	locale.h
	Category
	Miscellaneous Routines
	Prototype
	`char *setlocale(int category, const char *locale);`
	`wchar_t * _wsetlocale( int category, const wchar_t *locale);`
	Description
	Use the setlocale to select or query a locale.
	C++ Builder supports all locales supported in Win95/98/2000 operating systems. See your system documentation for details.
	The possible values for the category argument are as follows:

3.1.4.17.1 localeconv

Header File

locale.h

Category

Miscellaneous Routines

Prototype

```
struct lconv *localeconv(void);
```

Description

Queries the locale for numeric format.

This function provides information about the monetary and other numeric formats for the current locale. The information is stored in a **struct** lconv type. The structure can only be modified by the setlocale. Subsequent calls to localeconv will update the lconv structure.

The lconv structure is defined in locale.h. It contains the following fields:

char	**Decimal point used in nonmonetary formats. This can never be an empty string.**
char	Separator used to group digits to the left of the decimal point. Not used with monetary quantities.
char	Size of each group of digits. Not used with monetary quantities. See the value listing table below.
char	International monetary symbol in the current locale. The symbol format is specified in the ISO 4217 Codes for the Representation of Currency and Funds.
char	Local monetary symbol for the current locale.
char	Decimal point used to format monetary quantities.
char	Separator used to group digits to the left of the decimal point for monetary quantities.
char	Size of each group of digits used in monetary quantities. See the value listing table below.
char	String indicating nonnegative monetary quantities.
char	String indicating negative monetary quantities.
char	Number of digits after the decimal point that are to be displayed in an internationally formatted monetary quantity.
char	Number of digits after the decimal point that are to be displayed in a formatted monetary quantity.
char	Set to 1 if currency_symbol precedes a nonnegative formatted monetary quantity. If currency_symbol is after the quantity, it is set to 0.
char	Set to 1 if currency_symbol is to be separated from the nonnegative formatted monetary quantity by a space. Set to 0 if there is no space separation.
char	Set to 1 if currency_symbol precedes a negative formatted monetary quantity. If currency_symbol is after the quantity, set to 0.
char	Set to 1 if currency_symbol is to be separated from the negative formatted monetary quantity by a space. Set to 0 if there is no space separation.
char	Indicate where to position the positive sign in a nonnegative formatted monetary quantity.
char	Indicate where to position the positive sign in a negative formatted monetary quantity.

Any of the above strings (except decimal_point) that is empty " " is not supported in the current locale. The nonstring **char** elements are nonnegative numbers. Any nonstring **char** element that is set to CHAR_MAX indicates that the element is not supported in the current locale.

The grouping and mon_grouping elements are set and interpreted as follows:

CHAR_MAX	No further grouping is to be performed.
0	The previous element is to be used repeatedly for the remainder of the digits.
any other integer	Indicates how many digits make up the current group. The next element is read to determine the size of the next group of digits before the current group.

The p_sign_posn and n_sign_posn elements are set and interpreted as follows:

0	Use parentheses to surround the quantity and currency_symbol.
1	Sign string precedes the quantity and currency_symbol.
2	Sign string succeeds the quantity and currency_symbol.
3	Sign string immediately precedes the quantity and currency_symbol.
4	Sign string immediately succeeds the quantity and currency_symbol.

Return Value

Returns a pointer to the the filled-in structure of type **struct** lconv. The values in the structure will change whenever setlocale modifies the LC_MONETARY or LC_NUMERIC categories.

Example

```
#include <locale.h>
#include <stdio.h>
int main(void)
{
   struct lconv ll;
   struct lconv *conv = &ll;
/* read the locality conversion structure */
   conv = localeconv();
/* display the structure */
  printf("Decimal Point                : %s\n", conv-> decimal_point);
  printf("Thousands Separator          : %s\n", conv-> thousands_sep);
  printf("Grouping                     : %s\n", conv-> grouping);
  printf("International Currency symbol : %s\n", conv-> int_curr_symbol);
  printf("$ thousands separator        : %s\n", conv-> mon_thousands_sep);
  printf("$ grouping                   : %s\n", conv-> mon_grouping);
  printf("Positive sign                : %s\n", conv-> positive_sign);
  printf("Negative sign                : %s\n", conv-> negative_sign);
  printf("International fraction digits : %d\n", conv-> int_frac_digits);
  printf("Fraction digits              : %d\n", conv-> frac_digits);
  printf("Positive $ symbol precedes   : %d\n", conv-> p_cs_precedes);
  printf("Positive sign space separation: %d\n", conv-> p_sep_by_space);
  printf("Negative $ symbol precedes   : %d\n", conv-> n_cs_precedes);
  printf("Negative sign space separation: %d\n", conv-> n_sep_by_space);
  printf("Positive sign position       : %d\n", conv-> p_sign_posn);
  printf("Negative sign position       : %d\n", conv-> n_sign_posn);
  return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.17.2 setlocale, _wsetlocale

Header File

locale.h

Category

Miscellaneous Routines

Prototype

```
char *setlocale(int category, const char *locale);
wchar_t * _wsetlocale( int category, const wchar_t *locale);
```

Description

Use the setlocale to select or query a locale.

C++ Builder supports all locales supported in Win95/98/2000 operating systems. See your system documentation for details.

The possible values for the category argument are as follows:

LC_ALL	Affects all the following categories
LC_COLLATE	Affects strcoll and strxfrm
LC_CTYPE	Affects single-byte character handling functions. The mbstowcs and mbtowc functions are not affected.
LC_MONETARY	Affects monetary formatting by the localeconv function
LC_NUMERIC	Affects the decimal point of non-monetary data formatting. This includes the printf family of functions, and the information returned by localeconv.
LC_TIME	Affects strftime

The locale argument is a pointer to the name of the locale or named locale category. Passing a NULL pointer returns the current locale in effect. Passing a pointer that points to a null string requests setlocale to look for environment variables to determine which locale to set. The locale names are **not** case sensitive.

When setlocale is unable to honor a locale request, the preexisting locale in effect is unchanged and a null pointer is returned.

If the locale argument is a NULL pointer, the locale string for the category is returned. If category is LC_ALL, a complete locale string is returned. The structure of the complete locale string consists of the names of all the categories in the current locale concatenated and separated by semicolons. This string can be used as the locale parameter when calling setlocale with any of the LC_xxx values. This will reinstate all the locale categories that are named in the complete locale string, and allows saving and restoring of locale states. If the complete locale string is used with a single category, for example, LC_TIME, only that category will be restored from the locale string.

If an empty string "" is used as the locale parameter an implementation-defined locale is used. This is the ANSI C specified behavior.

To take advantage of dynamically loadable locales in your application, define _ _USELOCALES_ _ for each module. If _ _USELOCALES_ _ is not defined, all locale-sensitive functions and macros will work only with the default C locale.

If a NULL pointer is used as the argument for the locale parameter, setlocale returns a string that specifies the current locale in effect. If the category parameter specifies a single category, such as LC_COLLATE, the string pointed to will be the name of that category. If LC_ALL is used as the category parameter then the string pointed to will be a full locale string that will indicate the name of each category in effect.

```
.
.
.
localenameptr = setlocale( LC_COLLATE, NULL );
if (localenameptr)
printf( "%s\n", localenameptr );
.
.
```

.

The output here will be one of the module names together with the specified code page. For example, the output could be LC_COLLATE = English_United States.437.

.

.

.

```
localenameptr = setlocale( LC_ALL, NULL );
if (localenameptr)
printf( "%s\n", localenameptr );
```

.

.

.

An example of the output here could be the following:

```
LC_COLLATE=English_United States.437;
LC_TIME=English_United States.437;
LC_CTYPE=English_United States.437;
```

Each category in this full string is delimited by a semicolon. This string can be copied and saved by an application and then used again to restore the same locale categories at another time. Each delimited name corresponds to the locale category constants defined in locale.h. Therefore, the first name is the name of the LC_COLLATE category, the second is the LC_CTYPE category, and so on. Any other categories named in the locale.h header file are reserved for future implementation.

To set all default categories for the specified French locale:

```
setlocale( LC_ALL, "French_France.850" );
```

To find out which code page is currently being used:

```
localenameptr = setlocale( LC_ALL, NULL );
```

Return value

If selection is successful, setlocale returns a pointer to a string that is associated with the selected category (or possibly all categories) for the new locale.

If UNICODE is defined, _wsetlocale returns a **wchar_t** string.

On failure, a NULL pointer is returned and the locale is unchanged. All other possible returns are discussed in the Remarks section above.

Example

```
#include <locale.h>
#include <stdio.h>
int main(void)
{
   char *old_locale;
   /* The only locale supported in CodeGear C++ is "C" */
   old_locale = setlocale(LC_ALL,"C");
   printf("Old locale was %s\n",old_locale);
   return 0;
}
```

Portability

3.1.4.18 malloc.h

The following functions, macros, and classes are provided in `malloc.h`:

Topics

Name	Description
alloca (see page 920)	**Header File** malloc.h **Category** Memory Routines **Prototype** `void *alloca(size_t size);` **Description** Allocates temporary stack space. alloca allocates size bytes on the stack; the allocated space is automatically freed up when the calling function exits. The use of alloca is not encouraged. In the **try**-block of a C++ program the alloca function should never be used. If an exception is thrown, any values placed on the stack by alloca will be corrupted. **Return Value** If enough stack space is available, alloca returns a pointer to the allocated stack area. Otherwise, it returns NULL. **Example**

3.1.4.18.1 alloca

Header File

malloc.h

Category

Memory Routines

Prototype

```
void *alloca(size_t size);
```

Description

Allocates temporary stack space.

alloca allocates size bytes on the stack; the allocated space is automatically freed up when the calling function exits.

The use of alloca is not encouraged. In the **try**-block of a C++ program the alloca function should never be used. If an exception is thrown, any values placed on the stack by alloca will be corrupted.

Return Value

If enough stack space is available, alloca returns a pointer to the allocated stack area. Otherwise, it returns NULL.

Example

```
#include <malloc.h>
#include <stdio.h>
```

```
#include <stdlib.h>
void test(int a)
{
   char *newstack;
   int len = a;
   char dummy[1];
dummy[0] = 0;          /* force good stack frame */
   printf("SP before calling alloca(0x%X) = 0x%X\n",len,_SP);
   newstack = (char *) alloca(len);
printf("SP after calling alloca = 0x%X\n",_SP);
   if (newstack)
      printf("Alloca(0x%X) returned %p\n",len,newstack);
   else
      printf("Alloca(0x%X) failed\n",len);
}
void main()
{
   test(256);
   test(16384);
}
```

3.1.4.19 math.h

The following functions, macros, and classes are provided in `math.h`:

Topics

Name	Description
HUGE_VAL #defines (see page 931)	**Header File** math.h **Description** Overflow value for math functions.
M_E, M_LOGxxx, M_LNxx #defines (see page 932)	**Header File** math.h **Description** The constant values for logarithm functions.
M_SQRTxx #defines (see page 932)	**Header File** math.h **Description** Constant values for square roots of 2.
PI constants (see page 932)	**Header File** math.h **Description** Common constants of pi

atof, _wtof (see page 933)	**Header File**
	stdlib.h, math.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`double atof(const char *s);`
	`double _wtof(const wchar_t *s);`
	Description
	Converts a string to a floating-point number.
	• atof converts a string pointed to by s to **double**; this function recognizes the character representation of a floating-point number, made up of the following:
	• An optional string of tabs and spaces
	• An optional sign
	• A string of digits and an optional decimal point (the digits can be on both sides of the decimal point)
	• An optional e or E followed by an optional signed integer
	The characters must match this generic... more (see page 933)

_atold, _wtold (see page 933)	**Header File**
	math.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`long double _atold(const char *s);`
	`long double _wtold(const wchar_t *s);`
	Description
	Converts a string to a long double.
	_wtold is the wide-character version. It converts a wide-character string to a long double.
	_atof is the floating-point version of _atold.
	_atold converts a string pointed to by s to a **long double**; this functions recognizes:
	An optional string of tabs and spaces
	An optional sign
	A string of digits and an optional decimal point
	An optional e or E followed by an optional signed integer
	The first unrecognized character ends... more (see page 933)

_i64toa, _i64tow (see page 934)	**Header File**
	math.h, stdlib.h
	Category
	Conversion Routines, Math Routines,
	Prototype
	`char *_i64toa(__int64 value, char *string, int radix);`
	`wchar_t *_i64tow(__int64 value, wchar_t *string, int radix);`
	Description
	_i64toa converts an **__int64** to a string. _i64tow is the unicode version. It converts a **__int64** to a wide-character string.
	These functions convert value to a null-terminated string and store the result in string. value is an **__int64**.
	radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. If value is negative and radix is 10, the first character of string is the minus sign... more (see page 934)

_matherr, _matherrl (see page 935)	**Header File**
	math.h
	Category
	Diagnostic Routines, Math Routines
	Prototype
	`int _matherr(struct _exception *e);`
	`int _matherrl(struct _exceptionl *e);`
	Description
	User-modifiable math error handler.
	_matherr is called when an error is generated by the math library.
	_matherrl is the **long double** version; it is called when an error is generated by the long double math functions.
	_matherr and _matherrl each serve as a user hook (a function that can be customized by the user) that you can replace by writing your own math error-handling routine.
	_matherr and _matherrl are useful for information on trapping domain and range errors caused by the... more (see page 935)

abs (see page 936)	**Header File** stdlib.h, math.h **Category** Math Routines, Inline Routines **Prototype** `int abs(int x);` **Description** Returns the absolute value of an integer. abs returns the absolute value of the integer argument x. If abs is called when stdlib.h has been included, it's treated as a macro that expands to inline code. If you want to use the abs function instead of the macro, include #undef abs in your program, after the #include <stdlib.h>. **Return Value** The abs function returns an integer in the range of 0 to INT_MAX, with the exception that an argument with the value INT_MIN is returned... more (see page 936)

acos, acosl (see page 937)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double acos(double x);`
	`long double acosl(long double x);`
	Description
	Calculates the arc cosine.
	acos returns the arc cosine of the input value.
	acosl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Arguments to acos and acosl must be in the range -1 to 1, or else acos and acosl return NAN and set the global variable errno to:
	EDOM Domain error
	Return Value
	acos and acosl of an argument between -1 and +1 return a value in the range 0 to pi. Error... more (see page 937)

asin, asinl (see page 938)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double asin(double x);`
	`long double asinl(long double x);`
	Description
	Calculates the arc sine.
	asin of a real argument returns the arc sine of the input value.
	asinl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Real arguments to asin and asinl must be in the range -1 to 1, or else asin and asinl return NAN and set the global variable errno to
	EDOM Domain error
	Return Value
	asin and asinl of a real argument return a value in the range -pi/2 to... more (see page 938)

atan, atanl (see page 939)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double atan(double x);`
	`long double atanl(long double x);`
	Description
	Calculates the arc tangent.
	atan calculates the arc tangent of the input value.
	atanl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	atan and atanl of a real argument return a value in the range -pi/2 to pi/2. Error handling for these functions can be modified through the functions _matherr and _matherrl.
	Example

atan2, atan2l (see page 940)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double atan2(double y, double x);`
	`long double atan2l(long double y, long double x);`
	Description
	Calculates the arc tangent of y/x.
	atan2 returns the arc tangent of y/x; it produces correct results even when the resulting angle is near pi/2 or -pi/2 (x near 0). If both x and y are set to 0, the function sets the global variable errno to EDOM, indicating a domain error.
	atan2l is the **long double** version; it takes **long double** arguments and returns a **long double** result.
	Return Value
	atan2 and atan2l return a value in... more (see page 940)

cabs, cabsl (see page 940)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double cabs(struct complex z);`
	`long double cabsl(struct _complexl z);`
	Description
	cabs calculates the absolute value of a complex number. cabs is a macro that calculates the absolute value of z, a complex number. z is a structure with type complex; the structure is defined in math.h as
	`struct complex {`
	`double x, y;`
	`};`
	where x is the real part, and y is the imaginary part.
	Calling cabs is equivalent to calling sqrt with the real and imaginary components of z, as shown here:
	`sqrt(z.x * z.x + z.y * z.y)`
	cabsl... more (see page 940)

ceil, ceill (see page 942)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double ceil(double x);`
	`long double ceill(long double x);`
	Description
	Rounds up.
	ceil finds the smallest integer not less than x.
	ceill is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	These functions return the integer found as a **double** (ceil) or a **long double** (ceill).
	Example

cos, cosl (see page 943)	**Header File**
	math.h
	Category
	Math Routines, Inline Routines
	Prototype
	`double cos(double x);`
	`long double cosl(long double x);`
	Description
	Calculates the cosine of a value.
	cos computes the cosine of the input value. The angle is specified in radians.
	cosl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	cos of a real argument returns a value in the range -1 to 1. Error handling for these functions can be modified through _matherr (or _matherrl).
	Example

cosh, coshl (see page 943)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double cosh(double x);`
	`long double coshl(long double x);`
	Description
	Calculates the hyperbolic cosine of a value.
	cosh computes the hyperbolic cosine:
	coshl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	cosh returns the hyperbolic cosine of the argument.
	When the correct value would create an overflow, these functions return the value HUGE_VAL (cosh) or _LHUGE_VAL (coshl) with the appropriate sign, and the global variable errno is set to ERANGE. Error handling for these functions can be modified through the functions _matherr... more (see page 943)

exp, expl (see page 944)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double exp(double x);`
	`long double expl(long double x);`
	Description
	Calculates the exponential e to the x.
	expl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	exp returns e to the x.
	Sometimes the arguments passed to these functions produce results that overflow or are incalculable. When the correct value overflows, exp returns the value HUGE_VAL and expl returns _LHUGE_VAL. Results of excessively large magnitude cause the global variable errno to be set to

fabs, fabsl (see page 945)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double fabs(double x);`
	`long double fabsl(long double x);`
	Description
	Returns the absolute value of a floating-point number.
	fabs calculates the absolute value of x, a double. fabsl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	fabs and fabsl return the absolute value of x.
	Example

floor, floorl (see page 946)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double floor(double x);`
	`long double floorl(long double x);`
	Description
	Rounds down.
	floor finds the largest integer not greater than x.
	floorl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	floor returns the integer found as a **double**. floorl returns the integer found as a **long double**.
	Portability

fmod, fmodl (see page 946)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double fmod(double x, double y);`
	`long double fmodl(long double x, long double y);`
	Description
	Calculates x modulo y, the remainder of x/y.
	fmod calculates x modulo y (the remainder f, where x = ay + f for some integer a, and 0 < f < y).
	fmodl is the **long double** version; it takes **long double** arguments and returns a **long double** result.
	Return Value
	fmod and fmodl return the remainder f where x = ay + f (as described above). When y = 0, fmod and fmodl return 0.
	Example

frexp, frexpl (see page 947)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double frexp(double x, int *exponent);`
	`long double frexpl(long double x, int *exponent);`
	Description
	Splits a number into mantissa and exponent.
	frexp calculates the mantissa m (a **double** greater than or equal to 0.5 and less than 1) and the integer value n such that x (the original **double** value) equals m * 2n. frexp stores n in the integer that exponent points to.
	frexpl is the **long double** version; it takes a **long double** argument for x and returns a **long double** result.
	Return Value
	frexp and frexpl return the mantissa m.... more (see page 947)

hypot, hypotl (see page 948)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double hypot(double x, double y);`
	`long double hypotl(long double x, long double y);`
	Description
	Calculates hypotenuse of a right triangle.
	hypot calculates the value z where
	z2 = x2 + y2 and z >= 0
	This is equivalent to the length of the hypotenuse of a right triangle, if the lengths of the two sides are x and y.
	hypotl is the **long double** version; it takes **long double** arguments and returns a **long double** result.
	Return Value
	On success, these functions return z, a **double** (hypot) or a **long double**)... more (see page 948)

ldexp, ldexpl (see page 949)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double ldexp(double x, int exp);`
	`long double ldexpl(long double x, int exp);`
	Description
	Calculates x * 2^exp.
	lexpl is the **long double** version; it takes a **long double** argument for x and returns a **long double** result.
	Return Value
	On success, ldexp (or ldexpl) returns the value it calculated, x * 2^exp. Error handling for these routines can be modified through the functions _matherr and _matherrl.
	Example

ldiv (see page 950)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`ldiv_t ldiv(long int numer, long int denom);`
	Description
	Divides two **longs**, returning quotient and remainder.
	ldiv divides two **longs** and returns both the quotient and the remainder as an ldiv_t type. numer and denom are the numerator and denominator, respectively.
	The ldiv_t type is a structure of **long**s defined in stdlib.h as follows:
	`typedef struct {`
	`long int quot; /* quotient */`
	`long int rem; /* remainder */`
	`} ldiv_t;`
	Return Value
	ldiv returns a structure whose elements are quot (the quotient) and rem (the remainder).
	Example

log, logl (see page 950)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double log(double x);`
	`long double logl(long double x);`
	Description
	Calculates the natural logarithm of x.
	log calculates the natural logarithm of x.
	logl is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	On success, log and logl return the value calculated, ln(x).
	errno

log10, log10l (see page 951)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double log10(double x);`
	`long double log10l(long double x);`
	Description
	log10 calculates the base ten logarithm of x.
	log10l is the **long double** version; it takes a **long double** argument and returns a **long double** result.
	Return Value
	On success, log10 (or log10l) returns the calculated value log base ten of x.
	If the argument x passed to these functions is real and less than 0, the global variable errno is set to

modf, modfl (see page 952)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double modf(double x, double *ipart);`
	`long double modfl(long double x, long double *ipart);`
	Description
	Splits a **double** or **long double** into integer and fractional parts.
	modf breaks the **double** x into two parts: the integer and the fraction. modf stores the integer in ipart and returns the fraction.
	modfl is the **long double** version; it takes **long double** arguments and returns a **long double** result.
	Return Value
	modf and modfl return the fractional part of x.
	Example

poly, polyl (see page 953)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double poly(double x, int degree, double coeffs[]);`
	`long double polyl(long double x, int degree, long double coeffs[]);`
	Description
	Generates a polynomial from arguments.
	poly generates a polynomial in x, of degree degree, with coefficients coeffs[0], coeffs[1], ..., coeffs[degree]. For example, if n = 4, the generated polynomial is:
	polyl is the **long double** version; it takes **long double** arguments and returns a **long double** result.
	Return Value
	poly and polyl return the value of the polynomial as evaluated for the given x.
	Example

pow, powl (see page 954)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double pow(double x, double y);`
	`long double powl(long double x, long double y);`
	Description
	Calculates x to the power of y.
	powl is the **long double** version; it takes **long double** arguments and returns a **long double** result.
	Return Value
	On success, pow and powl return the value calculated of x to the power of y.
	Sometimes the arguments passed to these functions produce results that overflow or are incalculable. When the correct value would overflow, the functions return the value HUGE_VAL (pow) or _LHUGE_VAL (powl). Results of excessively large magnitude can... more (see page 954)

pow10, pow10l (see page 955)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double pow10(int p);`
	`long double pow10l(int p);`
	Description
	Calculates 10 to the power of p.
	pow10l is the **long double** version; it takes **long double** arguments and returns a **long double** result.
	Return Value
	On success, pow10 returns the value calculated, 10 to the power of p and pow10l returns a **long double** result.
	The result is actually calculated to **long double** accuracy. All arguments are valid, although some can cause an underflow or overflow.
	Example

sin, sinl (see page 955)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double sin(double x);`
	`long double sinl(long double x);`
	Description
	Calculates sine.
	sin computes the sine of the input value. Angles are specified in radians.
	sinl is the **long double** version; it takes a l**ong double** argument and returns a **long double** result. Error handling for these functions can be modified through the functions _matherr and _matherrl.
	Return Value
	sin and sinl return the sine of the input value.
	Example

sinh, sinhl (see page 956)	**Header File**
	math.h
	Category
	Math Routines, Inline Routines
	Prototype
	`double sinh(double x);`
	`long double sinhl(long double x);`
	Description
	Calculates hyperbolic sine.
	sinh computes the hyperbolic sine.
	sinl is the **long double** version; it takes a **long double** argument and returns a **long double** result. Error handling for sinh and sinhl can be modified through the functions _matherr and _matherrl.
	Return Value
	sinh and sinhl return the hyperbolic sine of x.
	When the correct value overflows, these functions return the value HUGE_VAL (sinh) or _LHUGE_VAL (sinhl) of appropriate sign. Also, the global variable errno is set to ERANGE.
	Example

sqrt, sqrtl (see page 957)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double sqrt(double x);`
	`long double sqrtl(long double x);`
	Description
	Calculates the positive square root.
	sqrt calculates the positive square root of the argument x.
	sqrtl is the **long double** version; it takes a **long double** argument and returns a **long double** result. Error handling for these functions can be modified through the functions _matherr and _matherrl.
	Return Value
	On success, sqrt and sqrtl return the value calculated, the square root of x. If x is real and positive, the result is positive. If x is real and negative, the global variable errno... more (see page 957)

tan, tanl (see page 958)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double tan(double x);`
	`long double tanl(long double x);`
	Description
	Calculates the tangent.
	tan calculates the tangent. Angles are specified in radians.
	tanl is the **long double** version; it takes a **long double** argument and returns a **long double** result. Error handling for these routines can be modified through the functions _matherr and _matherrl..
	Return Value
	tan and tanl return the tangent of x, sin(x)/cos(x).
	Example

tanh, tanhl (see page 958)	**Header File**
	math.h
	Category
	Math Routines
	Prototype
	`double tanh(double x);`
	`long double tanhl(long double x);`
	Description
	Calculates the hyperbolic tangent.
	tanh computes the hyperbolic tangent, sinh(x)/cosh(x).
	tanhl is the **long double** version; it takes a **long double** argument and returns a **long double** result. Error handling for these functions can be modified through the functions _matherr and _matherrl.
	Return Value
	tanh and tanhl return the hyperbolic tangent of x.
	Example

3.1.4.19.1 HUGE_VAL #defines

Header File

math.h

Description

Overflow value for math functions.

3.1.4.19.2 M_E, M_LOGxxx, M_LNxx #defines

Header File

math.h

Description

The constant values for logarithm functions.

Name	Meaning
M_E	The value of e
M_LOG2E	The value of log(e)
M_LOG10E	The value of log10(e)
M_LN2	The value of ln(2)
M_LN10	The value of ln(10)

3.1.4.19.3 M_SQRTxx #defines

Header File

math.h

Description

Constant values for square roots of 2.

Name	Meaning
M_SQRT2	Square root of 2
M_SQRT_2	1/2 the square root of 2

3.1.4.19.4 PI constants

Header File

math.h

Description

Common constants of pi

Name	Meaning
M_PI	pi
M_PI_2	One-half pi
M_PI_4	One-fourth pi
M_1_PI	One divided by pi
M_2_PI	Two divided by pi
M_1_SQRTPI	One divided by the square root of pi
M_2_SQRTPI	Two divided by the square root of pi

3.1.4.19.5 atof, _wtof

Header File

stdlib.h, math.h

Category

Conversion Routines, Math Routines

Prototype

