage of water and solutes. In some plants, as a result of the continued deposition of encrusting materials, these endodermal cells appear to be thick walled. Cells adjacent to the xylem that fail to thicken are identified as passage cells. The functional significance of the endodermis tissue remains obscure despite the attention given it by many investigators.

Casparian strips

Structure and function of conductive tissues: plant internal transport

Water and nutrients flow through conductive tissues in plants just as the bloodstream distributes nutrients throughout the body of animals. This internal circulation, usually called transport, is necessary in all plants, even the most primitive ones, unicellular algae. Nutrients are taken up through the cell membrane, and certain substances may in turn be released into the surrounding water. Transport across membranes is fundamental and may be regarded as the basis for long distance transport (see CELLS: *The biological membrane*). Molecules are moved actively—*i.e.,* with the expenditure of energy—across a cytoplasmic membrane, from one compartment (*e.g.,* one cell) to another.

Active transport

EVOLUTION OF THE TRANSPORT PROCESS

The importance of transport processes in plants increased as multicellular plants evolved and their tissues acquired specialized functions. In large marine algae, for example, carbohydrates (such as sugar alcohol) are transported over relatively long distances, from their site of formation in well-illuminated plant parts near the water surface to parts near the sea floor that receive only small amounts of light. As land plants developed, long-distance transport assumed a still more important role; in this case, not only are carbohydrates transported from the organs in which they are formed (the leaves) to other parts—such as reproductive organs (flowers and fruits), stems, and roots—but water and minerals must be transported to leaves, which are not submerged in water (as are those of most primitive plants) but are in a relatively dry air environment. Highly developed land plants, such as trees, have two types of tissues specialized for long-distance transport: the xylem and the phloem. Water and dissolved mineral nutrients ascend in the xylem (the wood of a tree, such as an oak or a pine) and products of photosynthesis, mostly sugars, move from leaves to other plant parts in the phloem (the inner bark of a plant).

Xylem and phloem

Evolving land plants faced not only the problem of transport but also the problem of supporting their weight. Aquatic plants are supported by their buoyancy in water. Even large seaweed do not need a rigid stem; flotation devices such as gas-filled bladders hold them upright and enable them to grow toward the water surface and obtain sufficient sunlight for photosynthesis. On land, a rigid, self-supporting structure is necessary for plants; this structure, the xylem, consists of tiny rigid tubes through which water and dissolved mineral nutrients can move. The rigidity of the tubes within a stem is sufficient to make it self-supporting.

Land plants take up water from the soil through the roots; the few rare exceptions, such as some plants of the Peruvian desert that grow in dry soil, rely on adaptations that enable them to obtain water from the air. In most plants, then, water ascends through the xylem, the tiny capillaries of the woody stem tissue, into all plant parts but primarily into the leaves, from which it is transpired (evaporated) into the air. In this way, the mineral nutrients are transferred from the soil to all above-ground plant parts.

Plants living in humid habitats, such as the small and primitive mosses and liverworts, do not have a well-developed xylem. Similarly, water plants that have returned from land to an aquatic habitat during evolution have a reduced xylem; such plants, which have readapted to an aquatic environment, are not woody, because they need neither water-conducting tissues nor a self-supporting structure. On the other hand, tall land plants such as trees and vines (lianas) have the most highly developed long-distance transport systems. Vines differ from trees in that their xylem serves primarily for water conduction; they depend, for the most part, on other plants for support. Certain vines are of great length (a few hundred metres) and have extremely highly developed tissues for transporting water and nutrients.

Most of the material that comprises a plant's dry weight is a consequence of photosynthesis, in which light energy is converted into chemical energy used to synthesize organic substances. Carbon dioxide from the air and water, which the plant takes from the soil, are utilized during photosynthesis, which occurs mostly in green plant parts—especially the leaves (see PHOTOSYNTHESIS). Since plants shed their leaves either continuously or periodically but still increase in size, it is clear that many photosynthetic products must be transported out of the leaves and carried to all other plant parts; this process takes place primarily in the phloem.

The discovery of the functions of xylem and phloem (wood and bark) was made following that of the circulation of blood in the 17th century. By the early 19th century, it had been established that water ascends from roots into leaves through xylem and that photosynthetic products descend through phloem. Experiments now called girdling experiments were performed, in which a ring of bark is removed from a woody plant. Girdling or ringing does not immediately interfere with upward movement of water in the xylem, but it does interrupt phloem movement. In some plants surgical removal of phloem is difficult; in this case phloem may be killed by using steam (steam girdling). Xylem conduction is normally not affected by such treatment, and movement in the two transport tissues can thus easily be distinguished. Girdling experiments, however, are not entirely foolproof. The question as to whether or not mineral nutrients can ascend in the phloem illustrates the kinds of difficulties that may be encountered. Much smaller amounts of mineral nutrients reach the leaves in girdled plants than in ungirdled ones. From this observation it might be concluded that some nutrients ascend in the phloem of ungirdled trees; girdling, however, interrupts the flow of sugars into roots. Roots are thereby starved and take up fewer mineral nutrients; the reduced flow of mineral nutrients to the leaves of girdled plants can thus be explained as a secondary effect.

Girdling experiments

It was once widely believed that flogging a fruit tree increases the crop. The rational explanation of this is simple: flogging a tree damages the phloem; *i.e.,* it girdles the

tree, perhaps partially. Girdling increases the sugar concentration of the leaves by restricting downward transport to the roots and may thus directly or indirectly stimulate flowering or, if done after fruit-set, may increase fruit size.

STRUCTURAL BASIS OF TRANSPORT

Cell-to-cell transport. Two features of plant cells differ conspicuously from those of animal cells. In plant cells the protoplast, or living material of the cell, contains one or more vacuoles, which are vesicles containing aqueous cell sap. Plant cells are also surrounded by a relatively tough but elastic wall. Water entering the vacuole by osmosis (*i.e.,* movement of water across a membrane into regions of lower water concentration, such as cell interiors, which normally contain dissolved substances) expands the protoplast and consequently the cell wall until the internal pressure is balanced by the elastic counterpressure of the wall. Spaces between and within cell walls are sufficiently large to permit water to flow around all cells. The space available for free water flow is called apoplast. Water in apoplast originates from the roots and contains nutrients taken up by them. Nutrients enter a cell by crossing the outer cytoplasmic membrane.

Entry into the protoplast

Because mature cell walls are dead structures, metabolic activities—the chemical reactions of living systems—occur within protoplasts. Substances can enter a protoplast by cytoplasmic connections between neighbouring cells (plasmodesmata) or by active transport mechanisms requiring energy and a group of enzymes called permeases. Plasmodesmata penetrate neighbouring cell walls at areas called pits. Some substances pass out of cells into the apoplast and are transported by energy-requiring processes into the protoplast of another cell.

Structure of xylem and phloem. *The xylem.* Cell-to-cell transport takes place in all multicellular plants, but it is a slow process; the higher plants evolved the specialized tissues, xylem and phloem, for rapid long-distance transport. The woody tissue, xylem, contains highly specialized cells for water conduction. The cells are long and reinforced by strong, woody walls; their protoplast breaks down and dissolves after wall growth is completed, so that the entire inside of the cell becomes available for rapid water conduction. In other words, the water-conducting cells of xylem are dead when functional. In the more primitive conifers the xylem consists largely of spindle-shaped cells called tracheids, which have a diameter around 0.04 millimetres (0.0016 inch) and a length of about three millimetres (0.12 inch). Flowering plants have a more highly specialized xylem, in which the mechanical function and the water conduction function have been separated during evolution. Tracheids, the primitive conducting cells, have evolved to form fibres for mechanical strength and vessels for water conduction. Vessel elements are barrel-like cells with widths of up to 0.5 millimetre (0.02 inch) in some plants. Vessel elements are arranged end-to-end; their end walls are partly or wholly dissolved, and rows of such cells thus form long capillaries (tubes), up to several metres in length. These tubes are the vessels.

Function of the pits

Conducting units—tracheids in conifers and vessels in flowering plants—have overlapping ends that are laterally connected by means of numerous pits. Pits are "windows" in the walls consisting of a thin wall membrane through which water but not an air–water interface (a bubble) can easily pass from one conducting unit to the next. Numerous vessels of limited length thus provide a certain protection against injury: that is, since water pressures in the xylem are often well below zero (*i.e.,* the water is under tension), air will be sucked into any injured xylem vessel and spread immediately throughout it but cannot pass through the wet pit membranes into the uninjured units. Damage is thus confined to the units that are injured and cannot easily spread; in addition, the smaller the conducting unit, the more confined is the damage. Plants with large, highly efficient vessels are much more vulnerable to injury, as is evident, for example, from the vulnerability of the elm, which has large vessels, to the Dutch elm disease, in which the water-conduction vessels are injured by beetle activity and fungal growth. In general, both the less efficient but safer coniferous wood and the more highly efficient but more vulnerable wood of flowering plants have been successful during evolution. Very tall trees occur in both groups; *e.g., Sequoia* among the conifers and *Eucalyptus* among the flowering plants.

The phloem. The conducting elements of the phloem underwent evolutionary changes somewhat similar to those of the xylem. The conducting elements of conifers, called sieve cells, are similar in shape and dimensions to tracheids. They do not have a woody wall, however, and they are alive at functional maturity even though their cytoplasm may be highly specialized and the cells have usually lost their nucleus during development. In flowering plants the conducting elements in the phloem, called sieve elements, are arranged end-to-end to form sieve tubes, a name derived from the sievelike end walls through which passage of food from one cell to the next occurs. Sieve cells and sieve elements are almost invariably accompanied by special companion cells believed to control, to a certain extent, the metabolism of the nucleus-free conducting cells.

Sieve elements

Vascular tissue. In primary tissues, such as leaves, strands of phloem and xylem run parallel, forming conducting bundles. These form a network of veins that can be seen when a leaf is held against a light. Xylem sap from the stem enters a leaf through the petiole (leaf stalk) and spreads throughout the leaf blade in the xylem part of the conducting bundles, or veins. Photosynthetic products enter the phloem tissues of the veins, and they are transported from the leaf through the phloem of the petiole.

Throughout most of the plant, xylem and phloem channels run more or less in an axial, or longitudinal, direction, although this path may not be precisely parallel with the stem axis. In most stems of monocotyledonous plants—flowering plants with one seed leaf, such as lilies, grasses, palms—the tissue is primary; *i.e.,* it is formed entirely by the growing shoot tip. Because such plants have no cambium tissue in their stems, they have no secondary growth and thus show relatively little increase in stem diameter. The conducting tissue consists of narrow strands, containing both xylem and phloem, distributed throughout the plant. A single crosswise section through the stem of a coconut palm may contain 20,000 vascular bundles, which are connected into a complex network by numerous cross connections; if the stem is injured, alternate pathways of transport are available.

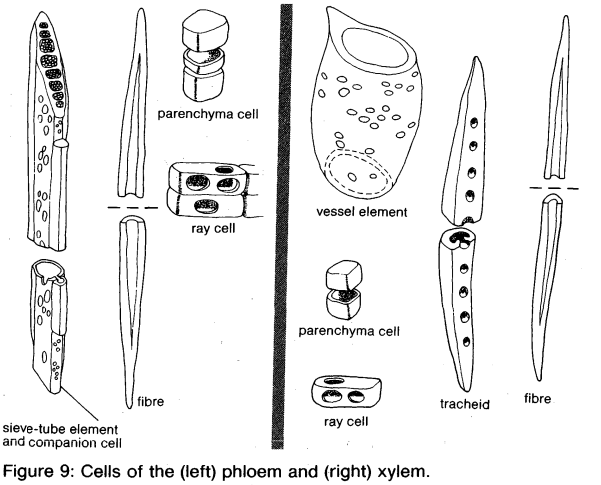

Figure 9: Cells of the (left) phloem and (right) xylem.

Tree stems of both conifers and dicotyledonous plants (flowering plants with two seed leaves, such as oaks, maples, elms) contain a cell layer called the vascular cambium that gives rise to secondary xylem and phloem. With each season's secondary growth, the stems increase in diameter. Xylem is formed as a woody cylinder on the inner side of the cambium layer near the centre of the stem. The vessels are deposited by the cambium as a complex network in such a way that an injury to the stem interrupts the local flow of water, but water continues to flow around the injury. Phloem is formed toward

the outside of the stem from the cambium layer, forming the inner, conducting bark. The conducting phloem layer remains very thin, less than 0.5 millimetre (0.02 inch), and is renewed each year. Older phloem serves only for food storage. Conducting and storing phloem comprise the living bark.

Both xylem and phloem have limited longevity. The oldest phloem layers are the outermost—the dead bark of the stem surface. The yearly amounts of xylem visible in cross sections of stems as distinct rings are known as annual rings. The oldest xylem layers (*i.e.*, the oldest annual rings) are in the dead central core, or heartwood, of the woody stem, which can often be recognized by its darker coloration. The lighter coloured sapwood is living and functions as storage tissue and, especially in the outermost sapwood, as conducting tissue; the younger annual rings comprise the sapwood. In some highly specialized tree species with large vessels (such as some oaks, ashes, and others) only the very outermost growth ring functions in water conduction. Conducting tissues seldom run straight

along a tree stem; usually they are arranged in a helical or spiral pattern, sometimes called the spiral grain of a tree. The angle of the spiral arrangement usually changes from year to year; the path of water up a tree stem may therefore be very complicated if more than one growth layer acts as a conducting tissue. Functionally, the effect of the variable spiral grain is to distribute water to all parts of the tree from any root.

Ray tissue

An important tissue in the stems of conifers and dicotyledonous trees is the ray tissue. Rays, small strands of radially running tissue, are continuous from the stem centre through the xylem and phloem and serve for radial conduction and storage of starch. No rays are present in monocotyledonous stems, however; more or less radially running bundles that originally connected the stem with leaves, which have fallen from lower stem parts, serve the same purpose.

Gas exchange and transport in leaves. Although some transpiration (evaporation) of water occurs from the surfaces of all leaf cells, most of it takes place through special structures called stomata; these structures are pores whose openings are controlled by a flexible pair of cells called guard cells. The movement of guard cells is controlled so that they open during daylight hours and close at night or under conditions of excessive water stress. The stomatal opening not only permits the escape of water vapour but also allows carbon dioxide to enter leaves for photosynthesis. Photosynthesis ceases as night falls, and excessive water loss is prevented by stomatal closure.

Most water, which is taken up by roots and ascends into leaves, is lost by transpiration. Transpiration is necessary for two reasons. One is the necessity of keeping stomata open throughout the daylight hours for the entry of carbon dioxide. The second is the fact that xylem sap is very dilute; *i.e.*, it contains much water. In order for sufficient quantities of soil nutrients to be accumulated in leaf cells, large amounts of water must be transpired.

Stomata are very efficient in transpiring water. Water molecules that emerge from such a small pore can escape without interference in all radial directions. (From an open surface water molecules can escape only in a straight line because of mutual interference of neighbouring molecules.) Thus, water can evaporate through a multiperforate membrane (with many pores) almost as efficiently as from an open water surface of equal size even though the total area of all the pores is extremely small. The advantage of the multiperforate membrane is that the size of the pore opening can be controlled.

Xylem sap entering leaves from the stem spreads out into the xylem tissues of all veins and from vein ends into the walls of other leaf cells. Thus surrounded by xylem sap, leaf cells live in an environment not unlike that of algal cells in water. Solutes—dissolved nutrients—brought up from roots can be taken up from the xylem sap into the cell interior. Any solute not actually used by the leaf cells can either be transported to the leaf surface or transferred into the phloem to be returned to the plant body for use in other plant parts; certain substances of no value to the plant are deposited in the form of crystals, sometimes in special crystal cells along the phloem path.

Movement of gases in leaves

Leaf tissue is very spongy—*i.e.*, the cells are surrounded by an abundance of communicating gas spaces. Water evaporates from cell walls into the gas space, diffuses into the stomatal cavity, and then moves into the air through the stomatal pore between the guard cells. Within the gas spaces of the leaf, gases presumably move by diffusion and perhaps, as leaves are moved about by wind, by convection.

The bark of the stem also contains stomata when young and secondary structures of similar function—openings in the bark called lenticels—when older. Very young stems are usually green and function somewhat like leaves; *i.e.*, they photosynthesize and transpire. Photosynthesis in older stems is negligible although transpiration continues. Transpiration through lenticels takes place in the summer, but closure of lenticels largely prevents transpiration in the winter.

Uptake of water and mineral nutrients from the soil. Water uptake from the soil by root cells is passive, in that water may be pulled into the root by low xylem pressure and also follows osmotic gradients caused by the mineral nutrients, which are taken up actively (*i.e.*, with the expenditure of metabolic energy) across root cell membranes. As the mineral nutrients—the ions (charged components) of inorganic salts—are taken up, they are largely incorporated into organic molecules. Thus, the solutes in xylem sap are mostly complex organic substances, sometimes of a specific nature; for example, nicotine synthesis takes place in the roots of tobacco plants, where nitrogen is incorporated into compounds that have moved to the roots through the phloem as sugars. If a tomato shoot is grafted onto a tobacco rootstock, nicotine-containing tomato leaves are formed. On the other hand, a tobacco shoot grafted onto a tomato rootstock results in a plant with nicotine-free tobacco leaves. Many other specific nitrogen-containing substances originate in the roots; in most plants, however, nitrogen is transported to the leaves from the roots in the form of compounds known as amino acids and amides.

The major chemical elements needed by a plant are: carbon, hydrogen, oxygen, phosphorus, potassium, nitro-

gen, calcium, iron, and magnesium; in addition, many others are required in very small amounts. A lack of any element may result in deficiency diseases. A few elements taken up by plants are of no nutritive value and usually are eliminated (*e.g.*, sodium chloride) or crystallized (*e.g.*, silica), sometimes by deposition in special cells.

The plant is able to control to some extent the substances that enter. If equal amounts of sodium and potassium are available to roots of plants, and the amount of the two elements inside the plant is analyzed, less sodium is likely to be found than potassium, which is a vital nutrient. The structural basis for the control of uptake of substances into roots is the so-called Casparian strip, a conspicuously thickened wall area of one cell layer around primary roots; it prevents excess soil solution from being pulled directly into the central part of the root where the xylem is located. As a result, the soil solution has to pass through a cell barrier in which uptake can metabolically be controlled. After nutrients are inside living root cells and have been converted to appropriate compounds, the latter are released into the xylem and move to above-ground parts.

Casparian strips

PROCESS OF XYLEM TRANSPORT

Quantitative aspects. The sum of the cross-sectional areas of all the branches of a tree approximately equals that of the stem; this means that the total amount of conducting tissue remains about the same from roots to leaves. In terms of water movement, the velocity of movement might be expected to be uniform throughout the entire axial system of stem, branches, and twigs. Because some trees (*e.g.*, oaks) have thick twigs, however, the velocity of water movement is greater in the stem than in the twigs at any time. Similarly, in tree species with slender branches (such as birches), the reverse is true. Normally the proportion of xylem to leaves supplied by that xylem is greater in plants growing in dry habitats than in plants found in wet ones and may be as much as 700 times greater in certain desert plants than in aquatic plants and herbs of relatively humid forest floors. The leaves of dry-habitat plants thus are more richly supplied with water-conducting xylem tissue than are those of moist habitats.

The velocity of sap movement in trees varies throughout a 24-hour period. During the night, especially a rainy night, sap flow may stop; velocity increases with daylight, peak rates being found in the early afternoon. Peak velocities correlate with vessel size; the rate of sap flow in trees with small vessels is about two metres (seven feet) per hour; that in trees with large vessels, about 50 metres (160 feet) per hour. The energy required to lift water in both cases is comparable; in large-porous trees water simply moves faster through fewer and larger vessels.

Mechanism of sap ascent. It was demonstrated about 1900 that living cells of the stem are not responsible for water movement. It is now generally recognized that water in the xylem moves passively along a gradient of decreasing pressures. Under certain special conditions water is pushed up the stem by root pressure. This may be the case with herbaceous (nonwoody) plants in the greenhouse under conditions of ample water supply and little transpiration. In nature, these conditions may be met in early spring before the leaves emerge, when the soil is wet and transpiration is low. Under such conditions, water movement is caused by active uptake of ions (charged particles) and by the entry of water from the soil into the roots. Most of the time, however, water is pulled into the leaves by transpiration. A gradient of decreasing pressures from the base to the top of a tree can be measured, even though pressures are low.

A vacuum pump cannot pull water to a height of more than 10 metres (about 33 feet). Since many trees are far taller than 10 metres, the mechanism by which they move water to their crowns has been sought. Is it possible for trees to pull water into their crowns along a decreasing pressure gradient or do they employ some other mechanism? If trees pull water, that in the xylem would have to be held on the tracheid and vessel walls by adhesion, and water molecules would have to hold together by cohesion. The hypothesis that water is pulled upward along a pressure gradient during transpiration has been called the cohesion theory. Two critical requirements of the cohesion mechanism of sap ascent are: (1) sufficient cohesive strength of water and (2) existence of tensions (*i.e.*, pressures below zero) and tension gradients in stems of transpiring trees.

The cohesion theory of sap ascent

Although the tensile strength of water is very high, an excessive pull exerted on a water column will break it. The tallest trees are about 100 metres (330 feet) high. A nonmoving water column at an atmospheric pressure of one atmosphere at the base of the tree is exposed to a pressure of minus nine atmospheres (*i.e.*, a tension of nine atmospheres) at the top. Calculations show that, under conditions of peak flow at midday, this gradient increases by about 50 percent; in other words, a transpiring sequoia would have a pressure in the xylem of minus 14 atmospheres at the top if the basal pressure is one atmosphere. If the pressure at the base is minus ten atmospheres because of dry soil, however, the pressure at the top drops to minus 25 atmospheres.

It has now been shown that negative pressures and gradients of negative pressures do exist in trees with an ingeniously simple device called the pressure bomb. A small twig is inserted in a container (the pressure bomb), its cut stump emerging from a tightly sealed hole. As pressure is applied to the container and gradually increased, water from the xylem emerges from the cut end as soon as the pressure being applied is equal to the xylem tension that existed when the twig was cut. This method has been used to measure gradients of negative pressures in trees; the cohesion theory thus would seem to explain the sap-ascent mechanism.

PROCESS OF PHLOEM TRANSPORT

Quantitative aspects. Products of photosynthesis, primarily sugars, move through phloem from leaves to growing tissues and storage organs. The rate at which these substances are transported can be measured in various ways; *e.g.*, as velocities in distance traveled per unit time or as mass transfer in (dry) weight transported per unit time. Velocities appear to be graded—*i.e.*, some molecules move faster than others within the same channel. Peak velocities of molecules usually are of the order of 100 to 300 centimetres (40 to 120 inches) per hour. Average velocities, more difficult to measure but significant in mass-transfer considerations, are lower.

Velocity of phloem transport

Mass transfer can be measured by weighing a storage organ, such as a potato tuber or a fruit, at given time intervals during its growth. Mass transfer per cross-sectional area of conducting tissue is referred to as specific mass transfer and is expressed as grams per hour per square centimetre of phloem or sieve tubes. With a given specific mass transfer, the velocity with which a liquid of a certain concentration flows can be calculated; in dicotyledonous stems, for example, specific mass transfer is between ten and 25 grams per hour per square centimetre of sieve tube tissue at times of peak performance. In certain tree species the sieve tubes can be tapped to obtain an exudate. The concentration of this exudate, multiplied by the measured average velocity, is of the same order of magnitude as specific mass transfer, indicating that liquid movement through sieve tubes could account for transport.

Much of the experimental work on phloem transport now is done with the aid of radioactive substances; radioactive carbon dioxide administered to an illuminated leaf is incorporated into sugar during photosynthesis and carried from the leaf. The velocity of this movement can be measured by determining the arrival of radioactivity at given points along the stem. Whole plants, as long as they are reasonably small, can be pressed against photographic film after the conclusion of a similar experiment, and the photographic image will indicate the portions to which radioactive sugar has moved.

Mechanism of phloem transport. The mechanism of phloem transport has been studied by plant physiologists for many years. A number of hypotheses have been put forth over the past years, but none is entirely satisfactory. One fundamental question is whether sugars and other solutes move en masse as a flowing solution or whether transport takes place independently of the solvent water.

The phenomenon of exudation from injured sieve tubes supports the first possibility, which has been further supported by a discovery involving aphids (phloem-feeding insects); when aphids are cut away from plants while feeding, their mouthparts remain embedded in the phloem. Exudate continues to flow through the mouthparts; the magnitude of the rate of this exudation indicates that transport within the sieve tube to the mouthparts occurs as a flow of solution.

Evidence against solution flow is the movement of substances in opposite directions through a section of phloem at any one given time. This, however, has never been convincingly demonstrated in just one sieve tube. On the other hand, attempts to find simultaneous movement of sugars and water along a phloem path, in order to demonstrate solution flow, have been only partially successful.

Mass flow

Mass-flow hypotheses include the pressure-flow hypothesis, which states that flow into sieve tubes at source regions (places of photosynthesis or mobilization of storage products) raises the osmotic pressure in the sieve tube; removal of sugars from sieve tubes in sink regions—*i.e.,* those in which sugars are removed for growth and storage—lowers it. Thus a pressure gradient from source to sink is established in sieve tubes that would allow solution flow. The electroosmotic hypothesis postulates that solution is moved across all sieve plates (areas at which individual sieve elements end) by an electrical potential that is maintained by a circulation of cations (positively charged chemical ions), such as potassium. Transport hypotheses postulating solute movement independent of solvent water include the spreading of solute molecules between two liquid phases and the active movement of molecules by a type of cytoplasmic movement that is often referred to as cytoplasmic streaming.

TRANSPORT AND PLANT GROWTH

Storage and circulation. It is important to realize that the plant, with its two transport systems, xylem and phloem, is able to move any substance to virtually any part of its body; the direction of transport is usually opposite in the two systems, and transfer from one system to the other takes place easily. An exception is transport into flowers and certain fruits, in which flow in each system is unidirectional.

Numerous substances move from roots to mature leaves through xylem and are transferred from the leaves, together with sugars, through the phloem to other plant parts. In the autumn months in temperate regions, plants store most of the products resulting from photosynthesis during the summer months in structures such as stems, bulbs, and tubers and mobilize it in the spring when new growth begins. A few plants, such as some tropical monocotyledons (certain palms, for example), store food for many years for use at the time of flowering and fruit-set at the end of their life-span.

Transport of growth-regulating substances. Plant hormones, or growth regulators, are effective in very small amounts; they induce or enhance specific growth phenomena. Because the site of hormone synthesis is different from its place of action, hormones must be transported before they can exert their effects. There are several groups of plant hormones; each has different effects on plant growth. The best known plant hormones are the auxins, the most common of which is called indole acetic acid. Auxins are formed in young, growing organs, such as opening buds, and are transported away from tips of shoots toward the base of the plant, where they stimulate the cells to elongate and sometimes to divide. Responses to gravity and light are also under auxin control. Auxin moves to the lower side of a leaning stem; cells on the lower side then elongate and cause the stem to bend back to a vertical position. Response to gravity in many roots is the opposite of that in shoots; the same mechanism of auxin distribution is responsible, but roots react to different quantities of the hormone than do shoots. Similar auxin distributions are responsible for phototropic responses—*i.e.,* the growth of plant parts such as shoot tips and leaves toward light. In certain cases auxin may be destroyed on the illuminated side.

Auxin transport

Auxin is not normally transported through vascular tissue; moreover, transport is polar—*i.e.,* it takes place along the stem from tip to base, regardless of the stem's position. Velocities of transport are of the order of five to 10 millimetres (0.2 to 0.4 inch) per hour, and transport requires the expenditure of metabolic energy. There is evidence that most growth hormones can be transported through xylem or phloem, but, at least in the case of auxin, the transport mechanism is specific.

Hormone transport is also involved in the stimulation of flowering. In some plants, flowering is triggered by short or long days. The receptor of this stimulus is in the leaves. A chemical substance, probably a flowering hormone of as yet unknown nature, then moves to the shoot apex and causes a transformation of the vegetative growing point into a flowering shoot.

Many growth-correlating phenomena are effected by transported hormonal stimuli. A vigorously growing terminal (topmost) shoot may inhibit lateral buds lower down from growing out and may force later branches to bend down. If the terminal shoot is removed, laterals grow out and topmost lateral branches bend upward. In leaning trees with secondary tissue (wood), the cambium produces compression wood on the lower side (in conifers) or tension wood on the upper side (in dicotyledons) in response to a hormone; the stem responds by pushing (in conifers) or pulling (in dicotyledons) itself upright. Transport of growth-regulating substances is thus largely responsible for the characteristic shape of each plant species (see also BIOCHEMICAL COMPONENTS OF ORGANISMS: *Hormone*).

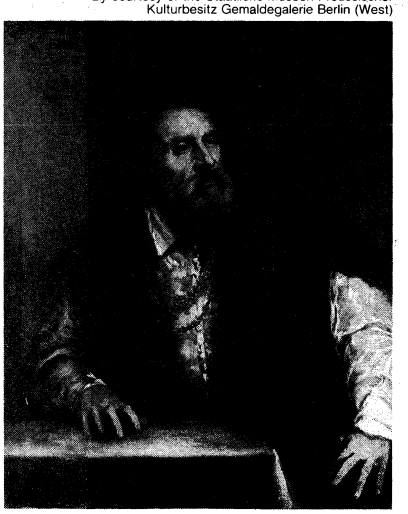
Titian



Titian was recognized early in his own lifetime as a supremely great painter, and his reputation has never suffered a decline in the intervening centuries. The art theorist Giovanni Lomazzo in 1590 declared him "the sun amidst small stars not only among the Italians but all the painters of the world." The universality of Titian's genius is not questioned today, for he was surpassingly great in all aspects of the painter's art. In his portraits he searched and penetrated human character and recorded it in canvases of pictorial brilliance. His religious compositions cover the full range of emotion from the charm of his youthful Madonnas to the tragic depths of the late "Crucifixion" and the "Entombment." In his mythological pictures he captured the gaiety and abandon of the pagan world of antiquity, and in his paintings of the nude Venus ("Venus and Adonis") and the Danae ("Danae with Nursemaid") he set a standard for physical beauty and often sumptuous eroticism that has never been surpassed. Other great masters—Rubens and Nicolas Poussin, for example—paid him the compliment of imitation.

EARLY LIFE AND WORKS

The traditional date of Titian's birth was long given as 1477, but today most critics favour a later date of birth—1488/90. Titian (in Italian Tiziano Vecellio), son of a modest official, Gregorio di Conte dei Vecelli, and his wife, Lucia, was born in the small village of Pieve di Cadore, located high amid mountain peaks of the Alps, straight north of Venice and not far from the Austrian Tyrol. At the age of nine he set out for Venice with his brother, Francesco, to live there with an uncle and to become an apprentice to Sebastiano Zuccato, a master of mosaics. The boy soon passed to the workshop of the Bellini, where his true teacher became Giovanni Bellini, the greatest Venetian painter of the day. Titian's early works are richly evident of his schooling and also of his association as a young man with another follower of the elderly Giovanni Bellini, namely, Giorgione of Castelfranco (1477–1510). Their collaboration in 1508 on the frescoes of the Fondaco dei Tedeschi (the German Exchange) is the point of departure for Titian's career, and it explains why it is difficult to distinguish between the two artists in the early years of the 16th century. Only ruined outlines of the frescoes survive, the "Allegory of Justice" being the chief scene assigned to Titian. The etchings (1760) of the frescoes by Antonio Maria Zanetti, already in a much faded condition, give a better notion of the idealism and the sense of physical beauty that characterize both artists' work. The problem of distinguishing between the paintings of Giorgione and the young Titian is virtually insuperable, for there is little solid evidence and even less agreement among critics about the attri-

Influence of Giorgione

"Self Portrait," by Titian, *c.* 1550. In the Staatliche Museen Preussischer Kulturbesitz, West Berlin.

bution of several works. The present tendency among Italian writers is to assign far too much to Titian in his youth.

It is certain that Titian's first independent commission was for the frescoes of three miracles of St. Anthony of Padua. The finest in composition is the "Miracle of the Speaking Infant"; another, the "Miracle of the Irascible Son," has a very beautiful landscape background that demonstrates how similar in topography and mood were Titian's and Giorgione's works at this time. In fact, after Giorgione's death in 1510, Titian assumed the task of adding the landscape background to Giorgione's unfinished "Sleeping Venus" (Gemäldegalerie, Dresden), a fact recorded by a contemporary writer, Marcantonio Michiel. Still Giorgionesque is the somewhat more lush setting of Titian's "Baptism of Christ" (*c.* 1515, Capitoline Museum, Rome), in which the donor, Giovanni Ram, appears at the lower right.

The authorship of individual portraits is the most difficult of all to establish, but the "Gentleman in Blue" (so-called "Ariosto") is certainly Titian's because it is signed with the initials T.V. (Tiziano Vecellio). The volume and the interest in texture in the quilted sleeve seem to identify Titian's own style. On the other hand, "The Concert" has been one of the most debated portraits, because since the 17th century it was thought to be most typical of Giorgione. The pronounced psychological content as well as the notable clarity of modelling in the central figure has led 20th-century critics to favour Titian. Technique and the clear intelligence of the young Venetian aristocrat in the "Young Man with Cap and Gloves" has led modern critics to attribute this and similar portraits to Titian.

The earliest compositions on mythological or allegorical themes show the young artist still under the spell of Giorgione in his creation of a poetic Arcadian world where nothing commonplace or sordid exists. The inspiration lies in the idyllic world of the love lyrics of the 16th-century Italian poets Jacopo Sannazzaro and Pietro Bembo. "The Three Ages of Man," where the erotic relationship of the young couple is discreetly muted and a mood of tenderness and sadness prevails, is one of the most exquisite of these. The contemporary "Sacred and Profane Love" is likewise set in a landscape of extraordinary beauty, but here the allegory is less easily understood. The most generally accepted interpretation holds that the two women are the twin Venuses, according to Neoplatonic theory and symbolism. The terrestrial Venus, on the left, stands for the generative forces of nature, both physical and intellectual, while the nude Venus, on the right, represents eternal and divine love. Essentially an ideally beautiful young woman rather than a cruel biblical antiheroine is the lovely "Salome."

MATURE LIFE AND WORKS

Marriage

Sometime in the early 1520s Titian brought to his house in Venice a young woman from Cadore whose name was Cecilia. Two sons were born in 1524 and 1525, first Pomponio, who became a priest, and second Orazio, later a painter and Titian's chief assistant. During Cecilia's grave illness in 1525, Titian married her. She recovered and later gave birth to two daughters, Lavinia (born 1529/30) and another who died in infancy. On Cecilia's death in 1530, the artist was disconsolate and he never remarried.

Mythological paintings. Titian's fame had spread abroad, and Alfonso I d'Este sought him as one of the chief masters in a cycle of mythological compositions for his newly rebuilt rooms called the Alabaster Chambers in the castle at Ferrara. Two of the canvases are now in the Prado at Madrid: the "Worship of Venus" and "The Andrians"; one of the most spectacular, the "Bacchus and Ariadne," is in the London National Gallery. The gaiety of mood, the spirit of pagan abandon, and the exquisite sense of humour in this interpretation of an idyllic world of antiquity make it one of the miracles of Renaissance art. Warmth and richness of colour help to balance the intentionally asymmetrical grouping of the figures, placed in richly verdant landscape that is also an integral part of the design. At this time Titian partially repainted the background of Giovanni Bellini's "Feast of the Gods" (National Gallery of Art, Washington, D.C.), so that the picture would better fit the series in the same room at Ferrara.

The standard for the reclining nude female obliquely placed in the picture space was established by Giorgione in the "Sleeping Venus." In Titian's "Venus of Urbino" the ideal rendering of the body and the position remain virtually unchanged, except that the goddess is awake and reclines upon a couch within the spacious room of a palace. For sheer beauty of form these two works were never surpassed. Despite the inherent eroticism of the subject, Titian managed it with restraint and good taste. Variations on the theme recur throughout his career.

The "Assumption"

Religious paintings. Among the religious paintings Titian produced between 1516 and 1538 is one of his most revolutionary masterpieces, the "Assumption" (1516–18). This large and at the same time monumental composition occupies the high altar of Sta. Maria dei Frari in Venice, a position that fully justifies the spectacular nature of the Virgin's triumph as she ascends heavenward, accompanied by a large semicircular array of angels, while the startled Apostles gesticulate in astonishment at the miracle. When the painting was unveiled it was quickly recognized as the work of a very great genius.

The posture of the Madonna in the "Assumption" and the composition of Titian's "Madonna and Child with SS. Francis and Alvise and Alvise Gozzi as Donor" reveal the influence of Titian's contemporary Raphael; and the pose of St. Sebastian in the "Resurrection Altarpiece," the influence of Michelangelo. These influences, however, are of secondary importance since the landscapes, the physical types, and the colour are totally Titian's own.

In the "Pesaro Madonna" (1519–26) Titian created a new type of composition, in which the Madonna and Saints with the male members of the Pesaro family are placed within a monumental columnar portico of a church. The picture is flooded with sunlight and shadows. This work established a formula that was widely followed by later Venetian Renaissance painters and served as an inspiration for some Baroque masters, including Rubens and Van Dyck.

Such a quantity of masterpieces by Titian followed that only a few can be mentioned. The poetic charm of the artist's pictures with landscape continues in the "Madonna and Child with St. Catherine and a Rabbit" and the "Madonna and Child with SS. John the Baptist and Catherine of Alexandria" (*c.* 1530). The "Entombment" is his first tragic masterpiece, where in a twilight setting the irrevocable finality of death and the despair of Christ's followers are memorably evoked. The stately "Presentation of the Virgin in the Temple," a very large canvas, reflects the splendour of Venetian Renaissance society in the great architectural setting, partly in the latest style of the contemporary architects Serlio and Jacopo Sansovino. The pageantry of the scene also belongs to well-established tradition in Venetian art, but the organization, with its emphasis on verticals and horizontals, constitutes Titian's interpretation of the High Renaissance style.

Titian and Charles V

Portraits. One of Titian's great triumphs came when he answered the call to Bologna in 1530 at the time of Charles V's coronation as Holy Roman emperor. In 1531, in keeping with his social state, he moved to a Venetian palace known as the Casa Grande, which survives as a 20th-century slum. Titian returned to Bologna to portray Charles V again on the occasion of the second meeting of Charles V and Pope Clement VII in the winter of 1532–33. The portrait of "Charles V in Armour" (1530) and another painted in January 1533 are lost, while only a less important work, "Charles V with Hound" (1532–33; Prado, Madrid), a copy of a portrait by Jakob Seisenegger, survives. Charles was so pleased with Titian's work that in May 1533 he bestowed upon the artist the most extraordinary honour of knighthood. Thereafter, the Austrian-Spanish Habsburgs remained Titian's most important patrons. Charles attempted to induce Titian to go to Spain in 1534 to prepare a portrait of the Empress, but the artist wisely refrained from undertaking the arduous journey.

Titian's other portraits in the 1520s and 1530s provide a gallery of the leading aristocrats of Italy. A splendid

example is "Alfonso d'Avalos, Marques del Vasto" (1533), brilliantly rendered in gleaming armour ornamented with gold. He is accompanied by a small page whose head reaches his waist. The introduction of a secondary figure to give scale is a device frequently adopted by Titian. Another refulgent portrait in armour, but without the secondary figure, is that of "Francesco Maria della Rovere, Duke of Urbino" (1536–38). Emphasis here is given to the Duke's military career, not only by the armour but also by the baton in hand and the three others in the background. These works are essentially idealized state portraits, although the heads are very convincingly rendered. "Doge Andrea Gritti" is to a greater extent a symbol of the office—that is, that of ruler of Venice. The gigantic body in a canvas of large size is sweeping in design and commanding in presence. In later works, too, Titian very effectively managed the scaling of a figure to appear massive by filling the space of the canvas—in his portraits of Pietro Aretino, for example, where he gives his subject a leonine bulkiness. Allowing more space around the figure in "The Young Englishman," he projected a personality of cultivated elegance and human warmth.

LATE LIFE AND WORKS

Travels and commissions. *Portraits.* The large number of masterpieces in portraiture that Titian continued to create throughout the rest of his life is astounding. Pope Paul III and his grandson, Cardinal Alessandro Farnese, began to compete with Emperor Charles V for Titian's services. At the request of the Pope, the painter travelled to Bologna in May 1543 and there prepared the celebrated official portrait of "Pope Paul III Without Cap." Although a state symbol of the Pontiff, the characterization of the crafty statesman, bent with age, comes through.

Titian's next major association with the Farnese came in 1545–46, when he made his only visit to Rome, lodged in the Belvedere Palace of the Vatican. For the first time Titian was able to see the archaeological remains of ancient Rome and also the Renaissance masterpieces of Michelangelo, Raphael, Sebastiano del Piombo, and others. The effect upon the master's own style was relatively slight, understandably enough, since he was already a mature and famous artist.

"Paul III and His Grandsons"

Of portraits of the Farnese family carried out at this time, few remain. The most celebrated of all is "Paul III and His Grandsons Ottavio and Cardinal Alessandro Farnese" (1546; Museo e Gallerie Nazionali di Capodimonte, Naples). A painting of a family group, it is most searching in psychological revelation. The feeble Pope, then aged 78, appears to turn suddenly in his chair toward Ottavio Farnese, his 22-year-old grandson. Ottavio's overly obsequious bow and his shrewd Machiavellian profile demonstrate Titian's sheer genius in understanding and recording character. As a foil, the great churchman Cardinal Alessandro Farnese stands quietly by. It is no wonder that the portrait is not completely finished, for Paul III must have found it too revealing of the feud within the Farnese family.

If one were forced to name Titian's two greatest portraits, the choice might fall upon the Farnese group and upon another, "The Vendramin Family." Here the situation is quite different, for the two heads of the clan kneel in adoration of a reliquary of the Holy Cross, accompanied by seven sons ranging in age from about eight to 20. This portrait group is a tour de force in technical brilliance, richly beautiful in colour, running the emotional gamut from gravity to the innocence of childhood.

On his departure from Rome, in June 1546, Titian's association with the Farnese ended. He received no payment for his pictures, and his hopes for recompense in the form of a benefice for his son Pomponio were never realized. Titian decided to throw in his lot with the Habsburgs. Consenting to undertake the arduous journey to Augsburg, he set out in the depths of winter in January 1548 to cross the Alps to reach the Emperor's court. There he carried out one of his most memorable works, the equestrian "Emperor Charles V at Mühlberg," designed to commemorate the Emperor's victory over the Protestants the year before. It is the great state portrait par excellence, intended to show the Emperor as a Christian knight, as he wished posterity to remember him. Titian minimized the disfiguring lantern jaw and gave great dignity of bearing to his subject. In sheer mastery of the painter's art, the picture is unsurpassed. The handsome armour, with its gleaming highlights and reflected colour, the rose sash across the chest (a symbol of the Catholic party and the Holy Roman Empire), and the superb sunset landscape all contribute to make it one of the masterpieces of all time.

In December 1548 Charles instructed Titian to proceed to Milan to prepare likenesses of Prince Philip on his first trip outside of Spain. Once again, in the fall of 1550, Charles obliged Titian to travel to Augsburg to remain until May 1551, when he executed one of his greatest state portraits, the "Philip II" in full length. In this portrait of Philip, when still a prince aged 23, Titian achieved another tour de force in sheer beauty of painting, and he treated gently the surly face of the arrogant young man.

Religious paintings. Like some of Titian's earlier religious paintings, "Christ Before Pilate" is a work in which Titian managed a large crowd in a processional manner leading to the focal point, the figure of Christ at the left. Here the people are in a state of turmoil as they demand Christ's crucifixion. The composition, however, marks a new phase in Titian's development, far removed from the Renaissance serenity of the "Presentation," which is not explainable by the subject alone. The compact massing of figures, the oblique position of the steps and the wall at the left, and the general effect of excitement are indicative of the mid-16th-century style known as Mannerism. Titian assimilated and recreated, however, to produce a masterpiece far surpassing anything of which the Mannerist artists were capable.

"Christ Before Pilate"

Titian's religious compositions after his visit to Rome in 1545–46 reveal to some degree his contact with ancient art and the works of Michelangelo. In "Christ Crowned with Thorns" the burly muscular figures are thus explained, as perhaps is the violence of the whole interpretation.

Last years in Venice. On his return to Venice in 1551, Titian remained there for the rest of his life except for summer visits to his native city of Pieve di Cadore. In his last 25 years his productivity was undiminished in quantity and in creative ideas.

Portraits. Among his portraits is the full-length, dashingly rendered figure of the Duke of Atri, who is dressed in red velvet. One of the latest and most dramatic was "Jacopo Strada," in which this brilliant antiquarian, writer, and art collector is shown presenting to the spectator a small statue, a Roman copy of an Aphrodite of Praxiteles. Here again, the scope and variety of Titian's invention is astonishing in this new composition, so notable for lively action, psychological perception, and pictorial beauty. One must not forget Titian's "Self Portrait," in which he presents himself with great dignity, wearing the golden chain of knighthood. The intelligent, tired face is fully rendered, while the costume is sketched in lightly with a free brush. One of the most remarkable late works is the "Triple Portrait Mask" or "Allegory of Prudence," in which Titian, gray-bearded and wearing a rose-coloured cap, represents old age, his son Orazio, maturity, and presumably Marco Vecellio stands for youth.

"Self Portrait"

Religious paintings. The "Trinity" (or "La Gloria"), painted for Charles V's personal devotion, reflects central Italian art to a lesser degree than the earlier "Christ Crowned with Thorns." The glowing richness of colour predominates in this adoration of the Trinity in which Charles V and his family appear among the elect. The "Martyrdom of St. Lawrence" marks a further step in new compositional directions that culminate in Baroque form in the following century. St. Lawrence upon his gridiron is placed obliquely in space, and the steps reverse the direction to the right. Although dramatic power invests the main action in the foreground, the night scene with the tall flares and mysterious light suggests the supernatural. In his late religious pictures Titian veils the human forms in shadowy light and so increases the dominant mood of spirituality. One sees this effect in the late "Entombment," in which muted colour prevails, and in the awesome tragedy of the "Crucifixion." The "Christ Crowned with

Thorns," employing essentially the same composition as in the earlier version, is now seen through a veil of darkness, and the colour is broken into tiny spots and areas. All is miraculous in the "Annunciation," in which Gabriel rushes in and an assembly of angels in glory hovers about the Virgin. Titian's final word and last testament is the "Pietà," intended for his own burial chapel but left unfinished and completed by Palma il Giovane. The master and his son, Orazio, appear as tiny donors on the small plaque to the right. The monumentality of the composition is established by the great architectural niche flanked by Moses and the Hellespontic sibyl, while the figures are grouped in a long diagonal. The subdued colour befits the all-prevailing sorrow and the immutability of death in this, one of the artist's most profound achievements.

"Pietà"

Mythological paintings. The "Venus and Cupid with an Organist" and the "Venus and the Lute Player" are variations on the theme of the earlier "Venus of Urbino." Aside from the emphasis on the idealized beauty of the nude goddess, it is generally believed that symbolism is involved in these pictures, although the precise meanings have been variously interpreted. Beauty of sound (music) and beauty of vision are common to both. In the first example, a Renaissance garden with fountain and trees in perspective completes the background, which is separated from the figures by a dark red velvet curtain. More symbolism of an erotic nature is present in the embracing couple, a stag, and the satyr on the fountain. In the second picture, the background consists of a broad river valley and the distant Alpine peaks so dear to Titian's heart. This late landscape, painted in the artist's free illusionistic style, is extraordinarily beautiful.

The "Venus with a Mirror" (National Gallery of Art, Washington, D.C.), the one original among several versions, is a natural theme for the goddess of love and beauty. Yet Titian is the first artist to show her with a mirror held by Cupid. Her form is somewhat more heroic than hitherto, and her head to a limited degree is inspired by ancient sculpture. The superb quality of the flesh tones is enhanced by the cloak of dark red velvet, trimmed with fur.

A group of several important pictures of mythological themes was created by the master in 1554–62 for Charles's successor, Philip II of Spain, who never bothered to remunerate Titian for any of them. From the letters of the artist to the King, it is clear that he planned the paintings in pairs, but otherwise they do not constitute a comprehensive iconographic program. The first pair (still in Madrid) consists of the "Danae with Nursemaid" and the "Venus and Adonis." The magnificent nude Danae lies upon her couch, knees raised, as Jupiter descends to her in the form of golden rain, and her nursemaid rather amusingly attempts to catch the coins in her apron. This work (of which there exist numerous replicas and copies) is undoubtedly the most voluptuous in Titian's entire repertory. In colour and technique, as well, the "Danae" is one of Titian's greatest achievements; one is tempted to say that no other artist ever equalled him in imagination and in the depiction of sheer beauty of this work. In the "Venus and Adonis," the goddess, depicted from the back, attempts to restrain her muscular young lover as he is about to depart for the hunt, his dogs straining at the leash. The rose of his costume and the red velvet cushion beneath Venus are foils in the colour composition to the flesh tones and the sunlit landscape.

The "Perseus and Andromeda" was intended to be a companion to "Medea and Jason," according to Titian's letter, but for some reason the second picture was never carried out. Andromeda, bound to the rock at the left, awaits deliverance as Perseus descends from the sky to slay the monster. Her powerful physique reflects Titian's familiarity with the work of Michelangelo, yet Andromeda's body is more feminine and graceful than any of the Florentine's masculine-looking women. Titian's sensitivity to female beauty is unfailing.

"The Rape of Europa" is surely one of the gayest of Titian's "poesies," as he called them. Taken by surprise, Europa is carried off, arms and legs flying, on the back of Jupiter in the form of a garlanded white bull. A putto (chubby, naked little boy) on the back of a dolphin appears to be mimicking her, and cupids in the sky follow the merry scene. Titian's fondness for oblique compositions is most successfully applied here, for it contributes to the sense of movement, and it allows for the extensive seascape and the mountainous shore. The sheer wizardry of Titian's technique is nowhere more fully demonstrated than in the misty distances shot through with blues and sunset rose and in the expanse of sea with its iridescent lights.

"The Rape of Europa"

In "The Rape of Europa" Titian reached the climax of his powers, and by good fortune the picture has survived in almost perfect condition. On the contrary, two other great "poesies" done for Philip II are sadly abused by time and restorers, particularly the "Diana and Callisto," and less so the "Diana and Actaeon." The assembly of female nudes in a variety of poses, befitting the action, illustrates two episodes of the Diana legend as told by Ovid in his *Metamorphoses,* books II and III. "Diana and Actaeon" depicts Actaeon, the youthful hunter of heroic body, just as he unwittingly happens upon Diana and her nymphs as they are bathing (and before Diana punishes him by transforming him into a stag). Behind him is a great rose-coloured curtain. A landscape of extraordinary beauty and a vaulted passage form the setting within which the maidens are gathered. The organization of the rather complex design once more presages Baroque compositional methods. In the companion picture, the goddess discovers that Callisto, one of her maidens who had taken the vow of chastity, is pregnant. Though she was deceived by Jupiter's trickery, she is, nevertheless, banished and later, according to the legend, transformed into a bear. A standing and rather fulsome nude rips the drapery from the reclining Callisto. The golden canopy in the trees above Diana is the cloth of honour referring to her divinity. The glorious deep blue sky with golden clouds and the green branches of the tree supply the backdrop for the nude bodies. Diana, tall and imperious, is magnificent, despite the surface damage that has destroyed much of the paint. Subtleties abound in every movement and every gesture.

The latest of these compositions carried out for Philip II was the "Tarquin and Lucretia," a dramatic work of great vigour that proves that the aged master had lost none of his creative powers. Rather than Lucretia's suicide because of her rape by Tarquin, which is the more common subject, Titian chose to represent Tarquin's violent attack upon her. Again the rich colour is equally as important as the action. Against the green curtain and white sheets the rose velvet breeches of Tarquin and his green and gold doublet stand out in rich brilliancy.

"Tarquin and Lucretia"

The end came on August 27, 1576, when the great master died of old age, while a plague was raging in Venice. He was interred in the church of Sta. Maria dei Frari, where two of his most famous works may still be seen.

Through his long life Titian was highly successful in all branches of the painter's art. In his interpretation of Christian iconography he was infused in his youth with the poetic styles of the elderly Giovanni Bellini and his contemporary Giorgione. Titian created new compositions such as the "Assumption" and the "Pesaro Madonna" and later in his life the "Martyrdom of St. Lawrence," and he carried out a never-ending succession of new conceptions as his career matured. He gained international fame as a portraitist, beginning as a Giorgionesque painter and developing into a major creator of the state portrait for the glorification of rulers. The revival of the culture of the ancient world lies at the root of Renaissance culture in the arts and in literature; inspired by the ancient poets such as Ovid, Catullus, and Theocritus, Titian recreated pictorially the legends of Greece and Rome in a series of incomparable masterpieces.

MAJOR WORKS

RELIGIOUS PAINTINGS: Frescoes of three miracles of St. Anthony of Padua (1510–11; Scuola del Santo, Padua); "Gipsy Madonna" (*c.* 1510; Kunsthistorisches Museum, Vienna); "Salome" (*c.* 1515; Galleria Doria-Pamphili, Rome); "Assumption" (1516–18; Sta. Maria dei Frari, Venice); "Madonna and Child with SS. Francis and Alvise and Alvise Gozzi As Donor" (signed 1520; Pinacoteca, Ancona); "Resurrection Altarpiece"

(signed 1522; SS. Nazaro e Celso, Brescia); "Pesaro Madonna" (1519–26; Sta. Maria dei Frari, Venice); "Entombment" (1526–32; Louvre, Paris); "Madonna and Child with St. Catherine and a Rabbit" (*c.* 1530; Louvre, Paris); "Madonna and Child with SS. John the Baptist and Catherine of Alexandria" (*c.* 1530; National Gallery, London); "The Presentation of the Virgin in the Temple" (1534–38; Accademia, Venice); "Christ Before Pilate" (signed 1543; Kunsthistorisches Museum, Vienna); three Old Testament subjects (1543–44; Sta. Maria della Salute, ceiling of the sacristy, Venice); "Christ Crowned with Thorns" (1546–50; Louvre, Paris); "Martyrdom of St. Lawrence" (1548–57; Gesuiti, Venice); "Trinity" ("La Gloria") (1554; Prado, Madrid); "Crucifixion" (1558; S. Domenico, Ancona); "Entombment" (1559; Prado, Madrid); "Magdalen" (*c.* 1560; Hermitage, Leningrad); "Annunciation" (1560–65; S. Salvatore, Venice); "Madonna and Child in Evening Landscape," (1562–65; Alte Pinakothek, Munich); "Christ Crowned with Thorns" (1570–76; Alte Pinakothek, Munich); "St. Jerome" (1575; Nuevos Museos, Escorial); "Pietà" (1576; Accademia, Venice).

MYTHOLOGICAL PAINTINGS: "Sacred and Profane Love" (1512–15; Borghese Gallery, Rome); "Flora" (*c.* 1515; Uffizi, Florence); "The Three Ages of Man" (*c.* 1515; National Gallery of Scotland, Edinburgh, lent by the Duke of Sutherland); "Bacchus and Ariadne" ("Ferrara Bacchanals," 1520–23, National Gallery, London); "Worship of Venus" (1518–19) and "The Andrians" (1523–24; both in Prado, Madrid); "Venus Anadyomene" (*c.* 1525; National Gallery of Scotland, Edinburgh, lent by the Duke of Sutherland; "Venus of Urbino" (1538; Uffizi, Florence); "Jupiter and Antiope," so-called "Venus of El Pardo" (*c.* 1540, perhaps finished *c.* 1560; Louvre, Paris); "Venus and Cupid with an Organist" (signed *c.* 1550; Prado, Madrid); "Venus with a Mirror" (1550–55; National Gallery of Art, Washington, D.C.); "Danae with Nursemaid" (1553–54; Prado, Madrid); "Venus and Adonis" (1553–54; Prado, Madrid); "Perseus and Andromeda" (1554–56; Wallace Collection, London); "Diana and Actaeon" and "Diana and Callisto" (1559; National Gallery of Scotland, Edinburgh, lent by the Duke of Sutherland); "The Rape of Europa" (*c.* 1559–62; Isabella Stewart Gardner Museum, Fenway Court, Boston); "Venus and the Lute Player" (*c.* 1560; Metropolitan Museum of Art, New York); "Nymph and Shepherd" (*c.* 1570; Kunsthistorisches Museum, Vienna); "Tarquin and Lucretia" (1571; Fitzwilliam Museum, Cambridge); "The Flaying of Marsyas" (*c.* 1570–76; Uměleckohistorické Muzeum, Kroměříž, Czech.).

PORTRAITS: "The Concert" (1510–12; Pitti Palace, Florence); "Gentleman in Blue," so-called "Ariosto" (signed *c.* 1512; National Gallery, London); "Young Man with Cap and Gloves" (1512–15; Earl of Halifax Collection, Garrowby Hall, London); "Man with a Glove" (1520–22; Louvre, Paris); "Federico II Gonzaga, Duke of Mantua" (*c.* 1523; Prado, Madrid); "Alfonso d'Avalos, Marques del Vasto" (1533; Marquis de Ganay Collection, Paris); "Francesco Maria della Rovere, Duke of Urbino" (1536–38; Uffizi, Florence); "Doge Andrea Gritti" (1535–38; National Gallery of Art, Washington, D.C.); "The Young Englishman," so-called (1540–45; Pitti Palace, Florence); "Pietro Aretino" (*c.* 1545; Pitti Palace, Florence); "Clarice Strozzi" (1542; Staatliche Museen Preussischer Kulturbesitz, Berlin); "Pope Paul III Without Cap" (1543; Museo e Gallerie Nazionali di Capodimonte, Naples); "The Vendramin Family" (1543–47; National Gallery, London); "Paul III and His Grandsons Ottavio and Cardinal Alessandro Farnese" (1546; Museo e Gallerie Nazionali di Capodimonte, Naples); "The Emperor Charles V at Mühlberg" (1548; Prado, Madrid); "Giovanni Battista Castaldo" (1548; Becker Collection, Dortmund); "Self Portrait" (*c.* 1550; Staatliche Museen Preussischer Kulturbesitz, Berlin); "Philip II" (1550–51; Prado, Madrid); "Giovanni Francesco Acquaviva, Duke of Atri" (1552; Staatliche Kunstsammlungen, Kassel); "Lavinia with Fan," so-called (1555–60; Gemäldegalerie, Dresden); "Jacopo Strada" (1567–68; Kunsthistorisches Museum, Vienna); "Triple Portrait Mask," "Allegory of Prudence" (*c.* 1570; National Gallery, London).

Tokyo–Yokohama Metropolitan Area

The Tokyo–Yokohama metropolitan area is an urban agglomeration on the Pacific coast of central Japan, including the capital city of Tokyo (Tōkyō), the port city of Yokohama, and the manufacturing centre of Kawasaki. Tokyo means eastern capital, the name given the city when the capital of Japan was moved eastward in 1868 from Kyōto, meaning capital. Yokohama derives from the fact that the original fishing village was situated on a lateral (*yoko*) beach (*hama*) of Tōkyō-wan (Tokyo Bay).

The centre of the Tokyo–Yokohama metropolitan area is Tokyo, part of the metropolitan prefecture (*to*) of Tokyo—comprising Tokyo, neighbouring industrial and residential cities, and rural districts, including the Bonin Islands (Ogasawara-guntō) in the Pacific. Tōkyō-to lies within the Tokyo–Yokohama metropolitan area, which also includes the prefectures of Saitama (Saitama-ken), Chiba (Chiba-ken), and Kanagawa (Kanagawa-ken). The cities of Yokohama and Kawasaki are in Kanagawa prefecture.

Physical and human geography

THE LANDSCAPE

Site. The Tokyo–Yokohama metropolitan area extends inland from the western coast of Tōkyō-wan. The city of Tokyo lies at the mouth of the Sumida-gawa (Sumida River). To its east, around the northern end of Tōkyō-wan, are suburbs comprising the prefecture of Chiba, which is separated from Tokyo by the Edo-gawa (Edo River). To the north of Tokyo city are the suburbs of Saitama Prefecture (Saitama-ken). South of Tokyo, separated from it by the Tama-gawa (Tama River), is the great industrial centre of Kawasaki. The port of Yokohama (Yokohama-kō) lies southwest of Kawasaki. Still farther south, on Miura-hantō (Miura Peninsula) and around Sagami-wan (Sagami Bay), are other municipalities that are part of the Tokyo–Yokohama metropolitan area. The metropolitan boundary in the southwest is roughly delimited by Kanagawa prefecture's border with Shizuoka and Yamanashi prefectures.

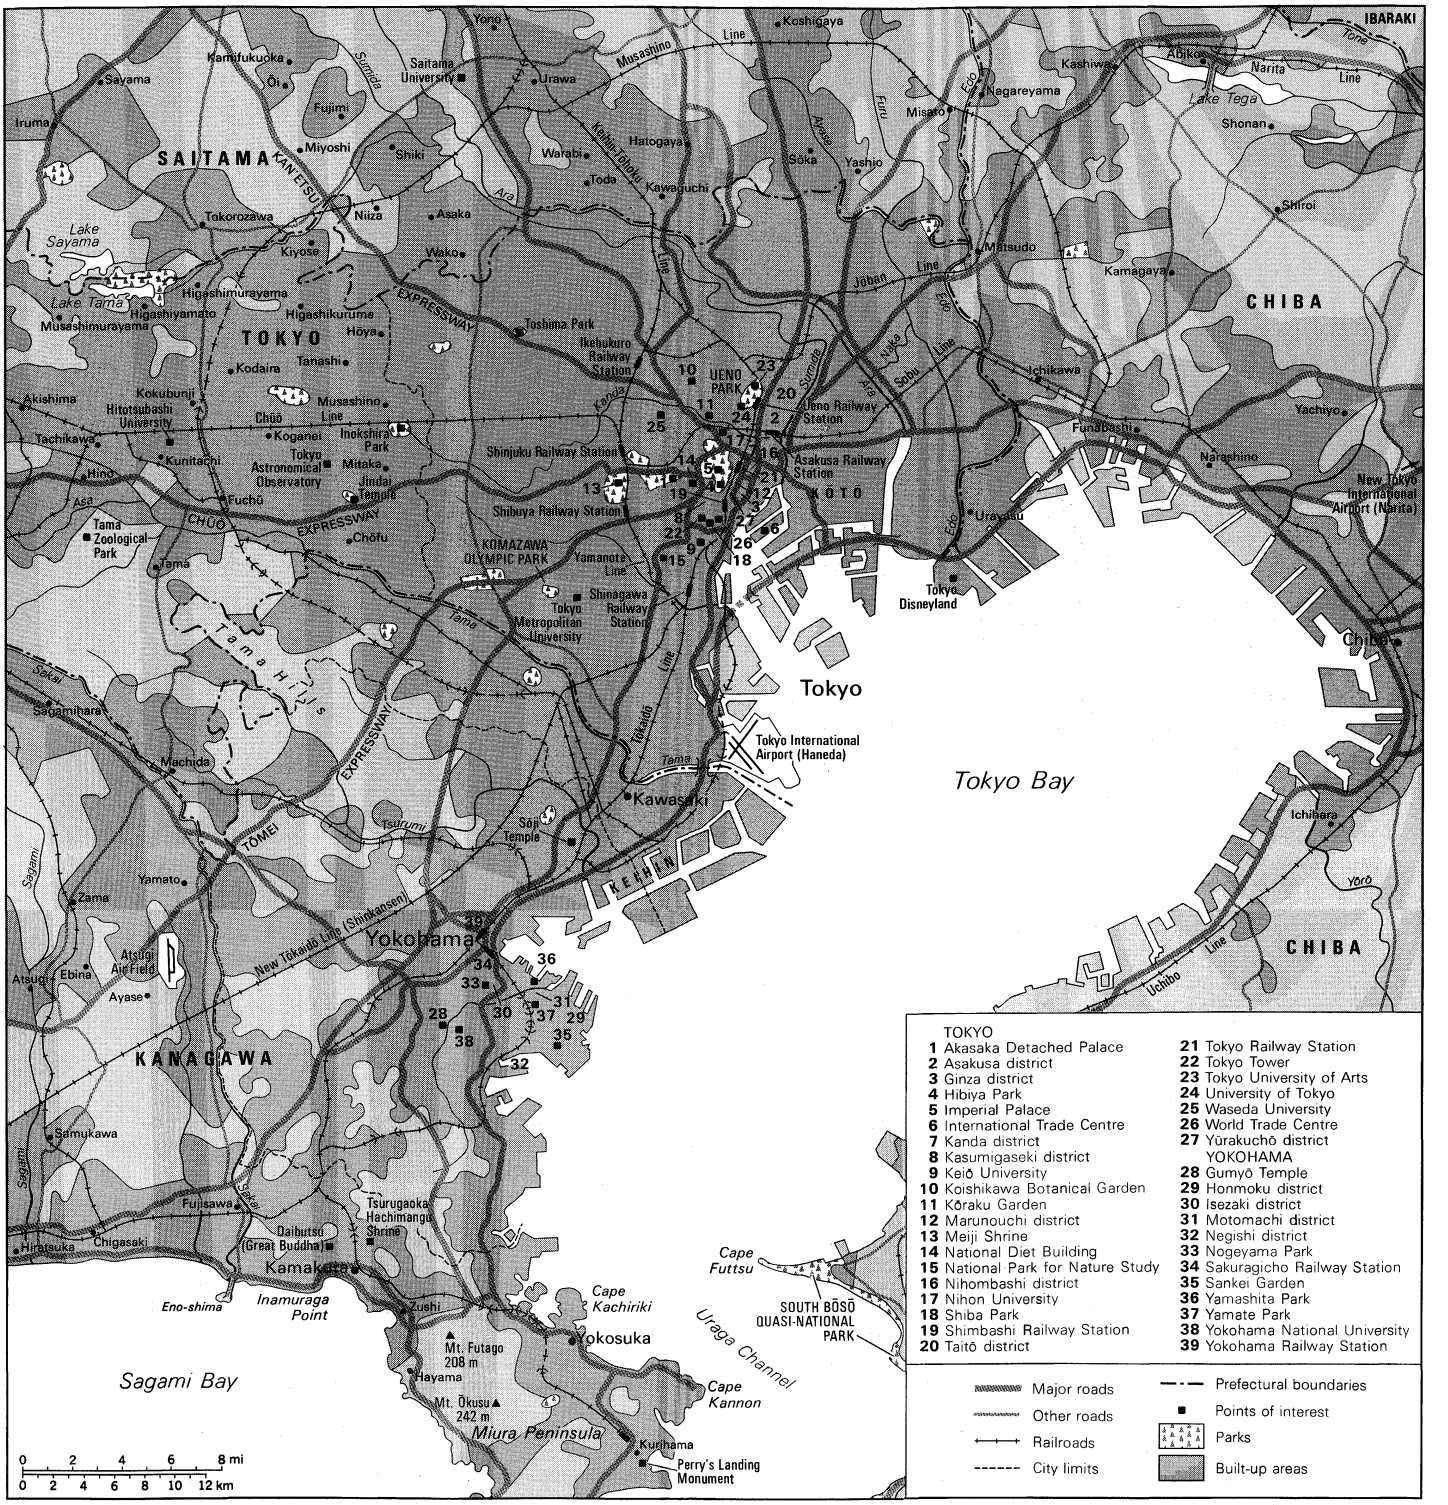
Terrain

The original terrain consisted mostly of river deltas, upland hills, and sand dunes. The present coastline is lined with warehouses, docks, and industrial sites. South of Yokohama is the rocky coast of Miura-hantō, with the naval harbour of Yokosuka (Yokosuka-kō). Farther south, on Sagami-wan, are the historic town of Kamakura and other resorts that are crowded with vacationers in summer.

Soil. The east side of the Sumida-gawa consists of alluvial soil that has settled as much as 13 feet in some places as the groundwater has been drawn off for industrial purposes. Efforts have been made to contain this process by regulation. Higher land in the metropolitan area consists of layers of volcanic origin on top of sand and gravel, sloping gently upward toward the mountains in the west.

To the south of Tokyo lies a hilly section, varying in height from 164 to 656 feet that has been developed as a residential area. Farther south and west, these plains and hills end in the steep Okutama and Chichibu mountains, consisting of old geologic formations cut by the Tama-gawa and its tributary valleys. The steeper slopes are wooded, and the foothills are terraced with cultivated fields; the river supplies water to Tokyo. The mountains form part of the Chichibu-Tama National Park.

Climate. The climate of Tokyo is generally mild, although the summers are hot and humid. The annual mean temperature is 58.5° F (14.7° C). The January mean is 40.5° F (4.7° C), and the August mean is 79.5° F (26.4° C). Japan's climate is controlled by the summer and winter monsoons: in summer, masses of warm, humid air from the Pacific; in winter, a flow of cold, dry air from Siberia. There are two rainy seasons: June–July and September–October. Tokyo usually has two or three typhoons a year during the autumn rainy season. The average annual rainfall is about 57 inches (1,460 millimetres).



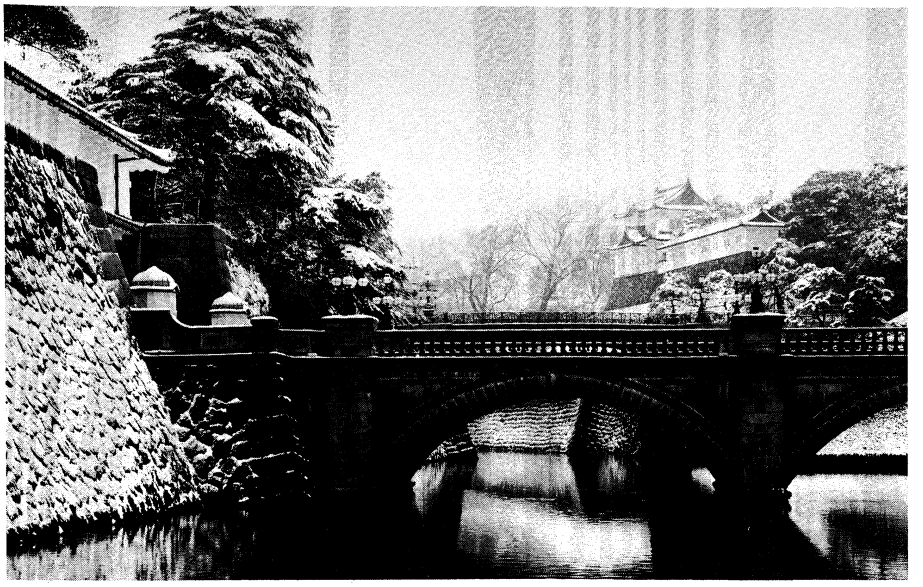
In midwinter, temperatures may fall below freezing in the mornings. From January to March there are several snowfalls. The plum and camelia bloom in January on the southern coast of the metropolitan area, and Tokyo's spring reaches its climax in March and April with cherry blossoms and many varieties of flowers. The iris and azalea blossom in May, followed by the gloomy monsoon month of June. In the summer months the blue and purple hydrangea appear. After the autumnal rains, the trees begin to turn—the maples red, the ginkgo yellow. This is the season when chrysanthemum shows are held.

Animal life. Wild animals are rare except in the mountains, where wild boars, foxes, and monkeys are found. Trout live in the mountain streams; in the lowlands the streams are polluted, but this situation is improving because of strict enforcement of antipollution laws. Birds are relatively abundant in the residential areas, particularly doves, sparrows, crows, and gulls. The Imperial Palace moats are visited by several kinds of waterfowl from northern regions. Other seasonal visitors include the Japanese bush warbler, great tit, dusky thrush, bull-headed shrike, grey starling, and swallows; in the suburbs one can see the white egret and hear the song of the skylark.

Industrialization, motorization, and population growth have brought water and air pollution. Fuji-san (Mt. Fuji), about 55 miles (90 kilometres) away, once visible on clear days in winter from the centre of Tokyo, now can be seen only when the factories are shut down for the January holidays or when wind blows away the smog. The prefectural and municipal governments have established environmental protection offices in an effort to combat pollution.

Plan of the old city

Layout. The inner part of Tokyo was the old town of Edo. The town was once dominated by the castle of Edo, which was burned during the Meiji period; the emperor now lives in the Imperial Palace, within the grounds of the former castle. The castle and the adjacent area where the high feudal lords had their dwellings was encircled by two moats, the *uchibori* ("inner moat") and *sotobori* ("outer moat"). Unlike European medieval cities, Japanese castle towns had no walls. The warriors and lords lived between and outside the moats, forming the *yashiki machi* ("resi-



The Tokyo–Yokohama metropolitan area.

dential town"). Along the roads and in the town area were merchants' shops and the houses of nonwarriors, comprising the *machiya* ("town house") section. Shintō shrines and Buddhist temples formed *tera machi* ("temple town") on the urban fringes.

The castle and the residences of the feudal lords had beautiful gardens, some of which have been preserved and are now open to the public. The town area was divided into rectangular blocks named after various occupational groups, such as *gofuku-chō* ("silk-goods town"), *sakana-machi* ("fish town"), and *kaji-chō* ("blacksmith town"). The residential areas of the lower samurai class also had their functional names: *okachi-machi* ("infantry town") and *takasho-machi* ("hunters with hawk"). There were also landscape names: *ta-machi* ("paddy town"), *hayashi-chō* ("wood town"), *komagome* ("horse grazing"), and *fujimi-chō* ("town from which Fuji-san can be seen").

The centre of trade was Nihombashi (Japan Bridge), from which five main highways began and which is still the zero-mile mark of the national-highway system. Nihombashi and its vicinity was a busy wholesale marketplace and also a retail and financial area. The banks of the rivers and canals were crowded with boats coming from Ōsaka and other coastal regions of Japan. On the highways there were post towns every few miles. The first post towns from Edo were Shinagawa, Shinjuku, Itabashi, and Senju, all now part of Tokyo city.

The marshy downtown area had to be drained with

The Imperial Palace with the Nijū-bashi (Double Bridge), used only on formal state occasions and on national holidays, in the foreground.
Shinichiro Morimoto—Orion Press

canals, and the Tone and Ara rivers had to be prevented from flooding. As Edo grew, water for human consumption was brought in by aqueduct and distributed through wooden pipes; this system became the basis of modern Tokyo's water supply.

The early houses were made of wood, and Edo was so repeatedly in flames that fires were called the flowers of Edo. A great fire in 1657 damaged large parts of Edo, destroyed the main tower of the castle, and killed 100,000 inhabitants. After the earthquake and fire of 1923, the downtown area was largely rebuilt, and it was rebuilt again after World War II.

The main shopping street is Ginza Street, running northeast to southwest and lighted brightly at night. A stroll on the Ginza is popularly known as Ginbura. The northern extension of Ginza is Nihombashi Street, a busy central shopping area that includes the best department stores. It passes through Tokyo's financial district. From Ginza a street leads westward to Hibiya Park and the Imperial Palace. Nearby are the government-office district and the Yūrakuchō amusement centre.

The Marunouchi district

To the east of the Imperial Palace, separated from it by broad gardens and a moat, lies the Marunouchi business district, the heart of Japanese business activity, with offices and banks, the Chamber of Commerce, the central railroad station, the Central Post Office, and the International Telephone and Telegraph Corporation building.

Tokyo's Metropolitan Government Offices are situated at the southern end of the Marunouchi district. To the north, across the outer moat, is the Kanda area, with many universities, bookstores, publishers, and hospitals. Other important areas are Taitō-ku, in the north, and Shiba, in the south—commercial and residential areas of high population density. To the east of the Sumida-gawa is Kōtō-ku, a low-lying marshy area drained by canals that create a checkerboard effect, which is an industrial and working-class district.

In the western part of Tokyo, roughly within the loop of the Yamanote Line, is the uplands residential area. This quiet, tree-shaded section contains most of the foreign embassies as well as Tokyo University, Waseda University, Keiō University, and other universities and research institutes. Farther west and southwest of the Yamanote loop are middle-class residential neighbourhoods, the growth of which began after the earthquake of 1923 when city dwellers moved outward into the upland fields. In these areas the houses are generally frame, with some multistoried apartment houses. With the improvement of commuting facilities, Tokyo's eastern and northeastern suburbs have also grown as middle-class residential areas.

Yokohama

The growth pattern of Yokohama and Kawasaki has been similar to that of Tokyo. The whole area within 20 to 30 miles of Tokyo's central railway station has become a commuting area. Older towns have become suburbs of Tokyo. Yokohama's business district is concentrated around its port. At the northern end of the business district, near Sakuragicho Station, is the central shopping street of Isezaki. South of the business district is the hilly Yamate residential area, separated by Motomachi Street where there are many interesting shops. The northern coast of Yokohama is an industrial area. Just south of the port, industrial and port facilities have been established along the coast at Honmoku and Negishi.

Tokyo and Yokohama are divided into wards (*ku*), composed of towns (*machi*) having several tens of thousands of inhabitants each; some *machi* are further divided into smaller blocks known as *chōme*. Originally these blocks were neighbourhood units, but they now function only as postal addresses and for purposes of registration. The older *machi* each have a tutelary deity (*ujigami*) with a shrine. Residents of a *machi* visit the shrine on festival days to pray for safety and prosperity. These festivals are full of colour: stalls are set up, and there is music and dancing. Among the more famous shrines are the Asakusa, Hie (Sannō), Kanda Myōjin, Nezu, and Fukagawa, dating from the Edo period. The Meiji Shrine in Tokyo, dedicated to the Meiji emperor and his consort, is a kind of national monument and centre of worship for the whole country.

Building styles. The dwellings in metropolitan Tokyo vary from the tiny wooden house of two or three stories sandwiched between high office buildings to the large suburban homes of affluent citizens. Some people live over their shops or behind them. As part of social and economic reforms instituted after World War II, the large estates in the Yamanote loop, once the site of feudal residences in the Edo period, were subdivided into small lots or adapted to such other uses as schools or public gardens. This residential area, however, is becoming increasingly commercial, with offices, hotels, and apartment buildings for the upper class. The uplands have been invaded by office buildings and apartment houses. Throughout the metropolitan area there are many housing developments, ranging in size from several hundred homes to more than 10,000. Construction is carried on by the Japan Housing Corporation, municipalities, prefectures, and private companies.

About 30 percent of the dwellings in Tokyo Urban Prefecture are wooden apartment units, although the number of fireproof ferroconcrete buildings is increasing. Building

Takanori Ishii—Bon

styles are a mixture of Eastern and Western. While few purely Japanese buildings remain, even a modern apartment will have one or two rooms with a tatami (reed-mat) floor and sliding doors. Kawagoe, an old castle town about 23 miles from Tokyo, has traditional merchant houses with heavy tile roofs and plaster walls.

The central business districts of Tokyo, Yokohama, and other cities consist mainly of ferroconcrete buildings. Their maximum height was formerly limited to about 100 feet to prevent earthquake damage, but since the late 1960s numerous taller buildings that can withstand earthquakes have been constructed. Outside of the central business district, buildings tend to be small in area because of the high price of land.

Central Tokyo. In the governmental district of Kasumigaseki, southwest of the Imperial Palace, one can study building styles by eras. The Sakuradamon (Sakurada Gate), formerly one of the entrances to the castle of the shoguns, leads across the moat to the Imperial Palace Plaza. The entrance passage is crooked for reasons of defense. To the south is the tall Police Department building and the older Ministry of Justice building of reddish brick, put up in the 19th century. Nearby is the Ministry of Foreign Affairs, a postwar modern building. The Prime Minister's Mansion, of an older (1930s) style, is at the core of the governmental district. The National Diet Building beyond is made of granite from the islands of the Inland Sea (Setonaikai). Overlooking these governmental buildings is the Kasumigaseki Building, rising 482 feet (147 metres).

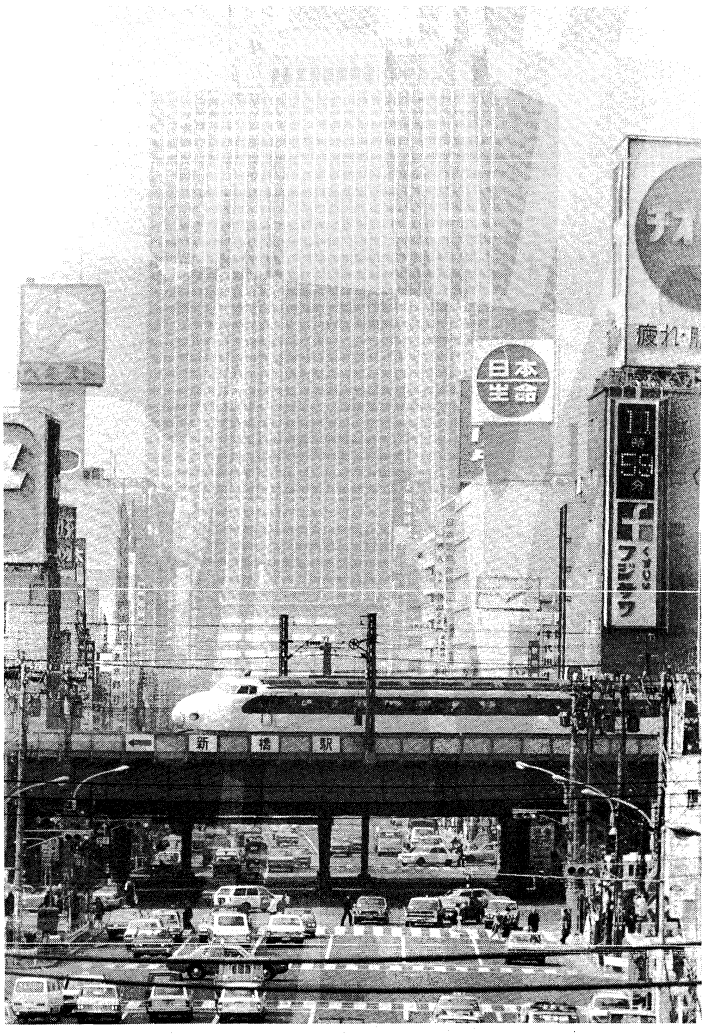
Government buildings

The Marunouchi district to the east of the Imperial Palace was developed as a business centre on vacant land formerly owned by the government. Marunouchi means inside castle; in this district is the outer-moat zone of the Edo castle, where the feudal lords had their mansions. A commercial centre, consisting of red-brick buildings of three or four stories, was built there around the turn of the 20th century. These gave way in the 1920s and 1930s and after World War II to ferroconcrete buildings that are resistant to fire and earthquake. The Dai-Ichi Life Insurance Building is in Renaissance style. The postwar buildings are of lighter and taller construction, an example being the Tokyo Metropolitan Government Office. The former Imperial Hotel, designed by Frank Lloyd Wright in 1916, withstood the earthquake of 1923; it was torn down in 1967 and replaced by a plainer, taller structure in 1970.

The uptown area to the south has changed much less; many older buildings are still preserved. The old lecture hall of Keiō University, of wooden construction with black-and-white-checkerboard walls, belongs to the early Meiji period. To the west, the Akasaka Detached Palace, completed in 1909, is now used for national guests.

To the north, near the Kanda-gawa (Kanda River), one finds a contrast of building styles and civilizations in the Yushima Seidō (a Confucian shrine rebuilt in 1935), the Kanda Myojin Shrine (a Shintō shrine rebuilt in 1934), and the Nikolai-dō (Eastern Orthodox Cathedral, dating from 1884).

Contemporary features. Modern buildings include the Palace-side Building adjacent to the northern moat, occupied by the Mainichi Press; the Tokyo Cathedral, with a sky-piercing tower; the National Theatre, the World Trade Centre Building, and the International Trade Centre on Harumi Pier. One of the highest structures in the world is a 1,092-foot television tower, erected in 1958 and modelled on the Eiffel Tower in Paris; it dominates the Tokyo skyline. The Shinjuku Railway Station on the western Yamanote line has been developed as a civic centre. The complex includes the station, two department stores, and other buildings with offices and shops. Nearby is another commercial district containing the Keiō Plaza Hotel. Similar complexes have been developed elsewhere in the metropolitan area—for example, at the Shimbashi Station in the central business district and at Yokohama Station. Department stores have decentralized by locating at railway stations throughout Tokyo—Shinjuku, Shibuya, Ikebukuro, Ueno, and Asakusa—where they compete with the stores of the central business district of Ginza–Nihombashi.



The Shinjuku development

THE PEOPLE

The population of the metropolitan area is growing, partly through migration from other parts of Japan and partly from natural increase. The western part of Tokyo and the uplands are chiefly middle-class and upper-class residential areas. Blue-collar workers live east of the Sumida-gawa and in the industrial areas of Kawasaki and Yokohama. Tokyo is a melting pot for all Japan, and in the downtown area one can hear the Kansai (Ōsaka-Kyōto) accent and the Tōhoku (northeastern region) dialect. Most of the many foreigners in the metropolis do not live in national enclaves. Exceptions are the Chinese in Yokohama and Koreans in several areas.

THE ECONOMY

The Tokyo metropolitan area is the largest commercial centre of Japan, and its port of Yokohama is the country's largest. Most important businesses and banks have their head offices in the central business district, as do foreign

The Kasumigaseki Building, overlooking the Shinkansen express train, which runs through downtown Tokyo.
Toichi Sakakibara

companies and banks. Before World War II, Tokyo was Japan's second industrial city after Ōsaka, but since the war Ōsaka has declined in comparison to Tokyo.

Industry. The Tokyo–Kawasaki–Yokohama manufacturing region, called the Keihin Industrial Zone (Keihin Kōgyō Chitai), is one of the four major industrial agglomerations in Japan. In the late 19th century, manufacturing developed within the cities of Tokyo, Kawasaki, and Yokohama. It later expanded into the suburbs: along the Tōkaidō Line (railway) to the southwest; westward to Sagamiōno, and along the Chūō Line to Tachikawa, Hino, and Hachiōji; along the Ara-kawa to the northwest; along the Keihin-Tōhoku Line to the north; along the Jōban Line to the northeast; and on the Sōbu Line around the northeastern coast of Tōkyō-wan into Chiba Prefecture.

Tokyo itself has much light manufacturing, including textiles, toiletries, and printing and publishing. It is a centre of cultural activity and information. It also produces goods requiring an abundant labour force, such as electrical products, cameras, and automobiles. A large proportion of the establishments are family-size or are relatively small shops with fewer than 30 workers, most of them subcontracting to larger concerns. The Yokohama–Kawasaki district is an area of heavy industry specializing in chemicals, machinery, metallurgy, petroleum refining, ships, motor cars, and fabricated metal products. A centre for iron and steel, petroleum refining, petrochemicals, electric power, and other heavy industries is also located on the Chiba–Ichihara coast at the northeast end of Tōkyō-wan. Another heavy-industrial centre is at Kashima about 60 miles northeast of Tokyo on the Pacific coast. The machinery and light industries have been decentralizing inland from Tokyo in the area 30 to 60 miles from the city, where a number of industrial parks have been established.

Commerce. Tokyo is a centre of wholesaling, drawing goods from all over the country and abroad and distributing them into the surrounding area. It is also Japan's financial centre. The banks, insurance companies, stockbrokers, and similar establishments are concentrated in the central business district.

Transportation. Tokyo is the national traffic centre; it is also an important international nodal point of the western Pacific and the Far East. The metropolitan area is spanned with a dense network of electric railways and subways, bus lines, and motor highways. Tokyo Station is not only the central railroad station of the metropolis but also central for all Japan. Trains to Ōsaka and beyond start from Tokyo Station. Another important Tokyo terminal is Ueno Station, from which lines run to various parts of northern Japan. Shinjuku Station is the terminus of trains from central Honshu and some trains from the east. Interurban service in the Tokyo area is by the Japan National Railways and various privately owned electric lines. Tokyo and Yokohama formerly had trams, almost all of which have been replaced by buses and subway lines.

Tokyo's system of automobile expressways consists of a loop around the central business district and several radial lines connecting with the national expressways.

The airport at Narita, more than 40 miles east of the city, handles most international traffic; the Haneda airport, about eight miles southwest of Tokyo, serves mainly domestic air passengers and cargo. Atsugi Air Field, west of Yokohama, is reserved for use by the U.S. Navy.

Tōkyō-wan has four major ports. Yokohama is the largest, followed by the industrial ports of Kawasaki and Chiba and the port of Tokyo. Ferryboats carrying cars have several lines across Tōkyō-wan.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. Tokyo is not only the national capital but also the centre of the Kantō region, which comprises the prefectures of Ibaraki, Tochigi, Gumma, Saitama, Chiba, and Kanagawa. It houses all the institutions of the national and regional governments, as well as the offices of the local government and of government corporations, such as the telephone and telegraph corporation. Most of these are located near the Imperial Palace. Foreign embassies and international institutions have their offices in the central business district and in the western part of the city. The metropolis of Tokyo is administered by a governor and a metropolitan assembly of 126 members; all are elected to office.

Because Tokyo is the place of political decision, nearly all of Japan's prefectures have offices there. Major cities and towns have their Tokyo offices. Federations of local government, such as the Mayors' Association, are located in Tokyo, as are the headquarters of political parties and many other semigovernmental institutions.

Efforts to break up and decentralize this massive agglomeration of power have never succeeded. The migration of governmental offices out of Tokyo will apparently be limited to research sections.

Public utilities. The water used in Tokyo, Yokohama, Kawasaki, and other parts of the metropolitan area is supplied by aqueduct systems. Local waterworks and private industrial and residential systems supplement the supply. Tokyo draws its water principally from the Tama and Tone-Edo rivers and from three reservoirs—at Murayama (Lake Tama), at Yamaguchi (Lake Sayama), and at Ogōchi on the upper Tama (Lake Okutama). To meet increasing demand, additional dams have been built on the upper Ara and Tone rivers, which are connected by a canal with the Murayama–Yamaguchi reservoirs. Yokohama, Kawasaki, Yokosuka, and neighbouring towns get their water from the Sagami-gawa, which is dammed at two points. Most of the metropolitan area is supplied with gas by the Tokyo Gas Company. Gas plants are located mainly on the coast, where domestic and imported coal, petroleum, liquid gas, and natural gas are brought in by ship. Petroleum and bottled propane gas are also widely used for heating and cooking.

The Ginza district, a principal shopping area located in central Tokyo.
Harald Sund

The city's electric supply

The Tokyo Electric Company serves the entire Kantō region, as well as Yamanashi Prefecture and the eastern half of Shizuoka Prefecture. About 15 percent of the power comes from hydroelectric stations on the Tone and Kinu rivers in Kantō; the rivers Shinano and Azusa in central Honshu; and Inawashiro-ko (Lake Inawashiro) in the Tohoku region of northern Honshu. The bulk of Tokyo's power comes from thermal stations located on Tōkyō-wan and at Kashima to the northeast. Electricity is also generated by atomic power stations, including one at Tokai, 65 miles northeast, and another on the Fukushima coast, 120 miles northeast, of Tokyo.

Health and security. The Tokyo–Yokohama metropolitan area shares the problems of other large urban areas with respect to pollution, noise, and lack of air and sunlight. Its residents nevertheless live better than people in small cities and towns because they have superior medical care and social services.

The medical school of Tokyo University, founded in the latter part of the 19th century, is known for its Institute of Medical Science. The medical school of Keiō University is another research hospital. A number of university hospitals in Tokyo are open to the public, but most hospitals are run by the national, prefectural, and municipal governments or public organizations such as the Red Cross. In addition, there are special hospitals for children, the aged, and patients suffering from cancer, tuberculosis, or heart disease.

Colleges and universities

Education. In Tokyo, as in other large cities, more than 90 percent of the ninth-year graduates go on to high school. Almost half of Japan's university and college students are to be found in Tokyo Metropolitan Prefecture and Kanagawa Prefecture. Tokyo University has several faculties and many research institutes. Other leading universities are Tokyo Institute of Technology, Hitotsubashi University (trade and commerce), and Tokyo University of Arts. There are also national universities for industry and agriculture, languages, medicine, dentistry, the merchant marine, and other fields. Tokyo Metropolitan University and Yokohama City University are public municipal institutions. Among private universities, Waseda and Keiō are the oldest and most highly regarded, especially in the fields of literature, politics, and business. The largest university is Nihon.

CULTURAL LIFE

Tokyo is at the centre of national cultural activity. It is also the home of various institutions for national and international cultural communication. Modern Japan has been strongly influenced by the West, to which Tokyo and Yokohama have been gateways; Western technology and life-styles first took root in those cities.

Museums

If Tokyo has been less a centre of Japanese traditions than have Kyōto, Ōsaka, and Nara, it has, nevertheless, many valuable cultural properties from the past. The Imperial Household Agency Library and the Tōyō Bunka Kenkyūjo (Institute of Oriental Culture; part of Tokyo University) hold collections of classical books. There are the National Archives and the National Diet Library. The Tokyo National Museum in Ueno Park concentrates on the art and history of Japan and Asia. The Kokuritsu Kagaku Hakubutsukan (National Science Museum), the Zoological Garden, and the National Museum of Western Art are also located in Ueno Park, as is the Tokyo Metropolitan Art Museum. Elsewhere in Tokyo there are numerous smaller collections and galleries. Near the Imperial Palace are the National Museum of Modern Art and the Technical and Engineering Museum. Tokyo and Yokohama also have their own local historical records and exhibits, such as a museum of folkways, in the city of Musashino, and a museum of old houses, in Kawasaki.

A wide range of theatre is available, from the traditional Kabuki to modern drama. Symphonic works, operas, and various other kinds of Western music and dance are performed.

Parks

Tokyo's parks are not as large as those of European and American cities, but they are numerous. Among the better known are the East Garden of the Imperial Palace, Hibiya Park, Ueno Park (with its zoo), and the Meiji Shrine's Outer Garden (with its baseball stadium and other playing fields). The latter, along with Komazawa Olympic Park and Yoyogi Sports Centre, was one of the main centres of the Olympic Games in 1964. In the western part of Tokyo are the smaller natural parks of Inokashira, Zenpukuji, and Shakujii, with lakes. Some of the larger private gardens of the Edo period are now open to visitors. The most impressive of these is the Inner Garden of the Meiji Shrine with its irises and water lilies, a favourite spot of the Meiji emperor. There are also several botanical gardens.

In Yokohama, the best parks are Nogeyama and Yamate,

Komazawa Olympic Park, Tokyo.
Shinichiro Morimoto—Orion Press

on hills overlooking the harbour, and Yamashita Park on the coast. Sankei-en (Sankei Garden), formerly a private estate, contains a collection of historic buildings brought from other parts of the country.

Suburban recreation areas include the Tama Zoological Park, where visitors can ride by bus through the lion section, and near it the *kodomo no kuni* ("children's country"). Places of excursion from Tokyo and Yokohama include the Okutama and Sagami valleys, the Chichibu and Tanzawa mountains, the Fuji-Hakone-Izu and the Nikko national parks, the Izu-hantō (Izu Peninsula) with its many hot springs, the active volcanic islands of Ō-shima and Miyake-jima, the Miura-hantō, and many others. There are also amusement parks with roller coasters and similar rides, such as Kōrakuen, Tamagawaen, Toshimaen, and Yomiuriland. Japan's first Disneyland (amusement park), which opened in 1983, is also located in Tokyo.

The most popular team sport in Japan is baseball. Tokyo has four professional teams; Kawasaki and Yokohama each have one team. There are also university teams, and the Waseda–Keiō games are followed intently. A number of golf courses are located in the suburbs.

History

The eastern part of the present central city of Tokyo was originally called Edo ("estuary"), because it stood at the point where the Sumida-gawa enters Tokyō-wan. A castle was built overlooking the marshy lowland of the river in 1457. The river separated the ancient provinces of Musashi in the west and Shimofusa in the east, and the castle occupied an important strategic position.

The area had been inhabited in prehistoric times by peoples of the Jōmon (2500–250 BC) and the Yayoi (250 BC–AD 250) cultures. The Yayoi lived on uplands and cultivated rice on marshy deltas and in valley bottoms. With the consolidation of a Japanese empire in the 6th century, the area became part of Musashi Province. Musashi and its surrounding regions were peripheral because the central government was located farther west. They rose in importance when Tokugawa Ieyasu established the shogunate (military government) in Edo in 1603. During the 17th century the old castle was rebuilt and enlarged, and the town was laid out, becoming the residence of the whole Tokugawa hierarchy. By the mid-19th century Edo had become a metropolis with a population of 1,200,000. After the fall of the Tokugawa shoguns and the reestablishment of the authority of the emperor, the capital of Japan was moved from Kyōto to Edo in 1868; the city was then renamed Tokyo.

Growth of Tokyo area

The municipal area of Tokyo city at the end of the 19th century consisted of 15 wards (*ku*). Together with the surrounding counties, it formed Tokyo Urban Prefecture. It had become not only the political but the commercial and financial centre of the country. Its growth was checked by the great earthquake and fire of September 1, 1923, which severely damaged the downtown areas of Tokyo and Yokohama. During Tokyo's reconstruction the streets were widened, and many ferroconcrete buildings were put up. At the same time, the suburbs began to grow. At the beginning of the 1930s Tokyo city had 2,000,000 people and the suburban municipalities 3,000,000. In 1932, 20 new wards were added. During World War II, metropolitan Tokyo was established by amalgamating the city and its surrounding suburbs and counties. Large parts of Tokyo and Yokohama were destroyed by U.S. air raids in 1944 and 1945. After the war, starting in the 1950s, the Tokyo area grew enormously with the expansion of the Japanese economy.

The port of Kanagawa (later incorporated into Yokohama), which was opened in 1859, expanded along with Japan's export trade. The city was completely new and Western in its characteristics. In 1872 it was connected to Tokyo by railroad. Along with Tokyo it was largely destroyed in the great earthquake and fire of 1923 and severely damaged by U.S. air raids in 1945. By the late 20th century Yokohama was the second largest city in Japan, after Tokyo.

Kawasaki, situated between Tokyo and Yokohama, was formerly a post town on the Tōkaidō (the ancient highway between Tokyo and Kyōto). The Tokyo–Yokohama railway had a station there, and it became a centre of industrial development. The city expanded rapidly during the 1930s, was almost completely destroyed in World War II, and was subsequently rebuilt. The coastal area is the centre of heavy industry, including iron and steel,

petroleum refining, chemicals, and thermoelectric power. Electrical machinery, food, and other light industries are in the centre of the city. Kawasaki is now a leading industrial city of Japan; its inland area has become a residential suburb of Tokyo.

BIBLIOGRAPHY. A dated but comprehensive source, in English, is the INTERNATIONAL GEOGRAPHICAL UNION, REGIONAL CONFERENCE, *Geography of Tokyo and Its Planning* (1957). The ASSOCIATION OF JAPANESE GEOGRAPHERS, *Japanese Cities* (1970), contains many useful studies of Tokyo. A German-language discussion is S. KIUCHI, "Tokio als Weltstadt," in J.H. SCHULTZE (ed.), *Zum Problem der Weltstadt* (1959). The TOKYO METROPOLITAN GOVERNMENT has published an atlas, *Regional and City Planning for Tokyo* (1964). H. AONO and S. BIRUKAWA, *Tōkyō-to* (1967), is an academically written study of the Tokyo region (in Japanese). EDWARD G. SEIDENSTICKER, *Low City, High City: Tokyo from Edo to the Earthquake, 1867–1923* (1983), is an analytical study of the city at a critical period in its modern development. S. KIUCHI, *Tokyo* (1968) and *Kanagawa, Saitama, Chiba* (1969), contain colour photographs and maps. K. KODAMA and H. SUGIYAMA, *Tōkyō-to no rekishi* (1969), is a history (in Japanese). (S.K.)

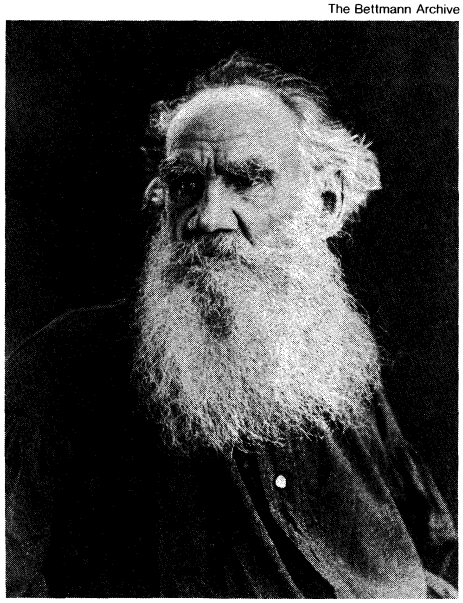
Tolstoy

The enduring fame of Leo Tolstoy, Russian author, reformer, and moral thinker, rests mainly on two novels, *War and Peace* and *Anna Karenina.* A deeply contradictory man, Tolstoy was an individualistic aristocrat who in his later years tried unsuccessfully to lead the life of a poor peasant, a sensualist who ended up as an intransigent puritan, a man of singular vitality who feared death at almost every step. This extraordinary duality of character led him in middle life to abandon his career of a mere writer of fiction to become a radical Christian; in a stream of essays, pamphlets, and largely didactic short stories and plays, he propagated his belief in a life of love and faith and his rejection of property and such man-made institutions as governments and churches.

Early years and marriage. Lev Nikolayevich, Graf (Count) Tolstoy (also spelled Tolstoi), was born on September 9 (August 28, old style), 1828, on his family's estate at Yasnaya Polyana, about 100 miles (160 kilometres) south of Moscow, in Tula Province. Tolstoy's parents died when he was a child, and he was raised by relatives. Private tutors had charge of his early education. At 16 he entered the Kazan University (now Kazan [V.I. Lenin] State University), but, disappointed with the formal instruction there, he returned to Yasnaya Polyana in 1847 to manage his estate and conduct his own education. In neither did he achieve much success, preferring the social whirl of Moscow and St. Petersburg to life in the country. In his diary, he recorded his moral transgressions. In his youthful entries there is already evidence of an unusual analytical talent in his realistic probing into the suppressed motives of his own behaviour.

Sketches of military life



Disgusted with this shiftless existence, Tolstoy in 1851 joined his soldier brother Nikolay in the Caucasus. In the following year he also entered the army and acted with bravery in several engagements against the hill tribes. Much of his leisure he spent in writing, completing his first published work, *Detstvo* (*Childhood*), which appeared in the magazine *Sovremennik* ("The Contemporary"). The material of *Childhood* is treated with conventional realism, except for digressive lyrical passages in the manner of the English novelist Laurence Sterne, whose *Sentimental Journey* Tolstoy partially translated at this time. He is autobiographical in this and in later works, but what captivates readers of *Childhood* is its fresh and precise choice of significant detail and the amazing reliving of forgotten common experiences of childhood that, once recalled, exert a nostalgic charm. Sequels to *Childhood—Otrochestvo* (*Boyhood*) and *Yunost* (*Youth*)—lack this special charm, perhaps because an analysis of the moral failings of youngsters tends to dominate these two works. Tolstoy's experiences in the Caucasus are reflected in "Nabeg" ("The Raid") and "Rubka lesa" ("The Woodfelling"), his first short stories dealing with war. The theme is treated in a youthful spirit, but the exacting realistic analysis of military activity is tinged with that critical awareness of false heroics that became a central feature of his *Sevastopolskiye rasskazy* (1855–56; *Sevastopol*).

Transferred to the Danube front in 1854, Tolstoy participated in the siege of Sevastopol during the Crimean War. He described these experiences in his *Sevastopol* sketches, in which he contrasted the simple heroism of the common soldier with the false heroics of military leaders. At the end of the fighting in 1856, he left the army and went to St. Petersburg, where he became the idol of competing literary groups that sought his support of their social and aesthetic views. A pronounced individualist, he rebuffed the coteries and left for Yasnaya Polyana.

Early short stories

He went abroad in 1857, to France, Switzerland, and Germany. The criticism of stories based on his travels (*e.g.,* "Lyutsern" ["Lucern"]) caused him to lose interest in literature. Yet he continued to write. Between 1855 and 1863 he wrote a series of short stories—including "Zapiski markera" ("The Memoirs of a Billiard-Marker"), "Dva gusara" ("Two Hussars"), "Albert," "Tri smerti" ("Three Deaths"), "Semeynoye schastye" ("Family Happiness"), "Polikushka," and "Kholstomer" (not published until 1886)—in which he concentrated mainly on moral problems. These stories anticipate his later concern with the harm a materialistic society inflicts on the natural, unspoiled man but represented no artistic advance on his earlier writing. In fact, the subjective moralistic emphasis is a defect, although many passages are persuasively argued. Only in the "Two Hussars" did Tolstoy avoid this pervasive subjectivism. There, the evil influences of society on one of the characters are artistically suggested rather than didactically argued. "Kholstomer," a satire on human beings from the point of view of a horse, is also

The Bettmann Archive

Tolstoy.

something of an exception, for by his art Tolstoy somehow convinces the reader that the noble horse's natural life is superior to man's absurd, unnatural existence. The contrast between the natural man and the spoiled product of sophisticated society deeply interested Tolstoy, and he treated the theme with brilliant artistry in *Kazaki* (*The Cossacks*). The highly civilized protagonist suffers in comparison with the freedom-loving uninhibited Cossacks of the village in which he lives. Several of them are among Tolstoy's most memorable characterizations.