```
double atof(const char *s);
double _wtof(const wchar_t *s);
```

Description

Converts a string to a floating-point number.

- atof converts a string pointed to by s to **double**; this function recognizes the character representation of a floating-point number, made up of the following:
- An optional string of tabs and spaces
- An optional sign
- A string of digits and an optional decimal point (the digits can be on both sides of the decimal point)
- An optional e or E followed by an optional signed integer

The characters must match this generic format:

[whitespace] [sign] [ddd] [.] [ddd] [e|E[sign]ddd]

atof also recognizes +INF and -INF for plus and minus infinity, and +NAN and -NAN for not-a-number.

In this function, the first unrecognized character ends the conversion.

The functions strtod and _strtold are similar to atof and provide better error detection, and hence are preferred in some applications.

Return Value

Returns the converted value of the input string.

If there is an overflow, atof returns plus or minus HUGE_VAL (or _LHUGE_VAL), errno is set to ERANGE (Result out of range), and _matherr (or _matherrl) is not called.

3.1.4.19.6 _atold, _wtold

Header File

math.h

Category

Conversion Routines, Math Routines

Prototype

```
long double _atold(const char *s);
long double _wtold(const wchar_t *s);
```

Description

Converts a string to a long double.

_wtold is the wide-character version. It converts a wide-character string to a long double.

_atof is the floating-point version of _atold.

_atold converts a string pointed to by s to a **long double**; this functions recognizes:

An optional string of tabs and spaces

An optional sign

A string of digits and an optional decimal point

An optional e or E followed by an optional signed integer

The first unrecognized character ends the conversion. There are no provisions for overflow.

The functions strtod and _strtold are similar to atof and _atold; they provide better error detection, and hence are preferred in some applications.

Return Value

Returns the converted value of the input string.

If there is an overflow, _atold returns plus or minus HUGE_VAL (or _LHUGE_VAL), errno is set to ERANGE (Result out of range), and _matherr (or _matherrl) is not called.

Portability

	POSIX	Win32	ANSI C	ANSI C++
_atold		+		
_wtold		+		

3.1.4.19.7 _i64toa, _i64tow

Header File

math.h, stdlib.h

Category

Conversion Routines, Math Routines,

Prototype

```
char *_i64toa(__int64 value, char *string, int radix);
wchar_t *_i64tow(__int64 value, wchar_t *string, int radix);
```

Description

_i64toa converts an **__int64** to a string. _i64tow is the unicode version. It converts a **__int64** to a wide-character string.

These functions convert value to a null-terminated string and store the result in string. value is an **__int64**.

radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. If value is negative and radix is 10, the first character of string is the minus sign (**-**).

Note: The space allocated for string must be large enough to hold the returned string, including the terminating null character (\0). These functions can return up to 33 bytes.

Return Value

Returns a pointer to string.

Portability

	POSIX	Win32	ANSI C	ANSI C++
_i64toa		+		
_i64tow		+		

3.1.4.19.8 _matherr, _matherrl

Header File

math.h

Category

Diagnostic Routines, Math Routines

Prototype

```
int _matherr(struct _exception *e);
int _matherrl(struct _exceptionl *e);
```

Description

User-modifiable math error handler.

_matherr is called when an error is generated by the math library.

_matherrl is the **long double** version; it is called when an error is generated by the long double math functions.

_matherr and _matherrl each serve as a user hook (a function that can be customized by the user) that you can replace by writing your own math error-handling routine.

_matherr and _matherrl are useful for information on trapping domain and range errors caused by the math functions. They do not trap floating-point exceptions, such as division by zero. See signal for information on trapping such errors.

You can define your own _matherr or _matherrl routine to be a custom error handler (such as one that catches and resolves certain types of errors); this customized function overrides the default version in the C library. The customized _matherr or _matherrl should return 0 if it fails to resolve the error, or nonzero if the error is resolved. When _matherr or _matherrl return nonzero, no error message is printed and the global variable errno is not changed.

Here are the _exception and _exceptionl structures (defined in math.h):

```
struct _exception {
int type;
char *name;
double arg1, arg2, retval;
};
struct _exceptionl {
int type;
char *name;
long double arg1, arg2, retval;
};
```

The members of the _exception and _exceptionl structures are shown in the following table:

type	The type of mathematical error that occurred; an enum type defined in the typedef _mexcep (see definition after this list).
name	A pointer to a null-terminated string holding the name of the math library function that resulted in an error.
arg1, arg2	The arguments (passed to the function that name points to) caused the error; if only one argument was passed to the function, it is stored in arg1.
retval	The default return value for _matherr (or _matherrl); you can modify this value.

The **typedef** _mexcep, also defined in math.h, enumerates the following symbolic constants representing possible mathematical errors:

DOMAIN	Argument was not in domain of function, such as log(-1).
SING	Argument would result in a singularity, such as pow(0, -2).
OVERFLOW	Argument would produce a function result greater than DBL_MAX (or LDBL_MAX), such as exp(1000).
UNDERFLOW	Argument would produce a function result less than DBL_MIN (or LDBL_MIN), such as exp(-1000).
TLOSS	Argument would produce function result with total loss of significant digits, such as sin(10e70).

The macros DBL_MAX, DBL_MIN, LDBL_MAX, and LDBL_MIN are defined in float.h

The source code to the default _matherr and _matherrl is on the C++Builder distribution disks.

The UNIX-style _matherr and _matherrl default behavior (printing a message and terminating) is not ANSI compatible. If you want a UNIX-style version of these routines, use MATHERR.C and MATHERRL.C provided on the C++Builder distribution disks.

Example

```
#include <math.h>
#include <string.h>
#include <stdio.h>
int _matherr (struct _exception *a)
{
  if (a->type == DOMAIN)
    if (!strcmp(a->name,"sqrt")) {
      a->retval = sqrt (-(a->arg1));
    return 1;
    }
  return 0;
}
int main(void)
{
  double x = -2.0, y;
  y = sqrt(x);
  printf("_Matherr corrected value: %lf\n",y);
  return 0;
}
```

3.1.4.19.9 abs

Header File

stdlib.h, math.h

Category

Math Routines, Inline Routines

Prototype

```
int abs(int x);
```

Description

Returns the absolute value of an integer.

abs returns the absolute value of the integer argument x. If abs is called when stdlib.h has been included, it's treated as a macro that expands to inline code.

If you want to use the abs function instead of the macro, include

#undef abs

in your program, after the #include <stdlib.h>.

Return Value

The abs function returns an integer in the range of 0 to INT_MAX, with the exception that an argument with the value INT_MIN is returned as INT_MIN. The values for INT_MAX and INT_MIN are defined in header file limit.h.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
  int number = -1234;
  printf("number: %d  absolute value: %d\n", number, abs(number));
  return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.19.10 acos, acosl

Header File

math.h

Category

Math Routines

Prototype

```
double acos(double x);
```

```
long double acosl(long double x);
```

Description

Calculates the arc cosine.

acos returns the arc cosine of the input value.

acosl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Arguments to acos and acosl must be in the range -1 to 1, or else acos and acosl return NAN and set the global variable errno to:

EDOM Domain error

Return Value

acos and acosl of an argument between -1 and +1 return a value in the range 0 to pi. Error handling for these routines can be modified through the functions _matherr_matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
  double result;
  double x = 0.5;
  result = acos(x);
  printf("The arc cosine of %lf is %lf\n", x, result);
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
acos	+	+	+	+
acosl		+	+	+

3.1.4.19.11 asin, asinl

Header File

math.h

Category

Math Routines

Prototype

```
double asin(double x);
```

```
long double asinl(long double x);
```

Description

Calculates the arc sine.

asin of a real argument returns the arc sine of the input value.

asinl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Real arguments to asin and asinl must be in the range -1 to 1, or else asin and asinl return NAN and set the global variable errno to

EDOM Domain error

Return Value

asin and asinl of a real argument return a value in the range -pi/2 to pi/2. Error handling for these functions may be modified through the functions _matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result;
```

```
   double x = 0.5;
   result = asin(x);
   printf("The arc sin of %lf is %lf\n", x, result);
  return(0);
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
asin	+	+	+	+
asinl		+	+	+

3.1.4.19.12 atan, atanl

Header File

math.h

Category

Math Routines

Prototype

```
double atan(double x);
```

```
long double atanl(long double x);
```

Description

Calculates the arc tangent.

atan calculates the arc tangent of the input value.

atanl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

atan and atanl of a real argument return a value in the range -pi/2 to pi/2. Error handling for these functions can be modified through the functions _matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result;
   double x = 0.5;
   result = atan(x);
   printf("The arc tangent of %lf is %lf\n", x, result);
return(0);
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
atan	+	+	+	+
atanl		+	+	+

3.1.4.19.13 atan2, atan2l

Header File

math.h

Category

Math Routines

Prototype

```
double atan2(double y, double x);
```

```
long double atan2l(long double y, long double x);
```

Description

Calculates the arc tangent of y/x.

atan2 returns the arc tangent of y/x; it produces correct results even when the resulting angle is near pi/2 or -pi/2 (x near 0). If both x and y are set to 0, the function sets the global variable errno to EDOM, indicating a domain error.

atan2l is the **long double** version; it takes **long double** arguments and returns a **long double** result.

Return Value

atan2 and atan2l return a value in the range -pi to pi. Error handling for these functions can be modified through the functions _matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result;
   double x = 90.0, y = 45.0;
   result = atan2(y, x);
   printf("The arc tangent ratio of %lf is %lf\n", (y / x), result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
atan2	+	+	+	+
atan2l		+	+	+

3.1.4.19.14 cabs, cabsl

Header File

math.h

Category

Math Routines

Prototype

```
double cabs(struct complex z);
```

```
long double cabsl(struct _complexl z);
```

Description

cabs calculates the absolute value of a complex number. cabs is a macro that calculates the absolute value of z, a complex number. z is a structure with type complex; the structure is defined in math.h as

```
struct complex {
double x, y;
};
```

where x is the real part, and y is the imaginary part.

Calling cabs is equivalent to calling sqrt with the real and imaginary components of z, as shown here:

```
sqrt(z.x * z.x + z.y * z.y)
```

cabsl is the **long double** version; it takes a structure with type _complexl as an argument, and returns a **long double** result. The structure is defined in math.h as

```
struct _complexl {
long double x, y;
};
```

Return Value

cabs (or cabsl) returns the absolute value of z, a double. On overflow, cabs (or cabsl) returns HUGE_VAL (or _LHUGE_VAL) and sets the global variable errno to

ERANGE	Result out of range

Error handling for these functions can be modified through the functions _matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
#ifdef __cplusplus
  #include <complex.h>
#endif
#ifdef __cplusplus /* if C++, use class complex */
  void print_abs(void)
  {
    complex<float> z(1.0, 2.0);
    double  absval;
    absval = abs(z);
    printf("The absolute value of %.2lfi %.2lfj is %.2lf",
      real(z), imag(z), absval);
  }
#else  /* below function is for C (and not C++) */
  void print_abs(void)
  {
    struct complex z;
    double absval;
    z.x = 2.0;
    z.y = 1.0;
    absval = cabs(z);
    printf("The absolute value of %.2lfi %.2lfj is %.2lf",
      z.x, z.y, absval);
  }
#endif
int main(void)
{
```

```
  print_abs();
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
cabs		+		
cabsl		+		

3.1.4.19.15 ceil, ceill

Header File

math.h

Category

Math Routines

Prototype

```
double ceil(double x);
```

```
long double ceill(long double x);
```

Description

Rounds up.

ceil finds the smallest integer not less than x.

ceill is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

These functions return the integer found as a **double** (ceil) or a **long double** (ceill).

Example

```
#include <math.h>
#include <stdio.h>
int main(void)
{
   double number = 123.54;
   double down, up;
   down = floor(number);
   up = ceil(number);
   printf("original number     %5.2lf\n", number);
   printf("number rounded down %5.2lf\n", down);
   printf("number rounded up   %5.2lf\n", up);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
ceil	+	+	+	+
ceill		+	+	+

3.1.4.19.16 cos, cosl

Header File

math.h

Category

Math Routines, Inline Routines

Prototype

```
double cos(double x);
```

```
long double cosl(long double x);
```

Description

Calculates the cosine of a value.

cos computes the cosine of the input value. The angle is specified in radians.

cosl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

cos of a real argument returns a value in the range -1 to 1. Error handling for these functions can be modified through _matherr (or _matherrl).

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result;
   double x = 0.5;
   result = cos(x);
   printf("The cosine of %lf is %lf\n", x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
cos	+	+	+	+
cosl		+	+	+

3.1.4.19.17 cosh, coshl

Header File

math.h

Category

Math Routines

Prototype

```
double cosh(double x);
```

```
long double coshl(long double x);
```

Description

Calculates the hyperbolic cosine of a value.

cosh computes the hyperbolic cosine:

coshl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

cosh returns the hyperbolic cosine of the argument.

When the correct value would create an overflow, these functions return the value HUGE_VAL (cosh) or _LHUGE_VAL (coshl) with the appropriate sign, and the global variable errno is set to ERANGE. Error handling for these functions can be modified through the functions _matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result;
   double x = 0.5;
   result = cosh(x);
   printf("The hyperbolic cosine of %lf is %lf\n", x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
cosh	+	+	+	+
coshl		+	+	+

3.1.4.19.18 exp, expl

Header File

math.h

Category

Math Routines

Prototype

```
double exp(double x);
```

```
long double expl(long double x);
```

Description

Calculates the exponential e to the x.

expl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

exp returns e to the x.

Sometimes the arguments passed to these functions produce results that overflow or are incalculable. When the correct value

overflows, exp returns the value HUGE_VAL and expl returns _LHUGE_VAL. Results of excessively large magnitude cause the global variable errno to be set to

ERANGE	Result out of range

On underflow, these functions return 0.0, and the global variable errno is not changed. Error handling for these functions can be modified through the functions _matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result;
   double x = 4.0;
   result = exp(x);
   printf("'e' raised to the power \
          of %lf (e ^ %lf) = %lf\n",
          x, x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
exp	+	+	+	+
expl		+	+	+

3.1.4.19.19 fabs, fabsl

Header File

math.h

Category

Math Routines

Prototype

```
double fabs(double x);
```

```
long double fabsl(long double x);
```

Description

Returns the absolute value of a floating-point number.

fabs calculates the absolute value of x, a double. fabsl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

fabs and fabsl return the absolute value of x.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
```

```
    float  number = -1234.0;

    printf("number: %f  absolute value: %f\n", number, fabs(number));
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
fabs	+	+	+	+
fabsl		+	+	+

3.1.4.19.20 floor, floorl

Header File

math.h

Category

Math Routines

Prototype

```
double floor(double x);
```

```
long double floorl(long double x);
```

Description

Rounds down.

floor finds the largest integer not greater than x.

floorl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

floor returns the integer found as a **double**. floorl returns the integer found as a **long double**.

Portability

	POSIX	Win32	ANSI C	ANSI C++
floor	+	+	+	+
floorl		+	+	+

3.1.4.19.21 fmod, fmodl

Header File

math.h

Category

Math Routines

Prototype

```
double fmod(double x, double y);
```

```
long double fmodl(long double x, long double y);
```

Description

Calculates x modulo y, the remainder of x/y.

fmod calculates x modulo y (the remainder f, where x = ay + f for some integer a, and 0 < f < y).

fmodl is the **long double** version; it takes **long double** arguments and returns a **long double** result.

Return Value

fmod and fmodl return the remainder f where x = ay + f (as described above). When y = 0, fmod and fmodl return 0.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double x = 5.0, y = 2.0;
   double result;
   result = fmod(x,y);
   printf("The remainder of (%lf / %lf) is %lf\n", x, y, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
fmod	+	+	+	+
fmodl		+	+	+

3.1.4.19.22 frexp, frexpl

Header File

math.h

Category

Math Routines

Prototype

```
double frexp(double x, int *exponent);
```

```
long double frexpl(long double x, int *exponent);
```

Description

Splits a number into mantissa and exponent.

frexp calculates the mantissa m (a **double** greater than or equal to 0.5 and less than 1) and the integer value n such that x (the original **double** value) equals m * 2n. frexp stores n in the integer that exponent points to.

frexpl is the **long double** version; it takes a **long double** argument for x and returns a **long double** result.

Return Value

frexp and frexpl return the mantissa m. Error handling for these routines can be modified through the functions _matherr and _matherrl.

Example

```
#include <math.h>
#include <stdio.h>
int main(void)
{
   double mantissa, number;
   int exponent;
   number = 8.0;
   mantissa = frexp(number, &exponent);
   printf("The number %lf is ", number);
   printf("%lf times two to the ", mantissa);
   printf("power of %d\n", exponent);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
frexp	+	+	+	+
frexpl		+	+	+

3.1.4.19.23 hypot, hypotl

Header File

math.h

Category

Math Routines

Prototype

```
double hypot(double x, double y);
```

```
long double hypotl(long double x, long double y);
```

Description

Calculates hypotenuse of a right triangle.

hypot calculates the value z where

z2 = x2 + y2 and z >= 0

This is equivalent to the length of the hypotenuse of a right triangle, if the lengths of the two sides are x and y.

hypotl is the **long double** version; it takes **long double** arguments and returns a **long double** result.

Return Value

On success, these functions return z, a **double** (hypot) or a **long double**) (hypotl). On error (such as an overflow), they set the global variable errno to

ERANGE	Result out of range

and return the value HUGE_VAL (hypot) or _LHUGE_VAL) (hypotl). Error handling for these routines can be modified through the functions _matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
```

```
int main(void)
{
 double result;
 double x = 3.0;
    double y = 4.0;
    result = hypot(x, y);
    printf("The hypotenuse is: %lf\n", result);
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
hypot		+	+	+
hypotl		+	+	+

3.1.4.19.24 ldexp, ldexpl

Header File

math.h

Category

Math Routines

Prototype

```
double ldexp(double x, int exp);
```

```
long double ldexpl(long double x, int exp);
```

Description

Calculates x * 2^exp.

lexpl is the **long double** version; it takes a **long double** argument for x and returns a **long double** result.

Return Value

On success, ldexp (or ldexpl) returns the value it calculated, x * 2^exp. Error handling for these routines can be modified through the functions _matherr and _matherrl.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
    double value;
    double x = 2;
    /* ldexp raises 2 by a power of 3
       then multiplies the result by 2   */
    value = ldexp(x,3);
    printf("The ldexp value is: %lf\n", value);
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
ldexp	+	+	+	+

ldexpl		+	+	+

3.1.4.19.25 ldiv

Header File

math.h

Category

Math Routines

Prototype

```
ldiv_t ldiv(long int numer, long int denom);
```

Description

Divides two **longs**, returning quotient and remainder.

ldiv divides two **longs** and returns both the quotient and the remainder as an ldiv_t type. numer and denom are the numerator and denominator, respectively.

The ldiv_t type is a structure of **long**s defined in stdlib.h as follows:

```
typedef struct {
long int quot; /* quotient */
long int rem; /* remainder */
} ldiv_t;
```

Return Value

ldiv returns a structure whose elements are quot (the quotient) and rem (the remainder).

Example

```
/* ldiv example */
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   ldiv_t lx;
   lx = ldiv(100000L, 30000L);
  printf("100000 div 30000 = %ld remainder %ld\n", lx.quot, lx.rem);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.19.26 log, logl

Header File

math.h

Category

Math Routines

Prototype

```
double log(double x);
long double logl(long double x);
```

Description

Calculates the natural logarithm of x.

log calculates the natural logarithm of x.

logl is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

On success, log and logl return the value calculated, ln(x).

errno

EDOM	Domain error

If x is 0, the functions return the value negative HUGE_VAL (log) or negative _LHUGE_VAL (logl), and set errno to ERANGE. Error handling for these routines can be modified through the functions _matherr and _matherrl.