In the late 1850s Tolstoy became concerned with the poor state of education among the peasantry, and, on returning from his travels, he started a school for peasant children at Yasnaya Polyana. The success of his original teaching methods, which anticipated modern progressive education, drew him deeper into pedagogical studies. He journeyed to Europe again in 1860–61, visiting Germany, France, Italy, England, and Belgium and investigating educational theory and practice. Absorbed by this interest, he published an educational magazine, in which he developed his pedagogical theories, and compiled textbooks that won wide acceptance because of their simplicity and attractive approach.

In 1862 Tolstoy married Sonya (Sofya) Andreyevna Bers, a girl from a middle class family with wide intellectual interests. He dropped his educational activities and for the next 15 years devoted himself with all his ardent nature to married life. For the most part it was an intense but happy existence, and 13 children were born. He now managed his estate with much success and resumed writing, creating his two greatest masterpieces, *Voyna i mir* (*War and Peace*) and *Anna Karenina.*

The great novels. It took Tolstoy almost seven years to write his vast epic *War and Peace,* generally regarded as one of the two or three greatest novels in world literature. In this supreme effort he went far beyond his previous writings both in scope and treatment. In it, all the stuff of life is woven in enormous tapestry, and the rich material and numerous characters are handled with unsurpassed objectivity. Perhaps in no other novel does the mastery of realistic detail and the amazing subtlety and variety of psychological analysis so successfully create the total impression of life being lived completely and naturally.

The scheme of *War and Peace*

War and Peace, covering the period 1805–14, is primarily concerned with the histories of five aristocratic families, the members of which are portrayed against a vivid background of Russian social life and the titanic struggle of clashing armies during Napoleon's invasion of Russia. In this huge panorama appear the aristocracy and the peasantry, officers and privates of the army, the Russian and French emperors, diplomats and courtiers, town life and country life, and realistic pictures of war. The theme of war, however, is subordinated to the story of family existence, which at that time involved Tolstoy's optimistic belief in the life-asserting pattern of the natural stages of man—birth, childhood, maturity, love, marriage, birth again, and death. As models for two of the families, Tolstoy drew upon members of his own family, and the unforgettable heroine Natasha is modelled on his sister-in-law Tanya Bers. One has only to read her published diary, however, to realize how the witchery of his art has transformed her into the vital, poetic, "natural" woman of the novel. The moral conflict between two of the main protagonists (bumbling, questing Pierre and polished, intellectually proud Andrey) is also Tolstoy's—Andrey's conviction that one should live for the sake of doing good for oneself being opposed to Pierre's ultimate belief that one should live for the sake of serving others. Tolstoy varied his realistic method of individualizing characters in accordance with the human types portrayed: it may be brilliant externalization, as in the case of a shallow society beauty; or psychological analysis in depth, as in that of an emotionally complex woman supposedly patterned after Tolstoy's mother; or acute symbolism, as in the creation of the peasant Platon Karatayev, who exists as a personification of the simplicity and truth living in the gray masses of Russia.

The sections of the novel that critics have frequently objected to are those in which Tolstoy set forth his philosophy of history and theorized about war and its architects. He anticipated these objections, and in 1868 he published an article explaining his views on these matters. There are two kinds of actions, he declared: those that do, and those that do not, depend upon individual will. In the historical process, he wrote, there is a minimum of freedom; the actions of so-called makers of history and leaders of war depend on the actions of countless other people and to this extent are predetermined. What troubled him was the historians' practice of fixing responsibility for what occurs in life upon individuals whom they call "great men" and endow with heroic virtues and vices. On the contrary, Tolstoy argued, natural law—the principles of right or justice regarded by many thinkers as common to all mankind and thus independent of formal law—determines the lives of human beings no less than the processes of nature itself. There is no free choice; all is ruled by an inexorable historical determinism. But it can hardly be denied that his labouring of such subjects interferes with the unity of *War and Peace* and represents an artistic lapse.

Though it is similar to *War and Peace* at least in narrative method and style, *Anna Karenina* has more artistic unity. Tolstoy's philosophy of life was in the process of changing between the writing of the two books. *War and Peace* is a life-loving, optimistic novel, and its main characters are morally robust and masters of their inner conflicts; *Anna Karenina,* which deals with Russian society in the 1860s, is pessimistic, and the inner conflicts of its characters, often unresolved, sometimes bring about human disaster. There is an inevitability about the tragic fate that hangs over the adulterous love of Anna and Vronsky. "Vengeance is mine, I will repay" is the epigraph of the novel and the leitmotiv of the whole story. Anna pays not so much because she transgresses the moral code but because she refuses to observe the proprieties customarily exacted in such liaisons by the hypocritical high society to which she belongs. Her love for Vronsky is a deep and lasting passion, and, unable to play the hypocrite, she unhesitatingly confronts high society with the sincerity of her love. Society's smug condemnation assures the tragic consequences of the affair. The sinful romance of Anna and Vronsky is effectively contrasted with the happy love and marriage of Kitty and Levin, which appears to have been inspired by Tolstoy's own experiences in marriage. Further, Levin's anguished doubts about the meaning of life, his haunting thoughts of suicide, and his desire to sympathize with the peasants are clear echoes of Tolstoy's own struggle at this time.

The moral basis of *Anna Karenina*

Last years as Christian reformer. Though happily married, famous as a novelist, and enjoying a large income, Tolstoy had become dissatisfied with himself by the time he finished *Anna Karenina.* An incessant probing into the purpose of life, which had troubled him since his youth, drove him to a state of spiritual crisis. In *Ispoved* (*A Confession*) he poignantly relates the moral and spiritual suffering he endured in his search for an answer to the meaning of life. The crisis came to a head in 1879. At one point he contemplated suicide. He found little help in the writings of philosophers, theologians, and scientists that he systematically examined, but the peasants, for whom he felt a deep sympathy, gave him a clue. One must serve God, they told him, and not live for oneself.

Ultimately Tolstoy became convinced that the teachings of Christ, as revealed in the New Testament, contained the answer to his question about the meaning of life. There is a power in each of us, he declared, that enables us to discern what is good, and we are in touch with that power. Our reason and conscience flow from it, and the purpose of our conscious life is to do its will; that is, to do good. From what he believed to be Christ's real utterances, corrected as he felt they should be if they were to retain their original substance, he formulated five commandments to guide him: do not be angry; do not lust; do not bind yourself by oaths; resist not him that is evil; and be good to the just and the unjust. These commandments, with some modifications, became the basis for his future activities and teachings.

Conversion to Christian anarchism

Tolstoy's new convictions took a form of Christian anarchism that led him to disavow immortality and reject the authority of the church, which in turn was to excommunicate him in 1901. Further, he opposed organized government because it maintained itself through coercion, and

he condemned private property because he believed that ownership was secured by force. He would have preferred to divest himself of his own property, but, bowing to the wishes of members of his family, he legally transferred his estate to them.

Following his spiritual crisis, Tolstoy devoted much time after 1880 to writing books, pamphlets, and articles on various aspects of his religious, social, moral, and artistic views. Though they lack the absorbing interest of the personal experience he related in *A Confession,* they are written in the same clear prose and often reveal his remarkable gift for logical and persuasive argumentation. The most important of these many discursive writings are *Kritika dogmaticheskogo bogoslaviya* (*An Examination of Dogmatic Theology*), a powerful attack on the Russian Orthodox Church; *V chyom moya vera* (*What I Believe*), an attempt to systematize his views on religion; *Tak chto zhe nam delat?* (*What Then Must We Do?*), a vivid account of his experiences in the slums of Moscow and an analysis of the causes of poverty; and *Tsarstvo bozhiye vnutri vas* (*The Kingdom of God Is Within You*), the fullest statement of his Christian anarchism, in which he developed his belief in nonresistance to evil and reached the conclusion that governments exist largely for the sake of the rich and powerful and by their use of force persecute the masses of mankind and murder them in the violence of war. Some essays attack specific social and governmental practices, such as the use of intoxicants and tobacco in "Dlya chego lyudi odurmanivayutsya?" ("Why Do Men Stupefy Themselves?") and the execution of revolutionists in "Ne mogu molchat!" ("I Cannot Be Silent!"). Others call for reforms, advocating, for instance, the land tax proposed by the American economist Henry George (*Pisma o genre dzhorzhe* [*Letters on Henry George*]).

Religious and social essays

In 1897 Tolstoy completed *Chto takoye iskusstvo?* (*What Is Art?*), an attempt to develop an aesthetic system in terms of his religious, moral, and social views. He maintained that a work is art only when it "infects" the reader, hearer, or viewer with the condition of the artist's soul. If there is no union between the artist and his audience through "infection"—that is, if a communication of sympathetic feelings is not conveyed—then the work has failed as art. Among the several degrees of art that Tolstoy recognized, the highest is "religious art"—that which infects people with feelings "flowing from the love of God and man." On this basis, he rejected as art some of the works of, for example, Shakespeare and Wagner. With that maddening consistency that is as much the hallmark of pride as of humility, he relegated his own great works of fiction up to this point to the category of "bad art," because they did not conform to the moral purpose of his new theory.

After his spiritual crisis Tolstoy, apart from his voluminous nonfiction, wrote several tales with a moral purpose, in a bare style devoid of the abundant details of his previous fiction. "Chem lyudi zhivy" ("What Men Live By"), "Dva starika" ("Two Old Men"), "Vrazhye lepko, a bozhye krepko" ("Evil Allures, but Good Endures"), "Mnogo li cheloveku zemli nuzhno?" ("How Much Land Does a Man Need?"), and "Tri voprosa" ("Three Questions") are cast in this new manner. These little masterpieces of construction, which focus on peasant life, belong to his category of "good universal art." Though a moral is present, it is never allowed to obtrude on the artistic unity of the story. Another series of tales, different in manner because they are intended to appeal to educated readers, are closer to the style of his earlier fiction. The finest are the unfinished "Zapiski sumasshedshego" ("Notes of a Madman"), a mystical treatment of man's despair in the face of life's defeats, and "Smert Ivana Ilicha" ("The Death of Ivan Ilich"), in which the hero, a symbolic Everyman, discovers the inner light of faith and love only when confronted by death. The problem of sex, which deeply concerned Tolstoy in his new belief that man's moral health depended on his ability to approach closer to the ideal of chastity, becomes the central theme of "Kreytserova Sonata" ("The Kreutzer Sonata"), a convincing artistic study of jealousy and ill-tempered polemic against society's sexual education of young men and women. Sex is also the main concern of "Dyavol" ("The Devil"), a story inspired by an episode in Tolstoy's life: a man, deeply in love with his young wife, cannot overcome his lust for a pretty peasant girl. The husband's despairing struggle with carnal desire is told with all Tolstoy's psychological mastery.

Sexual themes

A full-length novel, *Voskreseniye* (*Resurrection*), written when he was 71, was Tolstoy's major artistic effort after his "conversion." It is the story of a nobleman who seduces a young girl. She becomes a prostitute and is convicted of a crime that she did not commit, and the conscience-stricken hero, determined to marry her, follows her to Siberia. Though his love redeems her, in the end she refuses to marry him. There are many fine things, especially in the first part, where the account is cast in a bewitching poetic atmosphere. And the trial scene is a brilliant piece of realistic narrative. But *Resurrection* represents a marked falling off, artistically, from *War and Peace* and *Anna Karenina.* It bears evidence of haste, and the moral preaching and sharp attacks on the judicial and penal systems—however deserved—and on the religious services of the church are in the spirit of Tolstoy the polemicist rather than the literary artist.

After his "conversion" Tolstoy strove, by no means with complete success, to bring his daily existence into conformity with his altered views. He abandoned smoking and drinking, became a vegetarian, and often dressed in simple peasant clothes. Since he now believed that no one should depend upon the labour of others, he became as self-sufficient as possible, cleaning his own room, working in the fields, and making his own boots. In the hope of approaching closer to his ideal of chastity, he tried to conquer fleshly desires in his relations with his wife. He also engaged in philanthropic activities, such as the organization of famine relief. The eloquence of Tolstoy's moral and religious writings, his fame, and his vital personality attracted many adherents. Disciples organized colonies in which they endeavoured to live together according to his precepts. Tolstoy distrusted such organized efforts. The truth that brings happiness cannot be preached, he declared; it can be achieved only by individuals who honestly look within themselves. As his own reputation increased and knowledge of his views spread throughout Russia and abroad, hundreds of people from all over the world made their way to Yasnaya Polyana to see and talk with him.

But the older sons, and his wife especially, had little sympathy for Tolstoy's views and his altered way of life. Endless visits of "converts"—the "dark people," his wife called them—and the interference of one of them, V.G. Chertkov, in family affairs caused frequent quarrels between husband and wife. Contrary to his hopes, she refused to surrender her possessions and join him in a life of comparative asceticism. In fact, to secure the family's comfortable existence, she obtained, much against his will, the copyrights of his works printed before 1880, and these writings provided considerable income from editions that she herself published.

During the last part of his life Tolstoy withheld from publication various works, either because he was dissatisfied with them or because he wished to avoid quarrelling with his wife over copyright ownership. In 1911, a year after his death, several of them appeared; they are among his best creations. One is a short novel, *Khadzhi-Murat,* the story of a brave Caucasian warrior who deserts to the Russians and is killed attempting to see his son in secret. The vivid narrative method and psychological revelation of mutual misunderstandings entitle it to a place among the most superb examples of his art. Equally effective, though shorter, are "Otets Sergy" ("Father Sergius"), the story of an aristocrat who conquers his lust and spiritual pride and becomes a hermit-monk; "Falshivy kupon" ("The False Coupon"), a study in fictional form of how the example of goodness, in contrast with the evil-begetting power of evil, inspires good deeds; and "Alyosha Gorshok," a perfect short story of a peasant youth who finds contentment with his lot through submission to all adversities.

Several plays were included in the first posthumous collection of his works. Tolstoy believed that drama was "probably the most influential province of art," and at various periods he devoted much effort to writing plays. But he lacked certain of the qualifications necessary to the

Posthumous stories and plays

dramatist, and, though in some instances he succeeded, his plays are inferior, artistically, to his fiction.

Vlast tmy (*The Power of Darkness*), Tolstoy's highest achievement in drama, was first performed in 1888. It is a realistic tragedy of peasant life conceived as an illustration of one of his favourite later themes, suggested by the subtitle, "If a Claw Is Caught, the Whole Bird Is Lost." The initial evil action of the protagonist—his seduction of another man's wife—leads him to commit further sins, including the final sin of murder. A striking contrast is *Plody prosveshcheniya* (*The Fruits of Enlightenment*), a comedy that genially satirizes the foibles of aristocratic society. Tolstoy never finished *I svet vo tme svetit* (*The Light Shines in Darkness*), though it had a special autobiographical importance, for it concerns the hero's failure to convince his family of the wisdom of his beliefs. *Zhivoy trup* (written 1902; *The Living Corpse*) deals with the tragedy of a drunkard. Conscience-stricken over the harm he has caused his wife, he pretends to have died so that she may marry the man she loves. When the police reveal that he is actually alive, he kills himself. The moralizing that appears in Tolstoy's writing in his old age is absent from his play, which is filled with kindness and sympathetic understanding of the erring ways of mankind.

The aging Tolstoy felt keenly the painful contradiction between the life of ease that the family lived and the life he wanted to live—the simple existence of a religious hermit, free of worldly goods and dedicated to service to others. He realized that his position made a mockery of his professed faith. Finally, the worsening domestic situation forced him to leave home stealthily one night, accompanied by his doctor and youngest daughter, Aleksandra, in search of, he hoped, a refuge where he could live quietly and closer to God. A few days later, on November 20 (November 7, O.S.), 1910, he died of pneumonia at the remote railway junction of Astapovo, in Ryazan Province.

Assessment. Tolstoy's eminence as a literary artist has never been seriously questioned by critics; he is universally accepted as one of the greatest writers of fiction in the world. Although never dependent on preceding Russian authors, he may have been influenced by foreign writers, such as Jean-Jacques Rousseau, Sterne, Stendhal, and later, William Thackeray. But there has never been unanimity about his reputation as a thinker. The dualism of Tolstoy's moral and intellectual development, however, has come to be more thoroughly understood by modern students of his thought. In his tireless search for truth he sought for absolutes in a world of incomplete knowledge and imperfect men. As a consequence, his unwillingness to compromise, his compulsive need to achieve the ultimate rational explanation, often led him to push theory to the limits of absurdity, which many believe he came very close to doing in his views on history, nonviolence, education, and art. But any systematic study of his thought reveals its relation to the concepts of 19th-century liberalism. He believed that the whole history of the last 2,000 years had been shaped essentially by the moral development of individuals and the demoralization of governments. Tolstoy placed his faith in the moral development of the people as a final answer to what he regarded as the universal oppression of the many by the few. For him, the progressive movement toward a classless and stateless condition of mankind depended, contrary to the economic determinism and violent class struggle of Marxism, upon the growing moral perfection of each individual through observance of the supreme law of love and the consequent repudiation of every form of violence. Despite the extreme to which he carried his rationalism, Tolstoy is today generally considered to be one of the most influential moralists of the 19th century. (E.J.Si.)

MAJOR WORKS

NOVELS: *Voyna i mir* (1865–69; *War and Peace,* trans. by Louise and Aylmer Maude in "Great Books of the Western World," vol. 51, 1952; trans. by Constance Garnett, 1961); *Anna Karenina* (1875–77; trans. by R.S. Townsend, 2 vol., 1958); *Voskreseniye* (1899; *Resurrection,* trans. by Louise Maude, 1957).

STORIES: *Detstvo* (1852; *Childhood* in *Childhood, Boyhood, Youth,* trans. by R. Edmonds, 1964); "Nabeg" (1853; "The Raid," trans. by Constance Garnett in *Tolstoy Tales,* 1947); *Otrochestvo* (1854; *Boyhood*); "Rubka lesa" (1855; "The Woodfelling" in complete works: *Tolstoy Centenary Edition,* trans. by Louise and Aylmer Maude, 1928–37); "Dva gusara" (1856; "Two Hussars" in complete works); *Yunost* (1857; *Youth*); "Kholstomer" (written 1863, first published 1886; in complete works); *Kazaki* (1863; *The Cossacks,* in *The Cossacks; The Death of Ivan Ilyich; Happy Ever After,* trans., by R. Edmonds, 1960); "Chem lyudi zhivy" (1881; "What Men Live By" in *Tolstoy Tales,* trans. by Louise and Aylmer Maude, 1947); "Dva starika" (1885; "Two Old Men"); "Mnogo li cheloveku zemli nuzhno?" (1886; "How Much Land Does a Man Need?"); and "Tri voprosa" (1903; "Three Questions")—all in translation in complete works; "Zapiski Sumasshedshego" (1884; "Notes of a Madman" in *Notes of a Madman and Other Stories,* trans. by S.S. Koteliansky, 1943); "Smert Ivana Ilicha" (1886; "The Death of Ivan Ilich" in complete works); "Kreytserova sonata" (1891; "The Kreutzer Sonata" in *The Kreutzer Sonata, The Devil, and Other Tales,* trans. by Aylmer Maude, 1940) "Dyavol" (1889; "The Devil" in *The Kreutzer Sonata*); "Otets Sergy" (written 1898, first published 1911; "Father Sergius" in complete works); *Khadzi-Murat* (written 1904, first published 1911; trans. in complete works); "Falshivy kupon" (written 1904, first published 1911; "The False Coupon" in complete works); "Alyosha Gorshok" (written 1905, first published 1911; "Alyosha the Pot").

PHILOSOPHICAL AND SOCIAL WRITINGS: *Ispoved* (written 1878–79, first published 1882; *How I Came to Believe—"My Confession,"* trans. 1921); *Kritika dogmaticheskoga bogoslaviya* (written 1880, first published 1891; *An Examination of Dogmatic Theology*); *V chyom moya vera* (written 1883, banned 1884; *What I Believe,* trans. by Aylmer Maude, 1940); *Tak chto zhe nam delat?* (finished 1886, first published 1902; *What Then Must We Do?); Tsarstvo bozhiye vnutri vas* (1894, *The Kingdom of God Is Within You*); "Dlya chego lyudi odurmanivayutsya" (1890; "Why Do Men Stupefy Themselves?"); "Ne mogu molchat!" (1908; "I Cannot Be Silent!"); *Pisma o Genri Dzorzhe* (1897; *Letters on Henry George*); and *Chto takoye iskusstvo?* (1898; *What Is Art?*)—all translations in complete works.

BIBLIOGRAPHY

Editions, selections, letters, and diaries: ЛЕВ НИКОЛАЕВИЧ ТОЛСТОЙ, *Полное собрание сочинений,* 90 vol., ed. by ВЛАДИМИР Г. ЧЕРТКОВ (1928–58), is the most complete Russian edition of Tolstoy's works, the so-called Jubilee Edition, including his letters, notebooks, and diaries. Another major Russian edition is ЛЕВ НИКОЛАЕВИЧ ТОЛСТОЙ, *Собрание сочинений,* 20 vol. (1960–65). Of editions in English translation none is complete; the most useful are *The Complete Works of Count Tolstoy,* trans. by LEO WIENER, 24 vol. (1904–05, reprinted 1968); and *Tolstoy Centenary Edition,* trans. by LOUISE and AYLMER MAUDE, 21 vol. (1928–37). Translations of single fictional works are also available in the Everyman's Library and in Penguin Classics. Selections in English of nonfictional works include AYLMER MAUDE (ed.), *Tolstoy on Art* (1924, reprinted 1973); *Tolstoy's Writings on Civil Disobedience and Non-Violence* (1967); ALAN PINCH and MICHAEL ARMSTRONG (eds.), *Tolstoy on Education* (1982). See also *The Journal of Leo Tolstoi, 1895–1899,* trans. by ROSE STRUNSKY (1917); *The Diaries of Leo Tolstoy,* 3 vol., trans. by C.J. HOGARTH and A. SIRNIS (1917); *Last Diaries,* ed. by LEON STILMAN (1960, reprinted 1979); PAUL BIRYUKOV (ed.), *Tolstoi's Love Letters: With a Study on the Autobiographical Elements in Tolstoy's Work,* trans. by SAMUEL S. KOTELIANSKY and VIRGINIA WOOLF (1923); *The Private Diary of Leo Tolstoy, 1853–1857,* trans. by LOUISE and AYLMER MAUDE, 2nd ed. (1927, reprinted 1972); *The Letters of Tolstoy and His Cousin Countess Alexandra Tolstoy, 1857–1903,* trans. by LEO ISLAVIN (1929); *Tolstoy's Letters,* 2 vol., selected, ed., and trans. by REGINALD F. CHRISTIAN (1978).

Recollections of Tolstoy: SERGEI A. BERS, *Recollections of Count Leo Tolstoy,* trans. by CHARLES E. TURNER (1893); ILYA TOLSTOY, *Tolstoy, My Father,* trans. from the rev. Russian ed. by ANN DUNNIGAN (1971; originally published in Russian, 1914, rev. ed., 1969); MAXIM GORKY, *Reminiscences of Leo Nicolayevitch Tolstoi,* trans. by SAMUEL S. KOTELIANSKY and LEONARD WOOLF (1920, reprinted 1978; originally published in Russian, 1919); SOFIIA A. TOLSTAIA, *The Autobiography of Countess Sophie Tolstoi,* trans. by S.S. KOTELIANSKY and LEONARD WOOLF (1922); ALEKSANDR B. GOLDENVEIZER, *Talks with Tolstoi,* trans. by S.S. KOTELIANSKY and VIRGINIA WOOLF (1923, reprinted 1969); COUNT LEON L. TOLSTOI, *The Truth About My Father* (1924); AYLMER MAUDE (ed.), *Family Views of Tolstoy* (1926); SOFIIA A. TOLSTAIA, *The Diary of Tolstoy's Wife, 1860–1891,* trans. by ALEXANDER WERTH (1928), and *The Final Struggle: Being Countess Tolstoy's Diary for 1910,* trans. by AYLMER MAUDE (1936, reprinted 1980; originally published in Russian, 1932); TATIANA A. KUZMINSKAYA, *Tolstoy As I Knew Him,* trans. by NORA SIGERIST *et al.* (1948), recol-

lections by a sister of Tolstoy's wife; TATIANA TOLSTOY, *The Tolstoy Home: Diaries of Tatiana Sukhotin-Tolstoy,* trans. by ALEC BROWN (1951, reprinted 1966), and *Tolstoy Remembered* (1977; originally published in French, 1975), recollections by Tolstoy's daughter; SERGEI TOLSTOY, *Tolstoy Remembered by His Son,* trans. by MOURA BUDBERG (1961, originally published in Russian, 1949); VALENTIN BULGAKOV, *The Last Year of Leo Tolstoy,* trans. and abridged by ANN DUNNIGAN (1971; originally published in Russian, 2nd ed., 1918), recollections of Tolstoy's secretary.

Biographies: PETR A. SERGEENKO, *How Count L.N. Tolstoy Lives and Works* (1899; originally published in Russian, 1898); AYLMER MAUDE, *The Life of Tolstoy,* 2 vol. (1908–10; rev. ed. 1930), one of the best accounts of Tolstoy's post-confessional years; PAUL I. BIRYUKOV (comp.), *Leo Tolstoy: His Life and Work* (1911); VLADIMIR G. CHERTKOV, *The Last Days of Tolstoy,* trans. by NATHALIE A. DUDDINGTON (1922, reprinted 1973), a valuable account of the family struggle of the last years; ALEXANDER I. NAZAROFF, *Tolstoy: The Inconstant Genius* (1929, reprinted 1971); EMILE J. DILLON, *Count Leo Tolstoy: A New Portrait* (1934, reprinted 1972); DERRICK LEON, *Tolstoy: His Life and Work* (1944); ERNEST J. SIMMONS, *Leo Tolstoy* (1946, reissued in 2 vol., 1960); ALEXANDRA TOLSTOY, *Tolstoy: A Life of My Father,* trans. by ELIZABETH R. HAPGOOD (1953, reprinted 1973), and *Out of the Past* (1981); HENRI TROYAT, *Tolstoy* (1967, reprinted 1980; originally published in French, 1965), an excellent work on Tolstoy's life. On Countess Tolstoy, see CYNTHIA ASQUITH, *Married to Tolstoy* (1960, reprinted 1969); and ANNE EDWARDS, *Sonya: The Life of Countess Tolstoy* (1981). Works on Tolstoy as a literary figure include EDWARD CRANKSHAW, *Tolstoy: The Making of a Novelist* (1974); MARTIN GREEN, *The Challenge of the Mahatmas* (1978), *Dreams of Adventure, Deeds of Empire* (1979), and *Tolstoy and Gandhi, Men of Peace: A Biography* (1983), comprising the trilogy *The Lust for Power,* which explores the impact of great personalities on literature; WALTER KERR, *The Shabunin Affair: An Episode in the Life of Leo Tolstoy* (1982); BORIS EIKHENBAUM, *Tolstoi in the Sixties,* trans. by DUFFIELD WHITE (1982; originally published in Russian, 1931), and *Tolstoi in the Seventies,* trans. by ALBERT KASPIN (1982; originally published in Russian, 1960), the work of a renowned Russian historian of literature, exploring Tolstoy's period of maturity.

Criticism and interpretation: CHARLES E. TURNER, *Count Tolstoi As Novelist and Thinker* (1888, reprinted 1974); AYLMER MAUDE, *Tolstoy and His Problems,* 2nd ed. (1902, reprinted 1974); DMITRI S. MEREZHKOVSKI, *Tolstoi As Man and Artist* (1902, reprinted 1970), a classic interpretation that has exercised great influence; ALEXANDER H.G. CRAUFURD, *The Religion and Ethics of Tolstoy* (1912); GEORGE R. NOYES, *Tolstoy* (1918, reprinted 1968); JANKO LAVRIN, *Tolstoy: A Psycho-Critical Study* (1924; rev. as *Tolstoy: An Approach,* 1944, reprinted 1968); HELEN E. DAVIS, *Tolstoy and Nietzsche* (1929, reprinted 1971); DERK BODDE, *Tolstoy and China* (1950, reprinted 1967); ISAIAH BERLIN, *The Hedgehog and the Fox: An Essay on Tolstoy's View of History* (1953, reprinted 1967), one of the best books on Tolstoy's world view; GEORGE STEINER, *Tolstoy or Dostoevsky: An Essay in the Old Criticism* (1959, reprinted 1971), a vivid account of the man and his work; THEODORE REDPATH, *Tolstoy,* 2nd ed. (1969), including a note on modern Russian work on Tolstoy; REGINALD F. CHRISTIAN, *Tolstoy's "War and Peace"* (1962), a valuable source study, and *Tolstoy: A Critical Introduction* (1969), examining Tolstoy's lesser known works. See also THOMAS MANN, *Goethe und Tolstoi* (1932); К. ЛОМУНОВ, *Драматургия Л.Н. Толстого* (1956); НИКОЛАЙ К. ГУДЗИ, *Лев Толстой,* 3rd rev. ed. (1960); АНДРЕЙ А. САБУРОВ, *"Война и мир" Л.Н. Толстого: проблематика и поэтика* (1959), a representative Soviet study; RUTH G. BENSON, *Women in Tolstoy: The Ideal and the Erotic* (1973); THOMAS G.S. CAIN, *Tolstoy* (1977), an analysis of the major fiction; EDWARD B. GREENWOOD, *Tolstoy: The Comprehensive Vision* (1975); EDWARD WASIOLEK, *Tolstoy's Major Fiction* (1978), with a good bibliography; MALCOLM JONES (ed.), *New Essays on Tolstoy* (1978), including a valuable survey of Tolstoy studies. Comparative studies of Tolstoy's literary relationships include LOGAN SPEIRS, Tolstoy and Chekhov (1971); JOHN BAYLEY, *Tolstoy and the Novel* (1966); LEV SHESTOV, *Dostoyevsky, Tolstoy and Nietzsche* (1969); BORIS SOROKIN, *Tolstoy in Prerevolutionary Russian Criticism* (1979). Tolstoy's philosophical and political views are discussed in GORDON W. SPENCE, *Tolstoy the Ascetic* (1967); and RONALD V. SAMPSON, *The Discovery of Peace* (1973; U.K. title, *Tolstoy: The Discovery of Peace*). DAVID R. EGAN and MELINDA A. EGAN, *Leo Tolstoy: An Annotated Bibliography of English-Language Sources to 1978* (1979), includes more than 2,000 items.

Tools

A tool is an implement or device used directly upon a piece of material to shape it into a desired form. The date of the earliest tools is extremely remote. Tools found in northern Kenya in 1969 have been estimated to be about 2,600,000 years old, and their state of development suggests that even older tools may remain to be discovered.

The present array of tools has as common ancestors the sharpened stones that were the keys to early human survival. Rudely fractured stones, first found and later "made" by hunters who needed a general-purpose tool, were a "knife" of sorts that could also be used to hack, to pound, and to grub. In the course of a vast interval of time, a variety of single-purpose tools came into being. With the twin developments of agriculture and animal domestication, roughly 10,000 years ago, the many demands of a settled way of life led to a higher degree of tool specialization; the identities of the ax, adz, chisel, and saw were clearly established more than 4,000 years ago.

The common denominator of these tools is removal of material from a workpiece, usually by some form of cutting. The presence of a cutting edge is therefore characteristic of most tools, and the principal concern of toolmakers has been the pursuit and creation of improved cutting edges. Tool effectiveness was enhanced enormously by hafting—the fitting of a handle to a piece of sharp stone, which endowed the tool with better control, more energy, or both.

It is helpful to draw the distinction between hand and machine tools. Hand tools are those used by craftsmen in manual operations, such as chopping, chiseling, sawing, filing, or forging. Complementary tools, often needed as auxiliaries to the shaping tools, include such implements as the hammer for nailing and the vise for holding. A craftsman may also use instruments that facilitate accurate measurements: the rule, divider, square, and others. Power tools—usually hand-held, motor-powered implements such as the electric drill or electric saw—perform many of the old manual operations and as such may be considered hand tools. Machine tools are analogous to hand tools in their function as shaping implements, but they require stationary mounting and mechanical drive for the working of strong materials, primarily metal, and the mass processing of precision parts.

For information on the development of agricultural implements, see the article AGRICULTURE, THE HISTORY OF.

Early history of hand tools

GEOLOGICAL AND ARCHAEOLOGICAL ASPECTS

The oldest known tools date from 2,600,000 years ago; geologically, this is close to the end of the Pliocene Epoch, which had extended over 4,500,000 years and was the last of five epochs constituting the Tertiary Period (the 65,000,000 years of which had seen the rise of mammals). The Pliocene was succeeded by the Pleistocene Epoch, which began about 2,500,000 years ago and was terminated only recently, perhaps 10,000 years ago, with the recession of the last glaciers, when it was supplanted by the Holocene (Recent) Epoch. Pleistocene and Stone Age are in rough correspondence, for, until the first use of metal, about 5,000 years ago, stone was the principal material of tools and implements.

At first, humans were casual tool users, employing convenient sticks or stones to achieve a purpose and then discarding them. Although humans may have shared this characteristic with some other animals, their differentiation from other animals may have begun with the deliberate making of tools to a plan and for a purpose. A cutting instrument was especially valuable, for, of all carnivorous animals, humans are the only ones not equipped with tearing claws or canine teeth long enough to pierce and rend skin: humans need sharp tools to get through the skin to the meat. Naturally fractured pieces of stone with sharp edges that could cut were the first tools; they were followed by intentionally chipped stones. For archaeologists, the finding of primitive, intentionally made cutting tools indicates and confirms the early presence of humans at a site. Once understood, fire helped shape wooden implements before adequate stone tools were available for the purpose.

Fire was also the basis of metallurgy. When in historic time the powers of water and wind were applied to the daily tasks of grinding grain and raising water, the way to industrialization was opened.

Thomsen and the three-age system

The idea of relating human history to the material from which tools were made dates from 1836 when Christian Jürgensen Thomsen, a Danish archaeologist, was faced with the task of exhibiting an undocumented collection of clearly ancient tools and implements. Thomsen used three categories of materials—stone, bronze, and iron—to represent what he felt had been the ordered succession of technological development. The idea has since been formalized in the designation of a Stone Age, Bronze Age, and Iron Age.

The three-age system does not apply to the Americas, many Pacific Islands, or Australia, places in which no Bronze Age existed before the native inhabitants were introduced to the products of the Iron Age by European explorers. The Stone Age is still quite real in some remote regions of Australia and South America, and it existed in the New World at the time of Columbus' first visit. Despite these qualifications, the Stone–Bronze–Iron sequence is of value as a concept in the early history of tools.

The Stone Age was of great duration, having occupied practically all of the Pleistocene Epoch. Copper and bronze appeared more than 5,000 years ago; iron followed in the

next millennium or so and as an age includes the present.

The apparently abrupt transition from stone to bronze tends to mask the critical discovery of native metals and their utilitarian use and fails to indicate the significant discoveries of melting and casting. From bronze one can infer the crucial discovery of smelting, the process by which most of the common metals can be recovered from their ores. Smelted copper necessarily preceded bronze, a mixture of copper and tin, the first alloy. Iron came later, when technique, experience, and equipment were able to provide higher temperatures and cope with problems involved with its use.

STONE AS A MATERIAL

The Stone Age is divided into two contrasting periods: the Old Stone Age, a long era of stagnation; and the New Stone Age, a brief period of swift progress.

The Paleolithic Period, or Old Stone Age, endured until about 10,000 years ago and was characterized by tools of chipped stone, cutting tools with rough and pock-marked surfaces and generally serrated cutting edges. The later Paleolithic was also an era of wood, horn (antler), and bone. These three materials, all softer than stone but nevertheless intractable, could not be worked successfully without the aid of harder stone tools, such as serrated blades and gravers, or burins, small scrapers with either pointed or narrow, chisel-like ends. Bone was a particularly useful material, for its toughness made feasible barbed fishhooks, eyed needles, and small leatherworking awls.

The term Neolithic Period, or New Stone Age, defines the second period, at the beginning of which ground and usually polished stone tools, notably axes, came into widespread use after the adoption of a new technique of stoneworking. The beginning of the Neolithic, the retreat of the last glaciers, and the invention of food crops, involving agriculture and animal domestication, were more or less contemporary events. The period terminated with the discovery of metals.

The revolutionary art that created the definitive ground and polished tools of Neolithic man was essentially a finishing operation that slicked a chipped tool by rubbing it on or with an abrasive stone to remove the scars of the chipping process that had produced the rough tool. Not only was the edge keener than ever before, but the smooth sides of the edge also promoted deeper penetration and, hence, greater effectiveness, with the added advantage of easier tool extraction from a deep and wedging cut.

Stones for toolmaking

As a tool material, the term stone covers a wide variety of rocks, ranging from the dense and grainless flint and obsidian to coarse-grained granite and quartzite. Each kind of stone has certain unique properties that are further influenced by temperature and humidity. Stone of any kind is difficult to manipulate. It has been noted, for example, that the Australian Aborigines reject as unsuitable a great many of the flints they have worked on, sometimes in the ratio of 300 rejects to one accepted tool. This high discard rate may help explain the thousands upon thousands of stone artifacts that have been found.

Flint, homogeneous and isotropic (having equal properties in all directions), is the stone of first choice for toolmaking. Reasonably well distributed over much of the world, it is an impure quartz, a form of silica, usually opaque and commonly of gray or smoky-brown colour. It is harder than most steels, having no cleavage planes, but displaying the conchoidal, or shell-like, fracture of a brittle material that leaves a sharp edge when flakes are detached. (Glass, which may be considered an artificial quartz, also exhibits the conchoidal fracture.) Obsidian, a volcanic glass of rather limited distribution, is usually black or very dark and, because of its conchoidal fracture, was used like flint. Most edged stone tools, however, were of flint. Flint was once an object of trade, and flint mines were in Neolithic time what iron mines became at a later age.

Types of stone tools. Three principal types of tools appeared in the long Paleolithic Period, with substantial variations occurring within each type. The types are distinguished principally by workmanship but also vary in size and appearance and are known as core, flake, and blade tools. The core tools are the largest; the earliest and most primitive were made by working on a fist-sized piece of stone (core) with a similar stone (hammerstone) and knocking off several large flakes on one side to produce a jagged but sharp crest. This was a general-purpose implement for the roughest work, such as hacking, pounding, or cutting. The angle of the cutting edge was rather large because of the sphericity of the stone. In time, thinner, sharper, and more versatile core tools were developed.

Although large flakes with sharp edges of small angle were a by-product of core-tool manufacture and were well suited for slitting and scraping, they were not flake tools in the proper sense. True flake tools derived from an advanced technique practiced more than 2,000,000 years later that sought the flake and discarded the core from which it had been detached; flake tools were made deliberately to serve a certain function and were not the casual spin-off of another operation. Finally, there were blade tools, longish slivers of stone with keen unserrated edges, directly useful as knives or as stock from which other pieces might be skillfully broken to serve numerous purposes. While flake and blade tools were developing, core tools were refined by overall chipping to create thinner and more efficient forms.

Techniques for making stone tools. Archaeologists have noted three different techniques for working stone to successive stages of refinement in the Paleolithic Period. The first and always basic method employed the hammerstone to fashion either a large and rude core tool such as the chopper, whose form persisted for perhaps 2,000,000 years, or to rough out (block in) large tool blanks that would be brought to final form by removing small flakes. The hammerstone technique produced short and deep flake scars. A variation employed the anvil stone, a large stationary stone against which the workpiece was swung to batter off large flakes.

Soft-hammer technique

The second method was the soft-hammer, or baton, technique, based on a discovery of perhaps 500,000 years ago that hard stone (flint in particular) could be chipped by striking it with a softer material. The baton was a light "hammer," an almost foot-long piece of bone, antler, or even wood, whose gentler blows detached only quite small flakes that left smooth, shallow scars. Such small flakes, when removed from the large scars left by the hammerstone, reduced the coarse and jagged edge to many small serrations, giving a straighter and more uniform cutting edge whose angle was also more acute than formerly and, hence, sharper.

Pressure flaking was the third technique. In this, a short, pointed instrument of bone, antler, or wood was used to pry, not strike, off tiny flakes in order to leave the smallest scars. As the least violent and most advanced of the methods of working stone, it gave the craftsman the ultimate in control for the removal of materials in the shaping of an implement.

To judge from the few remaining hand-tool-making societies, it is likely that every early man was adept at making new tools quickly and easily and on the spot, as fast as the old ones were blunted or broken. The earliest simple tools, made by taking convenient hand-sized stones and giving them sharp crests by a few well-placed blows, were evidently discarded after use, for their widespread dispersal suggests that they were made at the place of use and abandoned after serving their purpose. Tens of thousands of prehistoric stone tools survive, compared with only very few bits and pieces of the skeletal remains of the makers. Stone, of course, is imperishable, whereas bone is not, and one individual might have made several hundred tools.

Limitations of stone tools. The possibilities in the design of stone tools were limited by the inflexibility and brittleness of the material. The design effort was constrained to the sizing of the tool to the intended task and the development of sharper, longer, and more usefully shaped cutting edges that always required backing to support them. In use, the bending and twisting of long knifelike tools had to be avoided lest the action destroy them; this would also have been true of chisels and gouges. Similarly, even the much later heavier tools, such as the ax and adz, required care in use.

The effectiveness of stone tools has been demonstrated from time to time by both archaeologists and modern workers unaccustomed to such tools. An experienced operator using a stone knife can skin a small animal about as quickly and deftly as he can using steel. When the stone tool is subjected to substantial forces, however, the worker must use caution, intelligence, and control. Care is required to avoid twisting or prying with a stone blade (knife or ax); a thin blade may snap, and a thick one may collect local nicks.

PALEOLITHIC TOOLS

Classifying early tools

Early tools are classified by their industry, or type of workmanship. Such tool traditions are identified by a name derived from the site at which the type first drew archaeological attention. For example, the primitive chopping tools that persisted for nearly 2,000,000 years, first identified in Olduvai Gorge, east of Lake Victoria, Tanzania, constitute the so-called Oldowan industry, regardless of the part of the world in which implements of similar workmanship happen to be found.

The sequence of traditions shows growth and development; it does not imply abrupt transitions at certain times or the disappearance of an old industry with the advent of another. A new technique simply meant that something better or different could be accomplished, from the refinement of the cutting edge or the upgrading of old tool forms to the manufacture of a completely new tool. Innovation sometimes was possible only by drawing upon previously unworkable materials.

An overview of the products of the successive toolmaking industries shows that much effort went into cutting edges in the longitudinal direction of the pieces of flint. Knifelike instruments predominated and, thus, defined the nature of the fundamental need, namely, that of a cutting tool which could slit and sever.

With the passage of time and the acquisition of skills, the average size of the tool decreased; there was more cutting edge per pound of material, an important factor when flint had to be imported to a region. This trend was reversed in the Neolithic Period, when the heavy woodsman's ax and adz became essential elements for clearing forests for agriculture and timber. The world was then changing from an economy based on gathering and hunting food to a way of life founded on raising food.

Archaeologists have named the early tools by guessing at their presumed use, often in the light of other known facts about the culture in which the tradition appeared. As the tools move closer to the present, and specialized forms are seen in the creation of a wider variety of products, the descriptive name is on firmer ground.

Eoliths. The first act of the drama of tools is hazy. There are what have been called eoliths, "tools from the dawn of the Stone Age." Such stones with sharp fractures, found in great quantities in layers from the geological epochs before the Pleistocene, were once assumed to be tokens of human presence in the preceding Pliocene and even earlier Miocene epochs. These rocks, fractured by glacier pressure, wave action, or temperature change, are no longer taken as indexes of humans, although primitive peoples undoubtedly used them as ready-made objects before they deliberately started to fracture similar rocks in the late Pliocene. There are detailed criteria by which human-flaked and nature-flaked stones can be distinguished almost unerringly. Human origin is also evidenced by association with detached flakes and the stones that served as hammers.

The oldest known tool

The tools found in 1969 at the Koobi Fora site, near Lake Rudolph in northern Kenya, consisted of five choppers, a number of flakes, and a couple of battered stones. The tools lay on the surface; the flakes were found three feet below them in tuff (volcanic rock) datable to about 2,600,000 years ago. The oldest previously known tools had been from Olduvai Gorge, Tanzania. These Oldowan tools, as well as the jaw and teeth of a man who may have been the toolmaker, were found in the 1950s under tuff having a potassium–argon date of about 1,800,000 years, a lower Pleistocene age.

All of these tools are of a single type, a general-purpose implement that changed little in form during the next 2,000,000 years. It is variously known as a pebble tool, pebble chopper, chopping tool, or simply as a chopper (see Figure 1A). Waterworn and hence rounded, up to about the size of a fist, the pebble, preferably flattish rather than spherical, was given a few violent but skillfully applied blows by a hammerstone. Several large flakes or chips were knocked off the stone to create on it a sharp and roughly serrated crest, or ridge, yielding an implement that was edged at one end and could be gripped at the opposite end. Rudimentary, yet versatile, the chopper could be used to hack, mash, cut, grub roots, scrape, and break bones for their marrow.

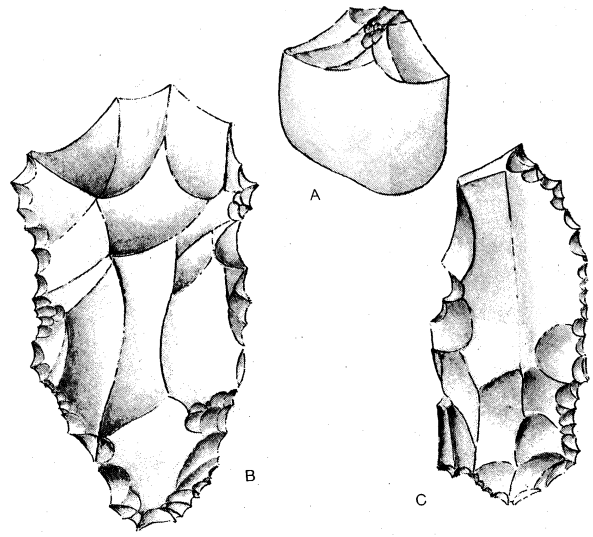

Figure 1: *Paleolithic tools.*
(A) Oldowan chopper, the oldest manufactured tool.
(B) Acheulian hand ax, or flat hatchet, a superior chopper.
(C) Scraper, a flake tool.

Although the large, sharp-edged flakes struck from the pebble were themselves useful for light cutting and scraping, it was not until perhaps 40,000 years ago that there was a development of flake-tool industries in which preshaped flakes were purposefully detached from a core that was then discarded. But the Oldowan chopper and the struck-off flakes—the earliest generalized primitive tools—between them solved the problems of how to get through the skin of a slain animal, dismember it, and divide the meat.

The Acheulian hand ax

The Acheulian industry. As the Pleistocene Epoch progressed, humans slowly developed the primitive chopper into a better instrument. About half a million years ago a superior implement finally appeared after nearly 2,000,000 years of effort. The industry, or style, is known as the Acheulian, and the typical implement was the flint hand ax (sometimes called a fist hatchet [Figure 1B]). Throughout the ages the plump chopper and its bluntly angled crest had been streamlined by starting with a longer piece of stone and flaking the entire surface to produce an almond-shaped (amygdaloid) implement eight to 10 inches (20 to 25 centimetres) long. This stone, much thinner than the chopper, was also sharper and more effective because the cutting edges were formed from the intersection of two curved and flaked surfaces (bifacial working).

This Acheulian hand ax was the product of evolution; certain of the intermediate stages, clearly leading to the typical and standardized form, have been identified as Chellean and Abbevillian. Despite the term ax, the tool was not hafted but was simply held in the hand. One end was tapered, the other rounded. The tapered end might be rather pointed or have a small straight edge. The tool was sharp for most of its periphery and seems to have been primarily a hunter's knife but probably very useful, too, for other purposes, such as chopping, scraping, grubbing, and even piercing. Sharp, thin and symmetrical, light and elegant, it was quite different from the heavy chopper, with its rather blunt edge.

Another biface, the Acheulian cleaver, assumed promi-

nence about 250,000 years later. A variant of the hand ax, it had a wide cutting edge across the end instead of a point and was better suited than the hand ax for hunting or hacking wood.

The Neanderthal tool kit

Neanderthal man, an excellent hunter and toolmaker, appeared on the scene about 110,000 years ago, just ahead of the last glaciation but well within the Acheulian. His tool kit was impressive for the wide variety of hand axes, borers, knives, and choppers it contained. The kit was novel for its scrapers and heavily serrated blades having a sawlike appearance, implements that were essential to the working of wood, bone, and horn into tools and weapons. The Neanderthals regularly used fire, and it is presumed that they could make it, although the direct evidence is missing. Fire was useful in tool manufacture, for charring the end of a stick not only helped shape the point by making it easier to scrape but also hardened it, as for a spear point. This fire hardening was probably the first man-made modification of a natural property. Thoroughly wet wood, bent to shape and brought to dryness over the heat of a fire, would retain its bent form, a most useful property.

The Mousterian flake tools. The Mousterian and related flake industries followed the Acheulian. A refinement of the prepared-core technique, termed Levallois, was developed during the middle to upper Acheulian. In this method, a core was craftily trimmed in such a manner that a skillfully applied last blow would detach a large, preshaped flake directly usable as an implement; the core was discarded. Such a flake tool, with one flat surface, is known as a unifacial tool because a single bevel forms the working edge. There are two principal kinds of flakes, points and scrapers. The former are roughly triangular, with two trimmed or sharp edges meeting in a point, the base or butt of the triangle being thick and blunt. The side scrapers have a sharp edge in the long direction of the flake, with an opposite, thicker butt section (Figure 1C). The scraper could function as a knife, although it is speculated that it was used for working wood and skins, a supposition leading to the idea that skins were being used for clothing.

Late Paleolithic toolmaking. The fourth phase of Paleolithic toolmaking was introduced perhaps 40,000 years ago by the Aurignacian industry, a forerunner of the last and most brilliant achievements of the Old Stone Age. Extraordinary inventiveness was characteristic of the Aurignacian tradition and its several short-term successors. They can be lumped into a unit of development that spans the next 25,000 years.

Fully modern man—whose first representative is the Cro-Magnon—emerged within this period, perhaps 35,000 years ago, during the time of the development and elaboration of stone technology, which, by providing a variety of specialized tools, mostly of the flake and blade types, at last brought materials other than stone into extensive use. It was also a time when the great plains in northern and eastern Europe carried such a heavy reindeer population, in addition to wild horses and mammoths, that it has been called the Reindeer Age. This produced a hunting economy providing food and great quantities of bone, horn, skin, sinews, and, while the mammoth lasted, ivory; with it grew new technologies exploiting the unique properties of materials hitherto unworkable because of their hardness. This technological diversification was made possible by new techniques and stone tools, whose specialization and complexity fit them to the fresh tasks. The most significant tool was the burin, or graver, a stout, narrow-bladed flint able to scrape narrow grooves in bone; two parallel grooves, for example, would allow a sliver of bone to be detached as stock for a needle, pin, awl, or other small object. Larger pieces of bone were worked into hooks with one or more barbs or points. Sections of antler were carved into splitting wedges to work out long pieces of bone to form the dartlike projectiles of the spear-thrower. Sandstone polishers were added to the tool kit to sharpen and shape tips, needles, and other articles.

The stone burin

A spectacular item that developed by the end of the Paleolithic was the spear-thrower, a hand-held stick, of wood or antler, notched at one end. Functioning as an extension of the arm, it added considerable kinetic energy, and therefore range, to a short spear tipped with flint or bone. The tipped projectile represented still another innovation, for it was the first hafted implement.

Hafting, or the fitting of a handle to a cutting edge, was a momentous and far-reaching invention of about 35,000 years ago. It was a critical step toward the creation of new tools and improved models of old ones. In its simplest form, the haft may have been no more than a grass or leaf bundle whose limited function was to protect the hand when a fractured stone was used as a knife. Mechanically, the handle became a force-transmitting intermediary between the source of the force and the toolhead. An extension of the arms, the handle provided an increased radius of swing. This moved the toolhead faster to give it more kinetic energy for a harder and more telling blow than the arms alone could provide. A man using a hand-held axhead could cut only small trees, whereas with a hafted ax he could fell a tree of almost any size.

The prepared-core technique that provided preshaped flakes was refined and extended to provide preshaped blades, long, slender pieces of flint of trapezoidal cross section, each corner having a straight cutting edge without the serrations of a chipped tool. This is known as the blade-tool industry, a final complement to the core- and flake-tool technologies. Such blades made thin and splendid knives of great variety; many of these knives were backed; that is, the back of the blade was blunted for safer handling. Thin blades were further reduced to smaller pieces, often having a geometric form such as triangular, square, or trapezoidal, called microliths. These small bits of sharp flint were cemented (using resin) into a groove in a piece of wood to form a tool with a cutting edge longer than it was feasible to produce in a single piece of brittle flint; examples are a spear with a long cutting edge or the farmer's sickle of later date.