Example

```
#include <math.h>
#include <stdio.h>
int main(void)
{
   double result;
   double x = 8.6872;
   result = log(x);
   printf("The natural log of %lf is %lf\n", x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
log	+	+	+	+
logl		+	+	+

3.1.4.19.27 log10, log10l

Header File

math.h

Category

Math Routines

Prototype

```
double log10(double x);
long double log10l(long double x);
```

Description

log10 calculates the base ten logarithm of x.

log10l is the **long double** version; it takes a **long double** argument and returns a **long double** result.

Return Value

On success, log10 (or log10l) returns the calculated value log base ten of x.

If the argument x passed to these functions is real and less than 0, the global variable errno is set to

EDOM	Domain error

If x is 0, these functions return the value negative HUGE_VAL (log10) or _LHUGE_VAL (log10l). Error handling for these routines can be modified through the functions _matherr and _matherrl.

Example

```
#include <math.h>
#include <stdio.h>
int main(void)
{
   double result;
   double x = 800.6872;
   result = log10(x);
   printf("The common log of %lf is %lf\n", x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
log10	+	+	+	+
log10l		+	+	+

3.1.4.19.28 modf, modfl

Header File

math.h

Category

Math Routines

Prototype

```
double modf(double x, double *ipart);
long double modfl(long double x, long double *ipart);
```

Description

Splits a **double** or **long double** into integer and fractional parts.

modf breaks the **double** x into two parts: the integer and the fraction. modf stores the integer in ipart and returns the fraction.

modfl is the **long double** version; it takes **long double** arguments and returns a **long double** result.

Return Value

modf and modfl return the fractional part of x.

Example

```
#include <math.h>
#include <stdio.h>
int main(void)
{
    double fraction, integer;
    double number = 100000.567;
    fraction = modf(number, &integer);
    printf("The whole and fractional parts of %lf are %lf and %lf\n",
           number, integer, fraction);
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
modf	+	+	+	+
modfl		+	+	+

3.1.4.19.29 poly, polyl

Header File

math.h

Category

Math Routines

Prototype

```
double poly(double x, int degree, double coeffs[]);
```

```
long double polyl(long double x, int degree, long double coeffs[]);
```

Description

Generates a polynomial from arguments.

poly generates a polynomial in x, of degree degree, with coefficients coeffs[0], coeffs[1], ..., coeffs[degree]. For example, if n = 4, the generated polynomial is:

polyl is the **long double** version; it takes **long double** arguments and returns a **long double** result.

Return Value

poly and polyl return the value of the polynomial as evaluated for the given x.

Example

```
#include <stdio.h>
#include <math.h>
/* polynomial:  x**3 - 2x**2 + 5x - 1 */
int main(void)
{
  double array[] = { -1.0, 5.0, -2.0, 1.0
};
  double result;
  result = poly(2.0, 3, array);
  printf("The polynomial: x**3 - 2.0x**2 + 5x - 1 at 2.0 is %lf\n", result);
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
poly		+		
polyl		+		

3.1.4.19.30 pow, powl

Header File

math.h

Category

Math Routines

Prototype

```
double pow(double x, double y);
long double powl(long double x, long double y);
```

Description

Calculates x to the power of y.

powl is the **long double** version; it takes **long double** arguments and returns a **long double** result.

Return Value

On success, pow and powl return the value calculated of x to the power of y.

Sometimes the arguments passed to these functions produce results that overflow or are incalculable. When the correct value would overflow, the functions return the value HUGE_VAL (pow) or _LHUGE_VAL (powl). Results of excessively large magnitude can cause the global variable errno to be set to

ERANGE	Result out of range

If the argument x passed to pow or powl is real and less than 0, and y is not a whole number, or if x is 0 and y is less than 0, or you call pow(0,0), the global variable errno is set to

EDOM	Domain error

Error handling for these functions can be modified through the functions _matherr and _matherrl.

Example

```
#include <math.h>
#include <stdio.h>
int main(void)
{
  double x = 2.0, y = 3.0;
  printf("%lf raised to %lf is %lf\n", x, y, pow(x, y));
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
pow	+	+	+	+

powl		+	+	+

3.1.4.19.31 pow10, pow10l

Header File

math.h

Category

Math Routines

Prototype

```
double pow10(int p);
long double pow10l(int p);
```

Description

Calculates 10 to the power of p.

pow10l is the **long double** version; it takes **long double** arguments and returns a **long double** result.

Return Value

On success, pow10 returns the value calculated, 10 to the power of p and pow10l returns a **long double** result.

The result is actually calculated to **long double** accuracy. All arguments are valid, although some can cause an underflow or overflow.

Example

```
#include <math.h>
#include <stdio.h>
int main(void)
{
  double p = 3.0;
  printf("Ten raised to %lf is %lf\n", p, pow10(p));
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
pow10		+		
pow10l		+		

3.1.4.19.32 sin, sinl

Header File

math.h

Category

Math Routines

Prototype

```
double sin(double x);
long double sinl(long double x);
```

Description

Calculates sine.

sin computes the sine of the input value. Angles are specified in radians.

sinl is the **long double** version; it takes a l**ong double** argument and returns a **long double** result. Error handling for these functions can be modified through the functions _matherr and _matherrl.

Return Value

sin and sinl return the sine of the input value.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result, x = 0.5;
   result = sin(x);
   printf("The sin of %lf is %lf\n", x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
sin	+	+	+	+
sinl		+	+	+

3.1.4.19.33 sinh, sinhl

Header File

math.h

Category

Math Routines, Inline Routines

Prototype

```
double sinh(double x);
long double sinhl(long double x);
```

Description

Calculates hyperbolic sine.

sinh computes the hyperbolic sine.

sinl is the **long double** version; it takes a **long double** argument and returns a **long double** result. Error handling for sinh and sinhl can be modified through the functions _matherr and _matherrl.

Return Value

sinh and sinhl return the hyperbolic sine of x.

When the correct value overflows, these functions return the value HUGE_VAL (sinh) or _LHUGE_VAL (sinhl) of appropriate sign. Also, the global variable errno is set to ERANGE.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result, x = 0.5;
   result = sinh(x);
   printf("The hyperbolic sin of %lf is %lf\n", x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
sinh	+	+	+	+
sinhl		+	+	+

3.1.4.19.34 sqrt, sqrtl

Header File

math.h

Category

Math Routines

Prototype

```
double sqrt(double x);
```

```
long double sqrtl(long double x);
```

Description

Calculates the positive square root.

sqrt calculates the positive square root of the argument x.

sqrtl is the **long double** version; it takes a **long double** argument and returns a **long double** result. Error handling for these functions can be modified through the functions _matherr and _matherrl.

Return Value

On success, sqrt and sqrtl return the value calculated, the square root of x. If x is real and positive, the result is positive. If x is real and negative, the global variable errno is set to

EDOM	Domain error

Example

```
#include <math.h>
#include <stdio.h>
int main(void)
{
   double x = 4.0, result;
   result = sqrt(x);
   printf("The square root of %lf is %lf\n", x, result);
```

```
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
sqrt	+	+	+	+
sqrtl		+	+	+

3.1.4.19.35 tan, tanl

Header File

math.h

Category

Math Routines

Prototype

```
double tan(double x);
```

```
long double tanl(long double x);
```

Description

Calculates the tangent.

tan calculates the tangent. Angles are specified in radians.

tanl is the **long double** version; it takes a **long double** argument and returns a **long double** result. Error handling for these routines can be modified through the functions _matherr and _matherrl..

Return Value

tan and tanl return the tangent of x, sin(x)/cos(x).

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result, x;
   x = 0.5;
   result = tan(x);
   printf("The tan of %lf is %lf\n", x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
tan	+	+	+	+
tanl		+	+	+

3.1.4.19.36 tanh, tanhl

Header File

math.h

Category

Math Routines

Prototype

```
double tanh(double x);
```

```
long double tanhl(long double x);
```

Description

Calculates the hyperbolic tangent.

tanh computes the hyperbolic tangent, sinh(x)/cosh(x).

tanhl is the **long double** version; it takes a **long double** argument and returns a **long double** result. Error handling for these functions can be modified through the functions _matherr and _matherrl.

Return Value

tanh and tanhl return the hyperbolic tangent of x.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   double result, x;
   x = 0.5;
   result = tanh(x);
   printf("The hyperbolic tangent of %lf is %lf\n", x, result);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
tanh	+	+	+	+
tanhl		+	+	+

3.1.4.20 mem.h

The following functions, macros, and classes are provided in `mem.h`:

Topics

Name	Description
memccpy (see page 962)	**Header File** mem.h, string.h **Category** Memory and String Manipulation Routines **Prototype** `void *memccpy(void *dest, const void *src, int c, size_t n);` **Description** Copies a block of n bytes. memccpy is available on UNIX System V systems. memccpy copies a block of n bytes from src to dest. The copying stops as soon as either of the following occurs: • The character c is first copied into dest. • n bytes have been copied into dest. **Return Value** memccpy returns a pointer to the byte in dest immediately following c, if c was copied; otherwise, memccpy returns NULL. **Example**

memchr, _wmemchr (see page 963)	**Header File**
	mem.h, string.h
	Category
	Memory and String Manipulation Routines, Inline Routines, C++ Prototyped Routines
	Prototype
	`void *memchr(const void s, int c, size_t n);/ C only */`
	`const void *memchr(const void *s, int c, size_t n);// C++ only`
	`void *memchr(void *s, int c, size_t n);// C++ only`
	`void *memchr(const void s, int c, size_t n);/ C and C++ */`
	`void * _wmemchr(void s, int c, size_t n);/ unicode version */`
	Description
	Searches n bytes for character c.
	memchr is available on UNIX System V systems.
	memchr searches the first n bytes of the block pointed to by s for... more (see page 963)

memcmp (see page 964)	**Header File** mem.h, string.h **Category** Memory and String Manipulation Routines, Inline Routines **Prototype** `int memcmp(const void *s1, const void *s2, size_t n);` **Description** Compares two blocks for a length of exactly n bytes. memcmp is available on UNIX System V systems. memcmp compares the first n bytes of the blocks s1 and s2 as **unsigned char**s. **Return Value** Because it compares bytes as **unsigned char**s, memcmp returns a value that is • < 0 if s1 is less than s2 • = 0 if s1 is the same as s2 • > 0 if s1 is greater than s2 For... more (see page 964)

memcpy, _wmemcpy (see page 965)	**Header File**
	mem.h, string.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`void *memcpy(void *dest, const void *src, size_t n);`
	`void *_wmemcpy(void *dest, const void *src, size_t n);`
	Description
	Copies a block of n bytes.
	memcpy is available on UNIX System V systems.
	memcpy copies a block of n bytes from src to dest. If src and dest overlap, the behavior of memcpy is undefined.
	Return Value
	memcpy returns dest.
	Example

memicmp (see page 965)	**Header File** mem.h, string.h **Category** Memory and String Manipulation Routines **Prototype** `int memicmp(const void *s1, const void *s2, size_t n);` **Description** Compares n bytes of two character arrays, ignoring case. memicmp is available on UNIX System V systems. memicmp compares the first n bytes of the blocks s1 and s2, ignoring character case (upper or lower). **Return Value** memicmp returns a value that is • < 0 if s1 is less than s2 • = 0 if s1 is the same as s2 • > 0 if s1 is greater than s2 **Example**
memmove (see page 966)	**Header File** mem.h, string.h **Category** Memory and String Manipulation Routines **Prototype** `void *memmove(void *dest, const void *src, size_t n);` **Description** Copies a block of n bytes. memmove copies a block of n bytes from src to dest. Even when the source and destination blocks overlap, bytes in the overlapping locations are copied correctly. **Return Value** memmove returns dest. **Example**

memset, _wmemset (see page 967)	**Header File**
	mem.h, string.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`void *memset(void *s, int c, size_t n);`
	`void *_wmemset(void *s, int c, size_t n);`
	Description
	Sets n bytes of a block of memory to byte c.
	memset sets the first n bytes of the array s to the character c.
	Return Value
	memset returns s.
	Example

setmem (see page 968)	**Header File** mem.h **Category** Memory and String Manipulation Routines **Prototype** `void setmem(void *dest, unsigned length, char value);` **Description** Assigns a value to a range of memory. setmem sets a block of length bytes, pointed to by dest, to the byte value. **Return Value** None. **Example**

3.1.4.20.1 memccpy

Header File

mem.h, string.h

Category

Memory and String Manipulation Routines

Prototype

```
void *memccpy(void *dest, const void *src, int c, size_t n);
```

Description

Copies a block of n bytes.

memccpy is available on UNIX System V systems.

memccpy copies a block of n bytes from src to dest. The copying stops as soon as either of the following occurs:

- The character c is first copied into dest.
- n bytes have been copied into dest.

Return Value

memccpy returns a pointer to the byte in dest immediately following c, if c was copied; otherwise, memccpy returns NULL.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   char *src = "This is the source string";
   char dest[50];
   char *ptr;
   ptr = (char *) memccpy(dest, src, 'c', strlen(src));
   if (ptr)
   {
      *ptr = '\0';
      printf("The character was found: %s\n", dest);
   }
   else
      printf("The character wasn't found\n");
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++

3.1.4.20.2 memchr, _wmemchr

Header File

mem.h, string.h

Category

Memory and String Manipulation Routines, Inline Routines, C++ Prototyped Routines

Prototype

```
void *memchr(const void s, int c, size_t n);/ C only */
const void *memchr(const void *s, int c, size_t n);// C++ only
void *memchr(void *s, int c, size_t n);// C++ only
void *memchr(const void s, int c, size_t n);/ C and C++ */
void * _wmemchr(void s, int c, size_t n);/ unicode version */
```

Description

Searches n bytes for character c.

memchr is available on UNIX System V systems.

memchr searches the first n bytes of the block pointed to by s for character c.

Return Value

On success, memchr returns a pointer to the first occurrence of c in s; otherwise, it returns NULL.

Note: If you are using the intrinsic version of these functions, the case of n = 0 will return NULL.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
    char str[17];
    char *ptr;
    strcpy(str, "This is a string");
    ptr = (char *) memchr(str, 'r', strlen(str));
    if (ptr)
       printf("The character 'r' is at position: %d\n", ptr - str);
    else
       printf("The character was not found\n");
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
memchr	+	+	+	+
_wmemchr		+		

3.1.4.20.3 memcmp

Header File

mem.h, string.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
int memcmp(const void *s1, const void *s2, size_t n);
```

Description

Compares two blocks for a length of exactly n bytes.

memcmp is available on UNIX System V systems.

memcmp compares the first n bytes of the blocks s1 and s2 as **unsigned char**s.

Return Value

Because it compares bytes as **unsigned char**s, memcmp returns a value that is

- < 0 if s1 is less than s2
- = 0 if s1 is the same as s2
- > 0 if s1 is greater than s2

For example,

```
memcmp(“\xFF”, “\x7F”, 1)
```

returns a value greater than 0.

Note: If you are using the intrinsic version of these functions, the case of n = 0 will return NULL.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *buf1 = "aaa";
   char *buf2 = "bbb";
   char *buf3 = "ccc";
   int stat;
   stat = memcmp(buf2, buf1, strlen(buf2));
   if (stat > 0)
      printf("buffer 2 is greater than buffer 1\n");
   else
      printf("buffer 2 is less than buffer 1\n");
   stat = memcmp(buf2, buf3, strlen(buf2));
   if (stat > 0)
      printf("buffer 2 is greater than buffer 3\n");
   else
      printf("buffer 2 is less than buffer 3\n");
   return 0;
}
```

Portability

+	+	+	+

3.1.4.20.4 memcpy, _wmemcpy

Header File

mem.h, string.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
void *memcpy(void *dest, const void *src, size_t n);
```

```
void *_wmemcpy(void *dest, const void *src, size_t n);
```

Description

Copies a block of n bytes.

memcpy is available on UNIX System V systems.

memcpy copies a block of n bytes from src to dest. If src and dest overlap, the behavior of memcpy is undefined.

Return Value

memcpy returns dest.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char src[] = "******************************";
   char dest[] = "abcdefghijlkmnopqrstuvwxyz0123456709";
   char *ptr;
   printf("destination before memcpy: %s\n", dest);
   ptr = (char *) memcpy(dest, src, strlen(src));
   if (ptr)
      printf("destination after memcpy: %s\n", dest);
   else
      printf("memcpy failed\n");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
memcpy	+	+	+	+
_wmemcpy		+		

3.1.4.20.5 memicmp

Header File

mem.h, string.h

Category

Memory and String Manipulation Routines

Prototype

```
int memicmp(const void *s1, const void *s2, size_t n);
```

Description

Compares n bytes of two character arrays, ignoring case.

memicmp is available on UNIX System V systems.

memicmp compares the first n bytes of the blocks s1 and s2, ignoring character case (upper or lower).

Return Value

memicmp returns a value that is

- < 0 if s1 is less than s2
- = 0 if s1 is the same as s2
- > 0 if s1 is greater than s2

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *buf1 = "ABCDE123";
   char *buf2 = "abcde456";
   int stat;
   stat = memicmp(buf1, buf2, 5);
   printf("The strings to position 5 are ");
   if (stat)
      printf("not ");
   printf("the same\n");
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.20.6 memmove

Header File

mem.h, string.h

Category

Memory and String Manipulation Routines

Prototype

```
void *memmove(void *dest, const void *src, size_t n);
```

Description

Copies a block of n bytes.

memmove copies a block of n bytes from src to dest. Even when the source and destination blocks overlap, bytes in the overlapping locations are copied correctly.

Return Value

memmove returns dest.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
  char *dest = "abcdefghijklmnopqrstuvwxyz0123456789";
  char *src = "******************************";
  printf("destination prior to memmove: %s\n", dest);
  memmove(dest, src, 26);
  printf("destination after memmove:    %s\n", dest);
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
memmove	+	+	+	+
_fmemmove				

3.1.4.20.7 memset, _wmemset

Header File

mem.h, string.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
void *memset(void *s, int c, size_t n);
```

```
void *_wmemset(void *s, int c, size_t n);
```

Description

Sets n bytes of a block of memory to byte c.

memset sets the first n bytes of the array s to the character c.

Return Value

memset returns s.

Example

```
#include <string.h>
#include <stdio.h>
#include <mem.h>
int main(void)
{
    char buffer[] = "Hello world\n";
    printf("Buffer before memset: %s\n", buffer);
    memset(buffer, '*', strlen(buffer) - 1);
    printf("Buffer after memset:  %s\n", buffer);
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
memset	+	+	+	+
_wmemset		+		

3.1.4.20.8 setmem

Header File

mem.h

Category

Memory and String Manipulation Routines

Prototype

```
void setmem(void *dest, unsigned length, char value);
```

Description

Assigns a value to a range of memory.

setmem sets a block of length bytes, pointed to by dest, to the byte value.

Return Value

None.

Example

```
#include <stdio.h>
#include <alloc.h>
#include <mem.h>
int main(void)
{
   char *dest;
   dest = (char *) calloc(21, sizeof(char));
   setmem(dest, 20, 'c');
   printf("%s\n", dest);
   return 0;
}
```

3.1.4.21 new.h

The following functions, macros, and classes are provided in `new.h`:

Topics

Name	Description

_new_handler (see page 969)	**Header File**
	new.h
	Syntax
	`typedef void (*pvf)();`
	`pvf _new_handler;`
	Description
	_new_handler contains a pointer to a function that takes no arguments and returns **void**. If **operator new()** is unable to allocate the space required, it will call the function pointed to by _new_handler; if that function returns it will try the allocation again. By default, the function pointed to by _new_handler simply terminates the application. The application can replace this handler, however, with a function that can try to free up some space. This is done by assigning directly to _new_handler or by calling the function set_new_handler, which returns... more (see page 969)

set_new_handler function (see page 970)	**Header File**
	new.h
	Category
	Memory Routines
	Syntax
	`typedef void (new * new_handler)();`
	`new_handler set_new_handler(new_handler my_handler);`
	Description
	set_new_handler installs the function to be called when the global **operator new** or **operator new[]()** cannot allocate the requested memory. By default the new operators throw an bad_alloc exception if memory cannot be allocated. You can change this default behavior by calling set_new_handler to set a new handler. To retain the traditional version of new, which does not throw exceptions, you can use set_new_handler(0).
	If new cannot allocate the requested memory, it calls the handler that was set by a previous call to set_new_handler.... more (see page 970)

3.1.4.21.1 _new_handler

Header File

new.h

Syntax

```
typedef void (*pvf)();
pvf _new_handler;
```

Description

_new_handler contains a pointer to a function that takes no arguments and returns **void**. If **operator new()** is unable to allocate the space required, it will call the function pointed to by _new_handler; if that function returns it will try the allocation again. By default, the function pointed to by _new_handler simply terminates the application. The application can replace this handler, however, with a function that can try to free up some space. This is done by assigning directly to _new_handler or by calling the function set_new_handler, which returns a pointer to the former handler.

As an alternative, you can set using the function set_new_handler, like this:

```
pvf set_new_handler(pvf p);
```

_new_handler is provided primarily for compatibility with C++ version 1.2. In most cases this functionality can be better provided by overloading **operator new()**.

Example

3.1.4.21.2 set_new_handler function

Header File

new.h

Category

Memory Routines

Syntax

```
typedef void (new * new_handler)();
new_handler set_new_handler(new_handler my_handler);
```

Description

set_new_handler installs the function to be called when the global **operator new** or **operator new[]()** cannot allocate the requested memory. By default the new operators throw an bad_alloc exception if memory cannot be allocated. You can change this default behavior by calling set_new_handler to set a new handler. To retain the traditional version of new, which does not throw exceptions, you can use set_new_handler(0).