The second major mechanical invention of the Upper Paleolithic was the bow, a device even more effective than the spear-thrower for increasing the distance between the hunter and the hunted. It is difficult to date precisely, for the only evidence of its use is found in cave paintings. Mere finds of stone points without bows prove nothing because such tips were used on the projectiles of spear-throwers. The earliest representations of the bow come from North Africa from 30,000 to 15,000 BC. Once the bow had been devised, it spread with astonishing rapidity, its effectiveness making it the weapon par excellence. When the bow was pulled, it stored the gradually expended energy of the archer's muscles; this energy was suddenly released to give the projectile a "muzzle velocity" far higher than that possible from a spear-thrower and of superior accuracy. It was a principal weapon through the 15th century AD and was ousted then only by gunpowder.

The first bows

NEOLITHIC TOOLS

The Neolithic Period, or New Stone Age, the age of the ground tool, is defined by the advent around 7000 BC of ground and polished celts (ax and adz heads) as well as similarly treated chisels and gouges, often made of such stones as jadeite, diorite, or schist, all harder than flint. A ground tool is one that was chipped to rough shape in the old manner and then rubbed on or with a coarse abrasive stone to remove the chip scars either from the entire surface or around the working edge (see Figure 2A). Polishing was a last step, a final grinding with fine abrasive. That such a tool is pleasing to the eye is incidental; the real worth of the smoothing lay in the even cutting edge, superior strength, and better handling. The new ax would sink deeper for a given blow while delivering a clean and broad cut; its smooth bit, more shock resistant than the former flaked edge, had less tendency to wedge in a cut.

Although the polished stone tool is the index to the Neolithic Period, it may be noted that the ice sheets were receding and climatic conditions were assisting the conversion of hunters into herdsmen. The new, relatively sedentary life spawned further inventions, such as pottery. From the standpoint of tools, the potter's kiln and art were necessary steps to metals, for a modification of the kiln probably provided the high temperatures and equip-

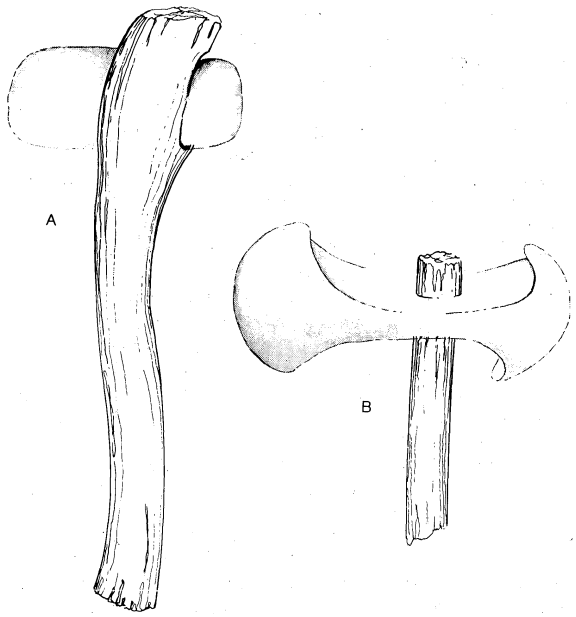

Figure 2: *Neolithic tools.*

ment needed for metalworking, first for melting native metals and later for the smelting process that gave rise to a wealth of metals, several of which proved to be superior materials for tools.

The ax in land clearance

The polished Neolithic ax, a heavy implement, was in sharp contrast to the delicate small-stone work of the last stages of the Paleolithic Period and was a reversal of the traditions of products that had yielded ever more lineal feet of cutting edge per pound of stone. The ax and its companion adz met the need to clear land as agriculture developed. An efficient tree-cutting tool was indispensable for the slash-and-burn agriculture then devised. Trees were either cut down or killed by ringing them with an ax; the debris was burned over, with the ashes conferring a slight enrichment of the stump-filled field. The earth was next scarified with sticks or stone-headed hoes resembling the adz to prepare it for seeding among the stumps. Without manuring or other treatment, the land was exhausted after a few years, necessitating a repetition of the clearing process elsewhere. The consequence was a shifting settlement pattern, with a good ax needed not only for felling trees but also for working timber for settlement.

Wood began its broad role in human life with the ground and polished tools of the Neolithic. Home and fire, furniture and utensils, cradle and coffin were products of the ax, adz, and chisel, which could fashion wood intricately and with precision. This kit of tools turned wood into an almost universal building material, for a host of new things was now possible, such as dugout canoes of oak, paddles and framing for hide-covered boats, sledges, skis, wooden platters and ladles, as well as other household gear. Mortise and tenon joints were invented for the structural framing of substantial habitations. Some of the gabled houses were up to 100 feet (30 metres) long and 20 wide and are believed to have served as both granaries and living quarters for perhaps 20 people comprising several families.

In a revealing experiment, 4,000-year-old polished stone axes, furnished by the Danish National Museum and carrying the sharpness left after their last use 4,000 years ago, were fitted with ash handles modeled after that of a Neolithic hafted ax preserved in a bog, giving the ax an overall length of nearly 25 inches (63 centimetres). (A modern steel felling ax has a 36-inch handle.) When these were used in a Danish forest, it was soon found that the violent action of the modern technique of swinging a steel ax and putting shoulder and weight behind the blade to give long and powerful blows was disastrous, either ruining the edge or breaking the blade. Proper handling meant short, quick strokes that chipped at the tree, the body action being constrained to mainly elbow and wrist motion. After getting into form, the men found it possible to fell an oak tree of more than one foot (0.3 metre) in diameter in half an hour or a pine, two feet in diameter, in less than 20 minutes. Six hundred square yards (one-eighth acre, or 0.05 hectare) of silver birch forest were cleared by three men in four hours. One axhead cut down more than 100 trees on its original (old) sharpening. It was concluded that Neolithic men and their ground flint axes had no great difficulties in making large clearings in the forest for the purposes of cultivation. It may also be remarked that it was less trouble to clear the forest than to break the age-old and tough sod of the plains.

The Neolithic farmer of northern Europe, with his practice of deforestation for agriculture, was completely dependent upon polished axes. This created a heavy demand for good stone that depleted local sources and resulted in flint mining in well-endowed locations in what are now England, Belgium, The Netherlands, France, Denmark, Sweden, Poland, Portugal, Sicily, and Egypt. Often more than just mining, these operations were ax factories where flints were shaped into rough form by chipping at the pithead and then traded. Grinding and polishing were done by the consumer.

Flint mining

An idea of the magnitude of such a mining enterprise is offered by the well-explored workings known as Grimes Graves, about 80 miles (130 kilometres) northeast of London. The site covers about 34 acres (14 hectares) and includes both opencast workings and 40-feet-deep shafts with radiating galleries that exploited the flint deposit laid down as a floor under chalk beds. Excavation was probably by wooden shovel (a product of the polished ax and chisel) or possibly the shoulder blades of oxen. It is estimated that 50,000 picks made of red-deer antler were used during the 600 years of activity in the mine, which began about 2300 BC.

A last innovation of the Neolithic was the augmentation of the two older techniques of working stone, chipping (or flaking) and grinding, by a third, the pecking, or crumbling, method (Figure 2B). In this procedure a point of the stone being worked was bruised by a hard hammerstone, the struck points crumbling into powder under relatively light but rapidly delivered blows. This technique allowed the manufacture of tools from numerous varieties of appropriate but nonflaking stone and the production of hollow ware, such as querns for grinding grain, mortars, and bowls. It also could be applied to flakable stone; such a stone, after having been roughed out by flaking, was pecked to level the ridges between flake scars before grinding and polishing.

Stone tools maintained themselves during the Metal Age, yielding only slowly to the new material, which was expensive and the product of special skills. The copper and bronze tools and weapons for hunting, warfare, husbandry, and domestic use that constitute impressive displays in museums were rare luxuries. Even the much more abundant iron, which overtook and replaced copper and bronze articles, was available only sparingly for many centuries.

EARLY METALS AND SMELTING

The discovery that certain heavy "stones" did not respond to hammerblows by flaking or fracturing but were instead soft and remained intact as their shapes changed marked the end of the long Stone Age. Of the pure, or native, metals, gold and silver seem to have attracted attention at an early date, but both were too soft for tools. The first metals of value for toolmaking were natural copper and meteoric iron. Although they were scarce, they were tough and potentially versatile materials that were suited for new purposes, as well as many of the old. They also introduced a new problem, corrosion.

Metalworking. Copper occurs in native state in many parts of the world, sometimes in nuggets or lumps of convenient size. It is malleable; that is, it can be shaped by hammering while cold. This also hardens copper and allows it to carry a sharp edge, the hammered edge being capable of further improvement on an abrasive stone. Af-

ter a certain amount of hammering (cold-working), copper becomes brittle, a condition that can be removed as often as necessary by heating the material and plunging it into cold water (quenching). The softening operation is known as annealing, and repeated annealings are necessary if much hammering is required for shaping.

Among early toolmakers, nuggets of copper were hammered into sheets, divided into strips, and then separated into pieces to be worked into arrowheads, knives, awls, choppers, and the like. Copper was also shaped by beating pieces of the soft metal into appropriately shaped stone cavities (molds).

Use of meteoric iron

Meteoric iron, widely distributed but not in heavy deposits, was a highly prized material more difficult to fabricate than the softer copper. Its celestial origin was recognized by the ancients, for the Egyptians called it black copper from heaven, and the Sumerians denoted it by two characters representing heaven and fire.

Like copper, iron hardens under the hammer and will then take a superior edge. Iron can be annealed, but the process is quite different from that of copper because, with iron, slow cooling from a high temperature is necessary. Meteoric iron is practically carbonless and, hence, cannot be hardened in the manner of steel; a high nickel content of about 8 percent makes it relatively corrosion resistant.

For early toolmakers, small meteorites were the most convenient sources of iron, but larger bodies were hacked at with copper and stone tools to yield tool-sized pieces for knives, spear points, arrowpoints, axheads, and other implements. Meteoric iron was beaten into tools in much the same way as copper, although it could not be forced into a mold in the manner of the softer metal. Much rarer than copper, meteoric iron also was often used for jewelry, attested to by burial finds of necklaces of iron and gold beads, iron rings along with gold rings, and ornaments in sheet form.

Casting. In casting, a liquid metal is poured into a cavity or a mold, where it takes the shape of the mold when it congeals; casting shapes the metal to essentially final form once a proper cavity has been prepared. Some touch-up work may be needed; for an edged copper tool, such as an ax or knife for example, hammering the cutting side gives a keen edge.

A great step forward was made with the discovery that gold, silver, and copper could be melted and cast with many advantages. Casting meant that the size of the tool was no longer dependent on the size of a chunk of available copper. Old tools could be added to a melt instead of being thrown out. This reuse of old metal accounts in part for the scarcity of virgin-copper implements.

To make the procedures of melting and casting possible, several innovations were required. Pottery making, already well established, provided the knowledge of heat-based processes. Clay vessels were essential to working with fluid metal, for, in all but the most primitive operations, it was necessary to convey the melt from furnace to mold. Aside from providing crucibles, pottery making taught how to restructure a fire with a deep bed of prepared charcoal to provide a heat superior to that of a simple campfire. Tongs of some sort had to be devised to carry the hot crucible; it is surmised that green branches were bent around the pot and replaced as needed.

Molds

A number of forms of molds were developed. The most primitive was simply an impression of a stone tool in clay or sand to give a cavity of the desired form. A more durable mold resulted when the cavity was worked into stone. Cavities of uniform depth allowed flat but profiled pieces to be cast. For example, some ax blade castings were roughly T-shaped, the arms of the T being afterward bent around to clasp a handle of some sort, with the bottom of the T becoming the cutting edge. A one-piece mold, prepared for a dagger, could have a groove for most of the length of the cavity to provide a stiffening rib on one side. With experience, closed but longitudinally split and, hence, two-piece molds were devised, each side having a groove down the middle to furnish a strengthening rib on both sides of the blade.

Split molds for copper were not desirable because pure copper is a poor metal for casting. It contracts a good deal on cooling and has a tendency to absorb gases and thereby become porous, blistered, and weak. Also, molten copper exposed to atmospheric oxygen contains embrittling cuprous oxide.

Smelting. Perhaps 1,000 years after humans learned about melting virgin copper, they found that still another stone, a brittle one directly useless for tools, would produce liquid copper if sufficiently heated while in contact with charcoal. This step was epoch making, for it was the discovery of smelting, or the separation of a metal from a chemical compound called ore. Smelting, as differentiated from melting, was the first metallurgical operation and is still the principal method of gaining metals from their ores. Copper was the first metal to be smelted; it was another 1,000 years before iron was reduced from its ores.

As mined, raw ore is a nonchemical mixture of ore proper (heavy) and earthy matter, or gangue (light); the two may be largely separated by crushing the raw ore and washing away the lighter gangue. The ore proper is a chemical compound of oxides, sulfides, carbonates, hydrates, silicates, and small amounts of impurities such as arsenic and other elements. Smelting frees the metal from the various combinations with which it is bound into the compound form. A preparatory step is to heat the washed ore (roasting, or dressing) not only to dry it but also to burn off sulfides and organic matter. Early practice involved heating the ore in intimate contact with charcoal to provide the essential reducing atmosphere, producing a metallic sponge made up of metal and slag. For chemical as well as practical reasons, the iron of tools, wrought iron, continued to be worked out of the spongy mass until the Middle Ages.

Originally copper smelting was terminated at the spongy stage. Early smelters soon discovered that better results were obtained when the metallic sponge was left in the furnace and subjected to draft-induced high temperatures. The metal became liquid and seeped down to the hearth, as did the slag, which, being lighter than the metal, floated over it, permitting recovery of the copper.

At some time during the copper period, a new kind of "copper" happened to be made by smelting together two separate ores, one bearing copper, the other tin. The resulting metal was recognized as being far more useful than copper alone, and the short period of copper tools came to an end. The new metal, a copper–tin alloy of mostly copper, was bronze. It was produced in the fluid state at a temperature less than that needed for copper, could be formed economically by casting, and could be hammer-hardened more than copper. The tin noticeably increased the liquidity of the melt, checked the absorption of oxygen and other gases, and suppressed the formation of cuprous oxide, all features that facilitated the casting operation. A two-piece, or split, mold, impracticable for copper, worked very well with bronze. Furthermore, it was found that bronze expanded just a bit before solidifying and thus picked up the detail of a mold before it contracted in cooling.

Dawn of the Bronze Age

The earliest bronzes were of uneven composition. Later, the tin content was controlled at about 10 percent, a little less for hammered goods, a little more for ornamental castings. The edges of hammered bronze tools of this composition were more than twice as hard as those obtained from copper.

The Bronze Age of tools and implements began about 3000 BC. In the course of the following 2,000 years the much more abundant iron supplanted bronze for tools, but bronze continued to be used in the arts.

All of the early metals were expensive commodities in antiquity and were monopolized by kings, priests, and officials. Most metal was diverted to the manufacture of weapons for professional soldiers. Industrial use was severely limited. The metal chisel was used on stone for buildings of state or for fashioning furniture for the wealthy; the common man living in a mud or reed hut had no reason to own such a tool.

Generally speaking, molds for copper and bronze were of baked clay, although soft stone was sometimes carved; metal molds are known from about 1000 BC. Sectional molds of three and four pieces, permitting more complex

castings, are known from about 2600 BC. The earliest metal tools and implements were simply copies of existing stone models. It was only slowly that the plasticity of the new medium and especially the possibilities inherent in casting were appreciated. The stone dagger, for example, was necessarily short because of its extreme brittleness. With copper and then bronze, it became longer and was adapted to slashing as well as to stabbing. Casting allowed forms that were impossible to execute in flaked stone, such as deeply concave surfaces. Holes could be cast in, rather than worked out of, the solid.

Pottery imitations of bronze

Sometimes the process was reversed. There were, for example, pottery imitations of bronze vessels for the poorer classes, with such necessary adjustments as a heavier lip for the pottery jug. The lines of bronze daggers have been noted in stone daggers of a later date, despite the difficulty of imitating a metal object in stone. Bronze axheads were copied in stone, even to the shaft hole, which was difficult to produce and impractical for a stone tool; it is possible that some of the stone replicas of bronze daggers and axes were used for ceremonial rather than utilitarian purposes.

Malleable metal had several advantages over a brittle material, such as stone or bone or antler. It could be severely deformed without breaking and, if badly bent, could probably be returned to service after straightening. It was shock resistant and chip-proof, good qualities for use in the ax, adz, and chisel, and the edges could be kept keen by hammering or abrasion; its sharpness was, however, inferior to that of good stone. In particular, metal allowed the fashioning of many small items, articles of a size awkward to make of bone or horn, such as pins, fishhooks, and awls. Copper pins were stronger, tidier, and more attractive than the fish bones and thorns they replaced for securing clothing; even in the 3rd century BC there were shapes resembling the modern safety pin. Tweezers were invented, but whether for depilatory or surgical purpose is unknown; there are artifacts presumed to be scalpels. Plates, nails, and rivets also developed early.

The most common tools were awls and pointed instruments suitable only for wood and leather. Woodworking was facilitated by the invention of the toothed copper saw, made of smelted metal and cast to shape. Edged tools—the ax, adz, and chisel, at first similar to stone models—became predominant, and, although not nearly as sharp as the tools they replaced, they had the advantage of toughness and could easily be resharpened. In particular, the chisel made it possible to use cut stone for construction purposes, principally in temples and monuments. Abrasive sand under metal "saw blades" allowed stone to be cut neatly, just as the sand under tubes (made from rolled-up strips) that were turned provided a boring device for larger holes.

IRON AND STEEL TOOLS

Iron technology was derived from the known art of reducing copper and bronze. The principal requirement was a furnace capable of maintaining a reducing atmosphere—*i.e.*, one in which a high temperature could be maintained from a good draft of air. The furnace had to be tall enough to allow the iron to drop from the smelting zone and form a slaggy lump, usually called a bloom.

After aluminum, iron is the most abundant metal, constituting about 5 percent of the Earth's crust. Copper is in short supply, having a presence of only 0.01 percent. Iron ore suitable for simple smelting was widely distributed in the form of surface deposits that could be scraped up without elaborate mining procedures.

The limitations imposed by the dearth of metals in the Bronze Age were now lifted; new tools and implements became possible, and their numbers could increase until even the poorer classes would have access to metal tools. The iron of antiquity was wrought iron, a malleable and weldable material whose toughness was enhanced by forging. Brittle cast iron, versatile and widely used in modern industry, was unknown to the ancients, and it would have been of no value for their edged tools and implements. The earliest history of smelted iron is obscure, with the first scanty evidence of man-made iron dating from about 2500 BC in the Middle East. A thousand years later, the abundance of ores led to the displacement of copper and bronze by iron in the Hittite Empire.

During most of its history, iron was not recovered in a molten state but was reduced to a spongy aggregate of iron and slag formed at a temperature well below the melting point of pure iron (1,535° C, or 2,795° F). This plastic metallic sponge was consolidated by hammering to squeeze out slag and weld the iron particles into a compact and ductile mass; thus it was called wrought iron, essentially pure iron with remnants of unexpelled slag coating the iron particles. Wrought iron contains so little carbon that it does not harden usefully when cooled rapidly (quenched). When iron containing 0.4 to 1.25 percent carbon is heated to 950° C, or 1,740° F, and then plunged into water or oil, it is hardened.

Iron importance in the Middle East

By about 1200 BC, when iron had become important in the Middle East, humans had learned how to create on wrought iron a steel surface, or case, that could be hardened by heating and quenching. This case was produced by the prolonged heating of wrought iron packed in a deep bed of glowing charcoal. The procedure worked because a surface of red-hot carbonless iron readily absorbs carbon from the carbon monoxide generated in the enveloping charcoal fire.

Knowledge of casting gathered from working with smelted copper and bronze did not apply to a metal whose shape could be changed only by hammering. Moreover, the malleability of iron is less than that of copper for the same temperatures, which means that the smith has to work harder to change the shape of the metal. Stone hammers gave way to hafted bronze hammers, iron itself coming into use later. The first anvils—for copper and bronze—were convenient flat stones; they were followed by increasingly larger cast-bronze models that in turn were superseded by rudimentary forms of the modern type, in which several pieces of iron are welded together. The earliest iron artifacts are of ruder appearance than the bronze articles that came before them.

A valuable property of wrought iron is the ease with which two or more pieces may be united by hammering while the metal is at a high temperature. Even at the production stage, small pieces of spongy iron were united into larger blooms. Hammer welding had been practiced before by goldsmiths and, in spite of the difficulties due to gassing, was even used for joining copper to make, for example, tape by welding together strips cut from plate. Welding became an essential production procedure. When iron tools had reached the end of a useful life, they could be reused by welding the scrap into a blank and starting over, a process akin to the melting of copper and bronze scrap to cast new tools.

Iron compared to bronze

Iron ordinarily has twice the flexibility of bronze and is much tougher, for a bar of iron can be bent back upon itself without fracturing, whereas a bronze bar (such as a sword blade) breaks after only a light bend (bronze blades repaired by casting new metals into the fractured sections are known). Bronze, in other words, is brittle when compared to iron, although copper is not. As the tin content of bronze rises, hardness increases, but ductility is lost. Most of the malleability is missing from cold bronze with 5 percent tin, and ductility becomes practically nil at a 20 percent tin content. The cutting edge of a hammered bronze tool is superior to that of a similarly treated iron tool, and it is corrosion resistant.

In the Early Iron Age, when the metal was still in scarce supply, local armament makers were the chief consumers of the new metal. Agricultural tools, needed for clearing forests and for cultivation, were the next iron tools to develop. Axes, picks, and hoes also were needed. Iron was smelted in the Middle East before 2500 BC, but the Iron Age proper was 1,000 or more years in maturing. Its full development came with the discovery of hardening by carburization (addition of carbon) and heat treating, which led to superior edged tools of great toughness.

Later development of hand tools

During the evolution of tools over more than 2,000,000 years, using as principal materials, successively, stone,

bronze, and iron, humans developed a number of particular tools. Taken together, these specialized tools form an inverted pyramid resting upon the first general-purpose tool, the nearly formless chopper. With the discovery of metals and the support of numerous inventions allowing their exploitation, the first approximations to the modern forms of the basic tools of the craftsman established themselves, with the main thrust of further development directed at improving the cutting edges.

The need for specialized tools

The earliest tools were multipurpose; specialized tools were latecomers. A multipurpose tool, although able to do a number of things, does none of them as well as a tool designed or proportioned for one job and one material. The way in which a tool is hafted provides the primary distinction between the knife, ax, saw, and plane. An application or craft is best served by a further specialization or form within a category: the knives of the butcher, woodcarver, and barber reflect their particular tasks. When confronted with the unusual, a skilled craftsman develops a special tool to cope with the situation. In the early 19th century, for example, a joiner had dozens of planes in his kit to deal with the many moldings, rabbets, and jointings he had to produce before the day of machine-made stock and mill-planed lumber.

PERCUSSIVE TOOLS

Several tools involve a violent propulsion to deliver a telling blow. These have been named percussive tools, and their principal representatives are the ax and hammer. Under these two names are found an immense number of variations. The percussive group may also be called dynamic because of the swift motion and the large, short-term forces they develop. This means that mass and velocity and, hence, kinetic energy and momentum are factors related to the force generated or transmitted. The distribution of weight between the head and handle and the mechanical properties of the head (*i.e.*, its suitability for a cutting edge or its lack of elasticity) must also be recognized in the design of a percussive tool. Obviously, these various influences were not formally considered during the agelong trial-and-error evolution of a now successful tool, but recognition of them aids in identifying the evolutionary stages of the tool.

Percussive tools generally have handles that allow them to be swung; that is, their rapid motion endows them with kinetic energy. The attainable energy of a blow depends upon a number of factors, including the weight of the toolhead, the angle through which it is swung while gaining speed, the radius of the swing (handle length plus part or all of the arm length), and the muscle behind it all. There is a permissible energy level for a given task and tool, set by either the nature of the task or the material of the tool. Thus, a blacksmith flattening a one-inch iron bar needs a heavy, fairly long-handled hammer, whereas a light and short-handled hammer, used with wrist action, is appropriate for forging a small, soft gold wire. A hafted flint ax is an effective tool, but it may be destroyed if swung too hard or if twisted while in the cut. Bronze and steel axes can, and do, take longer handles than the stone ax and, being of tougher material, will not break under use that would fracture a stone head.

The physics of percussive tools takes into consideration the centre of gravity and what is technically called the centre of percussion—*i.e.*, a unique point associated with a rotation, in this case the arc through which the tool is swung before delivering its blow and coming to rest. The tool's centre of gravity is readily found because it is the balance point, or location along the handle at which the tool can be picked up loosely and still remain in the horizontal position. The centre of percussion is the ideal point at which striking should occur on the toolhead to minimize the sting of the handle in the operator's hand as well as to deliver a blow with maximum force; this point is farther out than the centre of gravity and should be as close to the centre of the head as possible. This last condition is best met with a light handle and heavy toolhead, which places the centre of gravity close to the head and the centre of percussion in an optimum location in the cutting edge.

Centre of percussion

It is apparent that the sheer weight of the head is of paramount importance in promoting a proper balance, or hang, to the tool. On this basis alone, the shift from stone axheads to metal was a step in the proper direction because metal heads of the same size as those of stone are about three times as heavy. With the heavier head, the centre of gravity of the hafted tool is closer to the head, and the centre of percussion is more likely to be properly located.

With the mallet and chisel still other interrelations are involved. When working stone, a brittle material that responds to a sharp tool point by breaking into small chips, the sculptor strikes many light blows to remove material. As a consequence, mallets have short handles and the amplitude of swing is small, allowing a succession of rapid blows without undue fatigue. To provide energy and momentum, the mallet head is heavy. Being of wood, it does not rebound in the manner of a metal head but stays on the chisel, which transmits the blow to the cutting edge and focuses it into a small area of stone to be spalled off. The net effect of the proper combination of all elements—the properties of wood, chisel, and stone, the weight of the head (perhaps even heightened by a lead-filled cavity), and the short handle—is to waste the least energy. The wooden head is of course expendable, particularly if it is of a one-piece clublike construction, for it becomes badly battered from contact with the metal chisel. A more refined mallet consists of a separate head and handle, the head having a working face of end-grain wood.

Working metal with a chisel requires that heavy blows be struck to enable the chisel to dig into the metal and lift out a chip. A steel hammer with a hardened face is used, and in this operation it is the soft end of the chisel that is battered and needs periodic dressing.

Hammers and hammer-like tools. "Hammer" is used here in a general sense to cover the wide variety of striking tools distinguished by other names, such as pounder, beetle, mallet, maul, pestle, sledge, and others. The best known of the tools that go by the name hammer is the carpenter's claw type, but there are many others, such as riveting, boilermaker's, bricklayer's, blacksmith's, machinist's ball peen and cross peen, stone (or spalling), prospecting, and tack hammers. Each has a particular reason for its form. Such specialization was evident under the Romans, and a craftsman of the Middle Ages wrote in AD 1100 of hammers having "large, medium and small" weight, with further variations of "long and slender" being coupled with a variety of faces.

Since a pounder, or hammerstone, was the first tool to be used, it may also have been the first to be fitted with a handle to increase the blow. Although some craftsmen of the soft metals still favoured the hand-held stone, presumably for its better "feel," hafting was an enormous technological advance. Yet it created a problem of major proportions that still persists—the joint between the handle and the head must carry shock loads of high intensity, a situation even more complicated with the ax than the hammer because the ax may be subjected to twisting on becoming wedged in a cut. The most satisfactory solution for metal heads is to create a shaft hole in the toolhead; it is a poor solution for a stone tool because it weakens the head, although it was tried, especially in stone imitations of bronze axheads.

The hafting problem in percussive tools

In hammer hafting, it is possible to distinguish between long handles that allow tools to be swung to give them speed and those simpler handles by which a tool such as a pavement tamper may be picked up so that it can be dropped. A long handle, even if not needed for dynamic effect (as in a tool used only for light blows), makes the tool easier to control and generally reduces operator fatigue.

The oldest form of hafted hammer, probably the miner's maul of Neolithic date, had a conical or ovoid stone head with a circumferential groove at midheight; many such rilled stones have been found in flint, copper, and salt mines and elsewhere, though very few handles have survived. Such a stone could be bound to a short section of sapling with a branch coming off at an angle, twisted fibres or sinew serving as the ties (Figure 3A). With such a side-mounted head it is likely that the handle's principal

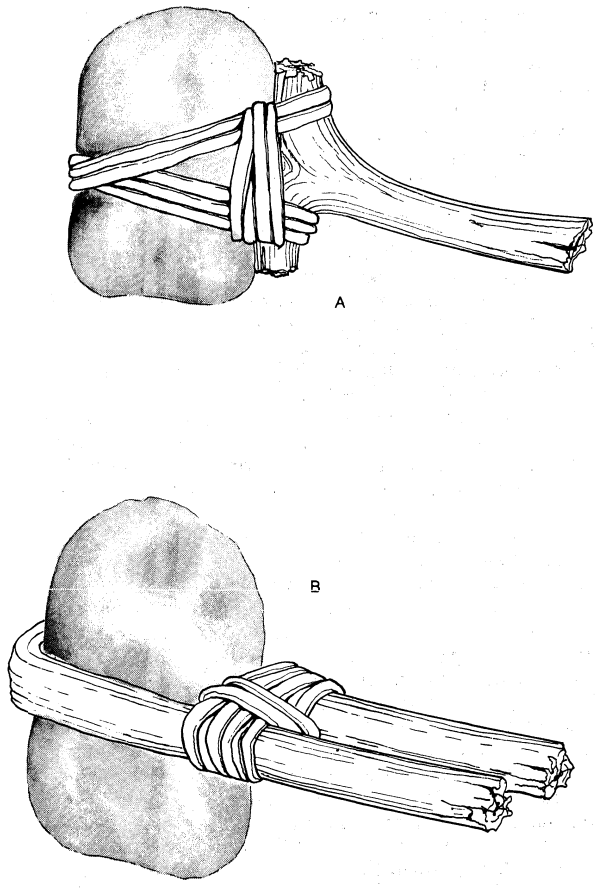

Figure 3: *Hafted hammers.*
(A) Hammer of rilled stone bound onto a knee-shaft handle, a device that was most satisfactory when merely lifted and dropped. (B) Hammer bound into a bent branch; used when the work required a heavier swing.

function was to lift and guide the head so that it might do its work by simply dropping, the binding being too weak to carry much of the extra shock produced by swinging the tool. Better shock resistance could be attained by bending a long flexible branch around the groove in the stone and securing it with lashings (Figure 3B).

Hammers and pounders of material other than stone were widely used; essentially clublike, they may be called self-handled. Clubs of hardwood might have one end thinned for grasping, or a mallet-like tool could be made from a short section of log with a projecting branch to serve as a handle. Similar mallets were made by piercing a short piece of wood and fitting a handle to it; this also gave an end-grain strike and made it more durable than a simple club. Antlers modified by trimming off tines are known from the Paleolithic Period. Such "soft" hammers were used for striking chisels of stone to prevent the destruction of the more valuable tool. Such tools, especially the wooden mallet, were used on metal chisels as well, particularly by stonecutters, because a very heavy blow on a light tool does not necessarily remove more stone than a moderate blow. There is a good deal of evidence that bone, antler, and flint wedges were used to split wood; here the use of a soft hammer would have been imperative.

The hammer as it is best known today—*i.e.*, as a tool for nailing, riveting, and smithing—originated in the Metal Age with the inventions of nails, rivets, and jewelry. For beating lumps of metal into strips and sheet, heavy and compact hammers with flat faces were needed. These, in lighter form, were suited to riveting and driving nails and wooden pegs.

In the beginning, hafting of metal hammers followed the stone-tool tradition. The first step away from lashing came with casting a socket opposite the head into which the short end of an L-shaped wooden handle was fitted and further supported by lashings. Such a tool was necessarily light. Ultimately the idea of piercing the head with a shaft hole for a handle occurred to the Europeans in the Iron Age. This was several hundred years after it had become common practice among the bronze workers of the Middle East. The shaft hole, although posing fastening problems that still exist, allowed heavy hammers—mauls and sledges—to be made for smithing iron. Shaft holes for handles

The familiar claw hammer that can pull bent nails dates from Roman times in a well-proportioned form, for the expensive handmade nails of square or rectangular cross section did not drive easily. Aside from the claw hammer, other special forms of the peen—the end opposite the flat face—were developed. Hemispherical, round-edged, and wedgelike shapes helped the metalworker stretch and bend metal or the mason to chip or break stone or bricks. An especially important hammer was the filemaker's; equipped with two chisel-like heads, it was used to score flat pieces of iron (file blanks) that were subsequently hardened by heating and quenching.

Ax and adz. The ax and adz are similar enough to be considered together. This is especially the case with ancient tools that were small and ineffective because they were made of brittle stone or had unsatisfactory hafting. The difference between the tools lies in the relation of the cutting edge to the handle. In the ax the cutting edge and handle are parallel, whereas in the adz they stand at right angles. The ax and some adzes chop diagonally across the grain of the wood, but the developed adz, with its long handle, cuts with the grain, and the nature of the chips is quite different. The ax is used for felling or cutting through, whereas the adz is used for smoothing and leveling, although some forms were developed to scoop out gutters or to dig out logs to make canoes. The adz was often shorter handled than the ax and, because of this, was essentially a chipping tool rather than the shaving tool it became when the handle was lengthened. The great problem of both tools is satisfactory hafting; the shock impact between the toolhead and handle threatens any type of connection, however ingenious.

The celt, a smooth chisel-shaped toolhead that formed either an ax or adz, dates from the invention of agriculture and the domestication of animals. The earliest true axheads, made of fine-grained rock with ground edges, are of Swedish provenance and date from about 6000 BC. Even earlier, self-handled axes, made of reindeer antler, were used. The brow tine, an antler branch running nearly at right angles to the main stem (beam), was sharpened, giving a small ax (Figure 4A) with a haft of about eight inches (20 centimetres). By sharpening the tine the other way, a tiny adz was created. Some of these small bone implements have survived as the Lyngby tools, named from a Danish site of perhaps 8000 BC.

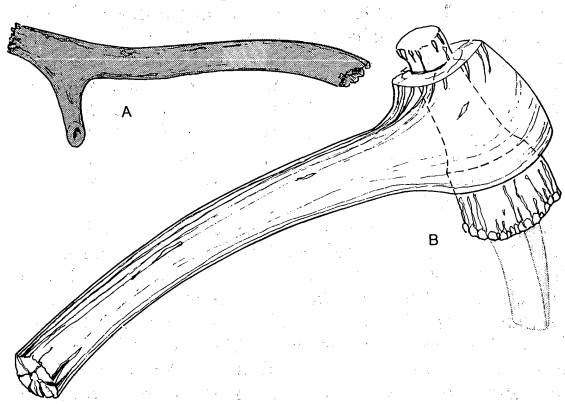

Figure 4: *Ax and adz.*
(A) Lyngby ax, a self-handled ax made from a reindeer antler. (B) Stone adz head with a socket of antler inserted in a wooden haft.

A subsequent design socketed a stone blade in a short length of antler that was perforated for a handle (Figure 4B). This Maglemosian style, from a Danish site of about 6000 BC, was a popular model for several thousand years despite its narrow cutting edge and length of about 20 inches.

The desire for a better feel or a longer cutting edge, or perhaps the shortage of antlers, led to a great variety of haftings. A common arrangement involved lashing heavy celts to knee-shaft handles made from branched tree sections (see Figure 3A). To permit the use of larger celts, the stone was sometimes fitted into a wooden handle, but this created the danger that the handle would fail due to the weakening hole. Heavy, clublike handles with ample strength at the hole gave the tool an unfavourable balance.

Surviving examples of celts of soft stone are believed to have been restricted to nonwoodworking axes, used for killing game or perhaps for certain ritual purposes. Hard-stone axes with shaft holes, often obvious imitations of bronze axes, are associated with the Bronze Age. They are among the supreme examples of stoneworking and are products of the pecking technique. From their delicacy it may be inferred that these axes were not for the working of wood.

An Egyptian relief of about 2500 BC, the time at which the pyramids were being built, shows a metal ax (copper or bronze) of curious shape, almost semicircular, lashed to a wooden handle along its diameter. The same picture shows a knee-shaft adz whose metal blade makes an angle of about 30° with the handle. If the number of pictures and artifacts of the adz is a guide, the adz was more widely used than the ax. Generally speaking, the adz had a short handle, with angles of the order of 60° between blade and handle. Although the Egyptians became skilled metalworkers, this was not reflected in their tools, the designs of which hardly changed over 2,000 years.

On the other hand, bronze axes and adzes from Mesopotamia of even the period 2700 BC are shaft-hole types, the hole for the handle being formed in the mold. Aside from eliminating the nuisance of lashing the blades, these castings permitted a heavier head than the thin-bladed Egyptian models and had better dynamic characteristics.

Shaft-hole axes and adzes were also being cast in Crete in about 2000 BC. At the same time, a new tool was created there. The double-bit (two-bladed) ax, classically associated with the Minoans, was first known in 2500 BC as a votive ax, a piece of tomb furniture made of riveted bronze plates. It became a working tool when it was cast in bronze with a shaft hole about 500 years later. Double-bit adzes also date from this time, as do ax–adz combinations. The succeeding Mycenaean, Greek, and Roman civilizations carried these designs forward. According to Homer, Ulysses used a double-bit ax of a type that disappeared with the use of bronze. Illustrations or artifacts from the Middle Ages reveal only iron single-bit types, although in a bewildering variety of profiles. By mid-19th century the double-bit was again in use, principally in the United States as a lumberman's ax. The ax was also used in Canada and Australia, where it is still marketed.

The ax of Ulysses

In western Europe the advent of metal was about 500 years later than in the Middle East. In making the transition from stone to metal, Europeans continued the tradition of the knee-shaft handle. Another type of metal head was given a wide slot, by either forging or casting, into which a cleft knee-shaft was fitted and lashed. This was the palstave. To minimize splitting of the shaft, a stop was later cast at the bottom of the slot. Subsequently, one or two eyes, or loops, were furnished in the casting to allow firmer lashing.

The socketed head, perhaps carried over from the spear-head, was an improvement because the knee-shaft stub sat in a socket with greater security, although it still required lashing. Like its predecessors, this tool was small, almost toylike; the cutting edges of about 1½ inches and short handles suggested a one-handed operation. Adzes were similarly proportioned, as were hammers.

The Bronze Age smiths of Europe were slow in inventing the shaft hole that those of the Middle East had developed in an earlier millennium. The knee-shaft tradition, with its socketed head, entered even the Iron Age before shaft-hole tools appeared in Europe. To forge a socket is a difficult enough operation with even modern equipment. A shaft hole, however, is fairly simple to make, but such tools appeared in northern Europe well after the Iron Age was under way, perhaps after 500 BC. By this time, expensive bronze had been supplanted by plentiful iron for use in tools.

Bronze tools had been relatively delicate in design; their iron successors soon gained size and developed in character and effectiveness to display specialized forms. Of these, two are especially important. First, there was the felling ax of the woodcutter, the blade beveled on both sides for symmetry and often fitted with a flat end suited to driving splitting wedges. There were numerous variations of this form as the tool evolved toward its finely balanced modern conformation.

The iron ax had little advantage over its bronze forerunners until smiths discovered carburization and could produce a temperable steel along the cutting edge. This must have occurred early, for repeated heatings of the edge in forging would draw in small quantities of carbon from the charcoal of the fire. A number of Roman axes subjected to analysis have been found to contain steel.

Steeling, or the welding of strips of steel to the iron head, was invented in the Middle Ages. The head was first rough-forged by bending a properly shaped piece of flat iron stock around an iron handle pattern to form the eye. Steeling could take one of two forms. In the first, a strip of steel was inserted between the overlapping ends and the whole welded into a unit (inserted steeling). For the second, the overlapping ends were welded together and drawn to a V-shape over which a V-shaped piece of steel was then welded (overcoat, or overlaid, steeling). Inserted steeling was regarded as superior because it furnished about three times as much steel to resist loss of metal by repeated grinding and sharpening. The manufacture of steeled, or two-piece, axes ended in the early 20th century. Thereafter heads were made of a single piece of high-carbon steel whose properly tempered edge was backed by a tough body.

Steeling the axhead

To convert felled timber into squared timber, special tools were required. As the log lay on the ground or on low blocking, vertical sides were produced by using a broadax, or side ax. Somewhat shorter handled than the felling ax, it had a flat face, the single bevel being on the opposite or right side; it sliced diagonally downward as the carpenter moved backward along the log. The head was heavy, about twice that of a felling ax, and, although it was a two-handed tool, the broadax was never swung in the manner of a felling ax but, instead, was raised to waist height and allowed to fall with minimum added pressure. The handle was bent, or offset to the right, to give finger clearance when "hewing to the line" on a debarked log. A felling ax was used to score a line, after which the broadax was used to split off the wood along the score line. Hewn timber found in old buildings often carries the faint marks of the scoring.

If the timber was to be presented to view it was smoothed by an adz that removed the last of the score marks and left a type of ripple finish. For this purpose a long-handled adz was used, the radius of its gentle swing originating in the carpenter's shoulder. The blade was beveled on the inside and removed material in the same manner as does a plane.

The adz was once an indispensable tool of general utility. In addition to surfacing, it was particularly useful for trueing and otherwise leveling framework such as posts, beams, and rafters, in setting up the frames of wooden ships, and in dressing ships' planking. For special purposes the blade was round instead of flat, allowing the adz to cut hollows such as gutters. Dugout canoes, log coffins, and stock watering troughs, all cut from a whole log, were products of the adz. Short-handled adzes were used by coopers and makers of wooden bowls.

CUTTING, DRILLING, AND ABRADING TOOLS

Knife. The same jagged crest on the Paleolithic chopper that developed into the ax also developed into another broad tool category, the knife, which combined a uniquely shaped sharp blade with a handle that optimized the position of the cutting edge. In contrast to the blades of the ax, adz, chisel, or plane, the motion of a knife is a slicing action made in the direction of its edge.

The first hafting of stone knives may have taken the form of a protective pad of leaves or grass. Next, pieces of flint were set into grooves of wooden handles and cemented with resin or bitumen to leave the sharp cutting edges exposed. The Metal Age produced a longer and tougher blade that could be set into a handle, or riveted to a handgrip. Some knives, such as surgical knives and razors, were cast with a handle (self-handled). Copper, bronze, and iron blades were hammered to produce a locally hard edge.

The knife handle

Aside from the utilitarian use of the knife in the field, kitchen, and workshop, variations giving it the status of a weapon appeared in the form of daggers and short and long swords. The stabbing dagger probably had its origin in the Neolithic Period, although an effectively thin and adequately strong blade did not appear until the Iron Age.

Hunting knives, equally useful as fighting knives, developed an overall style, proportion, and balance that changed little over the centuries after the introduction of iron. The first known folding knife is a Roman model of the 1st century AD. Beginning in the late Middle Ages many improvements in detail were introduced. These included fancy handles and springs and locks for the blade.

As individual crafts emerged, an impressive number of convenient but single-purpose knives were fashioned to suit the specialized tasks of various craftsmen, including goldbeaters, farriers, shoemakers, and farmers.

Drilling and boring tools. A varied terminology is related to making holes with revolving tools. A hole may be drilled or bored; awls, gimlets, and augers also produce holes. An awl is the simplest hole maker, for, like a needle, it simply pushes material to one side without removing it. Drills, gimlets, and augers, however, have cutting edges that detach material to leave a hole. A drilled hole is ordinarily small and usually made in metal; a bored hole is large and in wood or, if in metal, is usually made by enlarging a small hole. Drilling usually requires high speed and low torque (turning force), with little material being removed during each revolution of the tool. Low speed but high torque are characteristic of boring because the boring tool has a larger radius than a drill.

The Upper Paleolithic Period furnished the first perforated objects of shell, ivory, antler, bone, and tooth, although softer, perishable materials, such as leather and wood, were undoubtedly given holes by the use of bone or antler splinters. How holes were made in harder materials is subject to speculation; it has been suggested that flint blades were trimmed to sharp points by bilateral flaking and that these points were turned by hand, a very slow process. Another scheme involved the use of an abrasive sand under the end of a stick that was twirled back and forth between the palms. At some unknown time, more efficient rotation was attained by wrapping a thong around the stick or shaft and pulling on the ends of the thong. Such a strap, or thong, drill could be applied to drilling either with an abrasive or with a tool point hafted onto the end of the stick. The upper end of the shaft required a pad or socket (drill pad) in which it could rotate freely.

Invention of the bow drill

After the invention of the bow, sometime in the Upper Paleolithic Period, the ends of the thong were fastened to a bow, or a slack bowstring was wrapped around the shaft to create the bow drill. Because of its simplicity, it maintained itself in Europe in small shops until the 20th century and is still used in other parts of the world. Abrasive drilling in stone was well suited to the high-speed bow drill. For larger holes the amount of material that had to be reduced to powder led to the idea of using a tube, such as a rolled copper strip, instead of a solid cylinder. This is called a core drill because the abrasive trapped between rotating tube and stone grinds out a ring containing a core that can be removed.

A new and more complicated tool, the pump drill, was developed in Roman times. A crosspiece that could slide up and down the spindle was attached by cords that wound and unwound about it. Thus, a downward push on the crosspiece imparted a rotation to the spindle. A flywheel on the spindle kept the motion going, so that the cords rewound in reverse to raise the crosspiece as the drill slowed, and the next downward push brought the spindle into rotation in the opposite direction.

The earliest (perhaps Bronze Age) drill points had sharp edges that ultimately developed into arrow shapes with two distinct cutting edges. This shape was effective, especially when made of iron or steel, and remained popular until the end of the 19th century, when factory-made, spiral-fluted drills became available at reasonable cost to displace the blacksmith-made articles.

The basic auger originated in the Iron Age as a tool for enlarging existing holes. It had a crossbar so that it might be turned with two hands, and it resembled a pipe split lengthwise. The auger was sharpened in several ways: on the inside of the semicircular end, along the length, or on both. The end might be forged into a spoon shape and the edges sharpened so that cutting could take place at the bottom of the hole in addition to the sides. To clear the hole of parings it was necessary to pull the auger from its hole and turn the workpiece over. Augers with spiral or helical stems that brought the shavings or chips to the surface were an invention of the Middle Ages, although one example dates from Roman Britain.

The brace and breast swivel

The familiar and common brace, a crank with a breast swivel at one end and a drill point at the other, is first seen in a painting of about 1425 that shows the biblical Joseph at his bench. This brace and other early examples are shown fitted with a bit of small diameter. It has been suggested that the function of the new tool was to make a small, or pilot, hole for the larger auger bit. This is a reasonable assumption, for the crank, fashioned from a wide board, had insufficient strength (because of its cross grain) to drive a large bit (see Figure 5A). This weakness was later counteracted by reinforcing the two weak sections with metal plates, a practice that continued until

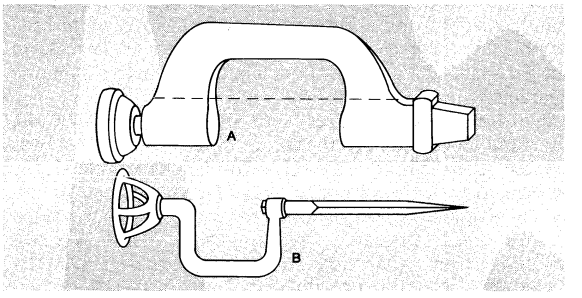

Figure 5: *Braces.*
(A) Early one-piece wooden brace showing weak sections (dotted lines). (B) All-metal blacksmith's "wimble" of late 17th century; the metal crank was not generally applied to the woodworker's brace until two centuries later.

about 1900 despite the commercial introduction of iron sweeps (cranks) in about 1860 (Figure 5B). This invention permitted the boring of holes of up to one inch in diameter with one-handed operation; larger holes still required two-handed augers. An iron sweep is noted in a German manuscript of 1505, and an English book of 1683 has a metal brace as part of a blacksmith's kit.

Early wooden braces were equipped with a large socket into which bits with appropriate shanks could be fitted interchangeably. When the sweep came to be made of iron, bits were given square shanks that fit into simple split chucks (holders) and were secured with a thumbscrew. Soon the screwed shell chuck and ratchet was devised to set the standard for the modern tool. By 1900 the swivel turned on ball bearings instead of a leather washer, and the metal parts were nickel-plated.

The bow and pump drills, suitable only to small work, required two hands, one to steady the tool, the other to operate it. One-hand drills began to appear in about 1825. Their essential elements were a steeply pitched screw and a nut that mated with it; when the latter was pushed down, the screw and attached bit turned. Many variations of the principle were offered before the modern push drill assumed its present, convenient form. It is still suitable for only light work in wood.

Both the bow and pump drills remained the metalworker's prime tool for drilling small holes until the first geared hand drill was invented in 1805. Like every other tool, it underwent many improvements before acquiring

its present rugged simplicity. Its great advantage lies in its unidirectional motion and the gearing that rotates the drill faster than the rate at which the crank is turned. The one-directional motion allowed better drills to be designed, and, with their greater efficiency in chip production, it was not long (1822) before drills with spiral flutes were proposed. A manufacturing problem—the flutes had to be hand filed—was not solved until the 1860s when the invention of a milling machine made possible the now universal twist drills.

The modern auger

Augers were used for boring both across the grain of wood and along the grain. The latter operation produced wooden pipes and pump casings or wheel hubs; special bits of many forms were designed for these purposes. The more common use of the auger or bit was in the cross-grain direction to make holes for wooden pins (treenails, or trunnels) or bolts for connections. The modern auger bit has a screw ahead of the cutting edges that pulls the auger into the workpiece. This screw provides an automatic feed and relieves the worker of the necessity of pushing the tool. Although the idea appeared in the mid-16th century, application of the principle was limited until the advent of screw-making machinery in the mid-19th century.

Saw. The chipped flint knife, with its irregular edge, was not a saw in the proper sense, for though it could sever wood fibres and gash bone or horn, it could not remove small pieces of material in the manner of a saw. Furthermore, the necessarily broad V-shaped profile of the flint saw severely limited its penetration into the workpiece; the nature of its cut was limited to making an encircling groove on a branch or a notch on something flat.

The true saw, a blade with teeth, one of the first great innovations of the Metal Age, was a completely new tool, able to cut through wood instead of merely gashing the surface. It developed with smelted copper, from which a blade could be cast. Many of the early copper saws have the general appearance of large meat-carving knives, with bone or wooden handles riveted to a tang at one end. Egyptian illustrations from about 1500 BC onward show the saw being used to rip boards, the timber being lashed to a vertical post set into the ground.

The use of relatively narrow, thin, and not quite flat blades made of a metal having a tendency to buckle, coupled with poorly shaped teeth that created high friction, required that the cutting take place on the pull stroke. In this stroke the sawyer could exert the most force without peril of buckling the saw. Furthermore, a pull saw could be thinner than a push saw and would waste less of the material being sawed.

The familiar modern handsaw, with its thin but wide steel blade, cuts on the push stroke; this permits down-hand sawing on wood laid across the knee or on a stool, and the sawing pressure helps to hold the wood still. Operator control is superior, and, because the line being sawed is not obscured by the fuzz of undetached wood fibres or sawdust, greater accuracy is possible. Some tree-pruning saws have teeth raked to cut on the pull stroke to draw the branch toward the operator. Blades that are thin and narrow, as in the coping saw (fretsaw or scroll saw), are pulled through the workpiece by a frame holding the blade. Electric reciprocating and sabre saws, which have narrow blades that are supported at only one end, pull the blade when cutting to prevent buckling. The carpenter's pull saw for wood requires the craftsman to sit on the floor and use his feet to stabilize the wood he is sawing. Long forgotten by the Western world, it has been kept alive in China and Japan, where some craftsmen still favour it.

Although there is no positive evidence of either the type of saw or the method used, the Egyptians were able to saw hard stone with copper and bronze implements. The blade, probably toothless, rode on an abrasive material such as moistened quartz sand. The 7½-foot (two-metre) granite coffer still in the Great Pyramid carries saw marks.

During the Bronze Age the use of saws for woodworking was greatly extended, and the modern form began to evolve. Some saws with narrow blades looked very much like hacksaw blades, even to the holes at either end. They might have been held in a frame or pinned into a springy bow of wood.

Iron saws resembling those of copper or bronze date from the middle of the 7th century BC. A major contribution to saw design was noted in the 1st century AD by Pliny the Elder, whose works are one of the major sources on the technology of the ancients. Pliny observed that setting the teeth—that is, bending the teeth slightly away from the plane of the blade alternately to one side and the other, so creating a kerf, or saw slot, wider than the thickness of the blade—helps discharge the sawdust. He seems to have missed the more practical point that the saw also runs with less friction in the now wider slot. The Romans, always ingenious mechanics, added numerous improvements to both simply handled saws and frame saws but did not make push saws despite the advantage of the kerf that made the saw easier to work with and less liable to buckle. Roman saw sets and files have been found in substantial numbers. The small handsaws were sometimes backed with a stiffening rib to prevent the buckling of thin blades; today's backsaw still carries the rib. Frame saws, in which a narrow blade is held in tension by a wooden frame (see Figure 6), were exploited in many sizes, from the small carpenter's saws to two-man crosscut saws and ripsaws used for making boards.

Roman improvements in saws

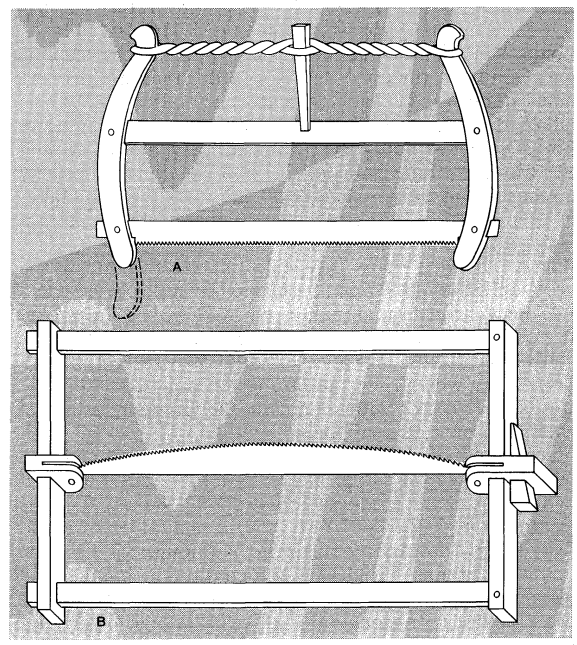

Figure 6: Framed saws in which a thin blade is put under tension (A) by a cord and twisting stick and (B) by a wedge.

The time and provenance of the push saw are uncertain, although it appears that it may date from the end of Roman times, well before the Middle Ages. Nevertheless, after the decline of the Roman Empire in the West, the use of the saw seems to have declined as well. The ax again became the principal tool on the return to the more primitive state of technology. Saw artifacts are very few in number, and even the Bayeux Tapestry of about 1100 shows no saw in the fairly detailed panels dealing with the construction of William the Conqueror's invasion fleet; only ax, adz, hammer, and breast auger are among the woodworking tools.

With the Middle Ages came the search for a nonclogging tooth to be used when crosscutting green and wet wood. The new saws were long, with handles at both ends, so that two men might each pull, adjacent teeth being raked in opposite directions. To provide space for the cuttings, M-shaped teeth with gaps (gullets) between them were developed; this tooth conformation, first noted in the mid-15th century, is still used in modern crosscut saws manufactured for coarse work and for cutting heavy timber.

Perhaps even more important than crosscutting was the need to rip a log lengthwise to produce boards. Saws for this purpose were generally called pit saws because they were operated in the vertical plane by two men, one of

whom, the pitman, sometimes stood in a pit below the timber or under a trestle supporting the timber being sawed. His mate stood on the timber above, pulling the saw up; the pitman and gravity did the work of cutting on the downstroke, for which the teeth were raked. A pit saw occasionally was nothing more than a long blade with two handles (a whipsaw), but more often it was constructed as a frame saw, which used less steel and put the blade under tension.

The fretsaw was a mid-16th century invention that resulted from innovations in spring-driven clocks. It consisted of a U-shaped metal frame, on which was stretched a narrow blade made from a clock spring, the best and most uniform steel available, for it was not forged but rolled in small, hand-powered mills. These relatively thin blades had fine teeth that were well suited to cutting veneer stock from decorative wood for furniture of all kinds.

Water-powered rolling mill products

By the middle of the 17th century, large waterpowered rolling mills in England and some parts of the Continent were able to furnish broad strips of steel from which wide saws could be fashioned in many varieties. In particular, the awkwardly framed pit saw was largely replaced by a long, two-handled blade of increased stiffness. Smaller general-purpose saws were developed from this rolling-mill stock into the broad-blade saws of today. The modern broad-blade handsaw is taper ground, that is, the blade is not of uniform thickness but is several thousandths of an inch thinner at the back than at the toothed edge. This makes possible no-bind cutting, and such saws require little set for fast and easy cutting. Continental craftsmen still use the frame saw for benchwork. Since the only purchased part is the blade itself, the worker often makes his own wooden frame, which is tightened by twisting a cord with a short stick.

File. The file's many tiny, chisel-like teeth point in the direction in which it must be pushed in order to be effective. Because little material is removed with each stroke, the tool is well suited to smoothing a rough workpiece or altering its details. The file was unknown in early antiquity, during which time smoothing was done with abrasive stone or powder or with sharkskin, the granular surface of which approximates sandpaper.

Files of copper are unknown, but bronze was shaped into flat files in Egypt in 1500 BC. A combined round and flat file of bronze was produced in Europe by 400 BC. The file became popular in the Iron Age and a number of specimens survive from Roman times. The longest is flat, one inch wide, about 15 inches long including the handle, and has eight inches of working length. A number of shorter files of about four-inch working length are particularly interesting because of the notch they carry near the handle. The V-shaped cross section (called knife-shaped today) indicates that these files were intended for dressing sawteeth. The notch enabled the workman to set the teeth—*i.e.,* bend successive teeth to alternate sides to gain a free-running saw. These files had straight-across and coarse toothing, but the advantages of obliquely cut teeth and of double-cut (intersecting) teeth were appreciated early.

A treatise written in AD 1100 mentions files of square, round, triangular, and other shapes. At this time files were made of carburized steel that was hardened after the files were cut by either a sharp, chisel-like hammer or a chisel and hammer. An illustrated manuscript of 1405 that was copied by a succession of later authors shows a polygonal file; the screeching of the filing operation is commented upon, too, with the curious suggestion that files be made hollow and filled with lead to eliminate the noise. In 1578 a writer asserted that the only way in which threads could be cut in screws was with the file.

Although Leonardo da Vinci had sketched a file-making machine, the first working machine was not produced until 1750, and it was a century later before machine-cut files substantially replaced those cut by hand. Power-driven, hand-cut rotary files are still used on dense metals because hand-formed, discontinuous teeth dissipate the heat well.

The ordinary file, in terms of its material and cut, is primarily used on cast iron and soft steel. Other materials—various nonferrous alloys, stainless steels, and plastics—are better accommodated with files of special composition and tooth formation (cut). A wide selection is manufactured.

Rasps, or, more correctly, rasp-cut files, have a series of individual teeth produced by a sharp, narrow, punchlike chisel. Their very rough cut is suited to the fast removal of material from soft substances, such as wood, hooves, leather, aluminum, and lead.

Chisel. The remote origin of the chisel may lie with the stone hand ax, the almond-shaped tool that was sharp at one end. Although long, rectangular chisel-shaped flints appeared in about 8000 BC, the later Neolithic Period evinced a more workmanlike version that was finished by grinding. With care, flint and obsidian chisels can be used on soft stone, as shown by intricate sculptures in pre-Columbian South and Central America. Gouges—*i.e.,* chisels with concave instead of flat sections, able to scoop hollows or form holes with curved instead of flat walls—were also used during this period. Chisels and gouges of very hard stone were used to rough out both the exteriors and interiors of bowls of softer stone such as alabaster, gypsum, soapstone, and volcanic rock. The final finish was produced by abrasion and polishing.

Copper chisels

The earliest copper chisels were long, in the manner of their flint forebears. Such so-called solid chisels of copper (and later of bronze) were used not only for working wood but soft rock as well, as many magnificent Egyptian monuments of limestone and sandstone testify.

By using bronze, a better casting metal than copper, and molds, it was possible to economize on metal by hafting a short chisel to a wooden handle. This also resulted in less damage to the mallet. The round handle was either impaled on a tang with a cast-on stop (tanged) or set into a socket (socketed); both forms of hafting presaged modern forms. The Egyptians used the chisel and clublike mallet with great skill and imagination to make joints in the construction of small drawers, paneled boxes, furniture, caskets, and chests.

The use of iron meant that tools had to be forged; no longer were the flowing lines and easily made cavities of casting available to the toolmaker. Consequently, early iron chisels were rude and solid. Tanged chisels were easier to make than socketed chisels, for which the socket had to be bent from a T-shaped forging. Hardened steel edges (first developed by accident) were created by repeatedly placing the iron in contact with carbon from the charcoal of the forge fire.

Chisels and gouges were made in great variety in later centuries as generally increasing wealth created a demand for more decoration and luxury in both religious and secular trappings and furniture. The rough and heavy tools of the carpenter were refined into more delicate models suited to woodcarvers, to joiners who did wall paneling and made stairs, doors, and windows, and to cabinetmakers. In the 18th century a woodcarver's kit may have contained more than 70 chisels and gouges.

Plane. The plane is a cleverly hafted cutting edge, the function of which is to skin or shave the surface of wood (see Figure 7). Used to finish and true a surface by removing the marks of a previous tool (adz, ax, or saw), a plane leaves the surface smooth, flat, and straight. The plane and the related spokeshave are unique tools because both depend upon a constant depth of cut that is given by the slight projection of the blade beyond the sole, or base, of the instrument.

The plane is an anomaly for which no line of descent has been identified. Pliny the Elder ascribes its invention to Daedalus, the mythical Greek representative of all handiwork.

Origins of the plane

It has been suggested that the Paleolithic unifacial (flat) scraper is the remote ancestor of the plane. While it is true that localized planing of a very poor sort, such as removing high spots, can be done with such a scraper, the difference in design and action between the two is too great to proclaim the scraper the forerunner of the plane. The adz seems a more likely progenitor. Early adzes were beveled (sloped) on the outside, although later, with better hafting and longer handles, the bevel was moved to the inside. The blade and handle of an outside-beveled adz could be used in a plane-like fashion to lift a shaving; however, the control of the blade projection, or depth of cut

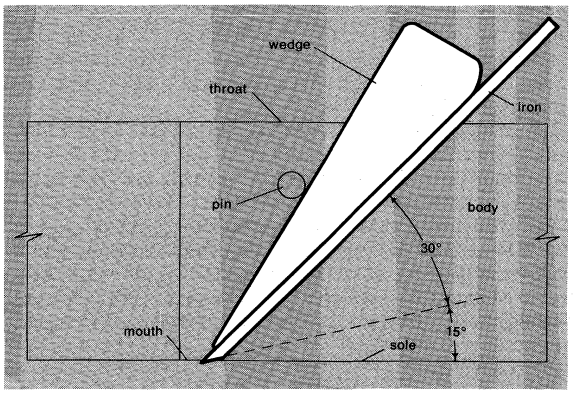

Figure 7: *Essential features of a plane.*
The body is pierced by a wide throat with a narrow slit (mouth) on the bottom, or sole. In this case, the iron (blade) is held in place by a wedge and pin, an arrangement common from Roman times to the 16th century. The cutting edge makes a 15° angle with the horizontal.

(or thickness of shaving), is critical to the concept of the plane and is met in only one other tool, the spokeshave.

The earliest illustrations of wood finishing, the surfacing of pieces of furniture, are Egyptian and show the surfaces being scrubbed with flat objects that appear to be abrasive stones or blocks riding on abrasive sand. Presumably the surfaces had been dressed by an adz, and the marks of this tool needed to be erased. Stone scrapers are not in evidence, and, although the adz is shown, it is being used as an adz, not as an improvised plane.

The Romans were the first known users of the plane, the earliest examples coming from Pompeii. In a manner of speaking, these planes are full-blown, without a prehistory and without even vague antecedents. The modern plane differs in details but not in principle or in general appearance.

These Pompeian planes were of comfortable size, being about eight inches long and 2¼ inches wide. The blade was relatively narrow, about 1½ inches as opposed to the modern width of about two inches. The sole was made of iron, one-quarter-inch thick, that was bent to form a shallow box filled with a wooden core; it was cut away at the back to form a handgrip, while the mouth was cut out about one-third of the way from the front. The cutting blade, or plane iron, was held in position by a wooden wedge tapped under an iron bar placed across the mouth. Frontier posts in Great Britain and Germany have yielded nearly a dozen Roman planes, ranging in length from 13 to 17 inches. Three constructions are represented: iron sole with a wooden core, all wood, and wood reinforced with iron plates at the sides of the mouth.

Planes can be divided into two main categories: the first, typified by the common bench plane, consists of a straight iron and a flat sole and is used for working flat surfaces; the second includes a variety of planes defined by the profile of the iron and sole. If the iron has a concavity, a projection or molding is created in the workpiece; if the iron has a projection, a groove is dug. Generally speaking, planes with profiled irons and correspondingly fluted soles are molding planes. Some of the Roman planes had irons for cutting rectangular grooves.

After the decline of the Roman Empire, the plane apparently fell into disuse. Practically no planes, and only a few other tools, have survived from the period of AD 800–1600. Secondary sources, such as illuminated manuscripts, legal documents, carvings, and stained-glass windows, do provide some information, but they lack details.

Categories of planes

By the late 17th century the plane was firmly reestablished in the craftsman's tool kit. Bench planes, or common planes, were used for surfacing panels or for creating straight edges on boards so that two or more might be joined into a wide panel. Boards were sawed or split (riven) from the log and were, consequently, quite rough. The first planing operation was done with the roughing, or fore, plane, which was of medium length, possibly 16–18 inches. This fore plane had a slightly convex iron that removed saw and adz marks but left hollows that needed to be leveled by straight-iron planing. If the workpiece was long, a long-bodied trying, or jointing, plane, having a length of about 30 inches, was needed to remove large curves in the wood. Short planes—a common length was about nine inches—were called smoothing planes for the final finish they produced.

Planes with straight irons and flat soles could easily be made by the craftsman himself. Taste and fashion in 17th-century wood carving, however, prized decorative features such as moldings and beadings, which led to a proliferation of plane types and established plane making as an industry.

The indispensable common (straight iron) plane was improved in a number of details throughout the years. In Roman planes the wedge holding the iron was jammed against a cross bar in the mouth of the plane. This feature, awkward because it impaired the free escape of the shaving, was eliminated in the 16th century by seating the wedge in tapered grooves.

The top iron

Another improvement was the invention of the top iron, apparently an English innovation of the late 18th century. This top iron, or chip breaker, used an inverted plane iron placed over the cutting iron to limit the thickness of the shaving and help it to curl out of the mouth. Now called the double iron, it is a feature of all but the smallest of modern planes.

As advanced metallurgy and machine tools allowed good castings to be accurately mass produced, wooden planes were gradually displaced in Britain and the United States by cast-iron bodies with wooden handles.

The 19th century saw much effort in Britain and the United States aimed at eliminating the wedge, which required the use of a hammer to adjust the iron. Various methods for the easy removal and accurate setting of the iron culminated in the screw and lever adjustor for the iron and the cam-actuated cap. This final evolution was completed about 1890, and changes since that time have been trivial. Despite their advantages, continental Europe has not been partial to iron-bodied planes with screw and lever adjustments, and such tools cost much more than the still common wooden plane with wedge and hammer adjustment.

The spokeshave, which may be likened to a short-bodied plane with a handle on either side allowing the tool to be pulled toward the operator, has left little in the way of a record. The term was first used about 400 years ago, but the earliest known example seems to be only half as old. Both the English word and the German *Speichenhobel* suggest that it was originally the specialized tool of a wheelwright that became generalized for use on convex surfaces. As with the plane, the cutting blade (iron) projects only slightly from the short sole to regulate the depth of cut.

The drawknife is a handled blade that is pulled toward the operator. It is a rather questionable relative of the plane, for, though it lifts shavings in a similar manner, it lacks the positive thickness control of the plane. The tangs at the ends of the modern knife are bent at right angles in the plane of the blade. While it is used in much the manner of a spokeshave, the drawknife is actually a roughing tool for the quick removal of stock. Skill is required in its use because the depth of cut is regulated by the tilt of the blade, and the grain of the wood tends to assert itself. The drawknife appears to be an older tool than the spokeshave and has undergone a change since the Viking times when it was first used. Under the Viking craftsmen the handles were bent at right angles to the plane of the blade, and the tool seems to have been used for smoothing axed or adzed timber in medieval Scandinavia, Russia, and elsewhere.

TOOL AUXILIARIES

Workbench and vise. The workbench and vise form an organic unit, for the vise is a fixture that is either part of the carpenter's bench or is attached to the machinist's bench.

Neither a bench nor a mechanical fixture would have offered an advantage in the early chipping or flaking of stone. On the contrary, complete freedom in the posi-

tioning of the workpiece and hammer was essential to permit the many small, yet discretely placed and directed, blows that were the crux of fashioning stone tools. When large and unidirectional forces needed to be applied, as in woodworking, many phases of metalworking, or even in the manipulation of bone and horn, the advantage of a bench or a fixed rest became apparent.

Wood assumed its important role in structures, furniture, and fittings with the development of polished stone tools (ax and chisel) in the Neolithic Period and was skillfully exploited for finer work with the advent of copper and bronze tools. Most of the furniture of ancient times no longer exists, but much visual evidence, provided largely by sculptures, representations on vases, mosaics, and wall frescoes, depicts all manner of furniture, such as thrones, stools, benches, footstools, couches, cupboards, tables, chests, and beds.

Evidences of ancient furniture

Oddly enough, a stout table or workbench is missing from the renderings of busy Egyptian shops. The workpieces are on the floor, and the craftsman is kneeling or bending over his work or sitting on a low stool, even in those scenes in which tables are being finished. Perhaps the craftsman used his feet to position the work on the floor while using a chisel and mallet to effect joinery work, a practice still known in some areas.

Evidence in Europe suggests that the woodworker made use of a table or workbench as long ago as the Neolithic Period. The simplest form of table bench was a short length of heavy board split from a trunk and supported on four legs made of saplings set into bored holes. This style of bench, with its four legs somewhat splayed for greater stability, became common in Roman times. As the first users of the plane, the Romans found that a stout workbench was a necessity; truing a surface without a bench on which to lay and secure the wood was nearly impossible.

Two early methods, still in use, were devised for holding the workpiece. The simplest procedure was to use wooden pegs set into holes in the bench top; the other was to use what are variously known as bench stops, holdfasts, or dogs. The stems of these T-shaped iron fittings were set into holes in the workbench, and a sharp end of the horizontal part of the T was turned to engage the wood.

Other arrangements came into use, including trestles for supporting wood to be sawed and specialized benches—horses—on which the leatherworker or coppersmith sat while facing a raised workpiece. A small workpiece was often held by a strap that was tightened when the craftsman placed his foot in a loop that formed the free end and dangled beneath the table. Such horses proliferated from medieval times onward as new specialties developed.

The anvil and horn

A frequent accessory of the metalworker's bench was the anvil, which is still informally present on many machinist's vises in a rudimentary form suited to light work. Aside from making castings, metalworking was largely concerned with forging. The earliest anvils were convenient flat stones, usable for only the simplest kind of flat work. Anvils with the characteristic overhang, or horn, were first cast in bronze and, later, welded from short lengths of iron. Bench anvils were necessarily small, and the large free-standing specimens of the smith had to await the development of cast iron. Only then were larger masses of metal conveniently available.

The medieval carpenter's bench was still very much like the Roman's, with pegs serving as end fixtures. The metalworker, especially the craftsman using a file to shape and clean small forgings and castings (harness gear, buckles, and so on), used a simple rest, essentially a notched post driven into the ground in front of his bench, to support his workpiece.

Within a century, according to the pictorial record, the metalworkers' rest was replaced by a screw vise, at first quite small. This vise was like a hinge; one leaf or jaw was fastened to the bench, and the other was pulled up to clamp the workpiece and was tightened by the use of a nut and bolt passing through the middle of the hinge. Portable clamp-on vises that can be attached to a plank, tabletop, or bench top date from 1570.

Closing the vise by turning the tightening nut with a wrench was a slow and awkward process. At the end of the 16th century the screw was inverted so that it could be turned from the front by means of the T-handle that is part of every modern vise. This form of vise would remain an integral element of the workbench of every smithy (see Figure 8).

The modern machinist's vise has jaws that run parallel, and some vises pivot as a unit on a vertical axis (swivel-base vise). Both of these features were in use before the end of the 18th century.

The carpenter's bench developed more slowly. For a woodworker, workpieces could be firmly fixed only with a screw arrangement of some sort. Although all of the necessary elements were known as early as 1505, for centuries nothing came of the idea of bench vises using the screw.

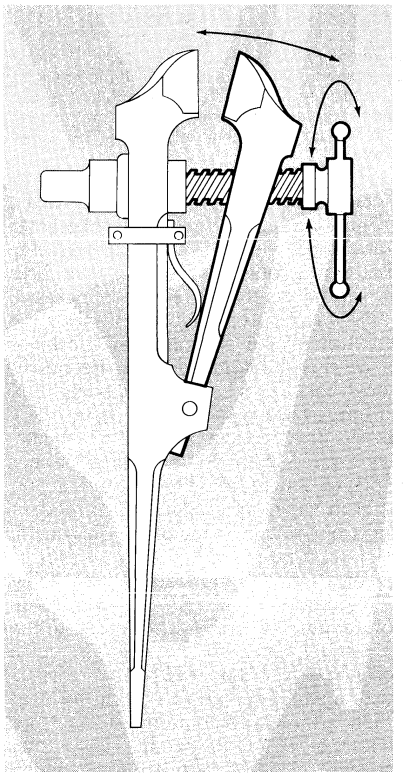

Figure 8: Blacksmith's vise, with long spikelike foot for extra support.

The woodworker needs two types of vises. One holds (clamps) the board into place so that its long edges may be trued and planed; custom places this vise at the left front of the bench, a convenient location for the right-handed workman. The second vise is at the right side of the table; its moving jaw has an adjustable bench stop that permits long pieces of wood to be held between it and a fixed stop in the bench top. Both types of vise were developed and made part of the same bench by the early 19th century.

Tongs, pincers, and pliers. Tongs, pincers, tweezers, and pliers have the common task of holding or gripping objects so that they may be handled more easily. The early use of fire created a new problem, that of handling hot coals. Two sticks probably served as the first uncertain holders, but bronze bars may have replaced wooden tongs as early as 3000 BC. An Egyptian wall painting of about 1450 BC shows a crucible supported between two bow-shaped metal bars. The same painting shows a craftsman with a blowpipe in his mouth holding a small object over a fire with a tweezer-like instrument about eight to 10 inches long. Bronze loops capable of handling large and heavy crucibles also appeared at this time.

Handling hot coals

Spring-back, or tweezer-like, tongs were the model used by the early ironsmith. The change to the mechanically more effective hinged tongs was slow, and it was not until 500 BC that they became common in the Greek blacksmith's kit. Pivoted tongs, with short jaws and a long handle, have quite a mechanical advantage over tweezer-like

tongs. A pair of 20-inch pivoted tongs is capable of exerting a gripping force of nearly 300 pounds (135 kilograms) with only a 40-pound squeeze from the smith's hand. Such tongs were constructed with one handle slightly shorter than the other so that an oval ring could be slipped over the two to help secure the grip.

Small tongs, often called pliers or forceps, were particularly valuable to the early craftsman, who put them to many and varied uses. The Romans sharpened the jaws of tongs to create cutters and pincers. The pincers were useful for pulling bent nails because of the leverage they were capable of exerting. Although they were originally a carpenter's tool, pincers became a principal tool of the farrier because old nails had to be pulled from horses' hooves before new shoes could be fitted and nailed on.

SCREW-BASED TOOLS

Invention of the screw. Although Archimedes is credited with inventing the screw in the 3rd century BC, his screw was not today's fastener but actually two other screw-type devices. One was a kind of water pump; still used today for large-volume, low-lift, industrial applications, the device is now called the inclined screw conveyor. The second was the "endless screw," actually the worm of a worm and gear set, one of the ancients' five devices for raising heavy weights. With the state of the mechanical arts as it was then, Archimedes' concept of the screw was actually as a motion-transforming device and was more hypothetical than practical.

By the 1st century BC, heavy wooden screws had become elements of presses for making wine and olive oil and for pressing clothes. The character of the screw took on a new dimension, for these screws were used to exert pressure; their modern counterparts are called power screws. These press screws were turned by means of hand spikes thrust into radial holes in the cylindrical end. The problem of making the internal thread of the nut prevented the use of small threaded fasteners in metal construction. The external thread, however, was readily, if tediously, made by filing.

Problem of the nut

Metal screws and nuts appeared in the 15th century. The square or hexagonal head or nut was turned with an appropriate box wrench; a T-handled socket wrench was developed in the 16th century. Some screws used in 16th-century armour have slots (nicks) in which a screwdriver may have been used, although this tool is not shown. Deep notches on the circumferences of the heads of other armour screws suggest that some type of pronged device was used to turn them. Slotted, roundheaded screws were used in the 16th century, but few screw-and-nut-fastened clocks are in evidence earlier than the 17th century. Metal screws were called machine, or machinery, screws since they were made of metal and mated with threaded holes.

The wood screw differs from the machine screw in that the wood into which it is turned is deformed into a nut. It must, however, be started in a hole made by awl or drill. Aside from a few and sometimes doubtful artifacts from Roman times, the wood screw is not mentioned until the mid-16th century, when it appears in a mining treatise. Here a screw tapered to a point, carrying a slotted head and looking very familiar except for its left-handed thread, is described so casually as to suggest that it was a common article. It is remarked that the screw is superior to the nail, which is also shown being driven by a claw hammer. There is no mention of a screwdriver.

Screwdrivers and wrenches. The simple screwdriver was preceded by a flat-bladed bit for the carpenter's brace (1744). The handled screwdriver is shown on the woodworker's bench after 1800 and appears in inventories of tool kits from that date. Screwdrivers did not become common tools until 1850 when automatic screw machines began the mass production of tapered, gimlet-pointed wood screws. In its early form, the screwdriver was made from flat stock; its sometimes scalloped edges contributed nothing to function. Being flat, the blade was easy to haft but weak when improperly used for prying. The present form of the screwdriver, round and flattened only at the end, was devised to strengthen the shaft and make use of readily available round-wire stock.

Origin of the screwdriver

Early box and socket wrenches fit only a particular nut or screw with flat surfaces on the head. The open-end wrench may have rectangular slots on one or both ends. In their earliest forms, such wrenches, with straight, angled, or S-shaped handles, were made of wrought iron. Cast iron came into use around 1800. Modern wrenches are drop forgings and come in many formats.

The limitations of fixed-opening wrenches were addressed in the early 19th century when sliding-jaw types were developed to accommodate a range of flats. In these, the end of an L-shaped handle provided the fixed jaw, and the parallel jaw was arranged to slide along the handle until it engaged the flats. In the first models, in the 1830s, the sliding jaw was fixed into position by a wedge that was hammered into place. By 1835 patents for screw wrenches began to proliferate; in these, the sliding jaw was positioned and held by means of a screw whose axis was parallel to the handle. The most common example is the monkey wrench, whose name first appeared in about 1858. A convenient variation of this type of wrench is the thin and angled Crescent wrench, a modern innovation.

The plumber's pipe wrench is a serrated-jaw variation of the monkey wrench, whose additional feature of a pivotable movable jaw enables it to engage round objects, such as rods and pipes.

MEASURING AND DEFINING TOOLS

Plumb line, level, and square. A plumb line is a light line with a weight (plumb bob) at one end that, when suspended next to a workpiece, defines a vertical line. "Plumb" comes from the Latin *plumbum,* or "lead," the material that replaced stone as the weight for the bob or plummet.

While an end-weighted string defines the vertical, its direct use for plumbing walls (making them vertical) is awkward. The Egyptians devised a tool resembling the letter E, from which a plumb line was suspended from the upper outboard part of the E. When the tool was placed against a wall, the wall was determined to be vertical when the string just touched the lower outboard part of the E. Oddly, this useful tool was apparently forgotten for many centuries and has reappeared only in modern times.

The tool for determining horizontal direction is called a level. The Egyptians used an A-frame, on which a plumb line was suspended from the vertex of the A. When the feet of the A were set on the surface to be checked, if the plumb line bisected the crossbar of the A, the surface was horizontal. The A-frame level was used in Europe until the middle of the 19th century. Sometimes a variation is shown in which the frame is an inverted T with a plumb line suspended from the top of the vertical stem.

Because the surface of a body of water is always horizontal, a trough or channel filled with water can serve as a reference in some situations. The hose level, first described in 1629, consisted of a length of hose fitted with a glass tube at each end. Water was added until it rose in both vertically held tubes; when the surfaces of the water in each tube were at the same height, the object was level. This idea was impractical with only leather hose, but the development of vulcanized rubber hose in 1831 led to a resurgence of the device in 1849. Because the hose could be carried through holes in the wall, around partitions, and so on, the instrument enabled levels to be established in awkward circumstances.

The hose level

The spirit, or bubble, level, a sealed glass tube containing alcohol and an air bubble, was invented in 1661. It was first used on telescopes and later on surveying instruments, but it did not become a carpenter's tool until the factory-made models were introduced in the mid-19th century. The circular level, in which a bubble floated under a circular glass to indicate level in all directions, was invented in 1777. It lacked the sensitivity of the conventional level.

The square appeared in the ancient Egyptian world as two perpendicular legs of wood braced with a diagonal member. In the following centuries many variations were designed for specific purposes, including a square with shoulders that allowed it also to cast a mitre of 45 degrees. Iron squares were rarely used before 1800, and factory-made metal squares did not appear until 1835. The ad-

justable, or bevel, square was used for angles other than 90 degrees beginning in the 17th century. In the earliest examples, the thin blade moved stiffly because it was riveted into a slot in the thick blade. Later models of the 19th century, however, were equipped with a thumbscrew that permitted the thin blade to be adjusted with respect to the thicker blade.

Compass, divider, and caliper. Compass, divider, and caliper are basically instruments that have two legs pivoted to each other at the top and are concerned with small-distance measurement or transfer. The compass and divider have straight legs; the caliper has curved legs.

The terms compass and divider are often interchanged, for each instrument can be used to draw circles, mark divisions (divide a given distance), or simply mark a distance. Technically, a compass is a drafting instrument that has one pen or pencil point and one sharp point that is positioned at the centre of the circle to be described; a divider, on the other hand, has two sharp points, one for the centre, the other for scribing or marking. Caliper is a corruption of "calibre," the diameter of a hole (as in a firearm) or of a cylindrical or spherical body. The outside caliper has inwardly curved legs that measure the diameters of solids created by rotating tools, such as lathe-turned objects; the inside caliper has outwardly curved legs for measuring bores.

Dividers and calipers were known to both the Greeks and Romans, though the caliper was uncommon. A divider with a circular sector, or wing, connecting the two legs was sketched in 1245; its modern counterpart is the wing divider with a thumbscrew clamp and screw for fine adjustment. The caliper is mentioned in the Middle Ages, but the divider was the principal tool of the architect working on full-scale layouts of stonework, such as in the construction of a cathedral. Such dividers were large, often half as tall as a man. The divider underwent refinements that made it an important drafting instrument for Albrecht Dürer and Leonardo da Vinci; Leonardo suggested improvements that included the knuckle-joint hinge (to increase rigidity) and the adjustable proportional divider (Roman proportional dividers had a fixed pivot that gave only one ratio). Leonardo's notes also show the beam compass with a screw adjustment for large radii, as well as a compass that had interchangeable points, in which one leg had a clamp for different drawing media, such as graphite or chalk.

Proportional dividers

Chalk line. "Snapping a line," a technique familiar in ancient Egypt, is employed in modern building construction. The procedure uses a taut, chalk-covered cord that is stretched between two points; the cord deposits a straight line of chalk when it is plucked and snapped onto the surface. After 5,000 years the only change in this technique is that, whereas the Egyptians used wet red or yellow ochre, the modern craftsman follows the method of Greek masons who employed white and red chalks in addition to wet ochre.

Rules. The unit of linear measure in the ancient world, the cubit, was simply the length from the elbow to the extremity of the middle finger. Although the cubit gave an order of magnitude, it was hardly a standard, and it varied widely in different times and places.

One of many royal Egyptian cubits had a length of $20^{64}/_{100}$ inches. It was divided into seven palms (measured across the fingers, not the knuckles), making a palm almost three inches. Each palm was, in turn, divided into four digits of about three-quarters of an inch apiece. Thus, 1 cubit = 7 palms = 28 digits. On occasion, digits were subdivided into 10ths, 14ths, or 16ths.

The common rule of Egyptian masons and carpenters was made of wood, had a narrow cross section, and had one beveled edge, with the two left-hand palms carrying the smaller divisions of digits. Some Egyptian rods were made of stone and used digits divided into 16ths. These may have been ceremonial rods or, perhaps, master gauges for calibration and comparison; their brittleness would make them unsuitable for the rough handling received by mason's tools.

The Romans introduced folding rules of bronze in 12- and six-inch sizes. These were probably "pocket" instruments for officials, too expensive to be used by ordinary craftsmen who probably used plain strip rules.

Only scanty evidence exists that graduated rules were used in the Middle Ages and the Renaissance; plain straightedges seem to have predominated. In 1683 an English writer described foot rules as having $^1/_8$-inch subdivisions. The folding rule, now made of wood, reappeared at the end of the 17th century.

Measurement was long characterized by great national and regional differences. Because every large city in Europe and most towns had a different, but locally standard, "foot," rules with four different graduations (one on each face) were made.

POWER TOOLS

A power tool is technically a power-driven hand tool or portable power tool; these names distinguish it from the stationary power tool such as the drill press. While power tools are generally driven by electricity, the category also includes small pneumatic tools driven by compressed air, such as air impact wrenches and hammers. Gasoline-engine-driven tools (chain saws, gas-powered drills, and so on) are not included.

The most popular power tools are the electric drill and the electric circular saw. Like its manual counterpart, the electric drill rotates a tool bit, but the circular saw has no manual prototype. Jigsaws, sabre, and reciprocating saws have familiar blades, as do electric screwdrivers, but many power tools are contemporary creations built around the ubiquitous electric motor. Among modern power tools are polishers, several kinds of sanders (circular, belt, oscillating, and reciprocating), shears, and nibblers. Power tools, in limited commercial and industrial use before World War II, are now produced by the millions, largely for the home workshop. (R.S.H./Ed.)

The two most popular power tools

Machine tools in industry

Machine tools are stationary power-driven machines that shape or form parts made of metal or other materials. The shaping is accomplished in four general ways: (1) by cutting excess material in the form of chips from the part; (2) by shearing the material; (3) by squeezing metallic parts to the desired shape; and (4) by applying electricity, ultrasound, or corrosive chemicals to the material. The fourth category covers modern machine tools and processes for machining ultrahard metals not machinable by older methods.

Machine tools that form parts by removing metal chips from a workpiece include lathes, shapers and planers, drilling machines, milling machines, grinders, and power saws. The cold forming of metal parts, such as cooking utensils, automobile bodies, and similar items, is done on punch presses, while the hot forming of white-hot blanks into appropriately shaped dies is done on forging presses.

Modern machine tools cut or form parts to tolerances of plus or minus one ten-thousandth of an inch (0.0025 millimetre). In special applications, precision lapping machines can produce parts that are within plus or minus two millionths of an inch (0.00005 millimetre). Because of the precise dimensional requirements of the parts and the heavy cutting forces exerted on the cutting tool, machine tools combine weight and rigidity with delicate accuracy.

Tolerances

HISTORY

Before the Industrial Revolution of the 18th century, hand tools were used to cut and shape materials for the production of goods such as cooking utensils, wagons, ships, furniture, and other products. After the advent of the steam engine, material goods were produced by power-driven machines that could only be manufactured by machine tools. Machine tools (capable of producing dimensionally accurate parts in large quantities) and jigs and fixtures (for holding the work and guiding the tool) were the indispensable innovations that made mass production and interchangeable parts realities in the 19th century.

The earliest steam engines suffered from the imprecision of early machine tools, and the large cast cylinders of the engines often were bored inaccurately by machines

powered by waterwheels and originally designed to bore cannon. Within 50 years of the first steam engines, the basic machine tools, with all the fundamental features required for machining heavy metal parts, were designed and developed. Some of them were adaptations of earlier woodworking machines; the metal lathe derived from woodcutting lathes used in France as early as the 16th century. In 1775 John Wilkinson of England built a precision machine for boring engine cylinders. In 1797 Henry Maudslay, also of England and one of the great inventive geniuses of his day, designed and built a screw-cutting engine lathe. The outstanding feature of Maudslay's lathe was a lead screw for driving the carriage. Geared to the spindle of the lathe, the lead screw advanced the tool at a constant rate of speed and guaranteed accurate screw threads. By 1800 Maudslay had equipped his lathe with 28 change gears that cut threads of various pitches by controlling the ratio of the lead-screw speed to the spindle speed.

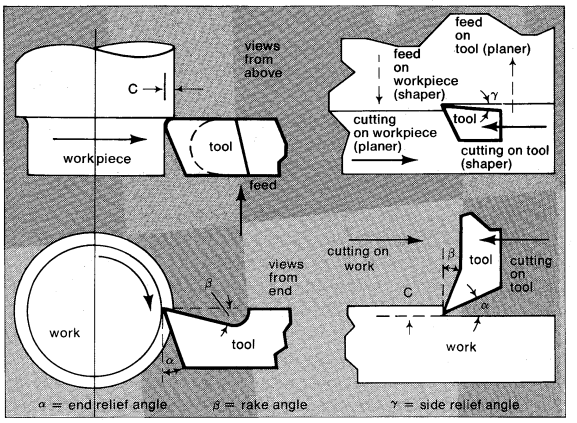

Figure 9: *Single-point cutting tools.*
(Left) Lathe tool; (right) planer and shaper tool.
Depth of cut is indicated by C.

Invention of the steam hammer

The shaper was invented by James Nasmyth, who had worked in Henry Maudslay's shop in London. In Nasmyth's machine, a workpiece could be clamped horizontally to a table and worked by a cutter using a reciprocating motion to plane small surfaces, cut keyways, or machine other straight-line surfaces. A few years later, in 1839, Nasmyth invented the steam hammer for forging heavy pieces. Another disciple of Maudslay, Joseph Whitworth, invented or improved a great number of machine tools and came to dominate the field; at the International Exhibition of 1862, his firm's exhibits took up a quarter of all the space devoted to machine tools.

Britain tried to keep its lead in machine-tool development by prohibiting exports, but the attempt was foredoomed by industrial development elsewhere. British tools were exported to continental Europe and to the United States despite the prohibition, and new tools were developed outside Britain. Notable among these was the milling machine invented by Eli Whitney, produced in the United States in 1818, and used by Simeon North to manufacture firearms. The first fully universal milling machine was built in 1862 by J.R. Brown of the United States and was used to cut helical flutes in twist drills. The turret lathe, also developed in the United States in the middle of the 19th century, was fully automatic in some operations, such as making screws, and it presaged the momentous developments of the 20th century. Various gear-cutting machines reached their full development in 1896 when F.W. Fellows, an American, designed a gear shaper that could rapidly turn out almost any type of gear.

The production of artificial abrasives in the late 19th century opened up a new field of machine tools, that of grinding machines. C.H. Norton of Massachusetts dramatically illustrated the potential of the grinding machine by making one that could grind an automobile crankshaft in 15 minutes, a process that previously had required five hours.

By the end of the 19th century a complete revolution had taken place in the working and shaping of metals that created the basis for mass production and an industrialized society. The 20th century has witnessed the introduction of numerous refinements of machine tools, such as multiple-point cutters for milling machines, the development of automated operations governed by electronic and fluid-control systems, and nonconventional techniques, such as electrochemical and ultrasonic machining. Yet even today the basic machine tools remain largely the legacy of the 19th century.

MACHINE-TOOL CHARACTERISTICS

All machine tools must provide work-holding and tool-holding devices and means for accurately controlling the depth of the cut. The relative motion between the cutting edge of the tool and the work is called the cutting speed; the speed in which uncut material is brought into contact with the tool is called the feed motion. Means must be provided for varying both.

Because an overheated tool may lose its cutting ability, temperatures must be controlled. The amount of heat that is generated depends on the shearing force and the cutting speed. Because the shearing force varies with the material being cut and the tool material varies in its tolerance for high temperatures, the optimum cutting speed depends both on the material being cut and the cutting-tool material. It is also influenced by the rigidity of the machine, the shape of the workpiece, and the depth of the cut.

Optimum cutting speed

CUTTING TOOLS

Metal-cutting tools are classified as single point or multiple point. A single-point cutting tool is shown in Figure 9 (left) performing a turning operation on a rotating cylindrical workpiece. Such tools are also used for increasing the size of holes, or boring. Turning and boring are performed on lathes and boring mills. Multiple-point cutting tools have two or more cutting edges and include milling cutters, drills, and broaches (Figure 10).

Figure 9 (right) represents two types of operation; either the tool is moving on a straight path against the stationary

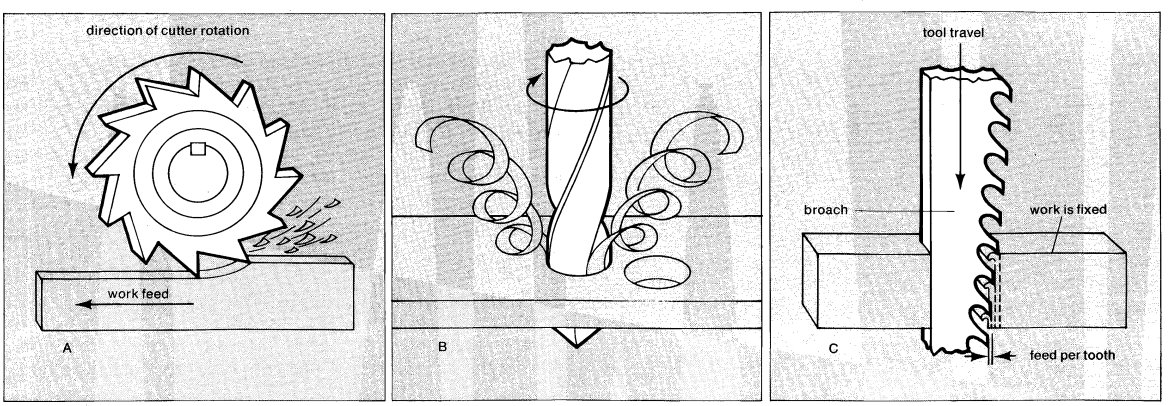

Figure 10: *Multiple-point cutting tools.*
(A) Milling with plain milling cutter. (B) Machining with twist drill. (C) Action of broaching tool.

workpiece, as on a shaper, or the workpiece is moving against the stationary tool, as on a planer. Relief or clearance angles (designated by the symbol α in Figure 9) must be provided to prevent the tool surface below the cutting edge from rubbing against the workpiece. Rake angles (symbol β in Figure 9) are often provided on cutting tools to cause a wedging action in the formation of chips and to reduce friction and heat.

Tool materials. In order to remove chips from a workpiece, a cutting tool must be harder than the workpiece and must maintain a cutting edge at the temperature produced by the friction of the cutting action.

Carbon steel. Steel with a carbon content ranging from 1 to 1.2 percent was the earliest material used in machine tools. Tools made of this carbon steel are comparatively inexpensive but tend to lose cutting ability at temperatures at about 400° F (205° C).

High-speed steel. In 1900 the introduction of high-speed steel permitted the operation of tools at twice or three times the speeds allowable with carbon steel, thus doubling or trebling the capacities of the world's machine shops. One of the most common types of high-speed steel contains 18 percent tungsten, 4 percent chromium, 1 percent vanadium, and only 0.5 to 0.8 percent carbon.

Cast alloys. A number of cast-alloy cutting-tool materials have been developed; these nonferrous alloys contain cobalt, chromium, and tungsten and are particularly effective in penetrating the hard skin on cast iron and retaining their cutting ability even when red hot.

Cutting at red heat

Cemented tungsten carbide. This material was first used for metal cutting in Germany in 1926. Its principal ingredient is finely divided tungsten carbide held in a binder of cobalt; its hardness approaches that of a diamond. Tungsten carbide tools can be operated at cutting speeds many times higher than those used with high-speed steel.

Oxides. Ceramic, or oxide, tool tips are one of the newest developments in cutting-tool materials. They consist primarily of fine aluminum oxide grains, which are bonded together.

Diamonds. Diamonds have been used for many years for truing grinding wheels, in wire-drawing dies, and as cutting tools. For cutting applications they are used largely for taking light finishing cuts at high speed on hard or abrasive materials and for finish-boring bronze and babbitt-metal bearings.

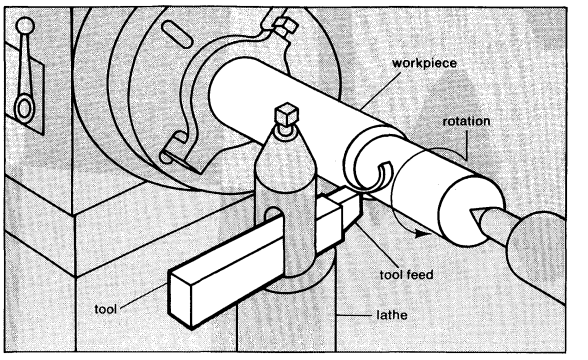

Figure 12: Turning of steel shaft mounted between centres.

Cutting fluids. In many machine-tool operations, cutting fluids or coolants are used to modify the harmful effects of friction and high temperatures. In general, the major functions of a coolant are to lubricate and cool. When cutting a screw thread, either on a lathe or with a tap, the lubricating function is most important; in production-grinding operations, the cooling function predominates. Water is an excellent cooling medium, but it corrodes ferrous materials. Lard oil has excellent lubricating qualities, but it tends to become rancid. Sulfurized mineral oil is one of the most popular coolants. The sulfur tends to prevent chips from the work from welding to the tip of the tool. For sawing and grinding operations, soluble oil, which is an oily emulsion freely miscible in water, is commonly used.

BASIC MACHINE TOOLS

Hundreds of varieties of metal machine tools, ranging in size from small machines mounted on workbenches to huge production machines weighing several hundred tons, are used in modern industry. They retain the basic characteristics of their 19th- and early 20th-century ancestors and are still classed as one of the following: (1) turning machines (lathes and boring mills), (2) shapers and planers, (3) drilling machines, (4) milling machines, (5) grinding machines, (6) power saws, and (7) presses.

Turning machines. The engine lathe, as the horizontal metal-turning machine is commonly called, is the most important of all the machine tools (Figure 11). It is usually considered the father of all other machine tools because many of its fundamental mechanical elements are incorporated into the design of other machine tools.

The engine lathe

The engine lathe is a basic machine tool that can be used for a variety of turning, facing, and drilling operations. It uses a single-point cutting tool for turning and boring (Figure 12). Turning operations involve cutting excess metal, in the form of chips, from the external diameter of a workpiece and include turning straight or tapered cylindrical shapes, grooves, shoulders, and screw threads and facing flat surfaces on the ends of cylindrical parts. Internal cylindrical operations include most of the common hole-machining operations, such as drilling, boring, reaming, counterboring, countersinking, and threading with a single-point tool or tap (Figure 13).

Boring involves enlarging and finishing a hole that has been cored or drilled. Bored holes are more accurate in roundness, concentricity, and parallelism than drilled holes. A hole is bored with a single-point cutting tool that feeds along the inside of the workpiece. Boring mills have circular horizontal tables that rotate about a vertical axis, and they are designed for boring and turning operations on parts that are too large to be mounted on a lathe.

Shapers and planers. Shaping and planing operations involve the machining of flat surfaces, grooves, shoulders, T-slots, and angular surfaces with single-point tools. The largest shapers have a 36-inch cutting stroke and can machine parts up to 36 inches long. The cutting tool on the

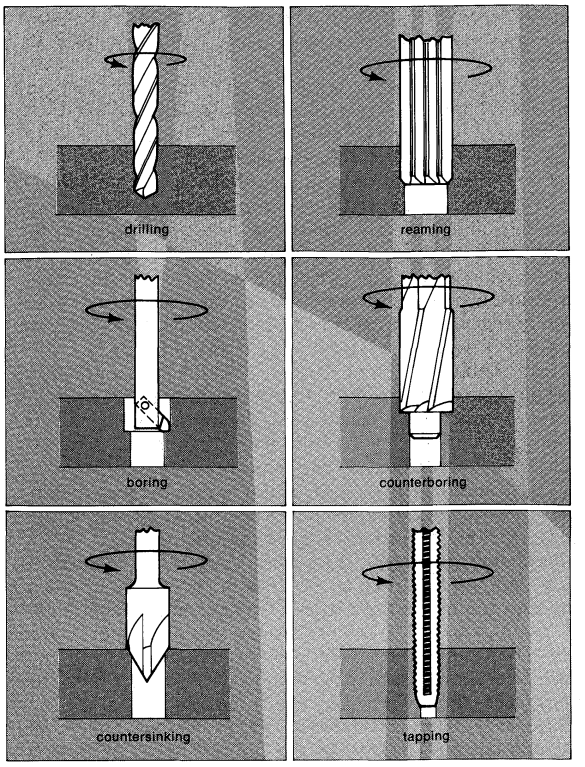

Figure 13: Common hole-machining operations.
Adapted from W.J. McCarthy and R.E. Smith, *Machine Tool Technology*

shaper oscillates, cutting on the forward stroke, with the workpiece feeding automatically toward the tool during each return stroke.

Planing machines perform the same operations as shapers but can machine longer workpieces. Some planers can machine parts up to 50 feet long. The workpiece is mounted on a reciprocating table that moves the workpiece beneath a cutting tool. This tool, which remains stationary during the cutting stroke, automatically feeds into the workpiece after each cutting stroke.

Drilling machines. Drilling machines, also called drill presses, cut holes in metal with a twist drill (Figure 10). They also use a variety of other cutting tools to perform the following basic hole-machining operations: (1) reaming, (2) boring, (3) counterboring, (4) countersinking, and (5) tapping internal threads with the use of a tapping attachment (Figure 13).

Tapping

Milling machines. A milling machine cuts metal as the workpiece is fed against a rotating cutting tool called a milling cutter (Figure 10). Cutters of many shapes and sizes are available for a wide variety of milling operations. Milling machines cut flat surfaces, grooves, shoulders, inclined surfaces, dovetails, and T-slots. Various form-tooth cutters are used for cutting concave forms and convex grooves, for rounding corners, and for cutting gear teeth.

Milling machines are available in a variety of designs that can be classified as the following: (1) standard knee-and-column machines, including the horizontal and the vertical types; (2) bed-type or manufacturing machines; and (3) machines designed for special milling jobs.

Grinding machines. Grinding machines remove small chips from metal parts that are brought into contact with a rotating abrasive wheel called a grinding wheel or an abrasive belt. Grinding is the most accurate of all of the basic machining processes. Modern grinding machines grind hard or soft parts to tolerances of plus or minus 0.0001 inch (0.0025 millimetre).

The common types of grinding machines include the following: (1) plain cylindrical, (2) internal cylindrical, (3) centreless (Figure 14), (4) surface (Figure 12), (5) off-hand, (6) special, and (7) abrasive-belt.

Power saws. Metal-cutting power saws are of three basic types: (1) power hacksaws, (2) band saws, and (3) circular disk saws. Vertical band saws are used for cutting shapes in metal plate, for internal and external contours, and for angular cuts.

Presses. This large class of machines includes equipment used for forming metal parts by applying the following processes: shearing, blanking, forming, drawing, bending, forging, coining, upsetting, flanging, squeezing, and hammering. All of these processes require presses with a movable ram that can be pressed against an anvil or base. The movable ram may be powered by gravity, mechanical linkages, or hydraulic or pneumatic systems.

Appropriate die sets, with one part mounted on the movable ram and the matching part mounted on the fixed bed or platen, are an integral part of the machine. Punch presses stamp out metal parts from sheet metal and form the parts to the desired shape. Dies with cavities having a variety of shapes are used on forging presses that form white-hot metal blanks to the desired shapes. Power presses are also used for shearing, bending, flanging, and shaping sheet metal parts of all sizes. Power presses are made in various sizes, ranging from small presses that can be mounted on a workbench to machines weighing more than 1,000,000 pounds (450,000 kilograms).

Dies

MODIFICATIONS OF BASIC MACHINES

Certain machine tools have been designed to speed up production. Although these tools include features of the basic machine tools and perform the same operations, they incorporate design modifications that permit them to perform complex or repetitive operational sequences more rapidly. Furthermore, after the production machine has been set up by a skilled worker or machinist, a less skilled operator also can produce parts accurately and rapidly. The following are examples of production machine tools that are modifications of basic machine tools: (1) turret lathes, including screw machines; (2) multiple-station machines; (3) gang drills; and (4) production milling machines.