If new cannot allocate the requested memory, it calls the handler that was set by a previous call to set_new_handler. If there is no handler installed by set_new_handler, new returns 0. my_handler should specify the actions to be taken when new cannot satisfy a request for memory allocation. The new_handler type, defined in new.h, is a function that takes no arguments and returns **void**. A new_handler can throw a bad_alloc exception.

- The user-defined my_handler should do one of the following:
- return after freeing memory
- throw an bad_alloc exception or an exception derived from bad_alloc
- call abort or exit functions

If my_handler returns, then new will again attempt to satisfy the request.

Ideally, my_handler would free up memory and return. new would then be able to satisfy the request and the program would continue. However, if my_handler cannot provide memory for new, my_handler must throw an exception or terminate the program. Otherwise, an infinite loop will be created.

Preferably, you should overload **operator new()** and **operator new[]()** to take appropriate actions for your applications.

Return Value

set_new_handler returns the old handler, if one has been registered.

The user-defined argument function, my_handler, should not return a value.

Example

```
#include <iostream>
#include <new.h>
#include <stdlib.h>
using std::cout;
using std::hex;
void mem_warn() {
  std::cerr << "\nCan't allocate!";
  exit(1);
}

void main(void) {
  std::set_new_handler(mem_warn);
  char *ptr = new char[100];
  cout << "\nFirst allocation: ptr = " << hex << long(ptr);
  ptr = new char[64000U];
```

```
  cout << "\nFinal allocation: ptr = " << hex << long(ptr);
  std::set_new_handler(0);  // Reset to default.
}
```

3.1.4.22 process.h

The following functions, macros, and classes are provided in `process.h`:

Topics

Name	Description
P_xxxx #defines (see page 975)	**Header File** process.h **Description** Modes used by the spawn... functions.
_adopt_thread (see page 975)	**Header File** process.h **Category** Process Control Routines **Prototype** `_PTHREAD_ADOPTION_DATA _adopt_thread(void (_USERENTRY *__start_address)(void *), void * __arglist, int free_flag );` **Description** “Adopts” a thread, created with the Windows API CreateThread function, to the C++Builder RTL by hooking up the necessary internal data (exceptions, stack info, and so forth). _adopt_thread thereby allows the RTL to handle exception issues in that thread. The execution path of this thread is then transferred to another function (the adoptive thread function). From the RTL's perspective, during the execution of this adoptive thread function, the thread appears as if it had been created by a call to... more (see page 975)
_beginthread (see page 976)	**Header File** process.h **Category** Process Control Routines **Prototype** `unsigned long _beginthread(void (_USERENTRY *__start)(void *), unsigned __stksize, void *__arg);` **Description** Starts execution of a new thread. **Note:** The start_address must be declared to be _USERENTRY. The _beginthread function creates and starts a new thread. The thread starts execution at start_address. The size of its stack in bytes is stack_size; the stack is allocated by the operating system after the stack size is rounded up to the next multiple of 4096. The thread is passed arglist as its only parameter; it can be NULL, but must be present. The thread function should... more (see page 976)
_beginthreadNT (see page 978)	**Header File** process.h **Category** Process Control Routines **Prototype** `unsigned long _beginthreadNT(void (_USERENTRY *start_address)(void *), unsigned stack_size, void *arglist, void *security_attrib, unsigned long create_flags, unsigned long *thread_id);` **Description** Starts execution of a new thread under Windows NT. **Note:** The start_address must be declared to be _USERENTRY. All multithread Windows NT programs must use _beginthreadNT or the _beginthread function instead of the operating system thread-creation API function because these functions perform initialization required for correct operation of the runtime library functions. The _beginthreadNT function provides support for the operating system security. These functions are available only in the multithread libraries. The _beginthreadNT... more (see page 978)

_beginthreadex (see page 980)	**Header File** process.h **Category** Process Control Routines **Prototype** `unsigned long _beginthreadex(void *__security_attr, unsigned __stksize, unsigned (__stdcall *__start)(void *), void *__arg, unsigned __create_flags, unsigned *__thread_id);` **Description** Creates a thread and allows specifying the other parameters of the OS API CreateThread (such as security and thread creation flags). The _endthreadex function will be called automatically when the thread function terminates. The value returned from your thread function will be passed along to _endthreadex, which in turn will pass it along to the ExitThread API. The return value can then be retrieved using the GetExitCodeThread API. Unlike _endthread, the _endthreadex function does **not... more (see page 980)**
_c_exit (see page 981)	**Header File** process.h **Category** Process Control Routines **Prototype** `void _c_exit(void);` **Description** Performs _exit cleanup without terminating the program. _c_exit performs the same cleanup as _exit, except that it does not terminate the calling process. **Return Value** None. **Example**
_cexit (see page 982)	**Header File** process.h **Category** Process Control Routines **Prototype** `void _cexit(void);` **Description** Performs exit cleanup without terminating the program. _cexit performs the same cleanup as exit, closing all files but without terminating the calling process. The _cexit function calls any registered "exit functions" (posted with atexit). Before _cexit returns, it flushes all input/output buffers and closes all streams that were open. **Return Value** None. **Example**
_endthread (see page 983)	**Header File** process.h **Category** Process Control Routines **Prototype** `void _endthread(void);` **Description** Terminates execution of a thread. The _endthread function terminates the currently executing thread by closing the thread handle and calling the ExitThread API. The thread must have been started by an earlier call to _beginthread or _beginthreadNT.. _endthread is called automatically by the runtime library when your thread function terminates. This function is available in the multithread libraries; it is not in the single-threaded libraries. **Return Value** The function does not return a value.

_endthreadex (see page 984)	**Header File** process.h **Category** Process Control Routines **Prototype** `void _endthreadex(unsigned thread_retval);` **Description** Terminates execution of the current thread by calling the ExitThread API, but without closing the handle. The thread must have been created by an earlier call to _beginthreadex. The runtime library will call _endthreadex autotmatically, when your thread function terminates. _endthreadex receives the return value of your thread function in thread_retval, and will pass it along to the Win32 ExitThread API. **Note:** Note: Performs the same operation as _endthread(), but does not close the thread handle. **Return Value** None.
_expand (see page 984)	**Header File** process.h **Category** Memory Routines **Prototype** `void *_expand(void *block, size_t size);` **Description** Grows or shrinks a heap block in place. This function attempts to change the size of an allocated memory block without moving the block's location in the heap. The data in the block are not changed, up to the smaller of the old and new sizes of the block. The block must have been allocated earlier with malloc, calloc, or realloc, and must not have been freed. **Return Value** If _expand is able to resize the block without moving it, _expand returns a pointer to the block,... more (see page 984)
_unadopt_thread (see page 985)	**Header File** process.h **Category** Process Control Routines **Prototype** `void _unadopt_thread(_PTHREAD_ADOPTION_DATA thd);` **Description** Frees the RTL thread-specific data associated with a previous call to _adopt_thread. **Return Value** None. **Portability**
cwait (see page 985)	**Header File** process.h **Category** Process Control Routines **Prototype** `int cwait(int *statloc, int pid, int action);` **Description** Waits for child process to terminate. The cwait function waits for a child process to terminate. The process ID of the child to wait for is pid. If statloc is not NULL, it points to the location where cwait will store the termination status. The action specifies whether to wait for the process alone, or for the process and all of its children. If the child process terminated normally (by calling exit, or returning from main), the termination status word is defined as follows:... more (see page 985)

execl, execle, execlp, execlpe, execv, execve, execvp, execvpe, _wexecl, _wexecle, _wexeclp, _wexeclpe, _wexecv, _wexecve, _wexecvp, _wexecvpe (see page 987)	**Header File**

	`int _wexecv(wchar_t *path, wchar_t *argv[]);`
	`int execve(char *path, char... more (see page 987)`

getpid (see page 989)	**Header File** process.h **Category** Process Control Routines **Prototype** unsigned getpid(void) **Description** Gets the process ID of a program. This function returns the current process ID--an integer that uniquely identifies the process. **Return Value** getpid returns the current process' ID. **Example**

spawnl, spawnle, spawnlp, spawnlpe, spawnv, spawnve, spawnvp, spawnvpe, _wspawnl, _wspawnle, _wspawnlp, _wspawnlpe, _wspawnv, _wspawnve, _wspawnvp, _wspawnvpe (see page 989)	**Header File**
	process.h
	Category
	Process Control Routines
	Prototype
	`int spawnl(int mode, char *path, char *arg0, arg1, ..., argn, NULL);`
	`int _wspawnl(int mode, wchar_t *path, wchar_t *arg0, arg1, ..., argn, NULL);`
	`int spawnle(int mode, char *path, char *arg0, arg1, ..., argn, NULL, char *envp[]);`
	`int _wspawnle(int mode, wchar_t *path, wchar_t *arg0, arg1, ..., argn, NULL, wchar_t *envp[]);`
	`int spawnlp(int mode, char *path, char *arg0, arg1, ..., argn, NULL);`
	`int _wspawnlp(int mode, wchar_t *path, wchar_t *arg0, arg1, ..., argn, NULL);`
	`int spawnlpe(int mode, char *path, char *arg0, arg1, ..., argn, NULL, char *envp[]);`
	`int _wspawnlpe(int mode, wchar_t *path, wchar_t *arg0, arg1, ...,... more (see page 989)`

wait (see page 992)	**Header File** process.h **Category** Process Control Routines **Prototype** int wait(int *statloc); **Description** Waits for one or more child processes to terminate. The wait function waits for one or more child processes to terminate. The child processes must be those created by the calling program; wait cannot wait for grandchildren (processes spawned by child processes). If statloc is not NULL, it points to location where wait will store the termination status. If the child process terminated normally (by calling exit, or returning from main), the termination status word is defined as follows:

3.1.4.22.1 P_xxxx #defines

Header File

process.h

Description

Modes used by the spawn... functions.

Constant	Meaning
P_WAIT	Child runs separately, parent waits until exit
P_DETACH	Child and parent run concurrently with child process in background mode
P_NOWAIT	Child and parent run concurrently (Not implemented)
P_NOWAITO	Child and parent run concurrently, but the child process is not saved
P_OVERLAY	Child replaces parent so that parent no longer exists

3.1.4.22.2 _adopt_thread

Header File

process.h

Category

Process Control Routines

Prototype

```
_PTHREAD_ADOPTION_DATA _adopt_thread(void (_USERENTRY *__start_address)(void *), void *__arglist, int free_flag );
```

Description

“Adopts” a thread, created with the Windows API CreateThread function, to the C++Builder RTL by hooking up the necessary internal data (exceptions, stack info, and so forth). _adopt_thread thereby allows the RTL to handle exception issues in that thread. The execution path of this thread is then transferred to another function (the adoptive thread function). From the RTL's perspective, during the execution of this adoptive thread function, the thread appears as if it had been created by a call to _beginthreadex and is allowed all the benefits, such as calling other RTL functions and throwing/catching exceptions.

To create a thread, a user normally calls _beginthread. This hooks up the internal data automatically. _adopt_thread is primarily used in cases in which this internal data is not present. For example, this happens when a user is called from a thread that came

from an outside source, such as ISAPI.

Using _adopt_thread thereby allows C++Builder compiled DLLs to be used from non-C++Builder EXEs. _adopt_thread works by:

- calling the user function (passing in the arglist param)
- unhooking the exception information
- returning a handle to the thread context

This process allows the same function to be used again (without reallocating all that data). At the end of this cycle, the _unadopt_thread function can be called to finally free up the rest of this data.

The last parameter, free_flag, determines whether the thread data structures are freed upon function exit:

- If free_flag is zero, then when the adoptive function exits only its exception handler is un-hooked. The rest of the RTL specific data that had been allocated during the thread's adoption, remains valid. If the same thread then calls _adopt_thread again, the existing data is used, the exception handler is rehooked, and the specified adoptive thread function is called.
- If free_flag is set to non-zero, the thread data structures will be freed before _adopt_thread returns. In this case the returned thread handle will be NULL since its associated date has already been freed.

Return Value

If the __free_flag parameter is **false** (zero), _adopt_thread returns a handle (thread context) that can later be used to free these data structures by passing it to _unadopt_thread().

If the __free_flag parameter to _adopt_thread is non-zero, the thread data is freed before _adopt_thread returns, and the returned handle is NULL.

If an error has occurred, errno is set to:

ENOMEM Not enough memory

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.22.3 _beginthread

Header File

process.h

Category

Process Control Routines

Prototype

```
unsigned long _beginthread(void (_USERENTRY *__start)(void *), unsigned __stksize, void *__arg);
```

Description

Starts execution of a new thread.

Note: The start_address must be declared to be _USERENTRY.

The _beginthread function creates and starts a new thread. The thread starts execution at start_address.

The size of its stack in bytes is stack_size; the stack is allocated by the operating system after the stack size is rounded up to the next multiple of 4096. The thread is passed arglist as its only parameter; it can be NULL, but must be present. The thread function should terminate by simply returning; the _endthread. function will be called automatically. The _endthread function will automatically close the handle, and set the return value of the thread to zero.

Either this function or _beginthreadNT must be used instead of the operating system thread-creation API function because _beginthread and _beginthreadNT perform initialization required for correct operation of the runtime library functions.

This function is available only in the multithread libraries.

Return Value

_beginthread returns the handle of the new thread. The return value is a standard Windows handle that can be used in operating system API's such as SuspendThread and ResumeThread.

On error, the function returns -1, and the global variable errno is set to one of the following values:

EAGAIN	Too many threads
EINVAL	Invalid stack size (i.e. less than 16 bytes, or equal to zero)
ENOMEM	Not enough memory

Also see the description of the Win32 API GetLastError, in the MSDN Library.

Example

```
/*  Use the -tWM  (32-bit multi-threaded target) command-line switch for this example  */
#include <stdio.h>
#include <errno.h>
#include <stddef.h>     /* _threadid variable */
#include <process.h>    /* _beginthread, _endthread */
#include <time.h>       /* time, _ctime */
void thread_code(void *threadno)
{
    time_t t;
    time(&t);
    printf("Executing thread number %d, ID = %d, time = %s\n",
        (int)threadno, _threadid, ctime(&t));

}

void start_thread(int i)
{
    int thread_id;
#if     defined(__WIN32__)
    if ((thread_id = _beginthread(thread_code,4096,(void *)i)) == (unsigned long)-1)
#else
    if ((thread_id = _beginthread(thread_code,4096,(void *)i)) == -1)
#endif
    {
        printf("Unable to create thread %d, errno = %d\n",i,errno);
        return;
    }
    printf("Created thread %d, ID = %ld\n",i,thread_id);
}
int main(void)
{
    int i;
    for (i = 1; i < 20; i++)
        start_thread(i);
    printf("Hit ENTER to exit main thread.\n");
    getchar();
    return 0;
}
```

3.1.4.22.4 _beginthreadNT

Header File

process.h

Category

Process Control Routines

Prototype

```
unsigned long _beginthreadNT(void (_USERENTRY *start_address)(void *), unsigned stack_size,
void *arglist, void *security_attrib, unsigned long create_flags, unsigned long *thread_id);
```

Description

Starts execution of a new thread under Windows NT.

Note: The start_address must be declared to be _USERENTRY.

All multithread Windows NT programs must use _beginthreadNT or the _beginthread function instead of the operating system thread-creation API function because these functions perform initialization required for correct operation of the runtime library functions. The _beginthreadNT function provides support for the operating system security. These functions are available only in the multithread libraries.

The _beginthreadNT function creates and starts a new thread. The thread starts execution at start_address. When your thread terminates, the _endthread function will be called automatically. _endthread will close the thread handle, and call the ExitThread API.

The size of its stack in bytes is stack_size; the stack is allocated by the operating system after the stack size is rounded up to the next multiple of 4096. The thread arglist can be NULL, but must be present.

The _beginthreadNT function uses the security_attr pointer to access the SECURITY_ATTRIBUTES structure. The structure contains the security attributes for the thread. If security_attr is NULL, the thread is created with default security attributes. The thread handle is not inherited if security_attr is NULL.

_beginthreadNT reads the create_flags variable for flags that provide additional information about the thread creation. This variable can be zero, specifying that the thread will run immediately upon creation. The variable can also be CREATE_SUSPENDED; in which case, the thread will not run until the ResumeThread function is called. ResumeThread is provided by the Win32 API.

_beginthreadNT initializes the thread_id variable with the thread identifier.

Return Value

On success, _beginthreadNT returns the handle of the new thread. The return value is a standard Windows handle that can be used in operating system API's such as SuspendThread and ResumeThread.

On error, it returns -1, and the global variable errno is set to one of the following values:

EAGAIN	Too many threads
EINVAL	Invalid stack size (i.e. less than 16 bytes, or equal to zero)
ENOMEM	Not enough memory

Also see the description of the Win32 API GetLastError, in the MSDN Library.

Example

```
/*  Use the -tWM  (32-bit multi-threaded target) command-line switch for this example  */
```

```
#pragma checkoption -tWM
#include        <windows.h>
#include        <process.h>
#include        <stdio.h>
#define NTHREADS 25
static LONG runningThreads = 0;
static HANDLE doneEvent;
/* This function acts as the 'main' function for each new thread */
static void threadMain(void *arg)
{
  printf("Thread %2d has an ID of %u\n", (int)arg, GetCurrentThreadId());
  /* Use InterlockedDecrement() to modify the global runningThreads in a
 * thread safe manner.  When the count hits 0, signal the main thread if
 * it created an event for us.
 */
  if (InterlockedDecrement(&runningThreads) == 0 && doneEvent)
      SetEvent(doneEvent);
}
int main(void)
{
   HANDLE hThreads[NTHREADS];
   int i;
   DWORD  threadId;
   SECURITY_ATTRIBUTES  sa = {
          sizeof(SECURITY_ATTRIBUTES), /* structure size */
          0,      /* No security descriptor */
          TRUE    /* Thread handle is inheritable */
   };
   /* Create NTHREADS inheritable threads that are initially suspended and that will run
starting at threadMain()*/
   for(i = 0; i < NTHREADS; i++) {
      hThreads[i] = (HANDLE)_beginthreadNT(
         threadMain,   /* Thread starting address */
         4096,         /* Thread stack size */
         (void *)i,    /* Thread start argument */
         &sa,          /* Thread security */
         CREATE_SUSPENDED,  /* Create in suspended state */
         &threadId);   /* Thread ID */
      if(hThreads[i] == INVALID_HANDLE_VALUE) {
         MessageBox(0, "Thread Creation Failed", "Error", MB_OK);
         return  1;
      }
      ++runningThreads;
      printf("Created thread %2d with an ID of %u\n", i, threadId);
   }
   printf("\nPress ENTER to thaw all threads\n\n");
   getchar();
   /* Create the event that will signal when all threads are done */
   doneEvent = CreateEvent(NULL, FALSE, FALSE, NULL);

   /* Resume the suspended threads */
   for(i = 0; i < NTHREADS; i++)
      ResumeThread(hThreads[i]);
   /* Wait for all threads to finish execution, if we can */
   if (doneEvent) {
     WaitForSingleObject(doneEvent, INFINITE);
     CloseHandle(doneEvent);
   }
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.22.5 _beginthreadex

Header File

process.h

Category

Process Control Routines

Prototype

```
unsigned long _beginthreadex(void *__security_attr, unsigned __stksize, unsigned (__stdcall *__start)(void *), void *__arg, unsigned __create_flags, unsigned *__thread_id);
```

Description

Creates a thread and allows specifying the other parameters of the OS API CreateThread (such as security and thread creation flags). The _endthreadex function will be called automatically when the thread function terminates. The value returned from your thread function will be passed along to _endthreadex, which in turn will pass it along to the ExitThread API. The return value can then be retrieved using the GetExitCodeThread API.

Unlike _endthread, the _endthreadex function does **not** close the thread handle, thereby allowing other threads to block on this one without fear that the handle will be freed out from under the system.

Other than the order of parameters and the closing of the thread handle, _beginthreadex performs same operation as _beginthreadNT.

Note: Note: The start address needs to be defined to return an unsigned, which is the thread exit code.

Return Value

_beginthreadex returns the handle of the new thread. The return value is a standard Windows handle that can be used in operating system API's such as SuspendThread and ResumeThread.

If unsuccessful, 0 is returned, and errno is set as follows:

EAGAIN	Too many threads
ENOMEM	Not enough memory
EINVAL	Bad stack value (i.e. less than 16 bytes or equal to zero)

Also see the description of the Win32 API GetLastError, in the MSDN Library.

Example

```
//*  Use the -tWM  (32-bit multi-threaded target) command-line switch for this example  */
#pragma checkoption -tWM
#include        <windows.h>
#include        <process.h>
#include        <stdio.h>
#define NTHREADS 25
/* This function acts as the 'main' function for each new thread */
static unsigned __stdcall threadMain(void *arg)
{
   printf("Thread %2d has an ID of %u\n", (int)arg, GetCurrentThreadId());
   return 0;
}
int main(void)
{
   HANDLE hThreads[NTHREADS];
   int i;
```

```
    unsigned threadId;
    SECURITY_ATTRIBUTES  sa = {
           sizeof(SECURITY_ATTRIBUTES), /* structure size */
           0,      /* No security descriptor */
           TRUE    /* Thread handle is inheritable */
    };
    /* Create NTHREADS inheritable threads that are initially suspended and that will run
starting at threadMain()*/
    for(i = 0; i < NTHREADS; i++) {
       hThreads[i] = (HANDLE)_beginthreadex(
          &sa,          /* Thread security */
          4096,         /* Thread stack size */
          threadMain,   /* Thread starting address */
          (void *)i,    /* Thread start argument */
          CREATE_SUSPENDED,  /* Create in suspended state */
          &threadId);   /* Thread ID */
       if(hThreads[i] == INVALID_HANDLE_VALUE) {
          MessageBox(0, "Thread Creation Failed", "Error", MB_OK);
          return  1;
       }
       printf("Created thread %2d with an ID of %u\n", i, threadId);
    }
    printf("\nPress ENTER to thaw all threads\n\n");
    getchar();

/* Resume the suspended threads */
    for(i = 0; i < NTHREADS; i++)
       ResumeThread(hThreads[i]);

/* Wait for the threads to run */
    WaitForMultipleObjects(NTHREADS, hThreads, TRUE, INFINITE);
/* Close all of the thread handles */
    for(i = 0; i < NTHREADS; i++)
       CloseHandle(hThreads[i]);
    return 0;
}
```

Portability

	+		

3.1.4.22.6 _c_exit

Header File

process.h

Category

Process Control Routines

Prototype

```
void _c_exit(void);
```

Description

Performs _exit cleanup without terminating the program.

_c_exit performs the same cleanup as _exit, except that it does not terminate the calling process.

Return Value

None.

Example

```
#include <process.h>
#include <io.h>
#include <fcntl.h>
#include <stdio.h>
main()
{
  int fd;
  char c;

  if ((fd = open("_c_exit.c",O_RDONLY)) < 0)
  {
    printf("Unable to open _c_exit.c for reading\n");
    return 1;
  }
  if (read(fd,&c,1) != 1)
    printf("Unable to read from open file handle %d before _c_exit\n",fd);
  else
    printf("Successfully read from open file handle %d before _c_exit\n",fd);
  _c_exit();
  if (read(fd,&c,1) != 1)
    printf("Unable to read from open file handle %d after _c_exit\n",fd);
  else
    printf("Successfully read from open file handle %d after _c_exit\n",fd);
 return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.22.7 _cexit

Header File

process.h

Category

Process Control Routines

Prototype

```
void _cexit(void);
```

Description

Performs exit cleanup without terminating the program.

_cexit performs the same cleanup as exit, closing all files but without terminating the calling process. The _cexit function calls any registered "exit functions" (posted with atexit). Before _cexit returns, it flushes all input/output buffers and closes all streams that were open.

Return Value

None.

Example

```
#include <windows.h>
```

```
#include <process.h>
#include <io.h>
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
void exit_func(void)
{
  printf("Exit function called\n\n");
  printf("Close Window to return to program... It will beep if able to read from file");
}
int main(void)
{
  int fd;
  char c;
  if ((fd = open("_cexit.c",O_RDONLY)) < 0)
  {
printf("Unable to open _cexit.c for reading\n");
return 1;
  }
  atexit(exit_func);
  if (read(fd,&c,1) != 1)
printf("Unable to read from open file handle %d before _cexit\n",fd);
  else
printf("Successfully read from open file handle %d before _cexit\n",fd);
  _cexit();
  if (read(fd,&c,1) == 1)
  MessageBeep(0);
  return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.22.8 _endthread

Header File

process.h

Category

Process Control Routines

Prototype

```
void _endthread(void);
```

Description

Terminates execution of a thread.

The _endthread function terminates the currently executing thread by closing the thread handle and calling the ExitThread API. The thread must have been started by an earlier call to _beginthread or _beginthreadNT.. _endthread is called automatically by the runtime library when your thread function terminates.

This function is available in the multithread libraries; it is not in the single-threaded libraries.

Return Value

The function does not return a value.

3.1.4.22.9 _endthreadex

Header File

process.h

Category

Process Control Routines

Prototype

```
void _endthreadex(unsigned thread_retval);
```

Description

Terminates execution of the current thread by calling the ExitThread API, but without closing the handle. The thread must have been created by an earlier call to _beginthreadex. The runtime library will call _endthreadex autotmatically, when your thread function terminates. _endthreadex receives the return value of your thread function in thread_retval, and will pass it along to the Win32 ExitThread API.

Note: Note: Performs the same operation as _endthread(), but does not close the thread handle.

Return Value

None.

3.1.4.22.10 _expand

Header File

process.h

Category

Memory Routines

Prototype

```
void *_expand(void *block, size_t size);
```

Description

Grows or shrinks a heap block in place.

This function attempts to change the size of an allocated memory block without moving the block's location in the heap. The data in the block are not changed, up to the smaller of the old and new sizes of the block. The block must have been allocated earlier with malloc, calloc, or realloc, and must not have been freed.

Return Value

If _expand is able to resize the block without moving it, _expand returns a pointer to the block, whose address is unchanged. If _expand is unsuccessful, it returns a NULL pointer and does not modify or resize the block.

Example

```
#include <stdio.h>
#include <malloc.h>
#include <stdlib.h>
void main(void)
{
  char *bufchar, *newbuf;
```

```
  printf( "Allocate a 512 element buffer\n" );
  if( (bufchar = (char *) calloc(512, sizeof( char ) )) == NULL)
    exit( 1 );
  printf( "Allocated %d bytes at %Fp\n",
    _msize ( bufchar ), (void __far *)bufchar );
  if ((newbuf = (char *) _expand (bufchar, 1024)) == NULL)
    printf ("cannot expand");
  else {
    bufchar = newbuf;
    printf (" Expanded block to %d bytes at %Fp\n",
      _msize( bufchar ) , (void __far *)bufchar );
  }
  free( bufchar );
  exit (0);
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.22.11 _unadopt_thread

Header File

process.h

Category

Process Control Routines

Prototype

```
void _unadopt_thread(_PTHREAD_ADOPTION_DATA thd);
```

Description

Frees the RTL thread-specific data associated with a previous call to _adopt_thread.

Return Value

None.

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.22.12 cwait

Header File

process.h

Category

Process Control Routines

Prototype

```
int cwait(int *statloc, int pid, int action);
```

Description

Waits for child process to terminate.

The cwait function waits for a child process to terminate. The process ID of the child to wait for is pid. If statloc is not NULL, it points to the location where cwait will store the termination status. The action specifies whether to wait for the process alone, or for the process and all of its children.

If the child process terminated normally (by calling exit, or returning from main), the termination status word is defined as follows:

Bits 0-7	Zero
Bits 8-15	The least significant byte of the return code from the child process. This is the value that is passed to exit, or is returned from main. If the child process simply exited from main without returning a value, this value will be unpredictable.

If the child process terminated abnormally, the termination status word is defined as follows:

Bits 0-7Termination information about the child:

	1	Critical error abort.
	2	Execution fault, protection exception.
	3	External termination signal.
Bits 8-15	Zero	

Bits 8-15	Zero

If pid is 0, cwait waits for any child process to terminate. Otherwise, pid specifies the process ID of the process to wait for; this value must have been obtained by an earlier call to an asynchronous spawn function.

The acceptable values for action are WAIT_CHILD, which waits for the specified child only, and WAIT_GRANDCHILD, which waits for the specified child and all of its children. These two values are defined in process.h.

Return Value

When cwait returns after a normal child process termination, it returns the process ID of the child.

When cwait returns after an abnormal child termination, it returns -1 to the parent and sets errno to EINTR (the child process terminated abnormally).

If cwait returns without a child process completion, it returns a -1 value and sets errno to one of the following values:

ECHILD	No child exists or the pid value is bad
EINVAL	A bad action value was specified

int _wexecvp(wchar_t *path, wchar_t *argv[]);
int execvpe(char *path, char *argv[], char **env);
int _wexecvpe(wchar_t *path, wchar_t *argv[], wchar_t **env);
```

Description

Loads and runs other programs.

The functions in the exec... family load and run (execute) other programs, known as child processes. When an exec... call succeeds, the child process overlays the parent process. There must be sufficient memory available for loading and executing the child process.

path is the file name of the called child process. The exec... functions search for path using the standard search algorithm:

- If no explicit extension is given, the functions search for the file as given. If the file is not found, they add .EXE and search again. If not found, they add .COM and search again. If found, the command processor, COMSPEC (Windows) or COMMAND.COM (DOS), is used to run the batch file.
- If an explicit extension or a period is given, the functions search for the file exactly as given.

The suffixes l, v, p, and e added to the exec... "family name" specify that the named function operates with certain capabilities.

l	specifies that the argument pointers (arg0, arg1, ..., argn) are passed as separate arguments. Typically, the l suffix is used when you know in advance the number of arguments to be passed.
v	specifies that the argument pointers (argv[0] ..., arg[n]) are passed as an array of pointers. Typically, the v suffix is used when a variable number of arguments is to be passed.
p	specifies that the function searches for the file in those directories specified by the PATH environment variable (without the p suffix, the function searches only the current working directory). If the path parameter does not contain an explicit directory, the function searches first the current directory, then the directories set with the PATH environment variable.
e	specifies that the argument env can be passed to the child process, letting you alter the environment for the child process. Without the e suffix, child processes inherit the environment of the parent process.

Each function in the exec... family must have one of the two argument-specifying suffixes (either l or v). The path search and environment inheritance suffixes (p and e) are optional; for example:

- execl is an exec... function that takes separate arguments, searches only the root or current directory for the child, and passes on the parent's environment to the child.
- execvpe is an exec... function that takes an array of argument pointers, incorporates PATH in its search for the child process, and accepts the env argument for altering the child's environment.

The exec... functions must pass at least one argument to the child process (arg0 or argv[0]); this argument is, by convention, a copy of path. (Using a different value for this 0th argument won't produce an error.)

path is available for the child process.

When the l suffix is used, arg0 usually points to path, and arg1, ..., argn point to character strings that form the new list of arguments. A mandatory null following argn marks the end of the list.

When the e suffix is used, you pass a list of new environment settings through the argument env. This environment argument is an array of character pointers. Each element points to a null-terminated character string of the form

```
envvar = value
```

where envvar is the name of an environment variable, and value is the string value to which envvar is set. The last element in env is null. When env is null, the child inherits the parents' environment settings.

The combined length of arg0 + arg1 + ... + argn (or of argv[0] + argv[1] + ... + argn[n]), including space characters that separate the arguments, must be less than 260 bytes. Null terminators are not counted.

When an exec... function call is made, any open files remain open in the child process.

Return Value

If successful, the exec... functions do not return. On error, the exec... functions return -1, and the global variable errno is set to one of the following values:

EACCES	Permission denied
EMFILE	Too many open files
ENOENT	Path or file name not found
ENOEXEC	Exec format error
ENOMEM	Not enough memory

Example

```
/* execl() example */
#include <stdio.h>
#include <process.h>

int main(int argc, char *argv[])
{
```

```
  int loop;
  printf("%s running...\n\n", argv[0]);

  if (argc == 1) {    /* check for only one command-line parameter */
    printf("%s calling itself again...\n", argv[0]);
    execl(argv[0], argv[0], "ONE", "TWO", "THREE", NULL);
    perror("EXEC:");
    exit(1);
  }
  printf("%s called with arguments:\n", argv[0]);
  for (loop = 1; loop <= argc; loop++)
    puts(argv[loop]);       /* Display all command-line parameters */
  return 0;
}
```

3.1.4.22.14 getpid

Header File

process.h

Category

Process Control Routines

Prototype

```
unsigned getpid(void)
```

Description

Gets the process ID of a program.

This function returns the current process ID--an integer that uniquely identifies the process.

Return Value

getpid returns the current process' ID.

Example

```
#include <stdio.h>
#include <process.h>
int main()
{
   printf("This program's process identification number (PID) "
          "number is %X\n", getpid());
   printf("Note: under DOS it is the PSP segment\n");
   return 0;
}
```

int spawnvpe(int mode, char *path, char *argv[], char *envp[]);
int _wspawnvpe(int mode, wchar_t *path, wchar_t *argv[], wchar_t *envp[]);
```

Note: In spawnle, spawnlpe, spawnv, spawnve, spawnvp, and spawnvpe, the last string must be NULL.

Description

The functions in the spawn... family create and run (execute) other files, known as child processes. There must be sufficient memory available for loading and executing a child process.

The value of mode determines what action the calling function (the parent process) takes after the spawn... call. The possible values of mode are

P_WAIT	Puts parent process on hold until child process completes execution.
P_NOWAIT	Continues to run parent process while child process runs. The child process ID is returned, so that the parent can wait for completion using cwait or wait.
P_NOWAITO	Identical to P_NOWAIT except that the child process ID isn't saved by the operating system, so the parent process can't wait for it using cwait or wait.
P_DETACH	Identical to P_NOWAITO, except that the child process is executed in the background with no access to the keyboard or the display.
P_OVERLAY	Overlays child process in memory location formerly occupied by parent. Same as an exec... call.

path is the file name of the called child process. The spawn... function calls search for path using the standard operating system search algorithm:

- If there is no extension or no period, they search for an exact file name. If the file is not found, they search for files first with the extension EXE, then COM, and finally BAT.

- If an extension is given, they search only for the exact file name.
- If only a period is given, they search only for the file name with no extension.
- If path does not contain an explicit directory, spawn... functions that have the **p** suffix search the current directory, then the directories set with the operating system PATH environment variable.

The suffixes p, l, and v, and e added to the spawn... "family name" specify that the named function operates with certain capabilities.

p	**The function searches for the file in those directories specified by the PATH environment variable. Without the p suffix, the function searches only the current working directory.**
l	The argument pointers arg0, arg1, ..., argn are passed as separate arguments. Typically, the l suffix is used when you know in advance the number of arguments to be passed.
v	The argument pointers argv[0], ..., arg[n] are passed as an array of pointers. Typically, the v suffix is used when a variable number of arguments is to be passed.
e	The argument envp can be passed to the child process, letting you alter the environment for the child process. Without the e suffix, child processes inherit the environment of the parent process.

Each function in the spawn... family must have one of the two argument-specifying suffixes (either l or v). The path search and environment inheritance suffixes (p and e) are optional.

For example:

- spawnl takes separate arguments, searches only the current directory for the child, and passes on the parent's environment to the child.
- spawnvpe takes an array of argument pointers, incorporates PATH in its search for the child process, and accepts the envp argument for altering the child's environment.

The spawn... functions must pass at least one argument to the child process (arg0 or argv[0]). This argument is, by convention, a copy of path. (Using a different value for this 0 argument won't produce an error.) If you want to pass an empty argument list to the child process, then arg0 or argv[0] must be NULL.

When the l suffix is used, arg0 usually points to path, and arg1, ..., argn point to character strings that form the new list of arguments. A mandatory null following argn marks the end of the list.

When the e suffix is used, you pass a list of new environment settings through the argument envp. This environment argument is an array of character pointers. Each element points to a null-terminated character string of the form

```
envvar = value
```

where envvar is the name of an environment variable, and value is the string value to which envvar is set. The last element in envp[] is null. When envp is null, the child inherits the parents' environment settings.

The combined length of arg0 + arg1 + ... + argn (or of argv[0] + argv[1] + ... + argv[n]), including space characters that separate the arguments, must be less than 260 bytes for Windows (128 for DOS). Null-terminators are not counted.

When a spawn... function call is made, any open files remain open in the child process.

Return Value

When successful, the spawn... functions, where mode is P_WAIT, return the child process' exit status (0 for a normal termination). If the child specifically calls exit with a nonzero argument, its exit status can be set to a nonzero value.

If mode is P_NOWAIT or P_NOWAITO, the spawn functions return the process ID of the child process. The ID obtained when using P_NOWAIT can be passed to cwait.

On error, the spawn... functions return -1, and the global variable errno is set to one of the following values:

E2BIG	Arg list too long
EINVAL	Invalid argument
ENOENT	Path or file name not found
ENOEXEC	Exec format error

ENOMEM	Not enough memory

Example

```
#include <process.h>
#include <stdio.h>
void spawnl_example(void)
{
   int result;
   result = spawnl(P_WAIT, "bcc32.exe", "bcc32.exe", NULL);
   if (result == -1)
   {
      perror("Error from spawnl");
      exit(1);
   }
}
int main(void)
{
  spawnl_example();
  return 0;
}
```

3.1.4.22.16 wait

Header File

process.h

Category

Process Control Routines

Prototype

```
int wait(int *statloc);
```

Description

Waits for one or more child processes to terminate.

The wait function waits for one or more child processes to terminate. The child processes must be those created by the calling program; wait cannot wait for grandchildren (processes spawned by child processes). If statloc is not NULL, it points to location where wait will store the termination status.

If the child process terminated normally (by calling exit, or returning from main), the termination status word is defined as follows:

Bits 0-7	**Zero.**
Bits 8-15	The least significant byte of the return code from the child process. This is the value that is passed to exit, or is returned from main. If the child process simply exited from main without returning a value, this value will be unpredictable. If the child process terminated abnormally, the termination status word is defined as follows:
Bits 0-7	Termination information about the child:

Bits 8-15	**Zero.**

Return Value

When wait returns after a normal child process termination it returns the process ID of the child.

When wait returns after an abnormal child termination it returns -1 to the parent and sets errno to EINTR.

If wait returns without a child process completion it returns a -1 value and sets errno to:

ECHILD	No child process exists

A later call to longjmp with jmpb restores the captured task state and returns in such a way that setjmp appears to have returned with the value val. Under Win32, a task state includes: • No segment registers are saved • Register variables • EBX, EDI, ESI • Stack pointer (ESP) • Frame pointer (EBP) • Flags are not saved A task state is complete enough that setjmp can be used to implement co-routines. setjmp must be called before... more (see page 995)

3.1.4.23.1 longjmp

Header File

setjmp.h

Category

Miscellaneous Routines

Prototype

```
void longjmp(jmp_buf jmpb, int retval);
```

Description

Performs nonlocal goto.

A call to longjmp restores the task state captured by the last call to setjmp with the argument jmpb. It then returns in such a way that setjmp appears to have returned with the value retval.

A Win32 task state includes:

- Register variables
- EBX, EDI, ESI
- Stack pointer (ESP)
- Frame pointer (EBP)
- No segment registers are saved
- Flags are not saved

A task state is complete enough that setjmp and longjmp can be used to implement co-routines.

setjmp must be called before longjmp. The routine that called setjmp and set up jmpb must still be active and cannot have returned before the longjmp is called. If this happens, the results are unpredictable.

longjmp cannot pass the value 0; if 0 is passed in retval, longjmp will substitute 1.

Return Value

None.

Example

```
#include <stdio.h>
#include <setjmp.h>
#include <stdlib.h>
void subroutine(jmp_buf);
int main(void)
{

    int value;
    jmp_buf jumper;
    value = setjmp(jumper);
    if (value != 0)
    {
       printf("Longjmp with value %d\n", value);
       exit(value);
    }
    printf("About to call subroutine ... \n");
    subroutine(jumper);
    return 0;
}
void subroutine(jmp_buf jumper)
{
    longjmp(jumper,1);
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.23.2 setjmp

Header File

setjmp.h

Category

Miscellaneous Routines

Prototype

```
int setjmp(jmp_buf jmpb);
```

Description

Sets up for nonlocal goto.

setjmp captures the complete task state in jmpb and returns 0.

A later call to longjmp with jmpb restores the captured task state and returns in such a way that setjmp appears to have returned with the value val.

Under Win32, a task state includes:

- No segment registers are saved
- Register variables

- EBX, EDI, ESI
- Stack pointer (ESP)
- Frame pointer (EBP)
- Flags are not saved

A task state is complete enough that setjmp can be used to implement co-routines.

setjmp must be called before longjmp. The routine that calls setjmp and sets up jmpb must still be active and cannot have returned before the longjmp is called. If it has returned, the results are unpredictable.

setjmp is useful for dealing with errors and exceptions encountered in a low-level subroutine of a program.

Return Value

setjmp returns 0 when it is initially called. If the return is from a call to longjmp, setjmp returns a nonzero value (as in the example).

Example

```
#include <stdio.h>
#include <setjmp.h>
#include <stdlib.h>
void subroutine(jmp_buf);
int main(void)
{

    int value;
    jmp_buf jumper;
    value = setjmp(jumper);
    if (value != 0)
    {
       printf("Longjmp with value %d\n", value);
       exit(value);
    }
    printf("About to call subroutine ... \n");
    subroutine(jumper);
    return 0;
}
void subroutine(jmp_buf jumper)
{
    longjmp(jumper,1);
}
```

3.1.4.24 share.h

The following functions, macros, and classes are provided in `share.h`:

Topics

Name	Description
SH_xxxx #defines (see page 997)	**Header File** share.h **Description** File-sharing mode for use with sopen.

3.1.4.24.1 SH_xxxx #defines

Header File

share.h

Description

File-sharing mode for use with sopen.

SH_COMPAT	Sets compatibility mode:
	Allows other opens with SH_COMPAT. The call will fail if the file has already been opened in any other shared mode.
SH_DENYNONE	Permits read/write access
	Allows other shared opens to the file, but not other SH_COMPAT opens
SH_DENYNO	Permits read/write access (provided for compatibility)
SH_DENYRD	Denies read access. Allows only writes from any other open to the file
SH_DENYRW	Denies read/write access. Only the current handle may have access to the file
SH_DENYWR	Denies write access. Allows only reads from any other open to the file
O_NOINHERIT	The file is not passed to child programs

These file-sharing attributes are in addition to any locking performed on the files.

3.1.4.25 signal.h

The following functions, macros, and classes are provided in `signal.h`:

Topics

Name	Description
SIGxxxx #defines (see page 998)	**Header File** signal.h **Description** Signal types used by raise and signal.
SIG_xxx #defines (see page 998)	**Header File** signal.h **Description** Predefined functions for handling signals generated by raise or by external events.
raise (see page 999)	**Header File** signal.h **Category** Process Control Routines **Prototype** `int raise(int sig);` **Description** Sends a software signal to the executing program. raise sends a signal of type sig to the program. If the program has installed a signal handler for the signal type specified by sig, that handler will be executed. If no handler has been installed, the default action for that signal type will be taken. The signal types currently defined in signal.h are noted here:

signal (C RTL) (see page 1000)	**Header File** signal.h **Category** Process Control Routines **Prototype** `void (_USERENTRY *signal(int sig, void (_USERENTRY *func)(int sig[, int subcode])))(int);` **Description** Specifies signal-handling actions. signal determines how receipt of signal number sig will subsequently be treated. You can install a user-specified handler routine (specified by the argument func) or use one of the two predefined handlers, SIG_DFL and SIG_IGN, in signal.h. The function func must be declared with the _USERENTRY calling convention. A routine that catches a signal (such as a floating point) also clears the signal. To continue to receive signals, a signal handler must be reinstalled by calling signal again.... more (see page 1000)

3.1.4.25.1 SIGxxxx #defines

Header File

signal.h

Description

Signal types used by raise and signal.

Signal	Note	Meaning	Default Action
SIGABRT	(*)	Abnormal termination	= to calling _exit(3)
SIGFPE		Bad floating-point operation	= to calling _exit(1)
		Arithmetic error caused by	
		division by 0, invalid operation, etc.	
SIGILL		Illegal operation	= to calling _exit(1)
SIGINT		Control-C interrupt	= to calling _exit(3)
SIGSEGV		Invalid access to storage	= to calling _exit(1)
SIGTERM	(*)	Request for program termination	= to calling _exit(1)

(*) Signal types marked with a (*) aren't generated by Borland C++ during normal operation. However, they can be generated with raise.

3.1.4.25.2 SIG_xxx #defines

Header File

signal.h

Description

Predefined functions for handling signals generated by raise or by external events.

Name	Meaning
SIG_DFL	Terminate the program
SIG_IGN	No action, ignore signal
SIG_ERR	Return error code

3.1.4.25.3 raise

Header File

signal.h

Category

Process Control Routines

Prototype

```
int raise(int sig);
```

Description

Sends a software signal to the executing program.

raise sends a signal of type sig to the program. If the program has installed a signal handler for the signal type specified by sig, that handler will be executed. If no handler has been installed, the default action for that signal type will be taken.

The signal types currently defined in signal.h are noted here:

SIGABRT	Abnormal termination
SIGFPE	Bad floating-point operation
SIGILL	Illegal instruction
SIGINT	Ctrl-C interrupt
SIGSEGV	Invalid access to storage
SIGTERM	Request for program termination
SIGUSR1	User-defined signal
SIGUSR2	User-defined signal
SIGUSR3	User-defined signal
SIGBREAK	Ctrl-Break interrupt

Note: SIGABRT isn't generated by C++Builder during normal operation. It can, however, be generated by abort, raise, or unhandled exceptions.

Return Value

On success, raise returns 0.

On error it returns nonzero.

Example

```
#include <signal.h>
int main(void)
{
    int a, b;
    a = 10;
    b = 0;
    if (b == 0)
    /* preempt divide by zero error */
       raise(SIGFPE);
    a = a / b;
    return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.25.4 signal (C RTL)

Header File

signal.h

Category

Process Control Routines

Prototype

```
void (_USERENTRY *signal(int sig, void (_USERENTRY *func)(int sig[, int subcode])))(int);
```

Description

Specifies signal-handling actions.

signal determines how receipt of signal number sig will subsequently be treated. You can install a user-specified handler routine (specified by the argument func) or use one of the two predefined handlers, SIG_DFL and SIG_IGN, in signal.h. The function func must be declared with the _USERENTRY calling convention.