Turret lathes. Horizontal turret lathes have two features that distinguish them from engine lathes. The first is a multiple-sided main turret, which takes the place of the tailstock on the engine lathe (Figure 15). A variety of turning, drilling, boring, reaming, and thread-cutting tools can be fastened to the main turret, which can be rotated intermittently about its vertical axis with a hand wheel. Either a hand wheel or a power feed can be used to move the turret longitudinally against the workpiece mounted on the machine spindle.

The second distinguishing feature of the turret lathe is the square turret mounted on the cross slide. This turret also can be rotated about its vertical axis and permits the use of a variety of turning tools. A tool post, or tool block, can be clamped to the rear of the cross slide for mounting

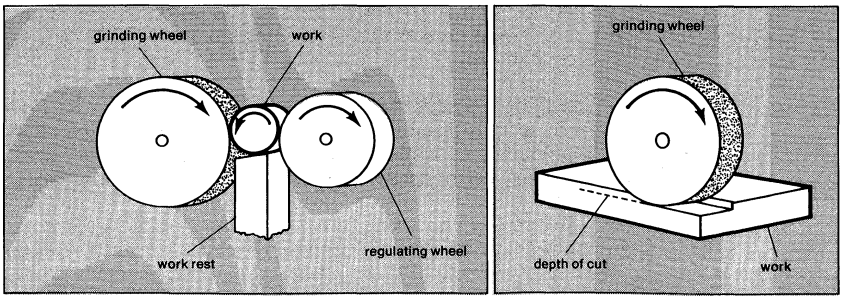

Figure 14: (Left) Centreless grinding operation. (Right) Surface grinding operation.

additional tools. The cross slide can be actuated either by hand or by power.

Turret lathes may be classified as either bar machines or chucking machines. Bar machines formerly were called screw machines, and they may be either hand controlled or automatic. A bar machine is designed for machining small threaded parts, bushings, and other small parts that can be created from bar stock fed through the machine spindle. Automatic bar machines produce parts continuously by automatically replacing of bar stock into the machine spindle. A chucking machine is designed primarily for machining larger parts, such as castings, forgings, or blanks of stock that usually must be mounted in the chuck manually.

The chucking machine

Multiple-station machines. Several types of multiple-station vertical lathes have been developed. These machines are essentially chucking-type turret lathes for machining threaded cylindrical parts. The machine has 12 spindles, each equipped with a chuck. Directly above each spindle, except one, tooling is mounted on a ram. Parts are mounted in each chuck and indexed for up to 11 machining operations. The finished part is removed at the 12th station.

Gang drills. A gang-drilling machine consists of several individual columns, drilling heads, and spindles mounted on a single base and utilizing a common table. Various numbers of spindles may be used, but four or six are common. These machines are designed for machining parts requiring several hole-machining operations, such as drilling, countersinking, counterboring, or tapping. The workpiece is moved from one drilling spindle to the next, where sequential machining operations are performed by one or more operators.

Production millers. Milling machines used for repetitive-production milling operations generally are classified as bed-type milling machines because of their design. The sliding table is mounted directly onto the massive bed of the machine and cannot be raised or moved transversely; table movement is longitudinal only. The spindle head may be adjusted vertically to establish the depth of cut. Some machines are equipped with automatic controls that require only a semiskilled operator to load parts in fixtures at each end of the table and start the machine. One part can be unloaded and replaced while the other is being machined.

SPECIAL-PURPOSE MACHINES

Special-purpose machine tools are designed to perform special machining operations, usually for production purposes. Examples include gear-cutting and gear-grinding machines, broaching machines, lapping and honing machines, and boring machines.

Gear-cutting machines. Three basic cutting methods are used for machining gears: (1) form cutting, (2) template cutting, and (3) generating. The form-cutting method uses a cutting tool that has the same form as the space between two adjacent teeth on a gear. This method is used for cutting gear teeth on a milling machine. The template-cutting method uses a template to guide a single-point cutter on large bevel-gear cutting machines.

Most cut gears produced in large lots are made on machines that utilize the gear-generating method. This method is based on the principle that two involute gears, or a gear and rack, with the same diametral pitch will mesh together properly. Therefore, a cutting tool with the shape of a gear or rack may be used to cut gear teeth in a gear or rack blank. This principle is applied in the design of a number of widely used gear-cutting machines of the generating type. Gear-generating machines that cut with reciprocating strokes are called gear shapers.

Gear-hobbing machines use a rotating, multiple-tooth cutting tool called a hob for generating teeth on spur gears, worm gears, helical gears, splines, and sprockets. More gears are cut by hobbing than by other methods because the hobbing cutter cuts continuously and produces accurate gears at high production rates. In gear-making machines gears can be produced by cutting, grinding, or a combination of cutting and grinding operations.

Hobbing

Broaching machines. In general, broaching is classified as a planing or shaping art because the action of a broaching tool resembles the action of planer and shaper tools. Broaching tools of various designs are available (Figure 10). The teeth on broaching tools are equally spaced, with each successive tooth designed to feed deeper into the workpiece, thus completing the broaching operation in a single stroke. Examples of internal broaching applications include cutting keyways in the hubs of gears or pulleys, cutting square or hexagonal holes, and cutting gear teeth. External grooves can be cut in a shaft with an external broaching tool. Some broaching machines pull or push broaching tools through or over the workpiece.

Lapping and honing machines. Lapping and honing operations are classified under the basic art of grinding. Lapping is a process in which a soft cloth impregnated with abrasive pastes or compounds is rubbed against the surface of a workpiece. Lapping is used to produce a high-quality surface finish or to finish a workpiece within close size limits. Dimensional tolerances of two millionths of an inch (0.00005 millimetre) can be achieved in the hand or machine lapping of precision parts such as gauges or gauge blocks.

Honing is a low-speed surface finishing process used for removing scratches, machine marks, or small amounts of metal, usually less than 0.0005 inch (0.0125 millimetre), from ground or machined surfaces. Honing is done with bonded abrasive sticks or stones that are mounted in a honing head. In a typical honing operation, such as honing automotive engine cylinder walls, a honing machine with one or more spindles is used. The honing head rotates slowly with an oscillating motion, holding the abrasive sticks against the work surface under controlled light pressure.

Abrasive sticks

Boring machines. Boring can be done on any type of machine that is equipped to hold a boring tool and a workpiece and that is also equipped to rotate either the tool or the workpiece in the proper relationship (Figure 13). Special boring machines of various designs are used for boring workpieces that are too large to be mounted on a lathe, drill press, or milling machine. Boring and turning operations are also performed on large vertical turret lathes or on larger boring mills. Standard boring machines are able to bore or turn work of up to 12 feet (3.6 metres) in diameter.

AUTOMATIC CONTROL

To be truly automatic, a machine tool must be capable of producing parts repetitively without operator assistance in loading parts, starting the machine, and unloading parts. In this sense, some bar-turning machines are automatic. In practice, however, some machine tools designated as automatic are actually semi-automatic, since they require an operator to load the workpiece into the machine, press the start button, and unload the part when the operation is completed.

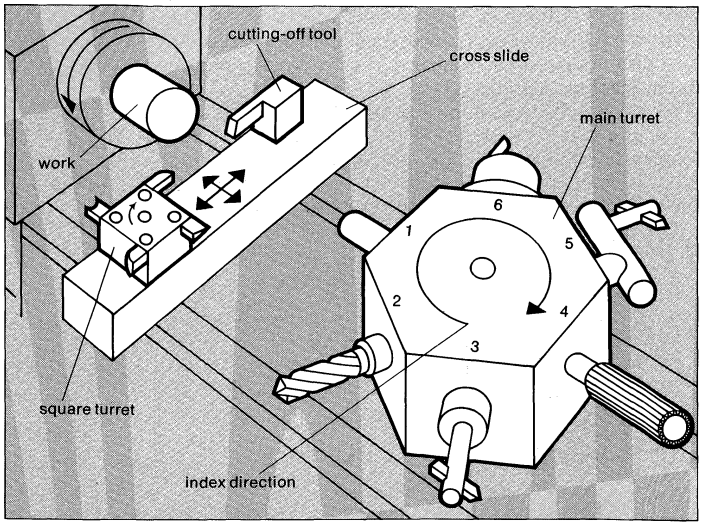

Figure 15: Horizontal turret lathe.

The tooling for automatic machines is more complex than for hand-controlled machines and usually requires a skilled worker to make the setup. After the setup, however, a less skilled operator can operate one or more machines simultaneously. Tracer lathes and numerically controlled machine tools are examples of machines that use varying degrees of automatic and semi-automatic control.

Tracer techniques. The tool slide on a tracer lathe is guided by a sensitive, hydraulically actuated stylus that follows an accurate template. The template may be an accurate profile on a thin plate or a finish-turned part. Although tracing mechanisms generally are accessory units attached to engine lathes, some lathes are especially designed as automatic tracing lathes. Optional accessories for use on tracing lathes include automatic-indexing toolheads and one or more cross slides for operations such as facing, grooving, and chamfering.

Tracing lathes can machine all common cylindrical shapes, straight and tapered shoulders, and irregular curves. Accessory tools permit facing, grooving, and chamfering operations. An unlimited combination of cutting speeds, feeds, and types of cuts may be used, including roughing cuts and finishing cuts. On machines equipped for automatic operation, changes in speed, feed, and cutting tools are automatic. (W.J.McC./Ed.)

Numerical control (NC). Many types of machine tools and other industrial processes are equipped for numerical control, commonly called NC. The earliest forms of NC were developed in the 1950s when the movements of the axes of machine tools were assigned numerical values to facilitate the replacement of handwheels and dials by control logic. NC requires accurate product design values; early systems were limited by the lack of detailed analyses for the geometrical drawings of the components to be manufactured. Later in the decade, this problem was overcome when computers were developed that could describe geometric tool movements as functions of a part-programming language. One of the best known of these early languages of tool instructions was APT (Automatically Programmed Tools).

A significant development of the early 1960s was a system known as Sketchpad, which enabled engineers to draw designs on a cathode-ray tube by using a light pen and a keyboard. When this system was connected to a computer, it enabled designers to study drawings interactively and facilitated the modification of their designs.

An NC system or device is one that controls the actions of a machine or process by the direct insertion of numerical data at some point; the system also must automatically interpret at least some portion of the data. Various kinds of numerical control systems use data coded in the form of numbers, letters, symbols, words, or a combination of these forms.

The instructions necessary for machining a part by NC are derived from the part drawing and are written in coded form on a program manuscript. The following kinds of data may be included on the manuscript: (1) sequence of operations, (2) kind of operation, (3) depth of cut, (4) coordinate dimensions for the centre of the cutting tool, (5) feed rate, (6) spindle speed, (7) tool number, and (8) other miscellaneous operations.

The coded information is punched into a ribbon of one-inch-wide machine-control tape with a tape-punching machine similar to a typewriter. The tape, usually made of paper or plastic, is inserted into the NC system, which is connected to the machine tool. The NC system interprets the information on the tape, thus activating relays and electrical circuits that cause the machine's servomechanisms and other controls to perform a sequence of operations automatically. On some NC systems, the coded information is inserted into the machines on punched cards or magnetic tape instead of punched tape. The tape can be stored for future use on the same machine or on others like it at any location. NC machines can produce parts accurately to tolerances of 0.001 or 0.0001 inch (0.025 or 0.0025 millimetre) depending on the design of the machine, the NC system, and other factors, such as environmental temperature.

NC systems on machine tools can be classified into two basic types: (1) point-to-point and (2) continuous-path. Point-to-point systems, commonly used on machines that perform hole-machining and straight-line milling operations, are relatively simple to program and do not require the aid of a computer.

Continuous-path NC systems are commonly used on machines that perform contouring operations, such as milling machines, lathes, flame-cutting machines, and drafting machines. Program preparation for continuous-path machines is more complex and usually requires the aid of a computer.

COMPUTER-AIDED MACHINING

Computer numerical control (CNC). Altering the operating procedures of early NC systems required changing the hardware of the machine tool itself. In the 1970s CNC systems (Figure 16), controlled by dedicated mini- or microcomputers, were developed to enable machine tools to be readily adapted to different jobs by altering the control program, or software. Consequently, CNC machine tools are easier to operate and more versatile than their NC counterparts, and their programming is simpler and can be rapidly tested. Since they have less control hardware, they are cheaper to maintain and are generally more accurate. CNC systems can be used with a wide range of machine tools such as milling machines and lathes. Many are equipped with graphic displays that plot the shapes of the components being machined. Some simulate tool movements, while others produce three-dimensional views of components.

From D. Gibbs, *An Introduction to CNC Machining* (1984), Cassell Computing

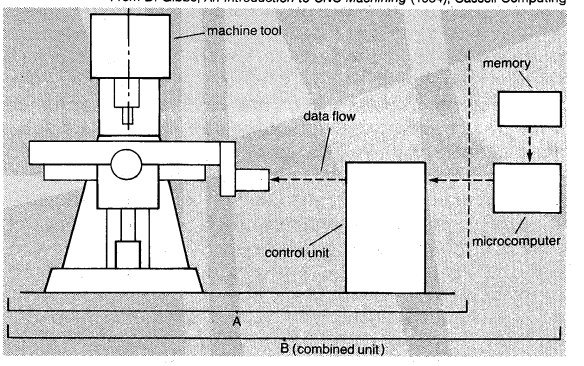

Figure 16: Machine tool with (A) numerical control and (B) computer numerical control.

When several CNC machine tools receive instructions for machining from a large central computer that stores and processes operational procedures, they are said to be under direct numerical control (DNC).

Adaptive control. Improvements in CNC machine tools depend on the refinement of adaptive control, which is the automatic monitoring and adjustment of machining conditions in response to variations in operation performance. With a manually controlled machine tool, the operator watches for changes in machining performance (caused, for example, by a dull tool or a harder workpiece) and makes the necessary mechanical adjustments. An essential element of NC and CNC machining, adaptive control is needed to protect the tool, the workpiece, and the machine from damage caused by malfunctions or by unexpected changes in machine behaviour. Adaptive control is also a significant factor in developing unmanned machining techniques.

One example of adaptive control is the monitoring of torque to a machine tool's spindle and servomotors. The control unit of the machine tool is programmed with data defining the minimum and maximum values of torque allowed for the machining operation. If, for example, a blunt tool causes the maximum torque, a signal is sent to the control unit, which corrects the situation by reducing the feed rate or altering the spindle speed.

Machining centres. A further development in the automation of machine tools is the "machining centre," usually a vertical milling machine fitted with automatic tool-changing facilities and capable of several axes of con-

trol. The tools, of which there can be more than 100, are generally housed in a rotary magazine and may be changed by commands from the machine tool program. Thus, different faces of a workpiece can be machined by a combination of operations without moving it to another machine tool. Machining centres are particularly suitable for the batch production of large and complex components requiring a high degree of accuracy.

Computer-aided design and computer-aided manufacturing (CAD/CAM). The technology of CNC machine tools has been enhanced by parallel advances in CAD/CAM. In the first NC systems, CAD and CAM were regarded as separate functions. Gradually they have come to be treated as an integrated operation, with manufacturing processes being considered at the product design stage.

CAD enables designers to use computers to analyze and manipulate design data. Using a graphics workstation or computer terminal to display three-dimensional figures, the designer can examine a proposed design from different angles, in various cross sections, and in many sizes. Details of the completed design are transferred to a second terminal on which a set of engineering drawings can be produced. All aspects of the design are closely scrutinized at this stage, and, after final changes are made, the finished, fully dimensioned design is drawn on a specialized computer printer called a plotter.

CAD/CAM systems also allow design data to be stored in numerical (digitized) form, from which machine-control tapes and disks may be prepared directly. The CAD and CAM systems may then be linked by computer-assisted part programming. With this technique a CAD system can produce a geometrical profile of a required component as, for example, a series of connected points. The position of each point, and the ways in which it can be reached by movements of the tool, is fed to the computer. After calculating the necessary tool movements, the computer develops a complete machining program for the part to be manufactured on the CNC machine.

Robots. The utilization of CNC machine tools has been stimulated by the introduction of robots—devices designed to move components, tools, and materials by specific motions and through defined paths. Robots can have memories (stored sets of instructions) and may be equipped with mechanisms that automatically perform many tasks such as the loading and unloading of parts, assembly, inspection, welding, painting, and machining. The main features of a robot are illustrated in Figure 17. Its arm and wrist move like those of humans, each axis of motion being driven by an electric or hydraulic motor. The wrist is usually fitted with an "end effector," an element to which devices are added to help perform specific required operations. These devices can include a two- or three-finger gripper for material handling, a power tool for drilling, or an arc-welding gun. "Intelligent" robots are also available. These have end effectors fitted with tactile or visual sensing devices that can determine the proximity of the object to be manipulated or machined.

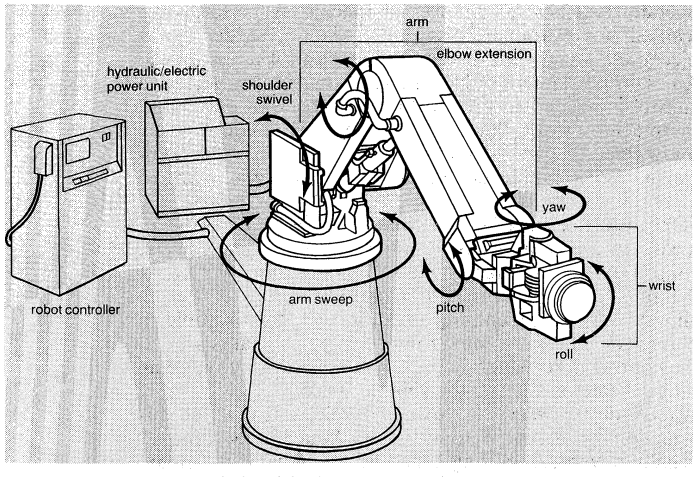

Figure 17: Industrial robot.

Flexible manufacturing system (FMS). A group of manufacturing cells linked by an automatic material handling system and a central computer is called a flexible manufacturing system. The computerized coordination of FMS enables components to be produced at very low costs, even when only small quantities are to be made. The main feature of FMS is its ability to switch from the machining of one component to another (or between separate manufacturing processes) without undue interruption. Each machine control unit stores many part-producing programs in its computer memory. The FMS master computer uses direct numerical control (DNC) to select and activate these programs as they are needed during the manufacturing process. As the master computer governs the supply of workpieces to the machine, the part program controls individual tooling. If a variety of machining operations are needed, a large number of tools may have to be carried: some milling operations, for example, require 60 to 100 tools.

Computer-integrated manufacturing. Computers have come to be used in all stages of manufacture: design, scheduling, management, manufacturing, and testing. The integration of these phases of computer involvement is called computer-integrated manufacturing. For further information about robots, see the articles AUTOMATION and COMPUTERS.

NONCONVENTIONAL METHODS OF MACHINING

Traditional machining processes work on the principle that the tool is harder than the workpiece. Some materials, however, are too hard or too brittle to be machined by conventional methods. The use of very hard nickel-based and titanium alloys by the aircraft engine industry, for example, has stimulated nonconventional machining methods, especially "electrical methods."

Electrical methods of machining. Some machining methods rely on electrical phenomena—rather than mechanical means—for cutting and machining workpieces.

Electron-beam machining (EBM). The EBM technique is used for cutting fine holes and slots in any material. In a vacuum chamber, a beam of high-velocity electrons is focused on a workpiece. The kinetic energy of the electrons, upon striking the workpiece, changes to heat, which vaporizes minute amounts of the material. The vacuum prevents the electrons from scattering, due to collisions with gas molecules. EBM is used for cutting holes as small as 0.001 inch (0.025 millimetre) in diameter or slots as narrow as 0.001 inch in materials up to 0.250 inch (6.25 millimetres) in thickness. EBM is also used as an alternative to light optics manufacturing methods in the semiconductor industry. Because electrons have a shorter wavelength than light and can be easily focused, electron-beam methods are particularly useful for high-resolution lithography and for the manufacture of complex integrated circuits. Welding can also be done with an electron beam, notably in the manufacture of aircraft engine parts.

Electrical-discharge machining (EDM). EDM involves the direction of high-frequency electrical spark discharges from a graphite or soft metal tool, which serves as an electrode, to disintegrate electrically conductive materials such as hardened steel or carbide. The electrode and workpiece are immersed in a dielectric liquid, and a feed mechanism maintains a spark gap of from 0.0005 to 0.020 inch (0.013 to 0.5 millimetre) between the electrode and the workpiece. As spark discharges melt or vaporize small particles of the workpiece, the particles are flushed away, and the electrode advances. The process is accurate, but slow, and is used for machining dies, molds, holes, slots, and cavities of almost any desired shape. In CNC wire machining, a thin copper wire is used as the tool for cutting out two- and three-dimensional fretwork profiles.

Electrochemical machining (ECM). ECM resembles electroplating in reverse. In this process metal is dissolved from a workpiece with direct current at a controlled rate in an electrolytic cell. The workpiece serves as the anode and is separated by a gap of 0.001 to 0.030 inch (0.025 to 0.75 millimetre) from the tool, which serves as the cathode. The electrolyte, usually an aqueous salt solution, is pumped under pressure through the inter-electrode gap,

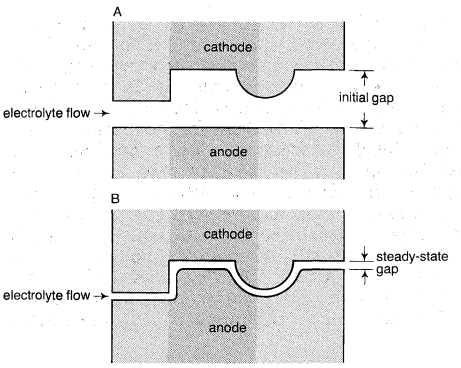

Figure 18: *Electrochemical machining (ECM).* (A) Initial electrode configuration and (B) final electrode configuration.

From J.A. McGeough, *Principles of Electrochemical Machining* (1971), Chapman and Hall, London

thus flushing away metal dissolved from the workpiece. As one electrode moves toward the other to maintain a constant gap, the anode workpiece is machined into a complementary shape (see Figure 18). The advantages of ECM are lack of tool wear and the fact that a softer cathode tool can be used to machine a harder workpiece. Applications of ECM can be found in the aircraft engine and automobile industries, where the process is used for deburring, drilling small holes, and machining extremely hard turbine blades.

Other versions of ECM include electrolytic grinding, which includes about 90 percent ECM with 10 percent mechanical action; electrochemical arc machining (ECAM), in which controlled arcs in an aqueous electrolyte remove material at a fast rate; and capillary drilling, in which acid electrolytes are used to machine very fine holes.

Ion beam machining (IBM). In IBM a stream of charged atoms (ions) of an inert gas, such as argon, is accelerated in a vacuum by high energies and directed toward a solid workpiece. The beam removes atoms from the workpiece by transferring energy and momentum to atoms on the surface of the object. When an atom strikes a cluster of atoms on the workpiece, it dislodges between 0.1 and 10 atoms from the workpiece material. IBM permits the accurate machining of virtually any material and is used in the semiconductor industry and in the manufacture of aspheric lenses. The technique is also used for texturing surfaces to enhance bonding, for producing atomically clean surfaces on devices such as laser mirrors, and for modifying the thickness of thin films and membranes.

Laser machining (LM). LM is a method of cutting metal or refractory materials by melting and vaporizing the material with an intense beam of light from a laser. Drilling by laser, although costly in energy since material must be melted and vaporized to be removed, is used to cut small holes (0.005 to 0.05 inch [0.13 to 1.3 millimetres]) in materials that are too difficult to machine by traditional methods. A common application is the laser drilling of diamonds to be used as dies for drawing wire. Lasers also are used to drill and cut ceramics and substrates for integrated circuits; the aircraft industry uses CNC-controlled lasers to cut profiles and to drill holes in engine parts.

Plasma arc machining (PAM). PAM is a method of cutting metal with a plasma-arc, or tungsten inert-gas-arc, torch. The torch produces a high-velocity jet of high-temperature ionized gas (plasma) that cuts by melting and displacing material from the workpiece. Temperatures obtainable in the plasma zone range from 20,000° to 50,000° F (11,000° to 28,000° C). The process may be used for cutting most metals, including those that cannot be cut efficiently with an oxyacetylene torch. With heavy-duty torches, aluminum alloys up to six inches (15 centimetres) thick and stainless steel up to four inches (10 centimetres) thick have been cut by the PAM process. The process is used for the profile cutting of flat plate, for cutting grooves in stainless steel, and, on lathes, for turning large, hardened steel rolls.

Other methods of machining. *Ultrasonic machining (USM).* In USM, material is removed from a workpiece with particles of abrasive that vibrate at high frequency in a water slurry circulating through a narrow gap between a vibrating tool and the workpiece. The tool, shaped like the cavity to be produced, oscillates at an amplitude of about 0.0005 to 0.0025 inch (0.013 to 0.062 millimetre) at 19,000 to 40,000 hertz (cycles per second). The tool vibrates the abrasive grains against the surface of the workpiece, thus removing material. Ultrasonic machining is used primarily for cutting hard, brittle materials that may be conductors of electricity or insulators. Other common applications of USM include cutting semiconductor materials (such as germanium), engraving, drilling fine holes in glass, and machining ceramics and precious stones.

A modified version of the process is ultrasonic twist drilling, in which an ultrasonic tool is rotated against a workpiece without an abrasive slurry. Holes as small as 80 micrometres have been drilled by this type of USM.

Chemical machining (CHM). This nonelectrical process removes metal from selected or overall areas by controlled chemical action. Masking tape can be used to protect areas not to be removed. The method is related to the process used for making metal printing and engraving plates. Two types of chemical machining processes include chemical blanking, which is used for cutting blanks of thin metal parts, and chemical milling, which is used for removing metal from selected or overall areas of metal parts.

Photochemical machining (PCM). PCM is an extension of CHM that uses a series of photographic and chemical etching techniques to produce components and devices in a wide range of metals, especially stainless steel.

Water-jet machining. In the water-jet machining process, water is forced through tiny nozzles under very high pressures to cut through materials such as polymers, brick, and paper. Water-jet machining has several advantages over other methods: it generates no heat, the workpiece does not deform during machining, the process can be initiated anywhere on the workpiece, no premachining preparation is needed, and few burrs form during the process. An abrasive is occasionally added to the water to improve the rate of material removal, especially in finishing work. The offshore industry uses seawater as the working fluid when applying this technique.

(W.J.McC./J.A.McG.)

BIBLIOGRAPHY

Hand tools: The literature on hand tools is generally fragmented and without a single comprehensive treatment. Archaeological and anthropological information concerning the earliest tools may be found in: CHESTER S. CHARD, *Man in Prehistory,* 2nd ed. (1974); ROBERT J. BRAIDWOOD, *Prehistoric Men,* 8th ed. (1975); KENNETH P. OAKLEY, *Man the Tool-Maker,* 6th ed. rev. (1972); and F. CLARK HOWELL, *Early Man* (1973). Specific treatments are given in FRANÇOIS BORDES, *The Old Stone Age* (1968; orginally published in French, 1961); and JACQUES BORDAZ, *Tools of the Old and New Stone Age* (1970). The rise of metal tools is found in LESLIE AITCHISON, *A History of Metals,* 2 vol. (1960); and THOMAS A. RICKARD, *Man and Metals,* 2 vol. (1932, reprinted in 1 vol. 1974). From Roman times onward, WILLIAM L. GOODMAN, *The History of Woodworking Tools* (1964, reissued 1976), is definitive. R.A. SALAMAN, *Dictionary of Tools Used in the Woodworking and Allied Trades, c. 1700–1970* (1975), is a comprehensive and very well-illustrated account. HENRY C. MERCER, *Ancient Carpenters' Tools: Together with Lumbermen's, Joiners', and Cabinet Makers' Tools in Use in the Eighteenth Century,* 5th ed. (1975), should not be missed; and PETER C. WELSH, *Woodworking Tools, 1600–1900* (1966), PAUL B. KEBABIAN and WILLIAM C. LIPKE (eds.), *Tools and Technologies: America's Wooden Age* (1979), and ALDREN A. WATSON, *Hand Tools: Their Ways and Workings* (1982), include a wealth of illustrations. CHARLES SINGER *et al.* (eds.), *A History of Technology,* 8 vol. (1954–84); and MAURICE DAUMAS (ed.), *Histoire générale des techniques,* 5 vol. (1962–79), give wide but unconnected treatments. The first three volumes of Daumas's work cover the history of technology to the middle of the 19th century and have been published in English as *A History of Technology & Invention: Progress Through the Ages,* 3 vol. (1969–79). Illustrated by original drawings, ERIC SLOANE, *A Museum of Early American Tools* (1964); and EDWIN TUNIS, *Colonial Craftsmen and the Beginnings of American Industry* (1965), are highly informative because techniques and products of their period are shown in addition to tools. Relevant

articles also may be found in serial publications such as *Technikgeschichte* (quarterly); NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY, *Transactions* (annual); and *Technology and Culture* (quarterly). The EARLY AMERICAN INDUSTRIES ASSOCIATION, *Chronicle* (quarterly), frequently contains articles on the history of hand tools. Many 19th-century books give detailed accounts of tools as well as of processes. Examples are CHARLES HOLTZAPFFEL and JOHN JACOB HOLTZAPFFEL, *Turning and Mechanical Manipulation,* 5 vol. (1843–52). See also the article entitled "Tool" by JOSEPH G. HORNER in the 11th edition of the *Encyclopædia Britannica,* vol. 27, pp. 14–47, which contains a well-illustrated account of 19th-century developments in both hand and machine tools.

Machine tools: Good sources of general information on the subject are VICTOR E. REPP and WILLARD J. MCCARTHY, *Machine Tool Technology,* 5th ed. (1984); and E. PAUL DEGARMO, J. TEMPLE BLACK, and RONALD A. KOHSER, *Materials and Processes in Manufacturing,* 6th ed. (1984). The most authoritative, although highly technical, source for all phases of machine tools is the AMERICAN SOCIETY FOR METALS, *Machining,* ed. by TAYLOR LYMAN (1967). A useful source on the history of machine tools is L.T.C. ROLT, *A Short History of Machine Tools* (1965). VICTOR E. REPP, O.A. LUDWIG, and WILLARD J. MCCARTHY, *Metalwork: Technology and Practice,* 7th ed. (1982), is a good text for the secondary school level. A comprehensive source of technical data on machine tools is ERIC OBERG, FRANKLIN D. JONES, and HOLBROOK L. HORTON, *Machinery's Handbook,* 22nd ed. (1984).

Electrical methods of machining: A.E. DE BARR and D.A. OLIVER (eds.), *Electrochemical Machining* (1968), also covers other methods of electrical machining; JOHN F. WILSON, *Practice and Theory of Electrochemical Machining* (1971), is based on industrial experience, whereas J.A. MCGEOUGH, *Principles of Electrochemical Machining* (1974), deals for the most part with research findings. Detailed discussions on laser and ultrasonic machining can be found in F.T. ARECCHI and E.O. SCHULZ-DUBOIS (eds.), *Laser Handbook,* 5 vol. (1972–85); MORRIS COHEN (ed.), *Materials Science and Engineering: Its Evolution, Practice, and Prospects* (1978); see also L.D. ROZENBERG (ed.), *Physical Principles of Ultrasonic Technology,* 2 vol., trans. from the Russian (1973). D.M. ALLEN, *The Principles and Practice of Photochemical Machining and Photoetching* (1986), is a useful account of photochemical machining (PCM) and related techniques.

Computer-aided machining: SEROPE KALPAKJIAN, *Manufacturing Processes for Engineering Materials* (1984); and GEOFFREY BOOTHROYD, *Fundamentals of Metal Machining and Machine Tools* (1975), are both very informative sources on computer-aided machining as they relate to machine tool technology. For a more technical work, see RAYMOND SHAH, *NC Guide: Numerical Control Handbook,* 2nd ed. (1979). Two useful introductory texts are MIKELL P. GROOVER and EMORY W. ZIMMERS, JR., *CAD/CAM: Computer-Aided Design and Manufacturing* (1984); and DAVID GIBBS, *An Introduction to CNC Machining* (1984).

Toronto

Toronto is situated on the northern shore of Lake Ontario; it is Canada's most populous metropolitan area, the seat of government of the Canadian province of Ontario, and the financial and commercial heart of Canada. It is little more than an hour's flying time from both New York City and Chicago. Since the 1950s Toronto has grown phenomenally from a rather sedate provincial town—"Toronto the Good"—to a lively, thriving, cosmopolitan metropolitan area.

Physical and human geography

THE LANDSCAPE

The city layout. The site of the city is almost uniformly flat, although three to four miles (five to six kilometres) inland there is a fairly sharp rise of some 40 feet (12 metres)—the shoreline elevation of the former glacial Lake Iroquois. Streets are laid out in a grid, although the pattern is modified to some extent by diagonal roads roughly following the shoreline. The central business areas are located around Bloor and Yonge streets and Yonge and Queen streets. The central financial district, with its numerous insurance and banking offices and the Toronto Stock Exchange, is in the vicinity of King and Bay streets, south of the old City Hall (1899).

The city skyline is dominated by the CN Tower (1,815 feet), and the Toronto–Dominion Centre, Commerce Court, and First Canadian Place, each of which is more than 50 stories high. Other notable buildings include the new City Hall (1958), Eaton Centre, the Metropolitan Toronto Library, the Ontario Science Centre, and Roy Thomson Hall, noted for its excellent acoustics. Extensive new housing and mixed-use projects, together with the restoration and rehabilitation of heritage buildings, have brought extraordinary vitality to the urban core.

Toronto is a Great Lakes port and, through the St. Lawrence Seaway, an ocean port as well. It handles more than 2,500,000 tons of freight annually. The lakefront is separated from the downtown area by railway tracks and an expressway. Ferry service connects the dock area to the Toronto Islands, about half a mile offshore, which have yacht clubs, a small airport, recreational facilities, and a residential community.

North of the central business district is the fashionable Yorkville–Cumberland boutique shopping area, to the south of which are Queen's Park, the Ontario Parliament Buildings, and the University of Toronto. Large expanses of grass and tall shade trees make this a pleasant area, complementing the ravines that form so important an element in the metropolitan parks system. One of the most attractive residential areas in Toronto is Rosedale, an older neighbourhood of dignified houses and winding, tree-lined streets quite close to the downtown centre, which itself contains many attractive streets of modest, well-designed houses.

Climate. Toronto's geographical situation on Lake Ontario modifies the climate somewhat, although winter temperatures may frequently drop below zero. Heavy snowfall, however, is rare even in January and February, the coldest months. July and August are humid, with temperatures in the 90s (°F; 30° C).

THE PEOPLE

During part of the 1950s and 1960s Toronto became one of the fastest growing urban areas in North America. The influx of European immigrants transformed the character of the city: traditionally Protestant and largely of British origin, by 1961 less than half the inhabitants of the central

Ontario Place in Toronto, designed by Eberhard Zeidler and completed in 1971.
© Mike Dobel—Stockphotos, Inc.

city were of British extraction. During the 1970s and early 1980s European immigrants were augmented by large numbers from the West Indies and Asia.

THE ECONOMY

Industry and trade. Toronto enjoys the economic benefits of its position on the Great Lakes and of its development as a rail and trucking centre. It is readily accessible to major industrial centres in the United States and to oceangoing shipping. As the capital of Canada's richest and most populous province, the city has a widely diversified economy. Ontario produces more than half of Canada's manufactured goods and most of its manufactured exports; it has immense resources of raw materials—minerals, timber, water, agricultural products, and hydroelectric power. The Toronto Stock Exchange is, in value of trading, one of the largest stock exchanges in North America.

Transportation. Policy for public transportation is coordinated by the Metropolitan Toronto Transit Commission (TTC). The modern, efficient subway has two major lines, one running north–south and the other east–west. Additional lines operate during rush hours. Seventeen miles west of the centre of the city is Toronto International Airport, Canada's busiest air terminal.

ADMINISTRATIVE CONDITIONS

The Municipality of Metropolitan Toronto is governed by the Metropolitan Council. Each council member serves a three-year term and is also a member of a city or borough council. The responsibilities of the council include housing, finance, police protection, education, water supply, sewage disposal, and health and welfare provisions. Additional services for the city of Toronto itself are provided by a mayor and a city council.

CULTURAL LIFE

The city is an important cultural centre. The Toronto Symphony Orchestra and other musical groups have an international reputation. There are three major theatres, together with many small experimental theatres. The Art Gallery of Ontario and the Royal Ontario Museum have excellent collections, and there are numerous privately owned galleries. Other attractions include the Ontario Science Centre, with its imaginative working exhibits, and Ontario Place, a large complex of recreational facilities on man-made islands that are an extension to the permanent Canadian National Exhibition. The city has several institutions of higher learning—the University of Toronto with its colleges, Erindale and Scarborough, York University with Glendon College, and Ryerson Polytechnical Institute. The Ontario College of Art offers a wide diversity of excellent programs. A new zoo, opened in 1975; dozens of excellent restaurants, boutiques, and movie theatres; and the Toronto Maple Leafs (ice hockey), the Argonauts (football), and the Blue Jays (baseball) all add to the colour and vitality of this vigorous community.

There is an active winter season of cultural activities, with a rich fare of concerts, theatre, opera, ballet, and films. Lectures, seminars, evening classes, and meetings of all kinds cover a multitude of subjects, and the religious life of the community is sustained by a variety of churches, synagogues, mosques, temples, and other meeting places. Many ethnic groups organize traditional festivals, balls, entertainments, and social activities.

In 1967 the Metropolitan Toronto Corporation assumed responsibility for the Canadian National Exhibition—reputed to be the world's largest annual exhibition—which was first launched in 1879 as the Toronto Industrial Exhibition. An international air show; agricultural, animal, and flower displays; theatrical and musical events; and a fairground attract millions of visitors in the late summer each year. The permanent buildings are used for trade shows and other special events between seasons.

The Metropolitan Toronto Parks Department administers approximately 7,000 acres (2,800 hectares) of parkland, and ambitious plans have been made for the development of Toronto's waterfront. The Metropolitan Toronto and Region Conservation Authority is an important joint provincial-municipal agency concerned with the development of recreational areas, flood control, and the conservation of existing woodlands and waterways. It is responsible for the implementation of a large part of Toronto's regional waterfront-development plan. The authority also offers assistance and technical advice to rural landowners.

Local recreational areas

Toronto is the main regional tourist centre serving the Muskoka Lakes, the Haliburton Highlands, and Georgian Bay, all magnificent lakeland and forest areas with fine hunting, fishing, and camping facilities. There has been a remarkable increase in winter sports, and although Ontario's highest point is only 2,183 feet (665 metres), good skiing facilities are available within easy reach of the city. Algonquin Provincial Park is some 163 miles to the north, Niagara Falls is 80 miles south, and the city is surrounded by beautiful rolling farmland, with well-marked sites of historical and architectural interest. Camping, cottaging, boating, and fishing in summer and skiing, ice hockey, and curling in winter are the most popular forms of outdoor recreation.

History

EARLY SETTLEMENT

The first known settlement in the Toronto area, Teiaiagon, inhabited first by the Seneca and later by the Mississauga

Indians, was on the east bank of the Humber River. In the 17th century it became a trading post, strategically situated at the crossing of ancient Indian trails going west to the Mississippi and north to Lake Simcoe and beyond into vast wilderness areas. These land and water routes were followed by explorers, fur traders, missionaries, and others intent upon opening up and exploiting the resources of the Great Lakes region.

By the mid-18th century the name Toronto had come to be commonly used for one of three tiny forts built (1720–50) in the area by the French to defend their trade with the Indians against English and other European competitors. The French were defeated in 1759 and the forts were subsequently destroyed, but the settlement survived as a trading post.

At the end of the Seven Years' War with France (1763), Canada came under British sovereignty; during and after the U.S. War of Independence it was a haven for those American colonists who preferred British rule to that of the new Republic. Some 40,000 United Empire loyalists are said to have settled in the Great Lakes and St. Lawrence areas at this time, and during the 19th century large numbers of immigrants came from Great Britain.

In 1787 Lord Dorchester, governor in chief of Canada, opened negotiations with three Indian chiefs for the purchase of a site for the future capital of Ontario; about 250,000 acres (100,000 hectares) fronting the lake were acquired in exchange for £1,700, bales of cloth, axes, and other trading goods.

Ontario's first parliament met in 1792 at Niagara, but in 1793 Col. John Simcoe, lieutenant governor of Upper Canada, selected the present site of Toronto for his capital because of its fine harbour, strategic location for defense and trade, and the rich potential of its wilderness hinterland. He changed its name from Toronto to York; two years later (1795) Ontario's capital consisted of only 12 cottages and a small military establishment on the edge of the wilderness.

Occupation by U.S. forces in 1813

While the British were engaged with France in Europe, the United States declared war on Britain; and York, with a population of 700, was practically defenseless. It was taken in April 1813 and was pillaged and occupied by U.S. forces for 11 days before being retaken by the British. The Speaker's Mace was carried off but was returned in 1934; the Royal Standard is still in the U.S. Naval Academy, Annapolis, Maryland.

Economic depression in Great Britain following the Napoleonic Wars drove many overseas, and York's population increased from 720 (1816) to about 9,000 in 1834, when the city was incorporated and the old name of Toronto restored. In 1849 there was a disastrous fire that destroyed some 15 acres of the downtown area, including St. James' Cathedral, St. Lawrence Market, and many offices, stores, and warehouses, but the city soon recovered.

EVOLUTION OF THE MODERN CITY

Rapid development followed the coming of the Grand Trunk and Great Western railways in the 1850s, and for a decade prosperity was enhanced by a treaty with the United States (1854) that gave certain of Canada's products free entry to markets south of the border. The timber resources of the province were exploited, and large areas of land were converted to farming. Thus, Toronto grew rapidly as an industrial, trading, and distributing centre; its population was 45,000 in 1861, 208,000 in 1901, and 522,000 in 1921.

Prosperity and security were reflected in civic improvement, great building activity, and cultural progress. Between the city's incorporation (1834) and Canada's national confederation under the British North America Act of 1867, many of Toronto's buildings of historical and architectural importance were constructed, including the new St. James' Cathedral, St. Lawrence Hall, and University College (now part of the University of Toronto), all of which are still extant. The Grand Opera House (since demolished) was opened in 1874, a stolid successor to the numerous small theatres of midcentury that were mostly converted barns. King's College (founded 1827), later to become the University of Toronto, was constructed in 1843 on the site of the present Ontario Parliament Buildings (1886).

During the 50 years from 1834 to 1883, the city maintained its boundaries virtually unchanged. Some reclamation near the lake improved lakeshore properties and docking facilities. Largely by the annexation of adjacent villages and towns, the area of the city was doubled by 1900 and doubled again by 1920. In 1930 the metropolitan area included the central city, four towns (Leaside, Mimico, New Toronto, and Weston), three villages (Forest Hill, Long Branch, and Swansea), and five townships (Etobicoke, East York, North York, Scarborough, and York).

The Great Depression of the 1930s caused severe financial problems for suburban Toronto. Capital debt payments could not be met, and expenditure on public services—sewage and piped water supply in places remote from the lake, for example—had to be postponed. A rapid increase in population after World War II added to the municipal burden, and many solutions were investigated. In 1953 the Ontario Municipal Board recommended for the 13 municipalities the establishment of a federated form of government unique in North America. The Municipality of Metropolitan Toronto Act was passed, and a 25-member Council of Metropolitan Toronto met for the first time on January 1, 1954. One of the first tasks of the council was to find ways and means of dealing with common major problems by united action, while also permitting local matters to be handled independently. Since the joint credit of the combined municipalities was much greater than the sum of their credits as individual authorities, financing was greatly simplified. A common level of assessment and tax rate on property—the main source of revenue—was agreed upon by each municipality. A most significant feature of the system was that members of the Metropolitan Council were appointed by virtue of their election to office either as mayors, aldermen, or controllers of a particular municipality, thus ensuring a high degree of coordination and good communication between the central body and the local municipalities.

Uniting of the metropolitan area

The Metropolitan Council worked well: it resolved many of the difficult sewage and water problems; it greatly improved transportation by constructing expressways and roads, a new airport terminal building (1962), and an excellent subway; it authorized the construction of new schools and the renovation of old ones; and it introduced a regional parks system in an attempt to control future development.

Administrative reorganization

In 1967 the Corporation of Metropolitan Toronto was reorganized. The 13 municipalities were reduced to six, and the council was increased to 33 members. Later legislation gave the boroughs the option to rename themselves cities. The council considerably extended its responsibilities in education and the social services, adding, for example, urban renewal, waste disposal, and ambulance and library services. In 1975 and 1980 the council was again increased in size, and it added to its jurisdiction such problems as the control of urban development and housing for the elderly.

BIBLIOGRAPHY. The Municipality of Metropolitan Toronto publishes documents and statistical reports about constituent departments, and the City of Toronto Planning Board produces studies on developments as, for example, *The Central Waterfront Information Base Study, Uses* (1977). Torts

Tort is a legal term used by common-law jurisdictions to cover a variety of harmful behaviour, from physical attack on one's person to interference with one's goods or use and enjoyment of one's land, economic interests, and honour, reputation, and privacy. Other legal systems use different terms for this wide and amorphous area of the law. The Germans talk of unlawful acts; the French-inspired systems use interchangeably the terms *délits* (and *quasi-délits*) and civil responsibility. Despite differences of terminology, however, this area of the law is primarily concerned with liability for behaviour that the legal order regards as socially unacceptable, typically warranting the award of damages to the injured party. It is broadly true to say that most western European and common-law systems tend to regard as actionable the same factual situations. But if the results are often quite similar, the arrangement of the law and the methodology often differ significantly. The German Civil Code has a strong tendency to abstraction and systematization, displaying its university origins and contrasting sharply with the more casuistic (here, law deriving from authority based on cases considered one-by-one as opposed to law deriving from a general principle) and judge-made law of the common-law systems. In between there are the 19th-century codifications, which are the products of the natural school of law and which have adopted manifesto-like provisions in their codes. Typical of this approach is the French Civil Code of 1804; much contemporary French law results from interplay between judicial activity and doctrinal writing.

Tort law, until recently the junior partner to contract law in the law of civil obligations, has since World War II expanded everywhere, though especially in continental Europe. At the same time, criticism of it has led to its replacement either partially by specialized schemes or, in rare cases, by complete systems of accident compensation. Criticism has also provoked serious discussion about the impact of the welfare state, modern insurance practices, and the importance of economic analysis in the proper development of the law.

FUNCTIONS OF TORT

Throughout its long history tort has pursued different aims: punishment, appeasement, deterrence, compensation, and efficient loss spreading of the cost of accidents. None offers a complete justification; all are important, though at different stages one may have been more prominent than the rest.

Punishment and appeasement. Originally tort and criminal law were indistinguishable, and even when the two branches began to acquire independent identities the former remained for a very long time in the shadow of the latter. Offenses against the community and the king's interests increasingly became the subject of criminal law, whereas wrongs against the individual came to be dealt with by the emerging (or, in the case of continental Europe, reemerging Roman-inspired) law of torts. Early tort law, however, was concerned only with the most serious kinds of wrongs—bodily injury, damage to goods, trespass to land—and not until the 19th century did it cover such conduct as intentional infliction of economic loss and, in modern times, negligently inflicted economic loss or other violations of subtler interests. This independent growth resulted from the need to buy off private vengeance and to strengthen law and order during the Middle Ages. Punishment and appeasement are no longer major aims. Nevertheless, some common-law jurisdictions—notably in the United States—retain the element of punishment for certain types of tortious conduct. These punitive or exemplary damages, as they are sometimes called, are in England limited to three rather narrow instances, of which perhaps the most difficult is the case of an activity calculated by the defendant to make a profit (a term not confined to moneymaking in the strict sense). In these instances it is felt that "it is necessary to teach the wrongdoer that tort does not pay" by making him not only "compensate" the plaintiff for the latter's "loss" but also disgorge any gain he may have made from his conduct. That this is right few would doubt. Less defensible, however, is the resulting windfall for the plaintiff and the loss of important procedural safeguards for the defendant where "punishment" is meted out by an unpredictable and unguided jury. Civil-law systems have, by contrast, taken a hostile attitude toward penal damages in civil actions, though there are limited instances in the German law of tort (privacy) and French law of contract (*astreinte*) in which a penal element is allowed to creep into the civil award.

Limited instances of punitive damages

Deterrence. In its modern, economic sense, deterrence aims at reducing the number of accidents by imposing

a heavy financial cost on unsafe conduct and promoting economic efficiency. A distinction is necessary between specific and general deterrence. The former depends largely on the admonitory effect of tort law. This, however, is limited where insurance cushions the defendant from the economic consequences of an adverse judgment (though insurance premiums may subsequently be increased); and it almost completely evaporates in instances such as road traffic accidents where harm is statistically inevitable and in most cases results from momentary inattention, the occurrence of which no tort award can ever prevent. Tort law is, therefore, in some cases a second-best means for preventing accidents.

Calabresi's theory of general deterrence

Very different is the theory of general deterrence principally argued by the U.S. legal scholar Guido Calabresi in *The Cost of Accidents* (1970). In Calabresi's words, general deterrence involves deciding

> what the accident costs of activities are and letting the market determine the degree to which, and the ways in which, activities are desired given such costs. Similarly it involves giving people freedom to choose whether they would rather engage in the activity and pay the costs of doing so, including accident costs, or, given the accident costs, engage in safer activities that might otherwise have seemed less desirable.

Calabresi's approach reflects the belief that the market mechanism not only achieves the optimum allocation of resources but also ensures that most of society's decisions vis-à-vis accident-causing activities are left to the cumulative choice of individuals rather than to imposition by government.

But is it possible to rely on the degree of rationality in human behaviour seemingly presupposed by economic theories? And is it always possible to identify the activity that causes the accident? For example, a tool defectively manufactured by A injures one of B's employees who has been supplied with it by B. Whose activity has caused this injury? And in accidents involving automobiles and pedestrians can such an economic choice be made? Calabresi treats the motorist as the best cost avoider on the grounds that he has both better information and the means of reducing such accidents, but are such assumptions truly tenable? Finally, general deterrence so conceived cannot provide all the answers, as Calabresi is well aware. Wider considerations of fairness and justice also obtain, and it would be a mistake to assert that certain antisocial activities can and will be allowed so long as those taking part in them are prepared to pay for them. Moreover, collective judgments are often reached, and an infinite number of calculated risks determined, according to political criteria rather than cost-benefit equations.

Compensation as the most important function of tort law

Compensation. Compensation is the most important function of tort law, and modern insurance practice has made it easier to satisfy the injured without financially crushing the injurer. The welfare state, however, is now the main source of accident compensation. But even where tort law plays a major compensatory role—for example, in the most serious cases of injury—it does not function with great efficiency. For though tort lawyers often regard tort as the compensation system that caters best to the particular victim on the basis of the pre-accident situation and prognosis of his future, it nonetheless remains expensive, capricious, and dilatory. The Royal Commission on Civil Liability and Compensation for Personal Injury (1978) in England estimated that it cost 85 pence to award £1 of net benefits to the victim. (The administrative cost of the New Zealand Scheme is apparently less than 10 percent.) The tort system is capricious in that compensation may depend on finding a tort-feasor (wrongdoer) and credible witnesses, not to mention a good lawyer. Delay can also produce injustice, especially since it tends to benefit wealthy defendants (usually insurance companies) who can sometimes delay payments in the hope that such delay will wear down a plaintiff so that he accepts a low settlement. Difficulties of this kind have led some authors to refer to the tort law as a "forensic lottery" and have given rise to remedial legislation in areas particularly affected, such as automobile accidents. Most importantly, they have led many jurists to reconsider the utility of modern tort law.

Loss spreading. Compensation in its crudest form meant that the cost of an accident was shifted from the victim to the tort-feasor. For a long time the only plausible excuse for such a shift was deemed to be the tort-feasor's fault. Certainly it seemed right to make wrongdoers pay. The corollary, that he who is not at fault need not pay, also appealed to 19th-century judges and jurists, who were often more concerned with shielding nascent industries from the crushing costs of litigation than with compensating the growing number of such industries' victims. Though the first argument still has its appeal, the second has lost cogency given the modern insurance system. This has revolutionized tort reasoning, for victims can now be compensated without tort-feasors' being ruined financially. It thus helps erode the requirement of fault, while strict liability correspondingly proliferates (see below *Liability without fault*). Finally, where liability without fault has not been introduced in an open manner, such notions as fault, foreseeability, and causation become stretched in an attempt to do justice to the victim while allegedly remaining faithful to a fault-based law of torts. It is only in recent times that Anglo-American courts have tended to refer openly to such considerations, and they have been active not only in shifting the loss but also in trying to pin it on the person who is in the best position to spread it.

COMPARATIVE CLASSIFICATION

Although the common law of torts is in many ways wider than the modern European law of delict, it offers similar solutions. For example, in English common law tort serves such modern problems as product liability or liability for negligent statements, whereas French and German law have frequently relied on contractual solutions. In contrast, the German Civil Code has a basic provision excluding compensation for negligently inflicted pure economic loss that, along with a narrow rule of vicarious liability, has encouraged the expansion of the law of contract. Defamation also is regarded primarily as a tort in the common law but as a crime in civil-law systems, although in the latter it is now seen as a potentially important heading of civil liability. A third difference exists between what the common law describes as trespass to land and the tort of nuisance and what civil lawyers have seen primarily as part of the law of immovable property.

PROTECTION OF LIFE, LIMB, AND FREEDOM OF MOVEMENT

Intentional interference. All legal systems offer protection to life, health, and physical integrity, to which they attach great importance. For example, they regard offenses leading to personal injury, such as assault (an act producing in the plaintiff/victim a reasonable expectation of immediate, unlawful force) and battery (the intentional application of unlawful force), as both torts and crimes capable of attracting serious criminal sanctions. The same is true of the complete restriction of the plaintiff's freedom of movement without lawful excuse, which can be actionable both as a tort and as a crime. Complicated rules—usually contained in specific criminal statutes—may, however, remove the unlawful element in some cases (*e.g.*, lawful arrest by a police officer and, in limited instances, by a private citizen). Consent by the victim/plaintiff may also make an otherwise unlawful interference lawful. Consent to the infliction of grievous bodily harm, however, is generally regarded as unacceptable, and consent in the context of negligent medical malpractice suits tends to raise complicated issues to which there exist various legal responses.

Some offenses as both torts and crimes

The importance attached by the modern law to human life and limb is also obvious from the appearance (mainly in the 1960s) of a number of statutory schemes intended to afford redress to victims of crimes of violence (*e.g.*, the English Criminal Injuries Compensation scheme). This is particularly useful in cases where the assailant is not known or not considered worth suing. Compensation comes through funds specifically allotted by Parliament, and the amounts are usually calculated in approximate accordance with normal tort rules.

Most tort rules covering intentionally inflicted personal injury, though important, are nowadays handled by the

criminal courts (sometimes with the plaintiff also appearing as a civil party and claiming damages, as in France). Tort law's main contribution is accordingly found in the numerically more significant negligent interferences with life and physical integrity.

Negligence. The conceptual approaches of the common-law, French, and German-inspired systems are quite different. In practice, however, where personal injury is concerned, there must be conduct that (a) is intentional or, more frequently, careless; (b) is not justifiable; and (c) leads to ("causes" in a legal sense) harm. Regarding (a), the common-law systems for various reasons have been slower than the civil-law systems in imposing liability for inaction. Nonetheless there is a marked tendency—especially in some jurisdictions in the United States—to relax this individualistic rule, with courts and statutes increasingly imposing liability, especially in the context of rendering assistance to victims of traffic accidents. This change typically imposes a duty to come to the aid of another person. More frequently, however, by-standers are encouraged to act as good samaritans by ensuring that the standard of care they have to display is lowered, thereby shielding them against subsequent actions by ungrateful victims. French law by contrast has since 1945 recognized a general duty to aid a person in physical danger if that can be done without risk to the rescuer.

Good samaritans

The conduct must be culpable—*i.e.,* intentional or, more typically, careless. Modern legal systems resort to objective criteria to determine the requisite standard of care: the defendant must behave as the *bonus pater familias* or, as common lawyers put it, the reasonable man. Both definitions are essentially the anthropomorphic conception of justice enabling courts to adjust the requisite standard according to factors such as the magnitude of the injury, the cost of avoiding it, and the likelihood of its being realized. Nowadays courts tend to treat as carelessness errors that even a reasonable man would make. Here the legal and ordinary meanings of negligence diverge, and this transformation commonly occurs where insurance is obligatory and the courts know that by characterizing the defendant's conduct as negligent they are actually compensating the victim without ruining the defendant.

Finally, the conduct must have caused the plaintiff's hurt. The problem of causation is widely discussed, though the solutions tend to be similar. The approach in Germany (and, at times, in the United States) is more theoretical than in France and England. Both in Germany and in France the test of causation is the "adequate cause," and, though differently understood by these systems, this tends to produce results analogous to those reached by the common-law test of "foreseeability."

Gray areas. Despite every system's concern for human life and health, interference with these interests is not automatically compensated. In some cases the manner of infliction of the harm determines whether compensation is decreed, as with physical injury resulting from some failure to act. In others the nature and timing of the interference influence the extent of tort compensation. Compensation for nervous shock is affected by the former consideration, injury to a fetus by the second.

Legal systems approach these problems differently. The concepts they use to achieve the desired aim of controlled compensation also differ. The German-inspired systems have long behaved as if the solution depended on a proper application of causative theories. Common law has also tended to disguise the real policy issues, judges often giving the impression that the answer depends on foreseeability or the presence or absence of a "duty of care." Actually, the policy reasons for such hesitation are common to all; and the modern tendency—evidenced both by judicial decisions and by doctrinal writing—is to admit this. For example, it is widely recognized that nervous shock can lead to multiplicity of actions—some no doubt based on faked claims. Equally important, however, must be the realization that claims of nervous shock have a low priority in a world of limited resources, a world unable to cope adequately or even at all with many kinds of serious accidents, illness, or disease. Though the present trend both in the United States and in England is to play down the validity of these administrative objections, most systems seem to rely on an impressive variety of rules of thumb in an attempt to limit the number of successful plaintiffs. One such rule depends on the distinction between nervous shock accompanied by physical or psychological manifestations and mere anguish, pain, or grief—the latter remaining uncompensated. Though widely accepted by both common-law and civil-law systems, this rule has been challenged in some U.S. jurisdictions. Another device is to limit compensation to a person within the danger zone; another and more liberal approach allows even those not within the danger zone to recover damages so long as their shock results from seeing or hearing the accident with their own unaided senses. But even here exceptions are being made in the case of "meritorious" plaintiffs. In England a mother who suffered shock through seeing her injured husband and children in the hospital soon after the accident (at which she was not present) was allowed to recover damages (*McLoughlin* v. *O'Brian,* [1983]).

Administrative barriers to compensation

Problems also arise when injury is inflicted to a fetus or when harm is suffered by a female prior to conception. Initially both common-law and civil-law systems were reluctant to sanction damages for prenatal injuries, due to evidentiary reasons—the difficulty of establishing a causal link between accident and fetal injury—and conceptual difficulties connected with the foreseeability of the victim/fetus. The precise legal status of the fetus has also troubled experts in criminal and property law. Damages were first awarded to a fetus in the United States in 1946, in Australia in 1972, in Canada in 1973, and in 1976 in England by the Congenital Disabilities (Civil Liability) Act. Differences remain as to details (*e.g.,* is it enough that the fetus was viable at the time of the injury or must it also be born alive?).

A more recent and even more troublesome development has been the so-called wrongful life and wrongful birth actions, appearing first in the United States (from about the early 1970s) and later in Europe. The harmful event is typically negligence on the part of a doctor who either fails to carry out effectively a sterilization operation, with the result that an "unwanted" child is born (whether impaired in health or otherwise), or fails to diagnose an illness in the mother—*e.g.,* rubella in the early stages of pregnancy—with the result that the opportunity for an abortion is lost and a child is born with impaired health. The child's action (for wrongful life) consists mainly of a claim that but for the doctor's negligence it would not exist at all; the parents' claim (for wrongful birth) is for pain and suffering and, most importantly, the extra costs of rearing the "unwanted" child. The first claim has been rejected by courts of all systems on grounds ranging from the most technical (how does one assess damages?) to the most philosophical (should the court be allowed to decide issues of the value and quality of life?). In reality, however, these and other arguments are excuses for the courts' refusal to come to grips with a serious problem on which there is no general consensus. Though courts have been slow to recognize such claims to children, they are, nonetheless, increasingly willing to grant them special damages connected with their handicap, and judges also are more generously inclined when compensating parents who bring wrongful birth actions.

Courts increasingly favouring special damages

PROTECTION OF PROPERTY

Land and its enjoyment. In modern civil-law systems protection is given by provisions found in both the property and tort sections of the codes. Common-law systems give property owners equivalent protection, but through the law of torts. Thus, direct physical intrusion on the property of another falls within the province of the old tort of trespass. This succeeds without any proof of special damage and is defeated only by rather narrowly defined pleas such as that of imminent necessity (to protect the intruder or his property) or inevitable accident.

Other interests in land, however, receive a more qualified protection and must yield to the test of reasonableness. A miscellany of wrongs, ranging from encroachment of branches or roots to falling tiles or slates from nearby roofs, are covered by the amorphous tort of private nui-

sance, which also covers such interferences as excessive vibrations, noise, smells, and other, more modern, instances of pollution. The emphasis is not on the unreasonableness of the defendant's conduct, as in the tort of negligence, but on the unreasonableness of the interference with the plaintiff's use and enjoyment of his land. The unifying element is the type of harm, and the law's overall aim is to protect an individual's right to enjoy the amenities of his land within the general framework of give and take necessary in an increasingly crowded world.

Balancing competing interests is, therefore, the key feature, and numerous judgments make it a difficult area of law. Its particular interest lies in the fact that along with other branches of the law (*e.g.*, administrative law, criminal law) it can help perform zoning functions in the use of land; however, attempts to utilize it in protecting the environment have not, on the whole, been very successful. In short this is an old tort that has been deployed to cope with modern developments, especially by North American systems.

The gravity of any interference with the plaintiff's land is a major consideration. Older English decisions distinguish between sensible material damage to the land and mere interference with its use and enjoyment. The distinction—not found in any rigid form in civil-law systems—is, however, often unworkable; and to the extent that it reflects a past valuing of tangible forms of property over intangible ones it may be inadequate. The duration of the interference may also be crucial, temporary annoyances being, on the whole, more tolerable. The nature of the locality has also been taken into account. This has a mixed effect, however. It has certainly helped preserve rural and residential areas against intruding noxious trades; but it has also permitted increased industrial pollution.

The more important the purpose of the activity complained about, the greater the tendency to grant effective authorization of the nuisance by legislative fiat. But the effect of the nuisance—typically an oil refinery or airport—on its victims can be catastrophic, often amounting to indirect expropriation of their land. Hence there exist special compensation acts or constitutional clauses providing for compensation.

Chattels. The law affords wide protection to proprietary interests over chattels. Again, this can involve using a proprietary remedy to reclaim goods removed from their rightful owner or to claim damages for chattels affected by a tort-feasor's intentional or negligent conduct. Intentional interference with goods is unusual and therefore receives specialized treatment by some systems. Most cases arise in connection with damaged movables, and here the more modern tort of negligence often applies, the problem usually being the extent of compensation. For example, if an automobile is damaged in a collision its owner will be able to claim from the wrongdoer the cost of repairs. But can such cost be claimed if it exceeds that of purchasing a similar vehicle? And what of extra transportation costs incurred during the period of repair or the expense of hiring an equivalent substitute? Even more controversial are recent claims for such injuries as a lost or ruined holiday following damage to the vehicle. Though the latter claim tends to be regarded as extravagant (and beyond the competence of tort law at least), the others tend to be satisfied, subject to the rules of remoteness and the pervading test of reasonableness (*e.g.*, the victim cannot hire a luxury automobile to replace a damaged economy car). In other instances, however, theoretical doubts may arise as to whether there is interference with property or mere economic loss. For example, if a canal leading to a millpond collapses, trapping but not damaging a vessel, has the owner of the vessel suffered property damage or mere economic loss? Or if a fire forces the police to cordon off an area, depriving its residents of access to their automobiles, have they suffered a property interference? Sometimes courts focus on the duration of the interference and treat prolonged deprivation as equivalent to property damage. In other cases, however, they treat these instances as cases of pure economic loss and reject any claim for compensation.

Majority of cases connected with damaged movables

Negligently inflicted pure economic loss. Economic loss can arise in numerous ways: an employer deprived of the services of a key employee; a child deprived of the financial support of its father; negligent advice given by A to B and relied upon by C; a defective will that deprives someone of a legacy; or road works that damage A's electricity cable, depriving many nearby factories of electrical power.

Common-law and German-inspired systems have here faced enormous difficulties, partly because the courts' reasoning seems to be motivated by administrative considerations: if one such claim is accepted many others will follow. Another difficulty stems from the fact that many of these cases sit uncomfortably on the traditional divide between contract and tort. Yet a third problem arises from the particular structural deficiencies of each system. For example, the narrow rule of vicarious liability found in the German Civil Code, along with its express exclusion of negligently inflicted pure economic loss from the protection of the main tort provision, has led German lawyers to expand their law of contract to provide a remedy in some of the above-mentioned situations. In contrast, a rigid law of contract, especially in the English common law, has led to an expansion—often farfetched and ill-considered—of the law of tort. On the whole, however, German law and common law have come up with fairly similar solutions proclaiming, unlike French law, a general though increasingly ill-defined hostility toward compensating pure economic loss.

PROTECTION OF HONOUR, REPUTATION, AND PRIVACY

The protection of individuals' honour, reputation, and privacy in Western systems is, on the whole, adequate, though varied. One factor is the difficulty of balancing proper protection and free speech. Another is the historical preference of civil-law systems for bringing many instances of defamation under criminal law. Finally, the constitutional environment has had a great impact on this part of tort law. In the United States the tendency since the mid-1960s has been to sacrifice the tort of defamation and human reputation to the First Amendment and free speech. Thus, American law does not allow an action (at any rate where media defendants are involved) unless the plaintiff/victim can prove that the allegation was made with "actual malice"—that is, with knowledge that it was false or with reckless disregard of whether it was false or not. In the United States the plaintiff must also prove that the defendant's statement is false, with the result that many of the traditional common-law defenses are bypassed. The idea behind this is that any contrary decision restricts the constitutional right to free speech.

Importance of constitutional environment

English law by contrast is much more jealous of reputation, though numerous complicated defenses also make sure that free speech is not totally throttled. But in the main the English law of defamation is complex and archaic. The old distinction between libel and slander (defamatory matter in permanent and in transient form, respectively) is preserved; the plaintiff is not entitled to legal aid (with the practical consequence that only wealthy people can afford to sue); the action can succeed without any proof of special damage (giving an unwarranted advantage to corporations, since they thus acquire the benefit of rules designed for human beings); the cause of action does not survive the death of either party; and, finally, juries are often used and are entitled (in one of the rare instances of English law) to award punitive damages. No summary can do justice to this peculiar but important tort; but, according to Tony Weir in *A Casebook on Tort,* it may well be that its defects arise "because it uses a single remedy, the action for damages, in order to perform three distinct purposes: (a) to permit people to clear their reputation from unfounded allegations; (b) to allow people to claim compensation for harm they suffer because others have abused freedom of speech; and (c) to repress gratuitous vituperation, scurrilous disparagement and malignant calumny." Weir goes on to say that "only for (b) are damages the appropriate remedy. For (a) we need a procedure for retraction or correction, and for (c) we need the public stocks."

Protecting the various aspects of the human personality and privacy is also a growing concern of Western legal

systems, though again they set about achieving this aim in different ways. The need for such a protection was first stressed by German and U.S. academics toward the end of the 19th century, but their arguments were rejected on both sides of the Atlantic because of fears that it would lead to increased litigation and inhibit free speech. By the beginning of the 20th century, however, the first attempts at protection were made in Germany and the United States. Many of these dealt with the unauthorized use of a person's likeness. Others concerned unauthorized use of names or publication of private correspondence. With litigation, a patchy but growing protection began to emerge. The Constitution of Bonn of 1949 reacted against the utter disregard for human dignity prevalent during the Third Reich and for the first time inserted into German law general provisions protecting human personality. Protection of this sort was transferred to the field of civil law in the early and middle 1950s, when a series of important decisions gradually shaped a general right of personality for the violation of which damages could be awarded under the general law of delict. The process was complicated and protracted, and what exists now is a casuistic, judge-made right. But in general the protection afforded to human privacy is extensive, with German judges attempting the difficult feat of balancing the competing interests with great courage and effectiveness.

Conflict between protecting human privacy and free speech

American law meanwhile was classifying and refining the many headings of actionable privacy created by statute or wide-ranging judicial pronouncements (appropriation of likeness; unreasonable intrusion; false light cases, *i.e.*, those in which the plaintiff claims to have been placed in a false light by the defendant; and public disclosure of private facts on a matter that would be highly offensive and objectionable to a reasonable person of ordinary sensibilities). The overall protection thus achieved was extensive and not dissimilar to that of German law, though once again the concern to protect First Amendment rights has seriously stunted certain headings of actionable privacy.

The protection of privacy acquired a new urgency in the 1960s and 1970s as increased technological ability to collect, collate, and disseminate information made it possible to interfere with human personality, solitude, and privacy to an unprecedented extent. In some countries, such as France, new articles were introduced in the civil code to deal with the matter, while others passed special legislation dealing with a modern and dangerous form of invasion connected with data banks and the linking-up of information contained within them. To this tendency even English law has not been immune, though the protection afforded remains patchy and casuistic. The creation of a general right of privacy was rejected in the early 1970s, partly on the grounds that it was difficult to define but also possibly because of sustained opposition from the press. Thus, although English law does not recognize a general right of privacy similar to that embodied in the French Civil Code or created by the German courts, it often achieves comparable results through the ingenious use of existing torts (defamation, trespass, nuisance, passing off) or the law of contract, criminal law, or restitution.

LIABILITY WITHOUT FAULT

The growing dissatisfaction with fault. Whatever the original foundations of tortious liability, by the 19th century it had come to rest firmly upon the notion of fault. The principle that a human being should make good the harm caused by his fault seemed eminently reasonable. But the converse of this principle, namely that there can be no liability where there is no fault, offered an additional attraction to an era that was concerned with not making nascent industries liable; in this sense fault could help retain the boundaries of liability within manageable proportions. To this coincidence of morality and economic expediency the notion of fault doubtless owes much of its aura of soundness and inevitability. Consequently, when the first serious challenge to the notion started to materialize toward the end of the 19th century, it invariably had to be disguised.

19th-century view of fault

Fault, as understood in the 19th century, presupposed free will and, further, that an agent could choose between performing an action in a perceptibly dangerous way and performing it in some safer way. Thus, legal negligence involved something of personal moral shortcoming; the person who was held liable had been guilty of ethical as well as legal wrong. And since fault involved a more or less informed choice, it was possible to see how the prospect of liability could influence a choice for the better—a concept embodying the principle of social utility, for it theoretically edified potential defendants by encouraging them to behave more carefully.

With the growing mechanization and industrialization of the second half of the 19th century and the resulting multiplication of accidents this kind of approach came under more and more scrutiny. Consequently both the moral and the purely educative aspects of the fault system were increasingly questioned, especially as insurance companies were now meeting the cost of accidents; in addition, the idea of leaving victims uncompensated became politically unattractive as the extended franchise made politicians more sensitive to voters' grievances. This change of attitude, however, could not alone have altered the legal system if economic changes had not also favoured reappraisal of the problems of civil liability. From the turn of the century, industry, with the help of insurance, became increasingly sturdy and less in need of protection. The shift toward the plaintiff's point of view manifested itself in three main ways: greater use of the doctrine of vicarious liability; increased objectivization of the notion of carelessness, coupled with the use of presumptions of carelessness; and, finally, the open introduction of strict liability.

Vicarious liability. Vicarious liability is liability imposed on the master of a servant for the tort of that servant when committed in the course of his employment. This is a form of strict liability since the "innocent" master is made liable for the fault of his servant.

Many reasons have been advanced to justify this departure from the fault principle. The doctrine seems to have developed more in response to the demands of social convenience and rough justice than as a consequence of clear, consistent legal planning.

Most systems have opted for true vicarious liability—*i.e.*, liability that makes the master liable for the servant's wrongs. However, German law and, in varying degrees, other German-inspired systems have opted for what is sometimes called the "master's tort" theory. This theory probably results from a misreading of Roman texts as well as the desire to protect small industrial concerns at the end of the 19th century. It makes the master liable only if he is personally at fault in selecting or supervising his servant or failing to supply him with proper equipment. It is enshrined in the German Civil Code, and in practice it has proved so unacceptable as to lead first, to the ingenious expansion of the law of contract (aided by a number of codal provisions) in order to rectify the shortcomings of the law of tort and, later, to the discovery of what common lawyers would call personal nondelegable duties, allowing the imposition of primary liability on the employer under the German code.

The "master's tort" theory

This peculiarity apart, all systems agree that vicarious liability will be imposed only if there is a master–servant relationship and the wrong is committed in the course of employment. Where simpler operations have been involved, the control test has been crucial for determining whether this relationship or that between employer and independent contractor is the one involved. (In the latter the employer bears no responsibility for the wrongdoing of the contractor.) But in more complicated situations all systems resort to a variety of tests that include, for example, how remuneration (wage or lump sum) is paid, to what extent a worker is integrated into the employer's business, who supplies the capital or equipment, and, more generally, all the surrounding circumstances and the other terms of the contract. By far the most troublesome problem, however, is whether the wrong was committed in the course of employment. Its solution tends to be impressionistic, depending on the skillful use of numerous and often contradictory decisions, which can be used only as helpful guidelines and not as rigid principles. There appears to be a tendency to interpret this requirement more

strictly in German than in French law and its derivatives, with the common law standing somewhere in between.

Presumptions of fault and responsibility. The trend away from identifying negligence with moral blameworthiness, coupled with a tendency to put the onus of proof of non-fault on the defendant, often resulted in liability that was in all but name strict liability. The most forthright developments occurred in France, where the courts transformed the code to accommodate problems arising in an industrial society.

This change came in the late 19th century when the French courts, faced with an inactive legislature and growing social pressures to compensate victims of industrial accidents, boldly created a new rule of liability out of the seemingly unpromising first paragraph of article 1384 of the code. The article in question, which proclaims generally that one is responsible not only for one's own acts but also for damage done by things in one's control, was originally conceived as a stylistically desirable linking sentence between the first two delict provisions, which enunciated the rule of fault liability, and the last two provisions, which dealt with some narrow instances of risk liability (*e.g.,* animals, collapsing buildings). But in 1896 the Cour de Cassation (the highest court of civil and criminal matters in France) felt that the time had come to give these words an independent significance, thereby enabling the widow of a victim of a boiler explosion to recover damages without having to prove the fault of the victim's employer. Within a year of this decision the French Chamber passed a workman's compensation act, in effect removing accidents at work from the province of tort law. This piece of legislation constituted a temporary delay in the development of the new rule. The appearance of the automobile, however, gave the rule fresh life, and after some hesitation, the Cour de Cassation finally accepted in the Jand'heur decision (1930) that article 1384 established a presumption of responsibility against the guardian of a thing; this responsibility could not be rebutted by evidence of no fault or lack of explanation of the cause of the damage but only by clear positive evidence that the damage was due to an event unforeseeable and external both to the guardian and to the thing that made the accident unavoidable. In the years that followed much refinement took place of the elements of liability (the meaning of "thing," causation, definition of guard, etc.), but the trend has been to expand liability, especially in the context of traffic accidents. This expansion, largely the result of increased insurance protection, received a boost in 1968 when the Cour de Cassation decided that the rule of article 1384 could be used in favour of nonpaying car passengers and, more recently, in 1982 when in the Desmares decision the defense of contributory fault of the victim was seriously restricted by the second chamber of the court. This decision represented a bold step toward protecting nonmotorists, but its precise ambit was unspecified, raising fears of increased insurance premiums and provoking considerable judicial uncertainty. Perhaps the most beneficial effect of this decision, however, was to hasten enactment of a strict liability road traffic act.

Strict liability road traffic act

Strict liability statutes. The French Road Traffic Act of July 5, 1985, a long and stylistically complicated enactment, has gone a long way toward improving the position of victims of traffic accidents, though not as far as some would have wished. For example, although any contributory negligence on the part of some victims (children under the age of 16 and adults over 70 [article 3]) is completely ignored, that on the part of others, notably the drivers themselves, may be taken into account (article 4), their negligence reducing or in appropriate circumstances even extinguishing their damages. It was only compromises such as this, however, that ensured the passing of the act. Be that as it may, the act is indicative of a modern trend to introduce strict liability through specialized statutes rather than to elaborate the already overworked article 1384 of the Civil Code.

Strict liability statutes are proliferating the world over and survive alongside judge-made rules such as that enunciated by the English decision of *Rylands* v. *Fletcher,* [1868], which held that anyone who in the course of "non-natural" use of his land accumulates thereon for his own purposes anything likely to do mischief if it escapes is answerable for all direct damage thereby caused. The German statutes, however, deserve special attention. First, in Germany strict liability has been introduced only by specific enactments, while the Civil Code, minor exceptions apart, remains faithful to the fault principle. Moreover, such is the monopoly of the legislator in this area that the courts have even restrained themselves from extending analogous strict liability statutes to similar situations (though other German-inspired systems—*e.g.,* the Austrian—have not followed this route). Second, the vast majority of German strict liability statutes contain similar clauses on the monetary limits of liability per damage-inflicting incident. Likewise, defenses such as contributory negligence appear in most statutes. Finally, the compensation under the statutes does not cover damages for pain and suffering, so that if such items are to be claimed, or the monetary limits are inadequate, recourse to the ordinary rules of tort is permissible. In other systems, however (*e.g.,* the Swiss), where the strict liability statutes do not contain the above-mentioned type of limitations, application of the ordinary law is excluded.

TORT LAW AND ALTERNATIVE METHODS OF COMPENSATION

Compensation for personal injury and damage to property is a major aim of tort law. The objective is full compensation wherever possible and in this respect tort compensation differs from funds received from the welfare state system in that the latter often tend to be calculated on a flat-rate basis.

Compensation for physical injury includes consideration of past and future economic losses as well as monetary satisfaction for a variety of nonfinancial items of damage, such as pain and suffering or loss of amenities, which are not amenable to precise mathematical calculation. The various headings of damage do not have exact parallels in all systems, but similar factors tend to be taken into account when calculating the final award. In some systems, such as the French, where the actual calculation of damages is treated as a question of fact and is left to the judge of first instance, regional variations in the size of awards occur. In England, by contrast, since the abolition of civil juries in personal injury cases there has been a greater standardization for certain headings of damages. Common-law systems prefer lump sum awards, whereas in civil-law systems periodic payments are favoured. In many instances the difference appears to be one of theory rather than of practice. Thus, even where periodic payments are preferred, courts often order or facilitate the award of damages in a lump sum, partly because victims tend to prefer this method and partly because any future complications are avoided. A third and perhaps equally important reason is that lawyers can more easily exact their fees from lump sums than from relatively small installments, however regular.

Lump sum awards

If the victim dies all systems tend to allow his estate to claim whatever he could have claimed had he been alive. The conditions for bringing this action, however, vary (German law, for example, is more restrictive than English law). Right to action is also given to the dependents of the deceased. In the common-law systems this is expressly created by statute (the so-called fatal accidents or wrongful death statutes); in German law the action is authorized by the Civil Code, while in French law and its derivatives it is based on the general provision of article 1382. Systems also tend to differ over the question of who should be allowed to sue under this heading. Common-law statutes specifically designate the list of dependents, insisting additionally that they are actually supported by the deceased at the time of his death or, at the very least, have a reasonable probability of an imminent dependency. In contrast, German law limits claims to persons having a legal right to maintenance. French law appears to be open-ended, insisting only on actual dependency at the time of the death. The difference with the other two major systems is, however, more apparent than real, the courts often excluding claims by non-relatives through various causative devices.

Alongside tort social welfare systems proliferate, operating through a tangle of complicated rules, often with little or no attempt to relate the two systems. The full picture of compensation for accidents depends on close study of parallel but limited schemes—*e.g.*, for accidents at work, for road traffic accidents, or for victims of crime—which in some systems coexist along with tort but in others tend to displace it. This unhappy coexistence is one of immense complexity and, no doubt, waste, both of which most commentators have criticized. Despite such criticisms, few countries have attempted the kind of wholesale reform of the all-embracing no-fault system of compensation that New Zealand introduced in the early 1970s, a system that is financed out of general taxation, contributions from employers and employees, and a levy on motor vehicles. There are several reasons for this but cost is, no doubt, an important factor, even though critics of the tort system maintain that one should also weigh the extra cost of automatic compensation against the savings brought by the abolition of the tort system. But further difficulties exist. Should such automatic compensation be linked to accidents or should it also cover disease and illness? Should compensation be determined by the victim's circumstances prevailing before the accident or should it be based on flat rates? And should the emphasis be on compensating the victim's economic loss with, perhaps, token sums being awarded for non-pecuniary loss (as with the New Zealand scheme); or should non-pecuniary loss receive more generous treatment (as under tort law)? The debate on all these points is continuing and, no doubt, adds to the theoretical and practical interest of this subject, even though there is little sign of the New Zealand system being adopted in any major Western country.

TORT AT THE CROSSROADS

Tort law is, on the one hand, increasingly attacked as complicated, slow, and costly; on the other hand, its province expands daily and awards made under it are often huge. The extent to which rules intended for a relatively primitive society have been adapted to meet new ends is impressive. The convergence attained by the various Western systems is also noteworthy, although that convergence was long concealed by different historical approaches and legal conservatism.

Organ and Tissue Transplants

A transplant, in the context of this article, refers to a section of tissue or to a complete organ that is removed from its original natural site and transferred to a new position in the same person or in a separate individual. The term, like its synonym, graft, was borrowed by surgeons from horticulture. Both words imply that success will result in a healthy and flourishing graft or transplant, which will gain its nourishment from its new environment.

This article is divided into the following sections:

Transplants and grafts 745
Tissue transplants 746
  Skin 746
  Other tissue transplants 746
Organ transplants 747
  The kidney 747
  The heart 748
  The liver 748
  The lung 748
  The heart and lungs 748
  The pancreas 748
Special legal and ethical problems 749

TRANSPLANTS AND GRAFTS

Transplants of animal tissue have figured prominently in mythology since the legend of the creation of Eve from one of Adam's ribs. Historical accounts of surgical tissue grafting as part of the cure of patients date back to the early Hindu surgeons who, about the beginning of the 6th century BC, developed techniques for reconstructing noses from skin flaps taken from the patient's arm. This method was introduced into Western medicine by the great Italian surgeon Gaspare Tagliacozzo in the 16th century. The flap was left attached to the arm for two to three weeks until new blood vessels had grown into it from the nose remnant. The flap was then severed and the arm freed from the reconstructed nose.

It was found that extremely thin pieces of skin could be cut free and would obtain enough nourishment from the serum in the graft bed to stay alive while new blood vessels were being formed. This free grafting of skin, together with the flap techniques already mentioned, have constituted the main therapeutic devices of the plastic surgeon in the correction of various types of defects. Skilled manipulations of such grafts can produce surprising improvements in the appearance of those born with malformed faces and in the disfigurements resulting from severe burns. Cornea, which structurally is a modified form of transparent skin, can also be free grafted, and corneal grafts have restored sight to countless blind eyes.

Blood transfusion can be regarded as a form of tissue graft. The blood-forming tissues—bone-marrow cells—can also be transplanted. If these cells are injected into the bloodstream, they home to the marrow cavities and can become established as a vital lifesaving graft in patients suffering from defective marrow.

Organ and limb grafts

The chief distinguishing feature of organ and limb grafts is that the tissues of the organ or limb can only survive if blood vessels are rapidly joined (anastomosed) to blood vessels of the recipient. This provides the graft with a blood supply before it dies from lack of oxygen and nourishment and from the accumulation of poisonous waste products.

As can be seen from the examples cited, living-tissue grafts may be performed for a variety of reasons. Skin grafts can save life in severe burns, can improve function by correcting deformity, or can improve appearances in a cosmetic sense, with valuable psychological benefits. Organ grafts can supply a missing function and save life in cases of fatal disease of vital organs, such as the kidney.

A tissue removed from one part of the body and transplanted to another site in the same individual is called an autograft. Autografts cannot be rejected. Similarly, grafts between identical twins or highly inbred animals—isografts—are accepted by the recipients indefinitely. Grafts from a donor to a recipient of the same species—allografts or homografts—are usually rejected unless special efforts are made to prevent this. Grafts between individuals of different species—xenografts or heterografts—are usually destroyed very quickly by the recipient. (The methods used to prevent rejection are discussed in full, below.)

Tissue or organ grafts may be transplanted to their normal situation in the recipient and are then known as orthotopic—for example, skin to the surface of the body. Alternatively, they may be transplanted to an abnormal situation and are then called heterotopic—for example, kidneys are usually grafted into the lower part of the abdomen instead of into the loin (the back between the ribs and the pelvis), as this is more convenient. If an extra organ is grafted, it is called auxiliary, or accessory—for example, a heterotopic liver graft may be inserted without removal of the recipient's own liver.

Grafts are usually performed for long-term effects. Occasionally, the limited acceptance of a skin allograft may be lifesaving, by preventing loss of fluid and protein from extensive burned surface in severely ill patients. The graft also provides a bacteria-proof covering, so that infection cannot occur. When the allograft is removed or rejected, the patient may be sufficiently recovered to receive permanent autografts (see BURNS).

Certain tissues, including bone, cartilage, tendons, fascia, arteries, and heart valves, can be implanted even if their cells are dead at the time of implantation or will be rejected shortly thereafter. These are structural implants rather than true grafts or transplants. They are more akin to the stick to which a rose is attached for support—although their support is essential, their function does not depend on biological processes. In fact, xenografts or inert manufactured devices may often be equally suitable substitutes.

TISSUE TRANSPLANTS

Skin. Most skin grafting is with autografts; the special indication for skin allografts in severely burned patients has been mentioned. Skin allografts seem to be rejected more aggressively than any other tissue, and there are many experimental situations in which skin grafts between two inbred strains of animal fail, although kidney grafts between the same strains survive indefinitely. There can be no doubt that if rejection could be predictably and safely overcome, there would suddenly be a whole new field of surgery. With autografts, the donor skin is limited to what the patient has available, and sometimes in extensive burn cases this becomes a matter of robbing Peter to pay Paul. If allografts were not rejected, skin from cadavers could be used for coverage of burned areas without the need for subsequent autografting, and many lives would be saved.

Flap grafts. Flap grafts as used by Tagliacozzo are particularly valuable if fat as well as skin has been lost. The procedure of raising a flap and keeping the donor site adjacent to the recipient bed can be complicated and uncomfortable for the patient. The cosmetic results are good, and the fat under the skin contained in the flap can be used to cover exposed bone or to allow movement in a contracted joint or to fashion a new nose.

Full-thickness free-skin grafts. Full-thickness free-skin grafts are the maximum thickness that can survive without a blood supply, and they are therefore in some danger of failure to survive. These grafts produce good cosmetic appearances and are especially useful on the face. The main defect of a full-thickness free-skin graft is that, unless it is very small, the donor site from which it comes becomes a defect that needs to be closed in its own right and may itself need skin grafting.

Split or partial-thickness skin grafts. Split, or partial-thickness, skin grafts are by far the most commonly used grafts in plastic surgery. Superficial slices of skin the thickness of tissue paper are cut with a hand or mechanical razor. The graft, which contains living cells, is so thin that it usually gains adequate nourishment directly from the raw surface to which it is applied, and the risk of failure to take (that is, to survive in the new location) is therefore much less than with full-thickness grafts. Another major advantage is that the donor site is not badly damaged. It is tender for only two or three weeks, and it resembles a superficial graze both in appearance and in the fact that healing takes place from the deep layer of the skin left behind. Split skin grafts can be taken quickly from large areas to cover big defects. They tend to have an abnormal shiny reddish appearance that is not as satisfactory cosmetically as the other types of skin graft.

Cornea, blood vessel, and heart valves

Other tissue transplants. *Cornea.* There are certain forms of blindness in which the eye is entirely normal apart from opacity of the front window, or cornea. The opacity may be the result of disease or injury, but, if the clouded cornea is removed and replaced by a corneal transplant, normal vision can result. Since cells of the cornea remain viable for some 12 hours after death, a cornea can be grafted if it is removed within that period. Cooling will slow the process of deterioration, although the sooner the section of cornea is transplanted the better. The graft bed to which a cornea is transplanted has no blood supply. Nourishment comes directly by diffusion from the tissues. Because most rejection factors are carried in the bloodstream, the lack of blood vessels permits most corneal allografts to survive indefinitely without rejection. Rejection can occur if, as sometimes happens, blood vessels grow into the graft.

Blood vessels. By far the most satisfactory blood-vessel transplant is an autograft, similar in principle to skin autografts. Blood-vessel grafts are frequently used to bypass arteries that have become blocked or dangerously narrowed by fatty deposits, a condition caused by degenerative atherosclerosis (hardening of the arteries). Such atherosclerotic deposits in the coronary and carotid arteries are responsible, respectively, for most heart attacks and strokes. If atherosclerosis affects the main artery of the leg, the result is, first, pain in the calves, and then gangrene of the foot, necessitating amputation of the leg. If dealt with early, the effects of the arterial blockage can often be overcome by removing a nonessential superficial vein from the leg, reversing it so that the valves will not obstruct blood flow, and then joining this graft to the affected artery above and below the block—thus bypassing the obstruction. Coronary-artery-bypass grafting has become one of the most common surgical operations in developed countries.

Vein or arterial allografts are far less successful. In time the walls tend to degenerate, and the vessels either dilate, with the danger of bursting, or become obstructed.

Heart valves. Valvular diseases of the heart can be dangerous, since both a blocked valve and a valve that allows blood to leak backward create a strain on the heart that can lead to heart failure. If the valve is seriously damaged it can be replaced with a xenograft valve or a manufactured mechanical valve. Neither is ideal. Xenograft valves have a normal central blood flow, but after a few years they may become rigid and cease to function. Plastic valves—usually of the ball-valve or trapdoor types—force blood to flow around the surface of the ball or trapdoor flap, and this tends to damage red blood cells and cause anemia.

Bone. When fractures fail to unite, autografts of bone can be extremely valuable in helping the bone to heal. Bone allografts can be used for similar purposes, but they are not as satisfactory, since the bone cells are either dead when grafted or are rejected. Thus, the graft is merely a

structural scaffold that, although useful as such, cannot partake actively in healing.

Fascia. Fascia, sheets of strong connective tissue that surround muscle bundles, may be used as autografts to repair hernias. The principle of use is like that for skin.

Nerves. Nerves outside the brain and spinal cord can regenerate if damaged. If the delicate sheaths containing the nerves are cut, however, as must happen if a nerve is partially or completely severed, regeneration may not be possible. Even if regeneration occurs it is unlikely to be complete, since most nerves are mixed motor and sensory paths and there is no control ensuring that regenerating fibres take the correct path. Thus, there will always be some fibres that end in the wrong destination and are therefore unable to function. Defective nerve regeneration is the main reason why limb grafts usually are unsatisfactory. A mechanical artificial limb is likely to be of more value to the patient.

Transfusions

Blood. Blood transfusion has been one of the most important factors in the development of modern surgery. There are many lifesaving surgical procedures that are possible only because the blood loss inevitable in the operation can be made up by transfusion. Blood transfusion is of value in saving life following major injury, bleeding ulcers, childbirth, and many other conditions involving dangerous loss of blood. Purified blood components can be transfused to treat specific defects; for example, platelets are used to correct a low platelet count, and clotting factor VIII is given to counteract the clotting defect in classic hemophilia.

Bone marrow. Diseases in which the bone marrow is defective, such as aplastic anemia, may be treated by marrow grafting. Some forms of leukemia can be cured by destroying the patient's bone marrow—the site of the cancerous cells—with drugs and irradiation. Marrow grafting is then necessary to rescue the patient. There is a tendency for the patient to reject the allografted marrow, and there is an additional hazard because immune-system cells in a marrow graft can react against the patient's tissues, causing serious and sometimes fatal graft-versus-host disease. To avoid these complications, special immunosuppressive treatment is given. The use of monoclonal antibodies (see below *Monoclonal antibodies*) to selectively remove harmful lymphocytes from the donor marrow has produced encouraging results in preventing graft-versus-host disease.

ORGAN TRANSPLANTS

Organ transplants are, for a variety of reasons, more difficult to perform successfully than are most other grafts. Despite these difficulties, kidney transplant has now become a routine operation in most developed countries. Heart and liver grafting have also become established, and promising results have been obtained with pancreas and combined heart–lung grafts.

The kidney. The surgery of kidney transplantation is straightforward, and the patient can be kept fit by dialysis with an artificial kidney before and after the operation. The kidney was the first organ to be transplanted successfully in humans, and experience is now considerable. Effective methods of preventing graft rejection have been available since the 1960s.

Effects of kidney disease

Fatal kidney disease is relatively common in young people. When there is deterioration of kidney function, eventually, despite all conventional treatment, the patient becomes extremely weak and anemic. Fluid collects in the tissues, producing swelling, known as dropsy or edema, because the kidneys cannot remove excess water. Fluid in the lungs may cause difficulty in breathing and puts an excessive strain on the heart, which may already be suffering from the effects of high blood pressure as a result of kidney failure.

Waste products that cannot be removed from the body can cause inflammation of the coverings of the heart and the linings of the stomach and colon. As a result, there may be pain in the chest, inflammation of the stomach leading to distressing vomiting, and diarrhea from the colitis. The nerves running to the limbs may be damaged, resulting in paralysis. Treatment with the artificial kidney followed by kidney grafting can eliminate all these symptoms and has a good chance of permitting the dying person to return to a normal existence. Unfortunately, in most countries only a minority of patients receive this treatment because of a shortage of donor kidneys.

Artificial kidney treatment for about 12 hours, two to three times a week, removes all the features of kidney failure in one to two months. The patient then is able to leave the hospital and can be assessed as to suitability for a transplant. As has been mentioned, the kidney graft is heterotopic. The diseased kidneys are left in place, unless their continued presence is likely to impair the patient's health after a successful graft.

Transplantation and postoperative care. The patient may receive a kidney from a live donor or a dead one. Cadaver kidneys may not function immediately after transplantation, and further treatment with the artificial kidney may be required for two to three weeks while damage in the transplanted kidney is repaired. The patient is given drugs that depress immune responses and prevent the graft from being rejected. Immediately after the operation, for the first week or two, every effort is made to keep the patient from contact with bacteria that might cause infection. The patient is usually nursed in a separate room, and doctors and nurses entering the room take care to wear masks and wash their hands before touching him. The air of the room is purified by filtration. Close relatives are allowed to visit the patient, but they are required to take the same precautions. When stitches have been removed the patient is encouraged to get up as much as possible and to be active, but, in the first four months after the operation, careful surveillance is necessary to make sure that the patient is not rejecting the graft or developing an infection. He may be discharged from the hospital within a few weeks of the operation, but frequent return visits are necessary for medical examination and biochemical estimations of the blood constituents, to determine the state of function of the graft, and to make sure that the drugs are not causing side effects. Each patient requires a carefully adjusted dose of the immunosuppressive drugs that prevent transplant rejection.

Maintenance of health after transplantation

Once the dosage of immunosuppressive drugs is stabilized, patients are encouraged to go back to a normal existence and return to work. The only restrictions are that they must continue to take their drugs and make frequent visits to the outpatient department for surveillance. Patients can return even to heavy work, such as driving a bulldozer, but more often a relatively light job is preferable. Women can bear children after a transplant, and men can become fathers. The course of events is not always so happy, unfortunately. If the patient rejects the kidney or develops a serious infection, it may be necessary to remove the graft and stop administration of the immunosuppressive drugs. The patient must then return to regular maintenance treatment with an artificial kidney but may receive a second or even a third graft.

Data on kidney transplant results. In kidney grafts involving identical twins, in which case rejection is not a problem, recipients have survived more than 25 years. A number of patients who have received kidneys from unrelated cadaver donors have survived more than 20 years, demonstrating that in some patients rejection can be controlled with standard immunosuppressive drugs. There has been a gradual improvement in the overall results of kidney transplants. The patient mortality has declined to around 10 percent per year, death usually being due to infection associated with immunosuppressive treatment; to complications of dialysis in patients whose kidneys have failed; or to other facets of kidney disease, such as high blood pressure and coronary artery disease. Recipients also face an increased risk of malignant growths, particularly lymphomata (growths of the lymphoid system that are probably due to virus infections). Kidney-graft survival has improved since the introduction of the immunosuppressive agent cyclosporine (also called cyclosporin A; see below), and many centres have achieved a one-year survival rate of 80 percent and a two-year rate of 70 percent for patients with a functioning kidney graft from an unrelated cadaver donor. One-year survival rates of 80 to 90 percent have been attained for kidney grafts between

parent and child and more than 90 percent for grafts from well-matched sibling donors. As these statistics indicate, the patient who develops permanent kidney failure now has a reasonable chance of good treatment from a combination of dialysis and kidney transplantation. Those fortunate enough to receive a well-functioning kidney can expect complete rehabilitation.

The heart. The heart is a pump with a built-in power supply; it has a delicate regulatory mechanism that permits it to perform efficiently under a wide range of demands. During moments of fear, passion, or violent exercise, the heart rate increases greatly, and the contractions become more forceful, so that the pumping of the blood intrudes on the consciousness; this is experienced by the individual as palpitations. Cessation of the heartbeat has also been, throughout the ages, the cardinal sign of death. Thus, it is perhaps not so surprising that there was an intense public interest when the first attempts were made at transplanting a human heart. The objectives of heart transplantation, nevertheless, are the same as those of other organ grafts.

One of the most important advances in surgery since World War II has been in direct operations on the heart. Heart valves are repaired or replaced with artificial valves, and techniques have been developed so that the heart can be stopped and its function taken over temporarily by an electrical pump. If, however, the muscle of the heart is destroyed, as occurs in certain diseases, the only operation that can cure the patient is to replace the heart with a graft or possibly an artificial heart. Blockage of the coronary arteries and certain other heart-muscle diseases can kill the patient because the muscle of the heart cannot contract properly. A patient with one of these diseases who is close to dying is, therefore, a possible recipient for a heart transplant.

Appropriate circumstances for a heart transplant

A group of American investigators perfected the technique of heart transplantation in the late 1950s. They showed that a transplanted dog's heart could provide the animal with a normal circulation until the heart was rejected. The features of rejection of the heart are similar to those of the kidney. The cells that produce immune reactions, the lymphocytes, migrate into the muscle cells of the heart, damage it, and also block the coronary arteries, depriving the heart of its own circulation. In most experiments it was more difficult to prevent rejection of the heart than of the kidney. Despite this, rejection was prevented for long periods in animals. Based on this experimental work, the next logical step was to transplant a human heart into a patient dying of incurable heart disease. This step was taken in 1967 by a surgical team in Cape Town, South Africa.

In the years immediately following the first transplant, numerous heart allografts were performed at medical centres throughout the world. Unfortunately, many recipients succumbed to rejection of the transplanted organ. Furthermore, the heart is more sensitive to lack of blood than the kidneys are; it must be removed from the donor more quickly and can be preserved without damage for only a short period of time. Because of these difficulties—particularly the problem of rejection—the number of heart transplants performed worldwide dropped considerably after the initial excitement abated. Steady advances in detecting and treating rejection were made throughout the 1970s, however; and the introduction of the immunosuppressant cyclosporine in the 1980s brought even further improvements in the long-term survival rates for heart-graft recipients. Interest in the procedure revived, and many hundreds of heart transplants have now been performed. A number of patients have lived five or more years after the operation, and heart grafting has become an accepted therapy for otherwise incurable heart disease. Experimental artificial hearts have also been implanted, but these require a cumbersome external power supply and long-term survival rates are not known.

The liver. Many of the functions of the liver are not known. It is a complicated organ that produces the clotting factors and many other vital substances in the blood and that removes many wastes and poisons from the circulation. It is, in effect, a chemical factory. The two categories of fatal liver disease that may be treated by liver grafting are nonmalignant destructive diseases of the liver cells—for example, cirrhosis—and primary cancer of the liver affecting either the main liver cells or the bile ducts. The liver is extremely sensitive to lack of blood supply and must be cooled within 15 minutes of the death of the donor. The operation can be difficult, since the liver is rather large and of complex structure. Both its removal from the cadaver and its grafting into the recipient are major surgical operations. The operation is more difficult in humans than in animals; particularly, the removal of the diseased liver from the recipient. This may be much enlarged and adherent to surrounding structures so that its removal may result in serious bleeding. Once transplanted, the liver must function immediately or the patient will die. There is no treatment available that is comparable to the use of the artificial kidney for kidney disease. If the liver functions well immediately after transplantation, the rest of the management is similar to that followed in kidney operations, and the same drugs are given. Many early liver transplantation operations failed, but an increasing number have successfully restored dying patients to normal existence. Children do especially well following liver transplantation. The commonest fatal liver disease in childhood is a congenital deficiency of bile ducts called biliary atresia. Several centres have obtained a 90 percent one-year survival in children after liver grafting, although up to 25 percent of these patients may require retransplantation due to failure of the first graft.

The lung. Chronic fatal disease of the lung is common, but the progress of the disease is usually slow, and the patient may be ill for a long time. When the lung eventually fails, the patient is likely to be unfit for a general anesthetic and an operation. The function of the lung is to allow exchange of gases between the blood and the air. The gas passes through an extremely fine membrane lining the air spaces. This exposure to air makes the lungs susceptible to infection, more so than any other organs that have been grafted. Lung infection is one of the commonest causes of death after the grafting of other organs, and it is consequently not surprising that infection has caused failure of many lung transplants. Even a mild rejection reaction can severely damage the gas-exchange membrane, and the patient may die before the rejection is reversed. The actual ventilation of the lungs by rhythmic breathing is a complicated movement controlled by nerves connecting the brain to the lungs and to the muscles that produce the breathing. Cutting the nerves can interfere with the rhythmicity of breathing, and this may be an important cause of the difficulties of successfully transplanting both lungs. Nevertheless, these difficulties have been overcome. If only one lung is transplanted, however, the patient's own diseased lung may interfere with the function of the graft by robbing it of air and directing too much blood into the graft. Further progress may depend on a safer, more perfect control of rejection. Currently, grafting both lungs with the heart is the best method of achieving a satisfactory lung graft.

Failure of lung transplants from infection

The heart and lungs. The technique of transplanting the heart and both lungs as a functioning unit was developed in animal experiments at Stanford Medical Center in California. Despite the technical feasibility of the operation, rejection could not be controlled by conventional immunosuppression. With the availability of cyclosporine researchers were able to obtain long-term survivors with combined heart–lung transplants in primate species. Applications to human patients have been remarkably successful. Two-thirds of the patients who received transplants at Stanford are surviving, and other centres have adopted this treatment for patients with severe lung fibrosis and failure of the right side of the heart, which pumps blood into the lungs. Unfortunately, many organ donors have been maintained on ventilators, a process that frequently leads to lung infections; as a consequence, the availability of donor heart–lung units is limited. Furthermore, the lungs are vulnerable to damage from lack of blood, and so transplantation must be performed expeditiously.

The pancreas. The pancreas consists of two kinds of tissues: endocrine and exocrine. The latter produces pancreatic juice, a combination of digestive enzymes that

empty via a duct into the small intestine. The endocrine tissue of the pancreas—the islets of Langerhans—secrete the hormones insulin and glucagon into the bloodstream. These hormones are vital to the regulation of carbohydrate metabolism and exert wide-ranging effects on the growth and maintenance of body tissues. Insufficient insulin production results in type I diabetes mellitus, a disease that is fatal without daily injections of insulin. Even with insulin therapy, many diabetics suffer kidney failure and blindness due to the disease's effects on the small blood vessels. There are reasons to believe that a normally functioning pancreas graft will prevent the progression of these complications.

Much effort has been devoted to removing the islets of Langerhans from the pancreas with a view to grafting the separated islets or even the isolated insulin-producing beta cells. Unfortunately, it is very difficult to obtain sufficient islets from the fibrotic human pancreas, and it appears that isolated islets are highly susceptible to rejection. A number of clinical attempts at islet grafting have been made without long-term success. Transplanting the vascularized pancreas has, however, been more encouraging. It is customary to graft the body and tail of the pancreas; that is, half the pancreas is transplanted, using the splenic artery and vein for vascular anastomosis. One of the difficulties with this procedure has been dealing with the digestive juice produced by the transplanted pancreas. A further complicating factor has been the fact that corticosteroids—frequently used for immunosuppression in transplant patients—aggravate diabetes. The availability of cyclosporine has permitted the avoidance of corticosteroids and has prompted renewed interest in pancreas grafting. The procedure is particularly attractive when a patient with diabetic kidney failure can receive a kidney and pancreas graft from the same donor. A technique with encouraging early results has been to insert the pancreas graft very close to the patient's own pancreas in the so-called paratopic position. This allows drainage of insulin directly into the liver, while the pancreatic juice is diverted into the stomach, where the digestive enzymes are inhibited by stomach acid. It is certainly most gratifying to patients who have been undergoing regular dialysis and taking insulin to be free from both these onerous treatments and to be permitted to eat and drink without restriction. The one-year functional survival rate for pancreatic grafts has reached 30 percent; further advances in surgical technique will be needed before the rate matches the results obtained in kidney grafts. It is of interest that the vascularized pancreas probably is less susceptible to rejection than the kidney.