A routine that catches a signal (such as a floating point) also clears the signal. To continue to receive signals, a signal handler must be reinstalled by calling signal again.

SIG_DFL	Terminates the program
SIG_ERR	Indicates an error return from signal
SIG_IGN	Ignore this type signal

The following table shows signal types and their defaults:

SIGBREAK	Keyboard must be in raw mode.
SIGABRT	Abnormal termination. Default action is equivalent to calling _exit(3).
SIGFPE	Arithmetic error caused by division by 0, invalid operation, and the like. Default action is equivalent to calling _exit(1).
SIGILL	Illegal operation. Default action is equivalent to calling _exit(1).
SIGINT	Ctrl-C interrupt. Default action is equivalent to calling _exit(3).
SIGSEGV	Illegal storage access. Default action is equivalent to calling _exit(1).
SIGTERM	Request for program termination. Default action is equivalent to calling _exit(1).
	User-defined signals can be generated only by calling raise. Default action is to ignore the signal.

signal.h defines a type called sig_atomic_t, the largest integer type the processor can load or store atomically in the presence of asynchronous interrupts (this is a 32-bit integer -- a Borland C++ integer).

When a signal is generated by the raise function or by an external event, the following two things happen:

- If a user-specified handler has been installed for the signal, the action for that signal type is set to SIG_DFL.

- The user-specified function is called with the signal type as the parameter.

User-specified handler functions can terminate by a return or by a call to abort, _exit, exit, or longjmp. If your handler function is expected to continue to receive and handle more signals, you must have the handler function call signal again.

Borland C++ implements an extension to ANSI C when the signal type is SIGFPE, SIGSEGV, or SIGILL. The user-specified handler function is called with one or two extra parameters. If SIGFPE, SIGSEGV, or SIGILL has been raised as the result of an explicit call to the raise function, the user-specified handler is called with one extra parameter, an integer specifying that the handler is being explicitly invoked. The explicit activation values for SIGFPE, SIGSEGV and SIGILL are as follows

Note: Declarations of these types are defined in float.h.

SIGFPE	FPE_EXPLICITGEN
SIGSEGV	SEGV_EXPLICITGEN
SIGILL	ILL_EXPLICITGEN

If SIGFPE is raised because of a floating-point exception, the user handler is called with one extra parameter that specifies the FPE_xxx type of the signal. If SIGSEGV, SIGILL, or the integer-related variants of SIGFPE signals (FPE_INTOVFLOW or FPE_INTDIV0) are raised as the result of a processor exception, the user handler is called with two extra parameters:

1.The SIGFPE, SIGSEGV, or SIGILL exception type (see float.h for all these types). This first parameter is the usual ANSI signal type.

2.An integer pointer into the stack of the interrupt handler that called the user-specified handler. This pointer points to a list of the processor registers saved when the exception occurred. The registers are in the same order as the parameters to an interrupt function; that is, EBP, EDI, ESI, EDS, ES, EDX, ECX, EBX, EAX, EIP, CS, EFL. To have a register value changed when the handler returns, change one of the locations in this list.

For example, to have a new SI value on return, do something like this:

```
*((int*)list_pointer + 2) = new_SI_value;
```

In this way, the handler can examine and make any adjustments to the registers that you want.

The following SIGFPE-type signals can occur (or be generated). They correspond to the exceptions that the 80x87 family is capable of detecting, as well as the "INTEGER DIVIDE BY ZERO" and the "INTERRUPT ON OVERFLOW" on the main CPU. (The declarations for these are in float.h.)

FPE_INTOVFLOW	INTO executed with OF flag set
FPE_INTDIV0	Integer divide by zero
FPE_INVALID	Invalid operation
FPE_ZERODIVIDE	Division by zero
FPE_OVERFLOW	Numeric overflow
FPE_UNDERFLOW	Numeric underflow
FPE_INEXACT	Precision
FPE_EXPLICITGEN	User program executed raise(SIGFPE)
FPE_STACKFAULT	Floating-point stack overflow or underflow
FPE_STACKFAULT	Stack overflow

The FPE_INTOVFLOW and FPE_INTDIV0 signals are generated by integer operations, and the others are generated by floating-point operations. Whether the floating-point exceptions are generated depends on the coprocessor control word, which can be modified with _control87. Denormal exceptions are handled by Borland C++ and not passed to a signal handler.

The following SIGSEGV-type signals can occur:

SEGV_BOUND	Bound constraint exception
SEGV_EXPLICITGEN	raise(SIGSEGV) was executed

The following SIGILL-type signals can occur:

ILL_EXECUTION	Illegal operation attempted
ILL_EXPLICITGEN	raise(SIGILL) was executed

When the signal type is SIGFPE, SIGSEGV, or SIGILL, a return from a signal handler is generally not advisable if the state of the floating point processor is corrupt, the results of an integer division are wrong, an operation that shouldn't have overflowed did, a bound instruction failed, or an illegal operation was attempted. The only time a return is reasonable is when the handler alters the registers so that a reasonable return context exists or the signal type indicates that the signal was generated explicitly (for example, FPE_EXPLICITGEN, SEGV_EXPLICITGEN, or ILL_EXPLICITGEN). Generally in this case you would print an error message and terminate the program using _exit, exit, or abort. If a return is executed under any other conditions, the program's action will probably be unpredictable.

Note: Take special care when using the signal function in a multithread program. The SIGINT, SIGTERM, and SIGBREAK signals can be used only by the main thread (thread one) in a non-Win32 application. When one of these signals occurs, the currently executing thread is suspended, and control transfers to the signal handler (if any) set up by thread one. Other signals can be handled by any thread.

Note: A signal handler should not use C++ runtime library functions, because a semaphore deadlock might occur. Instead, the handler should simply set a flag or post a semaphore, and return immediately.

Return Value

On success, signal returns a pointer to the previous handler routine for the specified signal type.

On error, signal returns SIG_ERR, and the external variable errno is set to EINVAL.

Example

```
/* signal example */
/*
    This example installs a signal handler routine for SIGFPE,
    catches an integer overflow condition, makes an adjustment to AX
    register, and returns.  This example program MAY cause your computer
    to crash, and will produce runtime errors depending on which memory
    model is used.
*/
#pragma inline
#include <stdio.h>
#include <signal.h>
#ifdef __cplusplus
   typedef void (*fptr)(int);
#else
   typedef void (*fptr)();
#endif
void Catcher(int *reglist)
{
   signal(SIGFPE, (fptr)Catcher);  //  ******reinstall signal handler
   printf("Caught it!\n"); *(reglist + 8) = 3; /* make return AX = 3 */
}
int main(void)
{
   signal(SIGFPE, (fptr)Catcher);  /* cast Catcher to appropriate type */
   asm     mov     ax,07FFFH       /* AX = 32767 */
   asm     inc     ax              /* cause overflow */
   asm     into                    /* activate handler */
   /* The handler set AX to 3 on return. If that had not happened,
```

```
      there would have been another exception when the next 'into'
      executed after the 'dec' instruction. */
   asm     dec     ax              /* no overflow now */
   asm     into                    /* doesn't activate */
   return 0;
}
```

	Description
	Implement a variable argument list.
	Some C functions, such as vfprintf and vprintf, take variable argument lists in addition to taking a number of fixed (known) parameters. The va_arg, va_end, and va_start macros provide a portable way to access these argument lists. They are used for stepping through a list of arguments when the called function does not know the number and types of the arguments being passed.
	The header file stdarg.h declares one type (**va_list**) and... more (see page 1003)

3.1.4.26.1 va_arg, va_end, va_start

Header File

stdarg.h

Category

Variable Argument List Routines

Prototype

```
void va_start(va_list ap, lastfix);
type va_arg(va_list ap, type);
void va_end(va_list ap);
```

Description

Implement a variable argument list.

Some C functions, such as vfprintf and vprintf, take variable argument lists in addition to taking a number of fixed (known) parameters. The va_arg, va_end, and va_start macros provide a portable way to access these argument lists. They are used for stepping through a list of arguments when the called function does not know the number and types of the arguments being

passed.

The header file stdarg.h declares one type (**va_list**) and three macros (va_start, va_arg, and va_end).

- **va_list**: This array holds information needed by va_arg and va_end. When a called function takes a variable argument list, it declares a variable ap of type **va_list**.
- **va_start**: This routine (implemented as a macro) sets ap to point to the first of the variable arguments being passed to the function. va_start must be used before the first call to va_arg or va_end.
- va_start takes two parameters: ap and lastfix. (ap is explained under va_list in the preceding paragraph; lastfix is the name of the last fixed parameter being passed to the called function.)
- **va_arg:** This routine (also implemented as a macro) expands to an expression that has the same type and value as the next argument being passed (one of the variable arguments). The variable ap to va_arg should be the same ap that va_start initialized.

  Note: Because of default promotions, you cannot use char, unsigned char

  , or **float** types with va_arg.

  Note: The first time va_arg is used, it returns the first argument in the list. Each successive time va_arg is used, it returns the next argument in the list. It does this by first dereferencing ap, and then incrementing ap to point to the following item. va_arg uses the type to both perform the dereference and to locate the following item. Each successive time va_arg is invoked, it modifies ap to point to the next argument in the list.
- **va_end:** This macro helps the called function perform a normal return. va_end might modify ap in such a way that it cannot be used unless va_start is recalled. va_end should be called after va_arg has read all the arguments; failure to do so might cause strange, undefined behavior in your program.

Return Value

va_start and va_end return no values; va_arg returns the current argument in the list (the one that ap is pointing to).

Example

```
#include <stdio.h>
#include <stdarg.h>
/* calculate sum of a 0 terminated list */
void sum(char *msg, ...)
{
   int total = 0;
   va_list ap;
   int arg;
   va_start(ap, msg);
   while ((arg = va_arg(ap,int)) != 0) {
      total += arg;
   }
   printf(msg, total);
   va_end(ap);
}
int main(void) {
   sum("The total of 1+2+3+4 is %d\n", 1,2,3,4,0);
   return 0;
}
```

3.1.4.27 stddef.h

The following functions, macros, and classes are provided in `stddef.h`:

Topics

Name	Description
NULL #define (see page 1005)	**Header File** stddef.h **Description** Null pointer constant that is compatible with any data object pointer. It is not compatible with function pointers. When a pointer is equivalent to NULL it is guaranteed not to point to any data object defined within the program.
_threadid (see page 1005)	**Header File** stddef.h **Syntax** `extern long _threadid;` **Description** _threadid is a long integer that contains the ID of the currently executing thread. It is implemented as a macro, and should be declared only by including stddef.h.
offsetof (see page 1006)	**Header File** stddef.h **Category** Memory Routines **Prototype** `size_t offsetof(struct_type, struct_member);` **Description** Gets the byte offset to a structure member. offsetof is available only as a macro. The argument struct_type is a **struct** type. struct_member is any element of the **struct** that can be accessed through the member selection operators or pointers. If struct_member is a bit field, the result is undefined. See also sizeof for more information on memory allocation and alignment of structures. **Return Value** offsetof returns the number of bytes from the start of the structure to the start of the named structure member. **Portability**

3.1.4.27.1 NULL #define

Header File

stddef.h

Description

Null pointer constant that is compatible with any data object pointer. It is not compatible with function pointers. When a pointer is equivalent to NULL it is guaranteed not to point to any data object defined within the program.

3.1.4.27.2 _threadid

Header File

stddef.h

Syntax

```
extern long _threadid;
```

Description

_threadid is a long integer that contains the ID of the currently executing thread. It is implemented as a macro, and should be declared only by including stddef.h.

3.1.4.27.3 offsetof

Header File

stddef.h

Category

Memory Routines

Prototype

```
size_t offsetof(struct_type, struct_member);
```

Description

Gets the byte offset to a structure member.

offsetof is available only as a macro. The argument struct_type is a **struct** type. struct_member is any element of the **struct** that can be accessed through the member selection operators or pointers.

If struct_member is a bit field, the result is undefined.

See also sizeof for more information on memory allocation and alignment of structures.

Return Value

offsetof returns the number of bytes from the start of the structure to the start of the named structure member.

Portability

POSIX	Win32	ANSI C	ANSI C++
	+	+	+

3.1.4.28 stdio.h

The following functions, macros, and classes are provided in `stdio.h`:

Topics

Name	Description
BUFSIZ #define (see page 1023)	**Header File** stdio.h **Description** Default buffer size used by setbuf function.
_F_xxxx #defines (see page 1023)	**Header File** stdio.h **Description** File status flags of streams
OPEN_MAX #define (see page 1024)	**Header File** stdio.h **Description** Number of files that can be open simultaneously.
L_ctermid #define (see page 1024)	**Header File** stdio.h **Description** The length of a device id string.

L_tmpnam #define (see page 1024)	**Header File** stdio.h **Description** Size of an array large enough to hold a temporary file name string.
TMP_MAX #define (see page 1024)	**Header File** stdio.h **Description** Maximum number of unique file names.
_IOxxx #defines (see page 1025)	**Header File** stdio.h **Description** Constants for defining buffering style to be used with a file.

_fsopen, _wfsopen (see page 1025)	**Header File**
	stdio.h, share.h
	Category
	Input/output Routines
	Prototype
	`FILE *_fsopen(const char *filename, const char *mode, int shflag);`
	`FILE *_wfsopen(const wchar_t *filename, const wchar_t *mode, int shflag);`
	Description
	Opens a stream with file sharing.
	_fsopen opens the file named by filename and associates a stream with it. _fsopen returns a pointer that is used to identify the stream in subsequent operations.
	The mode string used in calls to _fsopen is one of the following values:

_pclose (see page 1027)	**Header File** stdio.h **Category** Input/output Routines, Process Control Routines **Prototype** `int _pclose(FILE * stream);` **Description** Waits for piped command to complete. _pclose closes a pipe stream created by a previous call to _popen, and then waits for the associated child command to complete. **Return Value** On success, _pclose returns the termination status of the child command. This is the same value as the termination status returned by cwait, except that the high and low order bytes of the low word are swapped. On error, it returns -1. **Portability**

_popen, _wpopen (see page 1027)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`FILE *_popen (const char *command, const char *mode);`
	`FILE *_wpopen (const wchar_t *command, const wchar_t *mode);`
	Description
	Creates a command processor pipe.
	The _popen function creates a pipe to the command processor. The command processor is executed asynchronously, and is passed the command line in command. The mode string specifies whether the pipe is connected to the command processor's standard input or output, and whether the pipe is to be opened in binary or text mode.
	The mode string can take one of the following values:

_snprintf;_snwprintf (see page 1028)	**Header File**
	stdio.h
	Category
	Memory and String Manipulation Routines
	Syntax
	`int _snprintf(char* buffer, size_t nsize, const char* format, ...);`
	`int _snwprintf(wchar_t* buffer, size_t nsize, const wchar_t* format, ...);`
	Description
	Sends formatted output to a string of a maximum length specified by nsize. _snprintf and _snwprintf are Microsoft compatible with the _snprintf and _snprintfw functions, respectively.
	If the number of bytes to output is:
	• < nsize, then all of the characters have been written, including the terminating '\0' character.
	• == nsize, then nsize characters are written with no terminating '\0' character.
	If nsize is 0, then the string will not be... more (see page 1028)

_vsnprintf;_vsnwprintf (see page 1029)	**Header File**
	stdio.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int _vsnprintf(char* buffer, size_t nsize, const char* format, va_list param);`
	`int _vsnwprintf(wchar_t* buffer, size_t nsize, const wchar_t* format, va_list param);`
	Description
	Sends formatted output to a string of a maximum length specified by nsize. _vsnprintf and _vsnwprintf are Microsoft compatible with the _vsnprintf and _vsnprintfw functions, respectively.
	If the number of bytes to output is:
	• < nsize, then all of the characters have been written, including the terminating '\0' character.
	• == nsize, then nsize characters are written with no terminating '\0' character.
	If nsize is 0, then the string will... more (see page 1029)

clearerr (see page 1029)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `void clearerr(FILE *stream);` **Description** Resets error indication. clearerr resets the named stream's error and end-of-file indicators to 0. Once the error indicator is set, stream operations continue to return error status until a call is made to clearerr or rewind. The end-of-file indicator is reset with each input operation. **Return Value** None. **Example**
EOF #define (see page 1030)	**Header File** stdio.h **Description** A constant indicating that end-of-file has been reached on a file.

fclose (see page 1030)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int fclose(FILE *stream);` **Description** Closes a stream. fclose closes the named stream. All buffers associated with the stream are flushed before closing. System-allocated buffers are freed upon closing. Buffers assigned with setbuf or setvbuf are not automatically freed. (But if setvbuf is passed null for the buffer pointer it will free it upon close.) **Return Value** fclose returns 0 on success. It returns EOF if any errors were detected. **Portability**
_fcloseall (see page 1031)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int _fcloseall(void);` **Description** Closes open streams. _fcloseall closes all open streams except stdauxstdstreams When _fcloseall flushes the associated buffers before closing a stream. The buffers allocated by the system are released. **Note:** stdprn and stdaux streams are not available in Win32. **Return Value** _fcloseall returns the total number of streams it closed. The _fcloseall function returns EOF if any errors were detected. **Example**

_fdopen, _wfdopen (see page 1032)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`FILE *_fdopen(int handle, char *type);`
	`FILE *_wfdopen(int handle, wchar_t *type);`
	Description
	Associates a stream with a file handle.
	_fdopen associates a stream with a file handle obtained from creat, dup, dup2, or open.
	The type of stream must match the mode of the open handle.
	The type string used in a call to _fdopen is one of the following values:

feof (see page 1033)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int feof(FILE *stream);` **Description** Detects end-of-file on a stream. feof is a macro that tests the given stream for an end-of-file indicator. Once the indicator is set read operations on the file return the indicator until rewind is called or the file is closed. The end-of-file indicator is reset with each input operation. **Return Value** feof returns nonzero if an end-of-file indicator was detected on the last input operation on the named stream and 0 if end-of-file has not been reached. **Example**

ferror (see page 1034)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int ferror(FILE *stream);` **Description** Detects errors on stream. ferror is a macro that tests the given stream for a read or write error. If the stream's error indicator has been set it remains set until clearerr or rewind is called or until the stream is closed. **Return Value** ferror returns nonzero if an error was detected on the named stream. **Example**
fflush (see page 1035)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int fflush(FILE *stream);` **Description** Flushes a stream. If the given stream has buffered output fflush writes the output for stream to the associated file. The stream remains open after fflush has executed. fflush has no effect on an unbuffered stream. **Return Value** fflush returns 0 on success. It returns EOF if any errors were detected. **Example**

fgetc, fgetwc (see page 1036)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int fgetc(FILE *stream);`
	`wint_t fgetwc(FILE *stream);`
	Description
	Gets character from stream.
	fgetc returns the next character on the named input stream.
	Return Value
	On success fgetc returns the character read after converting it to an **int** without sign extension. On end-of-file or error it returns EOF.
	Example

_fgetchar, _fgetwchar (see page 1037)	**Header File**
	stdio.h
	Category
	Console I/O Routines
	Prototype
	`int _fgetchar(void);`
	`wint_t _fgetwchar(void);`
	Description
	Reads a character from stdin.
	_fgetchar returns the next character from stdin. It is defined as fgetc(stdin).
	Note: For Win32 GUI applications, stdin must be redirected.
	Return Value
	On success _fgetchar returns the character read after converting it to an **int** without sign extension. On end-of-file or error it returns EOF.
	Example

fgetpos (see page 1037)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int fgetpos(FILE *stream, fpos_t *pos);` **Description** Gets the current file pointer. fgetpos stores the position of the file pointer associated with the given stream in the location pointed to by pos. The exact value is unimportant; its value is opaque except as a parameter to subsequent fsetpos calls. **Return Value** On success fgetpos returns 0. On failure it returns a nonzero value and sets the global variable errno to

fgets, fgetws (see page 1039)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`char *fgets(char *s, int n, FILE *stream);`
	`wchar_t *fgetws(wchar_t *s, int n, FILE *stream); // Unicode version`
	Description
	Gets a string from a stream.
	fgets reads characters from stream into the string s. The function stops reading when it reads either n - 1 characters or a newline character whichever comes first. fgets retains the newline character at the end of s. A null byte is appended to s to mark the end of the string.
	Return Value
	On success fgets returns the string pointed to by s; it returns NULL on end-of-file... more (see page 1039)

_fileno (see page 1040)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int _fileno(FILE *stream);` **Description** Gets the file handle. _fileno is a macro that returns the file handle for the given stream. If stream has more than one handle _fileno returns the handle assigned to the stream when it was first opened. **Return Value** _fileno returns the integer file handle associated with stream. **Example**
_flushall (see page 1040)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int _flushall(void);` **Description** Flushes all streams. _flushall clears all buffers associated with open input streams and writes all buffers associated with open output streams to their respective files. Any read operation following _flushall reads new data into the buffers from the input files. Streams stay open after _flushall executes. **Return Value** _flushall returns an integer the number of open input and output streams. **Example**

fopen, _wfopen (see page 1041)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`FILE *fopen(const char *filename, const char *mode);`
	`FILE *_wfopen(const wchar_t *filename, const wchar_t *mode);`
	Description
	Opens a stream.
	fopen opens the file named by filename and associates a stream with it. fopen returns a pointer to be used to identify the stream in subsequent operations.
	The mode string used in calls to fopen is one of the following values:

fprintf, fwprintf (see page 1042)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int fprintf(FILE *stream, const char *format[, argument, ...]);`
	`int fwprintf(FILE *stream, const wchar_t *format[, argument, ...]);`
	Description
	Writes formatted output to a stream.
	fprintf accepts a series of arguments applies to each a format specifier contained in the format string pointed to by format and outputs the formatted data to a stream. There must be the same number of format specifiers as arguments.
	Note: For details on format specifiers, see printf Format Specifiers.
	Return Value
	fprintf returns the number of bytes output. In the event of error it returns EOF.
	Example

fputc, fputwc (see page 1043)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int fputc(int c, FILE *stream);`
	`wint_t fputwc(wint_t c, FILE *stream);`
	Description
	Puts a character on a stream.
	fputc outputs character c to the named stream.
	Note: For Win32 GUI applications, stdin must be redirected.
	Return Value
	On success, fputc returns the character c. On error, it returns EOF.
	Example

_fputchar, _fputwchar (see page 1044)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int _fputchar(int c);`
	`wint_t _fputwchar(wint_t c);`
	Description
	Outputs a character to stdout.
	_fputchar outputs character c to stdout. _fputchar(c) is the same as fputc(cstdout).
	Note: For Win32 GUI applications, stdout must be redirected.
	Return Value
	On success _fputchar returns the character c.
	On error it returns EOF.
	Example

fputs, fputws (see page 1044)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int fputs(const char *s, FILE *stream);`
	`int fputws(const wchar_t *s, FILE *stream);`
	Description
	Outputs a string on a stream.
	fputs copies the null-terminated string s to the given output stream; it does not append a newline character and the terminating null character is not copied.
	Return Value
	On success fputs returns a non-negative value.
	On error it returns a value of EOF.
	Example

fread (see page 1045)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `size_t fread(void *ptr, size_t size, size_t n, FILE *stream);` **Description** Reads data from a stream. fread reads n items of data each of length size bytes from the given input stream into a block pointed to by ptr. The total number of bytes read is (n * size). **Return Value** On success fread returns the number of items (not bytes) actually read. On end-of-file or error it returns a short count (possibly 0). **Example**

freopen, _wfreopen (see page 1046)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`FILE *freopen(const char *filename, const char *mode, FILE *stream);`
	`FILE *_wfreopen(const wchar_t *filename, const wchar_t *mode, FILE *stream);`
	Description
	Associates a new file with an open stream.
	freopen substitutes the named file in place of the open stream. It closes stream regardless of whether the open succeeds. freopen is useful for changing the file attached to stdin, stdout, or stderr.
	The mode string used in calls to fopen is one of the following values:

fscanf, fwscanf (see page 1047)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int fscanf(FILE *stream, const char *format[, address, ...]);`
	`int fwscanf(FILE *stream, const wchar_t *format[, address, ...]);`
	Description
	Scans and formats input from a stream.
	fscanf scans a series of input fields one character at a time reading from a stream. Then each field is formatted according to a format specifier passed to fscanf in the format string pointed to by format. Finally fscanf stores the formatted input at an address passed to it as an argument following format. The number of format specifiers and addresses must be the same as the number of... more (see page 1047)

fseek (see page 1048)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int fseek(FILE *stream, long offset, int whence);` **Description** Repositions a file pointer on a stream. fseek sets the file pointer associated with stream to a new position that is offset bytes from the file location given by whence. For text mode streams offset should be 0 or a value returned by ftell. whence must be one of the values 0. 1, or 2 which represent three symbolic constants (defined in stdio.h) as follows: fseek discards any character pushed back using ungetc. fseek is used with stream I/O; for file handle I/O use lseek.... more (see page 1048)
fsetpos (see page 1049)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int fsetpos(FILE *stream, const fpos_t *pos);` **Description** Positions the file pointer of a stream. fsetpos sets the file pointer associated with stream to a new position. The new position is the value obtained by a previous call to fgetpos on that stream. It also clears the end-of-file indicator on the file that stream points to and undoes any effects of ungetc on that file. After a call to fsetpos the next operation on the file can be input or output. **Return Value** On success fsetpos returns 0. On failure it returns a nonzero... more (see page 1049)
ftell (see page 1050)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `long int ftell(FILE *stream);` **Description** Returns the current file pointer. ftell returns the current file pointer for stream. The offset is measured in bytes from the beginning of the file (if the file is binary). The value returned by ftell can be used in a subsequent call to fseek. **Return Value** ftell returns the current file pointer position on success. It returns -1L on error and sets the global variable errno to a positive value. In the event of an error return the global variable errno is set to one of the following... more (see page 1050)
fwrite (see page 1051)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `size_t fwrite(const void *ptr, size_t size, size_t n, FILE *stream);` **Description** Writes to a stream. fwrite appends n items of data each of length size bytes to the given output file. The data written begins at ptr. The total number of bytes written is (n x size). ptr in the declarations is a pointer to any object. **Return Value** On successful completion fwrite returns the number of items (not bytes) actually written. On error it returns a short count. **Example**

getc, getwc (see page 1052)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int getc(FILE *stream);`
	`wint_t getwc(FILE *stream);`
	Description
	Gets character from stream.
	getc returns the next character on the given input stream and increments the stream's file pointer to point to the next character.
	Note: For Win32 GUI applications, stdin must be redirected.
	Return Value
	On success, getc returns the character read, after converting it to an **int** without sign extension.
	On end-of-file or error, it returns EOF.
	Example

getchar, getwchar (see page 1052)	**Header File**
	stdio.h
	Category
	Console I/O Routines
	Prototype
	`int getchar(void);`
	`wint_t getwchar(void);`
	Description
	Gets character from stdin.
	getchar is a macro that returns the next character on the named input stream stdin. It is defined to be getc(stdin).
	Note: Do not use this function in Win32 GUI applications.
	Return Value
	On success, getchar returns the character read, after converting it to an **int** without sign extension.
	On end-of-file or error, it returns EOF.
	Example

gets, _getws (see page 1053)	**Header File**
	stdio.h
	Category
	Console I/O Routines
	Prototype
	`char *gets(char *s);`
	`wchar_t *_getws(wchar_t *s); // Unicode version`
	Description
	Gets a string from stdin.
	gets collects a string of characters terminated by a new line from the standard input stream stdin and puts it into s. The new line is replaced by a null character (\0) in s.
	gets allows input strings to contain certain whitespace characters (spaces, tabs). gets returns when it encounters a new line; everything up to the new line is copied into s.
	The gets function is not length-terminated. If the input string is sufficiently large, data... more (see page 1053)

_getw (see page 1054)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int _getw(FILE *stream);` **Description** Gets an integer from stream. _getw returns the next integer in the named input stream. It assumes no special alignment in the file. _getw should not be used when the stream is opened in text mode. **Return Value** _getw returns the next integer on the input stream. On end-of-file or error, _getw returns EOF. **Note:** Because EOF is a legitimate value for _getw to return, feof or ferror should be used to detect end-of-file or error. **Example**

printf, wprintf (see page 1055)	**Header File**
	stdio.h
	Category
	Console I/O Routines
	Prototype
	`int printf(const char *format[, argument, ...]);`
	`int wprintf(const wchar_t *format[, argument, ...]);`
	Description
	Writes formatted output to stdout.
	The printf function:
	• Accepts a series of arguments
	• Applies to each argument a format specifier contained in the format string *format
	• Outputs the formatted data (to the screen, a stream, stdout, or a string)
	There must be enough arguments for the format. If there are not, the results will be unpredictable and likely disastrous. Excess arguments (more than required by the format) are merely ignored.
	Note: For Win32 GUI applications, stdout must be redirected.... more (see page 1055)

putc, putwc (see page 1057)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int putc(int c, FILE *stream);`
	`wint_t putwc(wint_t c, FILE *stream);`
	Description
	Outputs a character to a stream.
	putc is a macro that outputs the character c to the stream given by stream.
	Return Value
	On success, putc returns the character printed, c.
	On error, putc returns EOF.
	Example

putchar, putwchar (see page 1057)	**Header File**
	stdio.h
	Category
	Console I/O Routines
	Prototype
	`int putchar(int c);`
	`wint_t putwchar(wint_t c);`
	Description
	putchar is a macro defined to be putc(c, stdout).
	Note: For Win32 GUI applications, stdout must be redirected.
	Return Value
	On success, putchar returns the character c. On error, putchar returns EOF.
	Example

puts, _putws (see page 1059)	**Header File**
	stdio.h
	Category
	Console I/O Routines
	Prototype
	`int puts(const char *s);`
	`int _putws(const wchar_t *s);`
	Description
	Outputs a string to stdout.
	puts copies the null-terminated string s to the standard output stream stdout and appends a newline character.
	Note: For Win32 GUI applications, stdout must be redirected.
	Return Value
	On successful completion, puts returns a nonnegative value. Otherwise, it returns a value of EOF.
	Example

_putw (see page 1059)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int _putw(int w, FILE *stream);` **Description** Writes an integer on a stream. _putw outputs the integer w to the given stream. _putw neither expects nor causes special alignment in the file. **Return Value** On success, _putw returns the integer w. On error, _putw returns EOF. Because EOF is a legitimate integer, use ferror to detect errors with _putw. **Example**

remove, _wremove (see page 1060)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int remove(const char *filename);`
	`int _wremove(const wchar_t *filename);`
	Description
	Removes a file.
	remove deletes the file specified by filename. It is a macro that simply translates its call to a call to unlink. If your file is open, be sure to close it before removing it.
	The filename string can include a full path.
	Return Value
	On successful completion, remove returns 0. On error, it returns -1, and the global variable errno is set to one of the following values:

rename, _wrename (see page 1061)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int rename(const char *oldname, const char *newname);`
	`int _wrename(const wchar_t *oldname, const wchar_t *newname);`
	Description
	Renames a file.
	rename changes the name of a file from oldname to newname. If a drive specifier is given in newname, the specifier must be the same as that given in oldname.
	Directories in oldname and newname need not be the same, so rename can be used to move a file from one directory to another. Wildcards are not allowed.
	This function will fail (EEXIST) if either file is currently open in any process.
	Return Value
	On... more (see page 1061)

rewind (see page 1062)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `void rewind(FILE *stream);` **Description** Repositions a file pointer to the beginning of a stream. rewind(stream) is equivalent to fseek(stream, 0L, SEEK_SET), except that rewind clears the end-of-file and error indicators, while fseek clears the end-of-file indicator only. After rewind, the next operation on an update file can be either input or output. **Return Value** None. **Example**
_rmtmp (see page 1063)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int _rmtmp(void);` **Description** Removes temporary files. The _rmtmp function closes and deletes all open temporary file streams which were previously created with tmpfile. The current directory must the same as when the files were created, or the files will not be deleted. **Return Value** _rmtmp returns the total number of temporary files it closed and deleted. **Example**

scanf, wscanf (see page 1064)	**Header File**
	stdio.h
	Category
	Console I/O Routines
	Prototype
	`int scanf(const char *format[, address, ...]);`
	`int wscanf(const wchar_t *format[, address, ...]);`
	Description
	Scans and formats input from the stdin stream.
	Note: For Win32 GUI applications, stdin must be redirected.
	The scanf function:
	• scans a series of input fields one character at a time
	• formats each field according to a corresponding format specifier passed in the format string *format.
	• vsscanf scans and formats input from a string, using an argument list
	There must be one format specifier and address for each input field.
	scanf might stop scanning a particular field before it... more (see page 1064)

setbuf (see page 1066)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `void setbuf(FILE *stream, char *buf);` **Description** Assigns buffering to a stream. setbuf causes the buffer buf to be used for I/O buffering instead of an automatically allocated buffer. It is used after stream has been opened. If buf is null, I/O will be unbuffered; otherwise, it will be fully buffered. The buffer must be BUFSIZ bytes long (specified in stdio.h). stdin and stdout are unbuffered if they are not redirected; otherwise, they are fully buffered. setbuf can be used to change the buffering style used. Unbuffered means that characters written to a stream... more (see page 1066)
setvbuf (see page 1067)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int setvbuf(FILE *stream, char *buf, int type, size_t size);` **Description** Assigns buffering to a stream. setvbuf causes the buffer buf to be used for I/O buffering instead of an automatically allocated buffer. It is used after the given stream is opened. If buf is null, a buffer will be allocated using malloc; the buffer will use size as the amount allocated. The buffer will be automatically freed on close. The size parameter specifies the buffer size and must be greater than zero. The parameter size is limited by the constant UINT_MAX as defined... more (see page 1067)

snprintf;snwprintf (see page 1068)	**Header File**
	stdio.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int snprintf(char* buffer, size_t nsize, const char* fmt, ...);`
	`int snwprintf(wchar_t* buffer, size_t nsize, const wchar_t* fmt, ...);`
	Description
	Sends formatted output to a buffer of a maximum length specified by nsize.
	If the number of bytes to output is:
	• < nsize, then all of the characters have been written, including the terminating '\0' character.
	• == nsize, then nsize characters are written, with no terminating '\0' character.
	> nsize, then only nsize characters are written, with no terminating '\0' character.
	If nsize is 0, then the string will not be... more (see page 1068)

sprintf, swprintf (see page 1068)	**Header File**
	stdio.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int sprintf(char *buffer, const char *format[, argument, ...]);`
	`int swprintf(wchar_t *buffer, const wchar_t *format[, argument, ...]);`
	Description
	Writes formatted output to a string.
	Note: For details on format specifiers, see printf.
	sprintf accepts a series of arguments, applies to each a format specifier contained in the format string pointed to by format, and outputs the formatted data to a string.
	sprintf applies the first format specifier to the first argument, the second to the second, and so on. There must be the same number of format specifiers as arguments.
	Return... more (see page 1068)

sscanf, swscanf (see page 1069)	**Header File**
	stdio.h
	Category
	Memory and String Manipulation Routines
	Syntax
	`int sscanf(const char *buffer, const char *format[, address, ...]);`
	`int swscanf(const wchar_t *buffer, const wchar_t *format[, address, ...]);`
	Description
	Scans and formats input from a string.
	Note: For details on format specifiers, see scanf.
	sscanf scans a series of input fields, one character at a time, reading from a string. Then each field is formatted according to a format specifier passed to sscanf in the format string pointed to by format. Finally, sscanf stores the formatted input at an address passed to it as an argument following format. There must... more (see page 1069)

stderr, stdin, stdout (see page 1070)	**Header File** stdio.h **Description** Predefined streams automatically opened when the program is started.

_tempnam, _wtempnam (see page 1071)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`char *_tempnam(char *dir, char *prefix)`
	`wchar_t *_wtempnam(wchar_t *dir, wchar_t *prefix)`
	Description
	Creates a unique file name in specified directory.
	The _tempnam function accepts single-byte or multibyte string arguments.
	The _tempnam function creates a unique file name in arbitrary directories. The unique file is not actually created; _tempnam only verifies that it does not currently exist. It attempts to use the following directories, in the order shown, when creating the file name:
	• The directory specified by the TMP environment variable.
	• The dir argument to _tempnam.
	• The P_tmpdir definition in stdio.h. If you edit stdio.h... more (see page 1071)

tmpfile (see page 1072)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `FILE *tmpfile(void);` **Description** Opens a “scratch” file in binary mode. tmpfile creates a temporary binary file and opens it for update (w + b). If you do not change the directory after creating the temporary file, the file is automatically removed when it’s closed or when your program terminates. **Return Value** tmpfile returns a pointer to the stream of the temporary file created. If the file can’t be created, tmpfile returns NULL. **Example**

tmpnam, _wtmpnam (see page 1073)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`char *tmpnam(char *s);`
	`wchar_t *_wtmpnam(wchar_t *s);`
	Description
	Creates a unique file name.
	tmpnam creates a unique file name, which can safely be used as the name of a temporary file. tmpnam generates a different string each time you call it, up to TMP_MAX times. TMP_MAX is defined in stdio.h as 65,535.
	The parameter to tmpnam, s, is either null or a pointer to an array of at least L_tmpnam characters. L_tmpnam is defined in stdio.h. If s is NULL, tmpnam leaves the generated temporary file name in an internal static object and returns... more (see page 1073)

ungetc, ungetwc (see page 1073)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int ungetc(int c, FILE *stream);`
	`wint_t ungetwc(wint_t c, FILE *stream);`
	Description
	Pushes a character back into input stream.
	Note: Do not use this function in Win32 GUI applications.
	ungetc pushes the character c back onto the named input stream, which must be open for reading. This character will be returned on the next call to getc or fread for that stream. One character can be pushed back in all situations. A second call to ungetc without a call to getc will force the previous character to be forgotten. A call to fflush, fseek,... more (see page 1073)

vfprintf, vfwprintf (see page 1074)	**Header File**
	stdio.h
	Category
	Input/output Routines
	Prototype
	`int vfprintf(FILE *stream, const char *format, va_list arglist);`
	`int vfwprintf(FILE *stream, const wchar_t *format, va_list arglist);`
	Description
	Writes formatted output to a stream.
	The v...printf functions are known as alternate entry points for the ...printf functions. They behave exactly like their ...printf counterparts, but they accept a pointer to a list of arguments instead of an argument list.
	For details on format specifiers, see Printf Format Specifiers.
	vfprintf accepts a pointer to a series of arguments, applies to each argument a format specifier contained in the format string pointed to by format, and... more (see page 1074)

vfscanf (see page 1076)	**Header File** stdio.h **Category** Input/output Routines **Prototype** `int vfscanf(FILE *stream, const char *format,va_list arglist);` **Description** Scans and formats input from a stream. The v...scanf functions are known as alternate entry points for the ...scanf functions. They behave exactly like their ...scanf counterparts but they accept a pointer to a list of arguments instead of an argument list. For details on format specifiers, see Scanf Format Specifiers. vfscanf scans a series of input fields one character at a time reading from a stream. Then each field is formatted according to a format specifier passed to vfscanf in the format string pointed... more (see page 1076)

vprintf, vwprintf (see page 1077)	**Header File**
	stdio.h
	Category
	Console I/O Routines
	Prototype
	`int vprintf(const char *format, va_list arglist);`
	`int vwprintf(const wchar_t * format, va_list arglist);`
	Description
	Writes formatted output to stdout.
	Note: Do not use this function in Win32 GUI applications.
	The v...printf functions are known as alternate entry points for the ...printf functions. They behave exactly like their ...printf counterparts, but they accept a pointer to a list of arguments instead of an argument list.
	Note: For details on format specifiers, see Printf Format Specifiers.
	vprintf accepts a pointer to a series of arguments, applies to each a format specifier contained in the... more (see page 1077)

vscanf (see page 1078)	**Header File** stdio.h **Category** Console I/O Routines **Prototype** `int vscanf(const char *format, va_list arglist);` **Description** Scans and formats input from stdin. **Note:** Do not use this function in Win32 GUI applications. The v...scanf functions are known as alternate entry points for the ...scanf functions. They behave exactly like their ...scanf counterparts, but they accept a pointer to a list of arguments instead of an argument list. **Note:** For details on format specifiers, see Scanf Format Specifiers. vscanf scans a series of input fields, one character at a time, reading from stdin. Then each field is formatted according to a format... more (see page 1078)

vsnprintf;vsnwprintf (see page 1079)	**Header File**
	stdio.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int vsnprintf(char* buffer, size_t nsize, const char* format, va_list param);`
	`int vsnwprintf(wchar_t* buffer, size_t nsize, const wchar_t* format, va_list param);`
	Description
	Sends formatted output to a buffer of maximum length specified by nsize.
	If the number of bytes to output is:
	• < nsize, then all of the characters have been written, including the terminating '\0' character.
	• == nsize, then nsize characters are written, with no terminating '\0' character.
	> nsize, then only nsize characters are written, with no terminating '\0' character.
	If nsize is 0, then the string will not... more (see page 1079)

vsprintf, vswprintf (see page 1079)	**Header File**
	stdio.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int vsprintf(char *buffer, const char *format, va_list arglist);`
	`int vswprintf(wchar_t *buffer, const wchar_t *format, va_list arglist);`
	Description
	Writes formatted output to a string.
	The v...printf functions are known as alternate entry points for the ...printf functions. They behave exactly like their ...printf counterparts, but they accept a pointer to a list of arguments instead of an argument list.
	vsprintf accepts a pointer to a series of arguments, applies to each a format specifier contained in the format string pointed to by format, and outputs the formatted data to a string.... more (see page 1079)

3.1.4.28.1 BUFSIZ #define

Header File

stdio.h

Description

Default buffer size used by setbuf function.

3.1.4.28.2 _F_xxxx #defines

Header File

stdio.h

Description

File status flags of streams

Name	Meaning
_F_RDWR	Read and write

_F_READ	Read-only file
_F_WRIT	Write-only file
_F_BUF	Malloc'ed buffer data
_F_LBUF	Line-buffered file
_F_ERR	Error indicator
_F_EOF	EOF indicator
_F_BIN	Binary file indicator
_F_IN	Data is incoming
_F_OUT	Data is outgoing
_F_TERM	File is a terminal

3.1.4.28.3 OPEN_MAX #define

Header File

stdio.h

Description

Number of files that can be open simultaneously.

Name	Meaning
FOPEN_MAX	Maximum files per process
SYS_OPEN	Maximum files for system

3.1.4.28.4 L_ctermid #define

Header File

stdio.h

Description

The length of a device id string.

3.1.4.28.5 L_tmpnam #define

Header File

stdio.h

Description

Size of an array large enough to hold a temporary file name string.

3.1.4.28.6 TMP_MAX #define

Header File

stdio.h

Description

Maximum number of unique file names.

3.1.4.28.7 _IOxxx #defines

Header File

stdio.h

Description

Constants for defining buffering style to be used with a file.

Name	Meaning
_IOFBF	The file is fully buffered. When a buffer is empty, the next input operation will attempt to fill the entire buffer.
	On output, the buffer will be completely filled before any data is written to the file.
_IOLBF	The file is line buffered. When a buffer is empty, the next input operation will still attempt to fill the entire buffer.
	On output, however, the buffer will be flushed whenever a newline character is written to the file.
_IONBF	The file is unbuffered. The buf and size parameters of setbuf are ignored. Each input operation will read directly from the file, and each output operation will immediately write the data to the file.

3.1.4.28.8 _fsopen, _wfsopen

Header File

stdio.h, share.h

Category

Input/output Routines

Prototype

```
FILE *_fsopen(const char *filename, const char *mode, int shflag);
FILE *_wfsopen(const wchar_t *filename, const wchar_t *mode, int shflag);
```

Description

Opens a stream with file sharing.

_fsopen opens the file named by filename and associates a stream with it. _fsopen returns a pointer that is used to identify the stream in subsequent operations.