SPECIAL LEGAL AND ETHICAL PROBLEMS

Legal aspects. In most countries, the law on organ transplantation is poorly defined, as legislation has not yet been created to cope with this advance in surgery. The existing framework relating to physical assault and care of the dead has no provision for organ transplantation. It is customary to ask the permission of the relatives, but, because organ removal must take place immediately after death, it may be impossible to reach the relatives in time. It has been suggested that there should be a widespread campaign to encourage persons to provide in their wills that their organs be used for transplantation. An alternative is to provide by law that permission is assumed unless removal has been forbidden by the individual in his lifetime. Such laws have been passed in Denmark, France, Sweden, Austria, and Israel. Compulsory postmortem examination, a far more extensive procedure than organ removal for grafting, is required in most countries after unexpected death, and this compulsion is not a matter of public concern and debate.

There would seem to be no reason why organ removal for transplantation purposes should not also be acceptable to public opinion, provided there is a mechanism by which individuals in their lifetime can refuse this permission. This, of course, requires an efficient register of those who indicate their refusal; the register would be consulted before any organs would be removed. It is important that there be public reassurance that considerations of transplantation would not impair normal resuscitative efforts of the potential donor.

Ethical considerations. *Defining death.* Transplantation has obviously raised important ethical considerations concerning the diagnosis of death of potential donors, and, particularly, how far resuscitation should be continued. Every effort must be made to restore the heartbeat to someone who has had a sudden cardiac arrest or breathing to someone who cannot breathe. Artificial respiration and massage of the heart, the standard methods of resuscitation, are continued until it is clear that the brain is dead. Most physicians consider that beyond this point efforts at resuscitation are useless.

In many countries, the question of how to diagnose brain death—that is, irreversible destruction of the brain—has been debated by neurologists and other medical specialists. Most of these experts agree that when the brain stem is destroyed there can be no recovery. The brain stem controls the vital function of breathing and the reflexes of the eyes and ears, and it transmits all information between the brain and the rest of the body. Most countries have established strict guidelines for how brain-stem death is to be diagnosed and what cases are to be excluded—for example, patients who have been poisoned, have been given drugs, or have developed hypothermia. The neurological signs of brain-stem death must be elicited by a trained clinician who is not concerned directly with the transplant operation. These signs are reverified after an interval, and, if there is the slightest doubt, further reverifications are made until the criteria are unequivocally met. The guidelines are not seriously disputed, and there has never been a recovery in a case that fulfilled the criteria of brain-stem death.

Determination of brain death

Shortage of donors. Another area of ethical concern is the dilemma posed by the shortage of donor organs. Advances in immunosuppressive therapy have put increasing pressure on the supply of donor organs, and medical personnel sometimes find themselves having to determine who among the potential recipients should receive a lifesaving graft. Furthermore, there is a danger of commercial interests becoming involved with people willing to sell their organs for personal gain, and there is definite risk that organized crime might procure organs for rich and unscrupulous people.

REJECTION

Human beings possess complex defense mechanisms against bacteria, viruses, and other foreign materials that enter the body. These mechanisms, which collectively make up the immune system, cannot, unfortunately, differentiate between disease-causing microorganisms and the cells of a lifesaving transplant. Both are perceived as foreign, and both are subject to attack by the immune system. This immune reaction leads to rejection, the greatest problem in successful tissue and organ grafting.

Immune responses. In order to understand why rejection occurs and how it may be prevented, it is necessary to know something of the operations of the immune system. The key cells of the immune system are the white blood cells known as lymphocytes. These are of two basic types: T lymphocytes and B lymphocytes. These cells have the capacity to distinguish "self" substances from such "nonself" substances as microorganisms and foreign tissue cells. Substances that provoke an immune reaction are recognized by the presence of certain molecules, called antigens, on their surface.

T lymphocytes are responsible for what is called cell-mediated immunity, so named because the T cells themselves latch onto the antigens of the invader and then initiate reactions that lead to the destruction of the nonself matter. B lymphocytes, on the other hand, do not directly attack invaders. Rather, they produce antibodies, proteins that are capable of initiating reactions that weaken or destroy the foreign substance. The overall immune reaction is exceedingly complex, with T lymphocytes, B lymphocytes, macrophages (scavenger cells), and various circulating chemicals waging a coordinated assault on the invader.

The mechanisms of rejection

Transplant rejection is generally caused by cell-mediated responses. The process usually occurs over days or

months, as the T lymphocytes stimulate the infiltration and destruction of the graft. The transplant may be saved if the cell-mediated reactions can be suppressed. Antibody attack of transplanted tissues is most apparent when the recipient has preexisting antibodies against the antigens of the donor. This situation can arise if the recipient has been previously exposed to foreign antigens as the result of pregnancy (during which the mother is exposed to fetal antigens contributed by the father), blood transfusions, or prior transplants. Unlike a cell-mediated reaction, antibody-mediated rejection is rapid, occurring within minutes or hours, and cannot be reversed.

Selection of donor and tissue matching. The factors that provoke graft rejection are called transplantation, or histocompatibility, antigens. If donor and recipient have the same antigens, as do identical twins, there can be no rejection. All cells in the body have transplantation antigens except the red blood cells, which carry their own system of blood-group (ABO) antigens. The main human transplantation antigens—called the major histocompatibility complex, or the HLA (human leukocyte group A) system—are governed by genes on the sixth chromosome. HLA antigens are divided into two groups; class I antigens, which are the target of an effector rejection response; and class II antigens, which are the initiators of the rejection reaction. Class II antigens are not found in all tissues, although class I antigens are. Certain macrophage-like tissue cells—called dendritic cells because of their finger-like processes—have a high expression of class II antigens. There has been much interest in trying to remove such cells from an organ graft, so that the rejection reaction will not be initiated. There has been some experimental success with this approach, although it has not yet been applied clinically.

Histocompatibility antigens

Tissue typing involves the identification of an individual's HLA antigens. Lymphocytes are used for typing. It is important also that the red blood cells be grouped, since red-cell-group antigens are present in other tissues and can cause graft rejection. Although transplantation antigens are numerous and complicated, the principles of tissue typing are the same as for red-cell grouping. The lymphocytes being typed are mixed with a typing reagent, a serum that contains antibodies to certain HLA antigens. If the lymphocytes carry HLA antigens for which the reagent has antibodies, the lymphocytes agglutinate (clump together) or die. Typing serums are obtained from the blood of persons who have rejected grafts or have had multiple blood transfusions or multiple pregnancies; as previously stated, such persons may develop antibodies to transplantation antigens.

Tissue typing

If the lymphocytes of both the recipient and the potential donor are killed by a given serum, then, as far as that typing serum is concerned, the individuals have antigens in common. If neither donor nor recipient lymphocytes are affected, then donor and recipient lack antigens in common. If the donor lymphocytes are killed but not those of the recipient, then an antigen is present in the donor and is missing from the recipient. Thus, by testing their lymphocytes against a spectrum of typing sera, it is possible to determine how closely the recipient and donor match in HLA antigens. As a final precaution before grafting, a direct crossmatch is performed between the recipient's serum and donor lymphocytes. A positive crossmatch usually contraindicates the donor–recipient transplant under consideration.

There is now considerable knowledge concerning the inheritance of transplantation antigens, but, even so, tissue typing is not sufficiently advanced to give an accurate prediction of the outcome of a graft in an individual case, particularly when the donor and recipient are not related to one another. In accordance with Mendelian laws of inheritance, a person obtains one of a pair of chromosomes from each parent. Therefore, a parent-to-child transplant will always be half-matched for transplantation antigens. Siblings have a one-in-four chance of a complete match of the HLA antigens, a one-in-four chance of no match, and a one-in-two chance of a half-match.

The blood-transfusion effect. Since following a blood transfusion some patients become sensitized to the transplantation antigens of the donor, it was expected that prior blood transfusion could only harm the recipient's prospects for a successful organ graft. Careful analysis of results, however, showed the contrary. Specifically, the results of kidney grafting in patients who had received previous blood transfusions without regard to HLA matching were much better than in patients who had never received a blood transfusion. Although a great deal of effort has been expended to determine the mechanisms involved, researchers still do not know how the immune system is modified by prior blood transfusions. Most centres now give blood transfusions before transplantation, though some patients do develop HLA antibodies against a wide spectrum of the population and therefore become very difficult to transplant. This pool of highly sensitized patients is getting larger throughout the world, not only from blood transfusions, but also from patients who have rejected kidney grafts and are back on dialysis, and from women who have had multiple pregnancies.

A special application of the blood-transfusion effect involves repeated small blood transfusions from a potential donor who is a close relative of the patient. If sensitization does not occur, subsequent kidney-graft results are excellent. Some patients, however, develop a positive crossmatch to donor lymphocytes and cannot receive a graft from that donor.

Donor-specific blood transfusions

Immunosuppression. The aim of transplantation research is to allow the recipient to accept the graft permanently with no unpleasant side effects. With current drugs that are used for this purpose, after some months the dosage can often be reduced and sometimes even stopped without the graft's being rejected. In such a case, the patient is no longer susceptible to infections. There would appear to be adaptation of the recipient toward the graft and the graft toward the recipient. The adaptation is probably akin to desensitization, a process used sometimes to cure patients suffering from asthma by giving them repeated injections of small doses of the pollen to which they are sensitive.

Azathioprine. Azathioprine is one of the most widely used immunosuppressive agents; it also has been used to treat leukemia. It can be given by mouth, but the dose must be carefully adjusted so that the blood-cell-forming tissues in the bone marrow are not damaged, which could lead to infections and bleeding. The white-blood-cell and platelet counts need to be determined frequently to make sure that azathioprine is not being given in too large a dose. It is an extremely valuable drug and has been the basis of most immunosuppressive regimens in patients with organ grafts. At first, high doses are given, but eventually the doses may be reduced. Even years after transplantation, small doses of azathioprine may still be needed to maintain coexistence between graft and host.

Corticosteroids. Cortisone and its relatives, prednisone and prednisolone, are very useful in patients with organ grafts. They can be given by mouth, but although not damaging to the blood-forming cells, they do predispose the body to infection, cause stunted growth in children, and have other injurious effects. Persons receiving these substances may develop bloated complexions with swollen faces, may tend to gain weight and become diabetic, and their bones may become brittle. Few recipients of organ transplants, however, can do without corticosteroids, particularly during an active rejection crisis.

Antilymphocyte serum. If rabbits receive repeated injections of mouse lymphocytes, they become immunized and develop antibodies against the mouse cells. The serum from the rabbits' blood can be injected into mice and will often prevent them from rejecting grafts, both from other mice and even, sometimes, from other species. Such antilymphocyte serums can be produced between a variety of species, but in higher mammals, particularly humans, it has been difficult to obtain a powerful immunosuppressive serum without side effects of toxicity.

The activity of the serum lies in its gamma globulin, which contains the antibody proteins. Antilymphocyte globulin is used in humans but contains many proteins that are ineffective and may be harmful. It can be added to standard azathioprine and cortisone treatment without

adding to the toxicity of these agents, and it is extremely useful in treating rejection crisis in kidney-graft recipients who have not responded to corticosteroids. Unfortunately, it has been difficult to obtain a consistently effective product, and there are not good methods of assaying the potency of one serum compared with another. Even when they are prepared by exactly the same methods from the same species, one batch may differ greatly from another. The horse has usually been used to produce antilymphocyte serum for the treatment of human patients, but some persons are sensitive to horse proteins and become extremely ill when treated with horse serum. Such patients may, however, be successfully treated with rabbit antilymphocyte globulin.

Monoclonal antibodies. An important development in antibody production followed the discovery that an antibody-forming lymphocyte can be fused with a cancerous bone-marrow cell. The resulting hybrid cell produces the antibody specified by its lymphocyte progenitor, while from the cancer cell it obtains the characteristic of multiplying indefinitely in laboratory cultures. The culturing of the hybrid yields a clone of cells that produce one specific antibody—a "monoclonal" antibody. Such agents are exclusively specific in action and there is no theoretical limit to the number of antibodies that can be produced by different hybrid cell lines. Monoclonal antibodies can be regarded as highly specific antilymphocyte globulin without many of the unwanted materials that are present in the ordinary, polyclonal antilymphocyte serum described above. Some monoclonal antibodies have been produced that appear to be effective as immunosuppressive agents in humans. Further advances in this area are expected.

Cyclosporine. A new type of immunosuppressive agent was found as a natural product of an earth fungus by the Sandoz Laboratories. This material, called cyclosporine, is a stable, cyclic peptide with powerful immunosuppressive activity affecting especially the T lymphocytes. Cyclosporine was found to prevent organ graft rejection in a number of animal species, and when the drug was used in humans the expected immunosuppressive effect was again observed. It has been used in recipients of all types of organ grafts with improved immunosuppressive results. Unfortunately, cyclosporine is toxic to the human kidney, and there is fear that prolonged use of the agent could lead to permanent renal damage. Cyclosporine also increases the growth of hair on the face and body, which can be distressing to female patients. It is a difficult drug to use because, being fat soluble, its absorption is variable and each patient needs to be individually studied to ensure that the dosage is adequate but not excessive.

It is clear that none of the agents so far used to prevent rejection is ideal. No one would use such dangerous agents except as a last resort in a desperate situation. This, unfortunately, is the exact plight of a person in need of a vital organ transplant. Immunosuppression is, however, much more effective and less dangerous than it used to be, and we can expect advances with new chemical derivatives, in particular monoclonal antibodies and nontoxic analogues of cyclosporine.

ORGAN AND TISSUE BANKS

Without a blood supply organs deteriorate rapidly. Cooling can slow down the process but cannot stop it. Organs differ in their susceptibility to damage. At body temperature, irreversible destruction of the brain occurs after more than three to five minutes; of the heart, liver, pancreas, and lung, after 10 to 30 minutes; of the kidney, after 50 to 100 minutes; and of the skin and cornea, after six to 12 hours. Although the shorter the time the organ is deprived of its blood supply the better, the cornea can be removed for grafting at relative leisure, but every minute is of vital importance for a liver transplant. When a kidney is removed from a living donor, it is not necessary to use elaborate preservation techniques. The operations on the donor and recipient are performed at the same time, and the recipient is prepared to receive the graft by the time that the donor organ is removed. Cadaver kidneys are removed as soon as possible after the donor's death, preferably within an hour. Cool solutions are infused into the blood vessels of the kidney, which is then kept at 4° C (39° F) in a refrigerator or surrounded by ice in a vacuum flask. At the same time, the recipient is prepared for operation. Kidneys can be conserved in this simple way for 24 to 48 hours with little deterioration, and during this time they can be moved for long distances. For a kidney to be preserved from 48 to 72 hours, a complicated machine is required to provide artificial circulation. Cool, oxygenated, physiological solutions, with the same osmotic pressure as blood, are passed through the blood vessels of the kidney. The imperfections of the machinery mean that there is a slow deterioration of the organ that does not occur normally in the body. To keep a kidney undamaged for longer than 72 hours is difficult. Blood cells, spermatozoa, and certain other dissociated tissue cells can be frozen to subzero temperatures and kept alive indefinitely. Special preserving fluids will prevent cell destruction by ice crystals, but these fluids have damaging effects if introduced into whole organs such as the kidney.

Preservation of kidneys for transplantation

Long-term storage and banking of organs seem unlikely in the near future. Preservation techniques for the heart, lung, liver, and pancreas have not been so extensively studied as the kidney. The principles are the same, although these other organs will not tolerate such long periods without a blood supply. Grafting is performed as quickly as possible, preferably within eight hours for the liver and pancreas, four hours for the heart, and two hours for the combined heart-and-lung graft. Much research will be necessary before it is possible to keep organs banked in the way that blood can be stored.

Transportation

From earliest times the conditions in which man lives have been powerfully influenced by the ease and speed with which he has been able to move himself and his materials from point to point on the Earth's surface. By harnessing nature directly and indirectly, man has been able to explore and exploit the Earth's resources. The chief landmarks in the history of transportation—the wheel, the sail, the steam engine, the internal-combustion engine, the electric motor, and the great technological breakthrough of flight—promise, as the 21st century approaches, to be capped by the rocket engine, which frees man from dependence on Earth's atmosphere and permits him to visualize travelling to other planets. PRE-INDUSTRIAL TRANSPORTATION

Primitive transportation

EARLY LAND TRANSPORT

Early man was a wanderer—of necessity rather than choice. Food was scarce; enemies abounded. Techniques were invented for carrying loads, on the end of a stick on one shoulder, on the single yoke, or on both ends of a pole carried across the shoulders, the double yoke. A slain deer or buffalo could be carried on a pole borne by two men; a 5,000-year-old alabaster relief from Sumer shows a large vessel carried thus between two bearers.

The travois. The earliest agricultural workers probably shifted hay on the forked branch of a tree. From this developed the Y-shaped sledge, or travois, used in more recent times by North American Indians. The travois was two poles tied together, with the inverted V resting on the back of a man or animal. Between the poles was slung a wooden or net frame. The Y-sledge was widely used in northern Europe and in the cattle regions of Africa.

The slide car. Whereas the travois can be put together and taken apart as necessary, the slide car is permanent. In the slide car, two shafts are harnessed to a horse or other draft animal; their ends drag along the ground and the shafts are kept apart by crossbars. The very wide geographical distribution of the slide car is proof of its antiquity, and it held its own in some mountainous districts of Europe until recent times.

Sledges and skis. By 5000 BC the sledge was in common use in northern Europe, North America, Egypt, Assyria, and the Middle East. Originally a simple rectangular platform that could be either hauled or pushed, it was soon improved by the addition of runners. Sledges can travel well over snow, marsh, clay, or grass, and to this day are used in Lapland, northern Asia, and British Columbia.

Use of sledges for hauling

The Egyptians and Assyrians used them to move the materials required for their pyramids, obelisks, and huge river statues, and they constructed some of the earliest known roads to enhance the capabilities of the sledge. The use of runners in the form of skis is also very old. A carving on a rock-face in northern Norway dating to about 2000 BC is clearly identifiable as a man on skis.

Animal transport. The ass, native to northeastern Africa, was almost certainly the first draft animal and was in common use in northeast Africa, upper Egypt, the Mediterranean Basin, and the Near and Far East well before 3000 BC. By that date pack animals were in regular service on the caravan routes stretching from eastern Europe and North Africa to India and China. A graphic presentation of convoys of pack asses regularly crossing the Syrian Desert and the Taurus Mountains (Turkey) is obtained from the surviving business letters of a group of Assyrian merchants established in central Asia Minor about 2000 BC. An Egyptian relief from Bari Hasan, dated around 1900 BC, shows the arrival of the Canaanites with their pack asses laden with children and tribute. The ox, the reindeer, the elephant, the yak, the buffalo, and the llama were also used in earlier times.

The camel, both the one-hump (Arabian) and the two-hump (Bactrian) varieties, was uniquely fitted by nature for long overland journeys through desert regions, thanks to its extraordinary capacity to store food and water and its ability to walk on soft sand. The camel could carry up to 600 pounds (270 kilograms) in weight. The most important draft animal for the future, the horse, was a relative latecomer. When or where horses were first domesticated is not known; they were introduced to Egypt by the Hyksos about 1675 BC.

EARLY WATER TRANSPORT

Rafts. Before ships and even boats, man must have had a wide variety of rafts and similar craft. The type varied according to environment; in Egypt, where the Nile was flanked by papyrus and timber was scarce, the first floats consisted of bundles of rushes tied together. While the small models that have survived are not sufficiently detailed to indicate their mode of construction, a close parallel can be seen in modern Peru, where coastal fishermen use reed rafts, known as caballitos. Basically, the caballito consists of two or three conical bunches of reeds, cut off square at their bases and lashed side by side, with the pointed end turned up to form a prow. Caballitos have a considerable history; a pottery vase in the form of such a boat is dated around 1200 BC.

Inflated skins. In Mesopotamia and the eastern Mediterranean development proceeded on different lines. On the Tigris and Euphrates, where papyrus was lacking, an early skin float inflated with air provided a vehicle on which a man could lie and kick or paddle himself across a river. From the single or double float there evolved the wooden raft to which were attached a number of inflated skin floats, producing a platform capable of supporting a substantial load. One of the earliest pictorial records of these rafts comes from Nineveh. At destination, after disposal of the cargo, the timbers of the raft were sold and the skins deflated and transported by pack animal back to their place of origin for future use. Similar craft were used until recently on downstream journeys on the Tigris.

Boats of inflated skins

Closely allied to the skin float, which is kept buoyant by air pressure, is the skin boat, which consists of a flexible leather cover stretched around an internal frame. Such craft survive today in the kayaks of the Eskimo, the curraghs of the west coast of Ireland, the coracles of Wales, the modern canvas canoe, and other counterparts scattered widely over Asia and America. There is strong evidence that the coracle type was first developed in Asia. Coracles were in common use for carrying cargo on the Tigris and Euphrates as early as the 9th century BC.

The dugout. As Neolithic man acquired better tools, dugouts superseded bark canoes. Dugouts are found wherever there are suitable forests, the limiting factor being the tree diameter. Dugouts constructed in North Africa often had beams of no more than 18 inches (46 centimetres). The ancient British canoe of the Bronze Age was 35 feet (11 metres) long with a depth of two feet (0.6 metre) and a beam of nearly five feet (1.5 metres).

The development of larger craft from the primitive dugout involved more complex construction. From the remains of two boats, probably of the Iron Age, found in the river Humber in England, one possible line of advance can be deduced. The hull was roughly pontoon-shaped, with five thick floor planks bevelled and grooved to fit each other and sewn together with withies (willows). A more promising line of development may be inferred from various types of canoe hulls in the Pacific. In the Maori type of canoe, the tree trunk was hollowed out, and additional freeboard was provided by lashing beams to either side, thus providing bulwarks, which did not quite reach stem or stern. Where the available timber did not have a diameter large enough to provide sufficient stability, outrigger floats were fitted. To secure the necessary freeboard for any carrying capacity required, additional planks were fitted at each side, as in the canoes of the Marshall Islands today. As time went on and the craft became more and more complex, the dugout part of the hull made a smaller and smaller contribution to buoyancy and in the end survived only as the keel. Although the most primitive of the earliest forms of water transportation, the dugout led to the cargo ships and passenger liners of today. (D.O'N.)

The wheel and the road

The wheeled vehicle was one of man's most important technological developments, fundamental to trade and travel. Evidence indicates it was invented only once—in the Tigris-Euphrates Valley by the Sumerians about 3500 BC. Not surprisingly, this discovery occurred in this earliest urban civilization where farmers produced a surplus to support city dwellers and needed transportation for crops. The invention of wheeled vehicles necessarily followed the taming of draft animals and the development of metallurgy for making saws and axles. The earliest evidence for a wheeled vehicle is a pictograph on a late Uruk tablet from Erech (Warka) in Mesopotamia representing a roofed, boxlike sledge mounted on four solid wheels.

WHEELED VEHICLES IN ANCIENT TIMES

Early wheels

The earliest wheeled vehicles were furnished with a single pole and solid wheels. Wheels ordinarily were made of two or three segments fastened with transverse struts and strengthened with a swelling around the hub. The very careful construction of these wheels casts doubt upon theories that wheels evolved from logs turning under wagon beds. Actual wheels have survived from ancient times; pictures and toy vehicles supply additional details. The rims of the earliest wheels were studded with copper nails; specimens fitted with bronze tires (*c.* 2000 BC) have been unearthed. Circular axle holes and the use of linchpins to secure the wheels indicate that the wheels turned on the axletree, though this was not the only arrangement. A copper model from Tall Ajrab had wheels rigidly fastened to an axle that revolved in metal loops, which were fastened to the bottom of the car.

Little evidence survives to indicate the exact nature of the chassis of the four-wheeled wagon, despite the custom of burying the royal hearse with the corpse. Several models show wheels directly attached to the wagon bed. There is no evidence of pivoted front axles to facilitate turning. Four-wheeled military wagons on the Sumerian "Standard" of Ur show the body resting on the axles.

Oxen probably served as some of the earliest draft animals. Harnessed on either side of a pole as though drawing a plow, they pulled the vehicle with a yoke that rested on their shoulders and was fastened to the pole tongue. The earliest war chariots were drawn by the fast-moving onager (*Equus hemionus onager*), a wild ass native to western India and Baluchistan. Evidence for the manoeuvrable onager-drawn two-wheeled war chariot comes first from the Diyala region, nearer than Sumer to the native land of these animals. A copper model from Tall Ajrab (*c.* 2800 BC) shows a chariot with tripartite disk wheels studded with nails. The driver stands on a small platform over the axle and holds reins passing through nose rings

of four onagers. (Bridles were unknown in the 3rd millennium.) The chariot has a single pole with two animals on either side; the two outside onagers pull on their neighbours' collars. The animals are shown with the ox harness, which was unsuitable for them. A breast band, essential to supplement the yoke, pushed on the onager's windpipe, significantly decreasing his tractive power. Perhaps for this reason, or because of the diminutive size of the onagers, pictures show four of them abreast pulling these vehicles.

Wheeled vehicles spread from Sumer through Asia and Europe. There were wheeled vehicles in the Indus Valley and the Central Asia steppes by 2500 BC, in northern Syria in the Khābūr and upper Euphrates by about 2200 BC, on the Orontes by 2000 BC, in China by 1500 BC, and in Sweden by 1300 BC.

By about 2000 BC two important developments had greatly increased the use of two-wheeled vehicles. One was the domestication of the horse and the other the invention of spoked wheels. Together they revolutionized warfare by producing the light two-wheeled military chariot. A two-wheeled chariot with spoked wheels is depicted on a seal from Hissar in northeastern Iran *c.* 2000 BC. Technologically, chariots were triumphs of invention. They also were expensive. Since only kings, chieftains, or wealthy men could afford them, warfare acquired an aristocratic cast for hundreds of years. This new invention, the military chariot, enabled barbarians to burst into what is now the Middle East and overrun the civilized areas: the Hyksos conquered Egypt about 1700 BC, and the Kassites took Babylon about 1525 BC. About 1550 BC the war chariot reached Crete and was sculptured on a royal grave stela at Mycenae, the earliest European representation of a chariot. In the war chariot of the 2nd millennium, horses were yoked on either side of a pole and controlled by a snaffle bit; *i.e.,* a bit made of two links of metal. The pole was heat-bent to run under the platform up to the correct height for the yoke. The body of the chariot was very light, consisting of a high dashboard, perhaps of wickerwork, with a floor of planks or woven leather thongs resting on the axle. The wheels were demountable and fastened with linchpins. In Egyptian and Assyrian chariots the number of spokes varied from four to six or eight. Surviving chariots from Egyptian tombs are skillfully made from various woods. The Assyrians reintroduced the four-horse team.

The military chariot

Greece and Rome. Though the chariot, as an instrument of war, lost favour in classical Greece and Rome, it continued in use for circus races, frequently with a four-horse team. The Greeks used farm carts and the Romans both two- and four-wheeled baggage vehicles. Roman passenger vehicles were of varied types: two-wheeled (the *carpentum* and *cisium*) and four-wheeled (the *carruca* and *raeda*). Roman passenger vehicles evidently were not suspended, for the *arcera,* built especially for the ill, disappeared in favour of the litter, which was more comfortable. The Romans seem to have had the pivoted front axle; reliefs and mosaics show the wagons raised a considerable distance above the axles, thus implying an undercarriage. For this reason the Romans used four-wheeled conveyances for long and rapid journeys, even though two-wheeled vehicles were readily available.

The Romans made an important innovation by substituting two shafts for the pole that the Mesopotamians had used for pulling vehicles. This enabled the vehicle to be drawn by one instead of two animals. The first break with the pole-drawn vehicle is shown in a wall painting preserved at Pompeii, which was destroyed in AD 79. This painting depicts a goat, harnessed between shafts, drawing a two-wheeled chariot. His collar resembles that in the modern harness.

Scandinavia. Before the end of the 2nd millennium BC the wheeled vehicle had spread to Sweden, as shown by a rock carving at Kivik, where the outline of a four-wheeled wagon resembles one formed by coupling two carts. Much evidence of barbarian wagons comes from graves. Along with the pole and yoke form of traction, barbarians had taken over the idea of burying the hearse with the royal corpse. Wagons in Hallstatt burials are mostly four-wheeled with heat-bent rims and iron tires; the wheels turn on axles and are held in place by linchpins. The

Barbarian wagons

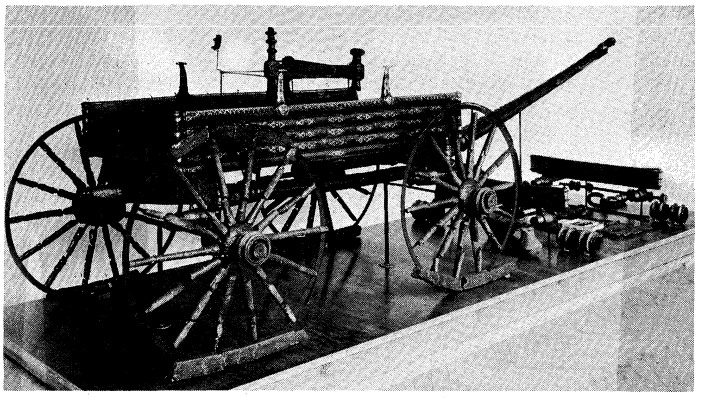

Figure 1: Dejbjerg wagon, made in a Celtic workshop in south Germany or northeast France, 1st century BC. In the Nationalmuseet, Copenhagen.

By courtesy of the Nationalmuseet, Copenhagen

Dejbjerg wagon, from Denmark, a sophisticated product of the wheelwright's art, dates from the 1st century BC. It had wheels with grooves for turning sticks to act as roller bearings. The Dejbjerg wagon has been reconstructed with a pivoted front axle (Figure 1). At Bell there is evidence for a movable front axle. Excavations uncovered three iron rods lying in such a position as to form a Y, with the arms attached to the rear axle and the point to the front axle, in the same manner as indicated on the rocks at Kivik. The most recent of these buried hearses is the four-wheeled wagon in the 9th-century Oseberg ship burial; with the coming of Christianity the custom disappeared. The Oseberg wagon has a curious clinker-built body; its construction is so impractical it can never have been used except for ceremonial purposes. Though the Oseberg wagon has also been reconstructed with a pivoted front axle, some maintain such a restoration is a mistake, that the Celts never knew the movable front axle. This theory ignores the evidence from Kivik and from Bell, the obvious expertise of barbarian craftsmen, and the fact that the Romans took over from the Celts their *raeda,* a four-wheeled wagon that was used for long distance travel.

Asian innovations spread west. From the point of view of internal security, trade and communications, literature, and education, the late classical and early medieval period in western Europe was one of decline, but with respect to technology the era was one of progress. A number of improvements in horse harness appeared in the West, brought from the East where they had been invented long before. A Chinese work of the 4th century BC describes wheels with 30 spokes; and such wheels, dating from the 4th or 3rd century BC, have been excavated. By this time the Chinese had already known the chariot for more than 1,000 years and had introduced a number of refinements into its construction. For example, they built dished wheels (for greater strength, a concave construction, the spokes inclining to the nave), and by the 4th century BC they were employing the shaft chariot.

Chinese chariots

When the West began using the breast and collar harness is uncertain. Linguistic evidence shows the Slavs had a word for breast strap before the 6th century AD; the term for shoulder collar was employed in Europe in the 8th and 9th centuries. Illustrations show the shoulder collar by AD 800 (perhaps at Pompeii in the 1st century), but it is difficult to tell how widely it was employed, because artists before the 14th and 15th centuries were little interested in realism. Other medieval improvements included the nailed horseshoe (early 9th century), whiffletree, dished wheel, harnessing in tandem, and suspended vehicles.

(M.N.B.)

THE ROADS OF THE ANCIENT WORLD

In the central and eastern Mediterranean areas, and particularly in Greece and Asia Minor, wheeled vehicles were in more common use than elsewhere, and some progress was made in primitive road construction. The deliberately made rut, characteristic of the central and eastern Mediterranean, makes its first and most prominent appearance in

Malta, in association with a society in the Late Neolithic and Early Bronze ages. These ruts were more or less uniform in their depth (three to six inches, or eight to 15 centimetres), width (eight inches, or 20 centimetres), and gauge (44–57 inches, or 112–145 centimetres). That they were deliberately constructed is shown by the fact that in some cases ruts occupy the centres of specially hollowed stone blocks placed in paved roads. Though they are of course a different type of construction, these roads foreshadowed the wooden and stone railways used in the mining industries of central Europe and Great Britain before the Industrial Revolution. Their likeness to modern railways is emphasized by the provision of sidings and passing places.

The roads of China. China developed the oldest known network of roads for everyday use; centuries before the Persian Empire, and over 2,000 years before the Incas, the Chinese had a fully developed system. Even before the Chou dynasty (*c.* 1122–221 BC) communications were controlled and roads maintained by a highways commissioner, with a separate budget of his own. During the Chou dynasty the volume of traffic necessitated the establishment of a uniform scale of size for wheeled vehicles, the prohibition of reckless driving, and traffic regulations for busy intersections. Roads were classified in five grades: pathways for men and pack animals; roads capable of taking narrow-gauge vehicles; roads that could accommodate larger vehicles; roads on which single vehicles could pass each other; and highways taking three wagons abreast.

Roads of the Persian Empire. The ruling dynasty in Persia, masters in their day (559–330 BC) of the entire Middle East, in order to maintain speedy communications with their provincial administrators, were forced to construct a road system. More accurately described as levelled and partly paved tracks, these roads were policed by guards posted at rest houses every 15 miles (24 kilometres). A continuous line of stations linked Sardis, on the Aegean shore, with Susa, the capital, 1,600 miles (2,600 kilometres) away; special messengers could cover the distance between Susa and Babylon (200 miles, or 320 kilometres) in two days.

The Roman road system. It was the Romans who brought the art of road building in antiquity to its highest pitch. The Romans may have taken their road-building techniques from the Etruscans. The roads built by the Greek colonists in southern Italy may also have had some influence.

The Appian and Flaminian ways

The first of the great Roman highways was the Via Appia, begun in 312 BC by the censor Appius Claudius. Built to link Rome with the military centre of Capua, it was later extended southeast to Tarentum (Taranto). The Via Flaminia, completed in 220 BC, gave Rome direct communications with the Po Valley.

By AD 200 the Roman system stretched from Hadrian's Wall in north Britain to the edge of the Sahara, and from Morocco to the Euphrates. Its primary purpose was to provide for speedy and safe military and civil contacts between the central seat of government and the capital cities of the imperial provinces. Horses that drew the two- or four-wheeled vehicles could be changed at stations along the road at intervals of six to 16 Roman miles. Rest houses were spaced at intervals of 20 to 30 Roman miles.

The Inca civilization. No account of the history of transportation would be complete without some mention of the astonishing achievements of the Incas in north and central South America. The Inca Empire reached its zenith under Pachacuti and Topa Inca (Tupac; 1438–93), when it stretched from the present Colombia–Ecuador border to central Chile, a coastal distance of over 2,500 miles (4,000 kilometres) and covering an area of approximately 380,000 square miles (984,000 square kilometres). From the capital, Cuzco, well constructed roads ran to all parts of the empire. Staging posts were frequent, and relay runners were stationed at them to carry messages and parcels quickly. The Incas knew something about bridging, and where necessary they carried their roads over canyons, using suspension bridges. (D.O'N.)

WHEELED VEHICLES IN THE MIDDLE AGES

In the early medieval period in the West, passenger vehicles such as the Romans used seem to have disappeared. Throughout the Middle Ages, Western men preferred travel on horseback. It was otherwise in eastern Europe, for the earliest description of a suspended carriage occurs in the 10th-century account of the travels of Ibrāhīm ibn Ya'qūb among the West Slavs. He said that the Slav kings travelled in great high wagons with four wheels and four tall posts from which a brocade-covered litter was suspended by strong chains, so that passengers would not feel the jolting of the wagon. The Slavs also used this wagon for the ill and wounded. Perhaps the earliest picture of a suspended vehicle is to be found in an 11th-century Anglo-Saxon manuscript. There, in a biblical illustration, Joseph is seen riding in a hammock suspended from two posts, each of which rises from the axle of a four-wheeled wagon. This vehicle looks like the imaginings of an artist who had heard of the Slav wagon but had never seen one. The suspension and body in this picture bear no relation to later illustrations of suspended vehicles.

The suspended carriage

During the later Middle Ages riding in vehicles in western Europe increased. In the 11th and 12th centuries, passenger vehicles were mostly two-wheeled, but in the 14th and 15th centuries they were almost invariably four-wheeled. The shift may have occurred because four-wheeled vehicles provided a steadier ride than the cart, which jerked as the horse raised or lowered his head. In the 13th century the four-wheeled chariot was the luxurious appointment of a great lady, and in 1294 Philip IV in a sumptuary ordinance forbade the use of *chars* to the wives of the bourgeoisie. In the 14th century the conveyance of a queen or duchess in England was called a whirlicote and in France a *char* or *curre.* Before the introduction into France in the 14th century of the *chariot branlant* ("trembling chariot"), the chassis of a lady's personal *char* was essentially no different from the chariot in which her baggage was transported. In either case the chariot's body rested directly on the axles. To the front axle were attached the supporting timbers (futchels), and pole, if two or four horses were to be attached in pairs, or the shafts, if horses were to be harnessed tandem. Chariots were ponderously built of wood and iron. The wheels, the pole connecting front and hind gear (perch), shafts, and body were of wood, but iron was necessary for the nails, cotter pins, axle spindles, strengthening pieces (hurters), chains, and bands around the futchels, the hub of the wheel, and frequently around the wheel as a tire. Such a chariot might weigh from 370 to 440 pounds (170–200 kilograms) and be pulled by as many as four or six horses. Pictures of vehicles drawn by one horse are uncommon.

The French *char*

Figure 2: Drawing of a 14th-century carriage suspended longitudinally by straps. From Rudolf von Ems's *Weltchronik.* In the Zentralbibliothek Zürich.

A careful examination of pictures of 14th- and 15th-century *chars* makes clear their relationship to wagons (Figure 2). The superstructure of a medieval vehicle consisted of hoops supporting a leather or woollen covering, definitely resembling the American covered wagon. The body and chassis have a family relationship to the German farm wagon. For example, the latter has "standards" (*i.e.,* sticks), jutting vertically above each axle. These make it easy to convert the wagon from one with ladders at the sides for haying to one with solid sides for other purposes. From "standards" such as these the body of the passenger vehicle of the 10th-century Slavs and of the Breslau Froissart was hung, the latter by transverse chains. Longitudinal suspension by straps, the method of the future, is shown in a 14th-century German manuscript (Figure 2).

Wheels. Wheels on medieval vehicles seem to have been much the same as earlier ones, except that disk wheels were used at some places for farm carts and wagons, whereas most pictures show spoked wheels. Before the 15th century front and rear wheels were the same size. Technologically, wheels were the most sophisticated part of a medieval vehicle. They were commonly made by wheelwrights, whereas the rest of the work might be produced by nonspecialists. In the 13th century Villard de Honnecourt was acquainted with dishing. Wheels usually had composite felloes (the exterior rim); rims were studded with iron nails or had iron tires. Accounts show that movable parts of chariots were greased regularly.

Axles. It has been claimed on the basis of contemporary illustrations that medieval four-wheeled chariots had a rigidly fastened front axle. Since illustrators before the 14th or 15th centuries commonly drew vehicles without undercarriages (*i.e.,* vehicles that could not have functioned), it would be a mistake to take these pictures as precise representations of actual vehicles. The turning train is essential to wagons used for long distance transportation. The four-wheeled chariot was much used in medieval France for transporting the luggage of aristocrats and for commercial carriage of goods between Toulouse and Béarn, Paris and Melun, and Paris and Dijon. Had the wagon actually possessed rigidly fastened axles, it would have been simpler for carriers to have used carts.

COACHES

Hungarian coaches

In the early 15th century, Hungarian vehicles were admired for their lightness and comfortable ride. A light-wheeled covered chariot with rear wheels much higher than the front, such a vehicle held eight people and could be pulled by a single horse. In 15th- and 16th-century Germany, despite sharp criticism from advocates of the arduous military life, more and more noblemen rode in coaches. The word coach derives ultimately from the Hungarian town of Kocs between Raab and Buda. In the 16th century the Hungarian vehicle spread throughout Europe. There began to be a striking divergence between the farm wagon and the passenger vehicle. For one thing, the coach was a suspended vehicle. Furthermore, instead of the familiar arched tilt, the 16th-century coach had a new silhouette. Four corner posts held a rectangular roof from which leather curtains rolled down. Entrance was now from the side instead of the rear, and there was a coachman's seat in front. In his *Survey of London* (1598), John Stow complained of the danger to pedestrians when coachmen drove with reins and whip instead of having footmen lead the horses. This may have been the custom in town, but in medieval pictures when horses were hitched tandem, there was a postilion riding on one of the front horses.

The medieval *char* and whirlicote provided great elegance in ceremonial processions, as did their successors in the modern period. The first coach in England was in use in 1555; in 1564 Queen Elizabeth had a state coach that opened on all four sides, so her subjects could have a good view of her. It probably resembled the coach in which King Henry IV of France was riding when he was assassinated in 1610: a rectangular body with corner posts, a peaked roof, open sides capable of being closed with curtains when desired, and a leather screen hung across the doorway located in one side. In 1625 hackney coaches were for hire in London and in 1640, stage coaches in England. In 1650, in Paris, coaches for hire were called *fiacres,* after the Hôtel Saint Fiacre, where their owner lived. In 1662, Blaise Pascal introduced *carrosses à cinq sous,* omnibuses with scheduled routes and a timetable, but the project lasted only a few years.

Coaches were criticized as contributing to arrogance and effeminacy, blocking the streets, and taking fares away from the London wherrymen on the Thames. In the early 17th century John Taylor, the "Water Poet," called the coach a toy and trifle, "whose beginning is Folly, continuance Pride, and whose end is Ruine." The hackney coaches were competing with the watermen: "Against the ground we stand and knock our heeles,/Whilst all our profit runs away on wheeles."

By the 17th century on the Continent, coaches had superseded the litter for travel, but in town they still met stiff competition from sedan chairs, popular in Naples, France, Spain, and England. Sedans, some of them beautifully decorated, were large enough for only one occupant and were carried by two chairmen. Boasting a more comfortable ride than coaches, they continued in use until the end of the 18th century.

WAGONS

The Hungarian coach was not the only vehicle introduced into England in the 16th century from Europe. Both the word wagon and the four-wheeled vehicle itself were brought over at this time from Germany. In the Middle Ages the cart was ubiquitous. Pulled by horses or oxen, it was often hitched tandem, had disk or spoked wheels studded with nails, and could be fitted with ladders over the wheels to extend its capacity in harvest time. There were a few carts in the British Isles on which the wheels revolved with the axles, a form going back to 3000 BC. The medieval English cart was a farm cart pressed into service for hauling, but the new wagons were built for long distance haulage. By the end of the 17th century, stage wagons could transport eight tons of goods. These heavy wagons required modification to become suitable for farm use; in the 18th century the box wagon and the bow wagon were developed.

The cart

On the Continent the use of carts and wagons has continued in the modern period. In France, however, there are distinct differences between the medieval and modern vehicles. In the Middle Ages the capacity of the wagon, as recorded by toll charges, had been two to four times that of the cart, and the wagon was usually pulled by more horses. In the modern period, however, the capacity of the French *charrette* (cart) and *chariot lorraine* (wagon) are roughly equal. The former therefore exerts more pressure on two points (two very large wheels) and requires a harder surface than the latter, where the weight is distributed among four wheels, the rear ones being much higher than the front. The cart is more manoeuvrable (though less stable) than the *chariot lorraine.*

In France, Germany, and Sweden the distribution of carts and wagons goes by localities. Attempts to account for this distribution by ethnic backgrounds have failed, and even geography only partially explains it. Although the region of the wagon to a great extent covers the great plain from Siberia to Alsace, the Central Pyrenees use the four-wheeled *char* and the Eastern Pyrenees the two-wheeled cart. (M.N.B.)

THE REVIVAL OF ROAD BUILDING

During the medieval period responsibility for making and repairing the roads rested as a rule on the parishes and landowners through whose land the road passed; those employed on road work were usually farmers and forced labourers. The widespread use of bundles of faggots, erroneously supposed to improve the drainage of the subsoil and the carrying quality of the road, was harmful. But in the 16th century Italian architects and engineers gave attention to the scientific study of road building; a Reims lawyer, Nicholas Bergier, studied the remains of a Roman road that he found in his garden and with the aid of material collected from classical texts and archaeological data compiled a book, *Histoire des grands chemins de l'empire romain,* which attracted wide attention.

The emergence of the nation states of western and central Europe made possible the gradual development of strong, centralized administrative and technical bodies to train engineers and impose uniform standards of road building. The change began to take place at the end of the 16th century, in the France of Henry IV. In 1599 Henry created the post of chief road engineer, with local lieutenants in the provinces. Royal grants were made for new roads. By 1664 the state of the road system allowed for the establishment of a stagecoach service. Many country roads were paved with stone blocks (the *pavés du roi*).

After a decline in road building caused by the demands of the wars of Louis XIV (1643–1715), progress was resumed under Louis XV. The Corps des Ponts et Chaussées, created in 1716, was the first body of road and bridge experts and engineers in Europe to be financed by a government. The method of construction employed was, in general, to trench the road and then lay successive layers of smaller and smaller stones until a smooth surface was reached. By 1776 France had no fewer than 25,000 miles (40,000 kilometres) of highway completed or under construction, of which half were being reconstructed or aligned as avenues.

Another factor contributing powerfully to the pressure for more and better roads was the expansion of trade and commerce and the constant pressure of merchants and manufacturers for improved communications. The process was most marked in Britain, where the presence of large quantities of easily mined coal and iron ore gave that country a head start in the Industrial Revolution. Indeed, the rapid growth of industrial production from the middle of the 18th century onward made better communications not so much a desirable objective as a pressing and immediate necessity. Initially, priority was given to canals, known in those days as navigations; cheap labour imported from Ireland in large quantities dug these canals, and the workmen were known as "navigators," hence the modern use of "navvies" to cover any type of unskilled heavy labourers. Canals, however, could not possibly be built on a sufficient scale to meet the demands of industry; thus, the crying need for more and better roads. John Loudon McAdam was the best known of a number of self-taught engineers, of whom John Metcalf and Thomas Telford were also outstanding. They were fully aware of the necessity for a proper drainage system, and McAdam

John Loudon McAdam's new road

invented an inexpensive, self-sealing road surface, consisting of small stones, chips, or gravel, which could be applied directly to the soil or subsoil of a properly made roadbed. His first experiments in Bristol in 1815 were so successful that they set in motion a road-building explosion that has continued with increasing momentum for 150 years (see also PUBLIC WORKS: *Roads and highways*). (D.O'N.)

WHEELED VEHICLES IN THE 17TH AND 18TH CENTURIES

At the opening of the 17th century, coaches were heavy vehicles, capable of carrying six to eight passengers. The boot, at this time a small seat on either side, between the wheels, later became a basket at the back of the coach for carrying luggage, and still later a seat at the rear for a groom.

Trends in coach design

During the 17th century, coaches tended to become smaller and lighter, to be enclosed, and to acquire improved springs. For example, in 1631, Mary, Infanta of Spain and consort of Emperor Frederick III, rode in a glass-enclosed coach accommodating only two persons. By the middle of the century most coaches had glass windows. Suspension received considerable attention. Although in 1625 a patent was granted in England "for hanging bodies of carriages on steel springs," nothing more is heard of this invention. Some 40 years later, however, Sir Harry Blount demonstrated to a committee of the Royal Society a chariot with four springs, which he claimed was "very easy." Samuel Pepys, the diarist, in 1668 bought one of the new coaches—"it being light, and will be very genteel and sober; to be covered with leather, but yet will hold four."

The most successful invention in the line of a light, fast coach was the Berlin, built by an Italian, Filippo di Chièse, in the city of Berlin about 1660 for use in distant travelling (Figure 3). It had two perches instead of one and was built with C springs and leather braces. The

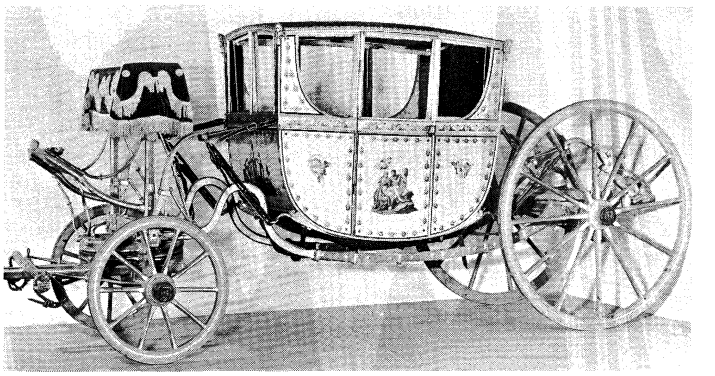

Figure 3: French Berlin coach, *c.* 1780.

bottom of the coach was curved and played up and down instead of swaying from side to side as before. There was a coachman's seat in front; the forward wheels were smaller than the rear, to permit sharp turns without scraping the carriage body. A hundred years earlier Queen Elizabeth's coach had been described as a "hollow-turning coach"; so the problem had long been under consideration. The first Berlins had glass doors, were narrow, and carried only two people. Berlins remained popular into the 19th century; their design was continually modified. For example, many later Berlins held four people.

Much more of a novelty was the development of two-wheeled carts for passengers, something hardly used since Roman times. About 1670 the *gig,* an English invention, was a light two-wheeled cart with a chair, the forerunner of the French *calèche,* the Norwegian *carriole,* the Neapolitan *calesso,* and the Cuban *volante.* The *calèche,* or *chaise* or chair, was known in America as a shay, the vehicle immortalized in the 19th century by Oliver Wendell Holmes in "The Deacon's Masterpiece, or the Wonderful 'One-Hoss-Shay'." The 18th-century American "cheer" was an open carriage hung upon springs made of wood with iron supports for the folding roof and with cloth curtains. A great advantage of the chaise was that it could be drawn by one horse between shafts. In the American colonies, coaches appeared in the last half of the 17th century, but before the Revolution the numbers were too small to support a local coachmaking industry.

The post-chaise

In France from 1664 and in England beginning in 1743, it became possible to travel post. The vehicle was a postchaise, and stations every few miles permitted the traveller to change horses and drivers. The early post-chaise was a two-wheeled vehicle suspended on leather braces, with shafts for one horse. Later post-chaises had four wheels. In France in the 18th century a two-wheeled post-chaise, drawn by three horses abreast and driven by a postilion, was called a diligence. In England, the name diligence was applied to John Palmer's Berlins, introduced in 1783, capable of a speed of seven miles an hour, while carrying four persons and the mail, but no luggage. The cumbersome stagecoaches with six passengers inside in addition to those outside were so slow that they could not compete with the mail coaches.

In the 18th century a landau was a four-wheeled carriage with a hood that could be opened and thrown back to allow the passengers to ride in the open air. The landaulet had the same distinguishing features but was smaller. After mid-century the most sporting carriage was the phaeton, a very high four-wheeled vehicle, renowned for its ability to negotiate sharp turns. Its reputation as a dangerous vehicle only added to its popularity with reckless drivers.

The vogue for lightness and speed did not extend to state coaches at this time. Such a heavy coach frequently carried in addition to a postilion and coachman (and of course the passengers) four to six grooms riding at the back, a supply of manpower frequently necessary to extricate the coach from country mudholes. Among the most famous of these coaches were that of the Lord Mayor of London (1757) and the English coronation coach (1761). The latter is 24 feet long, 8 feet 3 inches wide, and 12 feet high (7.3 by 2.5

by 3.7 metres) and weighs four tons. It is hung upon steel C springs by leather braces. The elaborate gilded figures of tritons, boys, lions' heads, and seashells make it a very impressive rococo monument (Figure 4). By the end of the 18th century, taste in coaches, in common with costumes and furniture, had become much simpler.

19TH-CENTURY DEVELOPMENTS