The mode string used in calls to _fsopen is one of the following values:

r	Open for reading only.
w	Create for writing. If a file by that name already exists, it will be overwritten.
a	Append; open for writing at end of file. or create for writing if the file does not exist.
r+	Open an existing file for update (reading and writing).
w+	Create a new file for update (reading and writing). If a file by that name already exists, it will be overwritten.

a+	Open for append; open (or create if the file does not exist) for update at the end of the file.

To specify that a given file is being opened or created in text mode append a t to the mode string (rt w+t and so on). Similarly to specify binary mode append a b to the mode string (wb a+b and so on). _fsopen also allows the t or b to be inserted between the letter and the + character in the mode string; for example rt+ is equivalent to r+t. If a t or b is not given in the mode string the mode is governed by the global variable _fmode. If _fmode is set to O_BINARY files are opened in binary mode. If _fmode is set to O_TEXT they are opened in text mode. These O_... constants are defined in fcntl.h.

When a file is opened for update, both input and output can be done on the resulting stream, however:

- output cannot be directly followed by input without an intervening fseek or rewind
- input cannot be directly followed by output without an intervening fseek, rewind, or an input that encounters end-of-file

shflag specifies the type of file-sharing allowed on the file filename. Symbolic constants for shflag are defined in share.h.

SH_COMPAT	Sets compatibility mode
SH_DENYRW	Denies read/write access
SH_DENYWR	Denies write access
SH_DENYRD	Denies read access
SH_DENYNONE	Permits read/write access
SH_DENYNO	Permits read/write access

Return Value

On successful completion _fsopen returns a pointer to the newly opened stream.

On error it returns NULL.

Example

```
#include <io.h>
#include <process.h>
#include <share.h>
#include <stdio.h>
int main(void)
{
  FILE *f;
  int status;
  f = _fsopen("TESTFILE.DAT", "r", SH_DENYNO);
  if (f == NULL)
  {
    printf("_fsopen failed\n");
    exit(1);
  }
  status = access("TESTFILE.DAT", 6);
  if (status == 0)
    printf("read/write access allowed\n");
  else
    printf("read/write access not allowed\n");
  fclose(f);
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_fsopen		+		
_wfsopen		NT only		

3.1.4.28.9 _pclose

Header File

stdio.h

Category

Input/output Routines, Process Control Routines

Prototype

```
int _pclose(FILE * stream);
```

Description

Waits for piped command to complete.

_pclose closes a pipe stream created by a previous call to _popen, and then waits for the associated child command to complete.

Return Value

On success, _pclose returns the termination status of the child command. This is the same value as the termination status returned by cwait, except that the high and low order bytes of the low word are swapped.

On error, it returns -1.

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.28.10 _popen, _wpopen

Header File

stdio.h

Category

Input/output Routines

Prototype

```
FILE *_popen (const char *command, const char *mode);
FILE *_wpopen (const wchar_t *command, const wchar_t *mode);
```

Description

Creates a command processor pipe.

The _popen function creates a pipe to the command processor. The command processor is executed asynchronously, and is passed the command line in command. The mode string specifies whether the pipe is connected to the command processor's standard input or output, and whether the pipe is to be opened in binary or text mode.

The mode string can take one of the following values:

rt	Read child command's standard output (text).
rb	Read child command's standard output (binary).

wt	Write to child command's standard input (text).
wb	Write to child command's standard input (binary).

The terminating t or b is optional; if missing, the translation mode is determined by the external variable _fmode.

Use the _pclose function to close the pipe and obtain the return code of the command.

Return Value

On success, _popen returns a FILE pointer that can be used to read the standard output of the command, or to write to the standard input of the command, depending on the mode string.

On error, it returns NULL.

Example

```
/* this program initiates a child process to run the dir command
   and pipes the directory listing from the child to the parent.
*/
#include <stdio.h>     // popen() pclose() feof() fgets() puts()
#include <string.h>    // strlen()
int main( )
{
  FILE* handle;        // handle to one end of pipe
  char message[256];   // buffer for text passed through pipe
  int status;          // function return value
  // open a pipe to receive text from a process running "DIR"
  handle = _popen("dir /b", "rt");
  if (handle == NULL)
  {
    perror("_popen error");
  }
  // read and display input received from the child process
  while (fgets(message, sizeof(message), handle))
  {
    fprintf(stdout, message);
  }
  // close the pipe and check the return status
    status = _pclose(handle);
  if (status == -1)
  {
    perror("_pclose error");
  }
  return(0);
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_popen		+		
_wpopen		NT only		

3.1.4.28.11 _snprintf;_snwprintf

Header File

stdio.h

Category

Memory and String Manipulation Routines

Syntax

```
int _snprintf(char* buffer, size_t nsize, const char* format, ...);
int _snwprintf(wchar_t* buffer, size_t nsize, const wchar_t* format, ...);
```

Description

Sends formatted output to a string of a maximum length specified by nsize. _snprintf and _snwprintf are Microsoft compatible with the _snprintf and _snprintfw functions, respectively.

If the number of bytes to output is:

- < nsize, then all of the characters have been written, including the terminating '\0' character.
- == nsize, then nsize characters are written with no terminating '\0' character.

If nsize is 0, then the string will not be written to (and may be NULL).

If nsize is too small, then return value is -1, and only nsize characters are written, with no terminating '\0' character.

Return Value

Number of bytes output or –1 if nsize is too small.

3.1.4.28.12 _vsnprintf;_vsnwprintf

Header File

stdio.h

Category

Memory and String Manipulation Routines

Prototype

```
int _vsnprintf(char* buffer, size_t nsize, const char* format, va_list param);
int _vsnwprintf(wchar_t* buffer, size_t nsize, const wchar_t* format, va_list param);
```

Description

Sends formatted output to a string of a maximum length specified by nsize. _vsnprintf and _vsnwprintf are Microsoft compatible with the _vsnprintf and _vsnprintfw functions, respectively.

If the number of bytes to output is:

- < nsize, then all of the characters have been written, including the terminating '\0' character.
- == nsize, then nsize characters are written with no terminating '\0' character.

If nsize is 0, then the string will not be written to (and may be NULL).

If nsize is too small, then return value is -1, and only nsize characters are written, with no terminating '\0' character.

Return Value

Number of bytes output or –1 if nsize is too small.

3.1.4.28.13 clearerr

Header File

stdio.h

Category

Input/output Routines

Prototype

```
void clearerr(FILE *stream);
```

Description

Resets error indication.

clearerr resets the named stream's error and end-of-file indicators to 0. Once the error indicator is set, stream operations continue to return error status until a call is made to clearerr or rewind. The end-of-file indicator is reset with each input operation.

Return Value

None.

Example

```
#include <stdio.h>
int main(void)
{
   FILE *fp;
   char ch;
   /* open a file for writing */
   fp = fopen("DUMMY.FIL", "w");
   /* force an error condition by attempting to read */
   ch = fgetc(fp);
   printf("%c\n",ch);
   if (ferror(fp))
   {
      /* display an error message */
      printf("Error reading from DUMMY.FIL\n");
      /* reset the error and EOF indicators */
      clearerr(fp);
   }
   fclose(fp);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.14 EOF #define

Header File

stdio.h

Description

A constant indicating that end-of-file has been reached on a file.

3.1.4.28.15 fclose

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fclose(FILE *stream);
```

Description

Closes a stream.

fclose closes the named stream. All buffers associated with the stream are flushed before closing. System-allocated buffers are freed upon closing. Buffers assigned with setbuf or setvbuf are not automatically freed. (But if setvbuf is passed null for the buffer pointer it will free it upon close.)

Return Value

fclose returns 0 on success. It returns EOF if any errors were detected.

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.16 _fcloseall

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int _fcloseall(void);
```

Description

Closes open streams.

_fcloseall closes all open streams except

stdauxstdstreams

When _fcloseall flushes the associated buffers before closing a stream. The buffers allocated by the system are released.

Note: stdprn and stdaux streams are not available in Win32.

Return Value

_fcloseall returns the total number of streams it closed. The _fcloseall function returns EOF if any errors were detected.

Example

```
#include <stdio.h>
int main(void)
{
   int streams_closed;
   /* open two streams */
   fopen("DUMMY.ONE", "w");
   fopen("DUMMY.TWO", "w");
   /* close the open streams */
   streams_closed = fcloseall();
```

```
    if (streams_closed == EOF)
       /* issue an error message */
       perror("Error");
    else
       /* print result of fcloseall() function */
       printf("%d streams were closed.\n", streams_closed);
    return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.28.17 _fdopen, _wfdopen

Header File

stdio.h

Category

Input/output Routines

Prototype

```
FILE *_fdopen(int handle, char *type);
```

```
FILE *_wfdopen(int handle, wchar_t *type);
```

Description

Associates a stream with a file handle.

_fdopen associates a stream with a file handle obtained from creat, dup, dup2, or open.

The type of stream must match the mode of the open handle.

The type string used in a call to _fdopen is one of the following values:

r	Open for reading only. _fdopen returns NULL if the file cannot be opened.
w	Create for writing. If the file already exists, its contents are overwritten.
a	Append; open for writing at end-of-file or create for writing if the file does not exist.
r+	Open an existing file for update (reading and writing). _fdopen returns NULL if the file cannot be opened.
w+	Create a new file for update. If the file already exists, its contents are overwritten.
a+	Open for append; open (or create if the file does not exist) for update at the end of the file.

To specify that a given file is being opened or created in text mode, append t to the value of the type string (for example, rt or w+t).

Similarly, to specify binary mode, append b to the type string (for example, rb or w+b).

If t or b is not given in the type string, the mode is governed by the global variable _fmode.

If _fmode is set to O_BINARY, files will be opened in binary mode.

If _fmode is set to O_TEXT, files will be opened in text mode.

Note: The O_... constants are defined in fcntl.h.

When a file is opened for update, both input and output can be done on the resulting stream; however,

- output cannot be directly followed by input without an intervening fseek or rewind
- input cannot be directly followed by output without an intervening fseek, rewind, or an input that encounters end-of-file

Return Value

On successful completion _fdopen returns a pointer to the newly opened stream. In the event of error it returns NULL.

Example

```
#include <sys\stat.h>
#include <stdio.h>
#include <fcntl.h>
#include <io.h>
int main(void)
{
   int handle;
   FILE *stream;
   /* open a file */
   handle = open("DUMMY.FIL", O_CREAT,
                 S_IREAD | S_IWRITE);
   /* now turn the handle into a stream */
   stream = fdopen(handle, "w");
   if (stream == NULL)
      printf("fdopen failed\n");
   else
   {
      fprintf(stream, "Hello world\n");
      fclose(stream);
   }
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_fdopen	+	+		
_wfdopen		+		

3.1.4.28.18 feof

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int feof(FILE *stream);
```

Description

Detects end-of-file on a stream.

feof is a macro that tests the given stream for an end-of-file indicator. Once the indicator is set read operations on the file return the indicator until rewind is called or the file is closed. The end-of-file indicator is reset with each input operation.

Return Value

feof returns nonzero if an end-of-file indicator was detected on the last input operation on the named stream and 0 if end-of-file

has not been reached.

Example

```
#include <stdio.h>
int main(void)
{
   FILE *stream;
   /* open a file for reading */
   stream = fopen("DUMMY.FIL", "r");
   /* read a character from the file */
   fgetc(stream);
   /* check for EOF */
   if (feof(stream))
      printf("We have reached end-of-file\n");
   /* close the file */
   fclose(stream);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.19 ferror

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int ferror(FILE *stream);
```

Description

Detects errors on stream.

ferror is a macro that tests the given stream for a read or write error. If the stream's error indicator has been set it remains set until clearerr or rewind is called or until the stream is closed.

Return Value

ferror returns nonzero if an error was detected on the named stream.

Example

```
#include <stdio.h>
int main(void)
{
   FILE *stream;
   /* open a file for writing */
   stream = fopen("DUMMY.FIL", "w");
   /* force an error condition by attempting to read */
   (void) getc(stream);
   if (ferror(stream))  /* test for an error on the stream */
   {
      /* display an error message */
      printf("Error reading from DUMMY.FIL\n");
```

```
      /* reset the error and EOF indicators */
      clearerr(stream);
   }
   fclose(stream);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.20 fflush

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fflush(FILE *stream);
```

Description

Flushes a stream.

If the given stream has buffered output fflush writes the output for stream to the associated file.

The stream remains open after fflush has executed. fflush has no effect on an unbuffered stream.

Return Value

fflush returns 0 on success. It returns EOF if any errors were detected.

Example

```
#include <string.h>
#include <stdio.h>
#include <io.h>
void flush(FILE *stream);
int main(void)
{
   FILE *stream;
   char msg[] = "This is a test";
   /* create a file */
   stream = fopen("DUMMY.FIL", "w");
   /* write some data to the file */
   fwrite(msg, strlen(msg), 1, stream);
   printf("Press ENTER to flush DUMMY.FIL:");
   getchar();
   /* flush the data to DUMMY.FIL without closing it */
   flush(stream);
   printf("\nFile was flushed, Press ENTER to quit:");
   getchar();
   return 0;
}
void flush(FILE *stream)
{
     int duphandle;
     /* flush the stream's internal buffer */
```

```
    fflush(stream);
    /* make a duplicate file handle */
    duphandle = dup(fileno(stream));
    /* close the duplicate handle to flush the DOS buffer */
    close(duphandle);
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.21 fgetc, fgetwc

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fgetc(FILE *stream);
```

```
wint_t fgetwc(FILE *stream);
```

Description

Gets character from stream.

fgetc returns the next character on the named input stream.

Return Value

On success fgetc returns the character read after converting it to an **int** without sign extension. On end-of-file or error it returns EOF.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   FILE *stream;
   char string[] = "This is a test";
   char ch;
   /* open a file for update */
   stream = fopen("DUMMY.FIL", "w+");
   /* write a string into the file */
   fwrite(string, strlen(string), 1, stream);
   /* seek to the beginning of the file */
   fseek(stream, 0, SEEK_SET);
   do
   {
      /* read a char from the file */
      ch = fgetc(stream);
      /* display the character */
      putchar(ch);
   } while (ch != EOF);
   fclose(stream);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
fgetc	+	+	+	+
fgetwc		+	+	+

3.1.4.28.22 _fgetchar, _fgetwchar

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
int _fgetchar(void);
```

```
wint_t _fgetwchar(void);
```

Description

Reads a character from stdin.

_fgetchar returns the next character from stdin. It is defined as fgetc(stdin).

Note: For Win32 GUI applications, stdin must be redirected.

Return Value

On success _fgetchar returns the character read after converting it to an **int** without sign extension. On end-of-file or error it returns EOF.

Example

```
#include <stdio.h>
int main(void)
{
   char ch;
   /* prompt the user for input */
   printf("Enter a character followed by <Enter>: ");
   /* read the character from stdin */
   ch = fgetchar();
   /* display what was read */
   printf("The character read is: '%c'\n", ch);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_fgetchar		+		
_fgetwchar		+		

3.1.4.28.23 fgetpos

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fgetpos(FILE *stream, fpos_t *pos);
```

Description

Gets the current file pointer.

fgetpos stores the position of the file pointer associated with the given stream in the location pointed to by pos. The exact value is unimportant; its value is opaque except as a parameter to subsequent fsetpos calls.

Return Value

On success fgetpos returns 0. On failure it returns a nonzero value and sets the global variable errno to

EBADF	Bad file number
EINVAL	Invalid number

Example

```
#include <stdlib.h>
#include <stdio.h>
void showpos(FILE *stream);
int main(void)
{
   FILE *stream;
   fpos_t filepos;
   /* open a file for update */
   stream = fopen("DUMMY.FIL", "w+");
   /* save the file pointer position */
   fgetpos(stream, &filepos);
   /* write some data to the file */
   fprintf(stream, "This is a test");
   /* show the current file position */
   showpos(stream);
   /* set a new file position, display it */
   if (fsetpos(stream, &filepos) == 0)
     showpos(stream);
   else
   {
      fprintf(stderr, "Error setting file pointer.\n");
      exit(1);
   }
   /* close the file */
   fclose(stream);
   return 0;
}
void showpos(FILE *stream)
{
   fpos_t pos;
   /* display the current file pointer
      position of a stream */
   fgetpos(stream, &pos);
   printf("File position: %ld\n", pos);
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.24 fgets, fgetws

Header File

stdio.h

Category

Input/output Routines

Prototype

```
char *fgets(char *s, int n, FILE *stream);
```

```
wchar_t *fgetws(wchar_t *s, int n, FILE *stream); // Unicode version
```

Description

Gets a string from a stream.

fgets reads characters from stream into the string s. The function stops reading when it reads either n - 1 characters or a newline character whichever comes first. fgets retains the newline character at the end of s. A null byte is appended to s to mark the end of the string.

Return Value

On success fgets returns the string pointed to by s; it returns NULL on end-of-file or error.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   FILE *stream;
   char string[] = "This is a test";
   char msg[20];
   /* open a file for update */
   stream = fopen("DUMMY.FIL", "w+");
   /* write a string into the file */
   fwrite(string, strlen(string), 1, stream);
   /* seek to the start of the file */
   fseek(stream, 0, SEEK_SET);
   /* read a string from the file */
   fgets(msg, strlen(string)+1, stream);
   /* display the string */
   printf("%s", msg);
   fclose(stream);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
fgets	+	+	+	+
fgetws		+	+	+

3.1.4.28.25 _fileno

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int _fileno(FILE *stream);
```

Description

Gets the file handle.

_fileno is a macro that returns the file handle for the given stream. If stream has more than one handle _fileno returns the handle assigned to the stream when it was first opened.

Return Value

_fileno returns the integer file handle associated with stream.

Example

```
#include <stdio.h>
int main(void)
{
   FILE *stream;
   int handle;
   /* create a file */
   stream = fopen("DUMMY.FIL", "w");
   /* obtain the file handle associated with the stream */
   handle = fileno(stream);
   /* display the handle number */
   printf("handle number: %d\n", handle);
   /* close the file */
   fclose(stream);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+		

3.1.4.28.26 _flushall

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int _flushall(void);
```

Description

Flushes all streams.

_flushall clears all buffers associated with open input streams and writes all buffers associated with open output streams to their respective files. Any read operation following _flushall reads new data into the buffers from the input files. Streams stay open after _flushall executes.

Return Value

_flushall returns an integer the number of open input and output streams.

Example

```
#include <stdio.h>
int main(void)
{
   FILE *stream;
   /* create a file */
   stream = fopen("DUMMY.FIL", "w");
   /* flush all open streams */
   printf("%d streams were flushed.\n", flushall());
   /* close the file */
   fclose(stream);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.28.27 fopen, _wfopen

Header File

stdio.h

Category

Input/output Routines

Prototype

```
FILE *fopen(const char *filename, const char *mode);
```

```
FILE *_wfopen(const wchar_t *filename, const wchar_t *mode);
```

Description

Opens a stream.

fopen opens the file named by filename and associates a stream with it. fopen returns a pointer to be used to identify the stream in subsequent operations.

The mode string used in calls to fopen is one of the following values:

r	Open for reading only.
w	Create for writing. If a file by that name already exists, it will be overwritten.
a	Append; open for writing at end-of-file or create for writing if the file does not exist.
r+	Open an existing file for update (reading and writing).

w+	Create a new file for update (reading and writing). If a file by that name already exists, it will be overwritten.
a+	Open for append; open (or create if the file does not exist) for update at the end of the file.

To specify that a given file is being opened or created in text mode append a t to the mode string (rt w+t and so on). Similarly to specify binary mode append a b to the mode string (wb a+b and so on). fopen also allows the t or b to be inserted between the letter and the + character in the mode string; for example rt+ is equivalent to r+t.

If a t or b is not given in the mode string the mode is governed by the global variable _fmode. If _fmode is set to O_B/INARY files are opened in binary mode. If _fmode is set to O_TEXT they are opened in text mode. These O_... constants are defined in fcntl.h.

When a file is opened for update, both input and output can be done on the resulting stream; however,

- output cannot be directly followed by input without an intervening fseek or rewind
- input cannot be directly followed by output without an intervening fseek, rewind, or an input that encounters end-of-file

Return Value

On successful completion fopen returns a pointer to the newly opened stream. In the event of error it returns NULL.

Portability

	POSIX	Win32	ANSI C	ANSI C++
fopen	+	+	+	+
_wfopen		NT only		

3.1.4.28.28 fprintf, fwprintf

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fprintf(FILE *stream, const char *format[, argument, ...]);
```

```
int fwprintf(FILE *stream, const wchar_t *format[, argument, ...]);
```

Description

Writes formatted output to a stream.

fprintf accepts a series of arguments applies to each a format specifier contained in the format string pointed to by format and outputs the formatted data to a stream. There must be the same number of format specifiers as arguments.

Note: For details on format specifiers, see printf Format Specifiers.

Return Value

fprintf returns the number of bytes output. In the event of error it returns EOF.

Example

```
#include <stdio.h>
int main(void)
```

```
{
   FILE *stream;
   int i = 100;
   char c = 'C';
   float f = 1.234;
   /* open a file for update */
   stream = fopen("DUMMY.FIL", "w+");
   /* write some data to the file */
   fprintf(stream, "%d %c %f", i, c, f);
   /* close the file */
   fclose(stream);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
fprintf	+	+	+	+
fwprintf		+	+	+

3.1.4.28.29 fputc, fputwc

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fputc(int c, FILE *stream);
```

```
wint_t fputwc(wint_t c, FILE *stream);
```

Description

Puts a character on a stream.

fputc outputs character c to the named stream.

Note: For Win32 GUI applications, stdin must be redirected.

Return Value

On success, fputc returns the character c. On error, it returns EOF.

Example

```
#include <stdio.h>
int main(void)
{
   char msg[] = "Hello world";
   int i = 0;
   while (msg[i])
   {
      fputc(msg[i], stdout);
      i++;
   }
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
fputc	+	+	+	+
fputwc		+	+	+

3.1.4.28.30 _fputchar, _fputwchar

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int _fputchar(int c);
wint_t _fputwchar(wint_t c);
```

Description

Outputs a character to stdout.

_fputchar outputs character c to stdout. _fputchar(c) is the same as fputc(cstdout).

Note: For Win32 GUI applications, stdout must be redirected.

Return Value

On success _fputchar returns the character c.

On error it returns EOF.

Example

```
#include <stdio.h>
int main(void)
{
   char msg[] = "This is a test";
   int i = 0;
   while (msg[i])
   {
      fputchar(msg[i]);
      i++;
   }
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_fputchar		+		
_fputwchar		+		

3.1.4.28.31 fputs, fputws

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fputs(const char *s, FILE *stream);
```

```
int fputws(const wchar_t *s, FILE *stream);
```

Description

Outputs a string on a stream.

fputs copies the null-terminated string s to the given output stream; it does not append a newline character and the terminating null character is not copied.

Return Value

On success fputs returns a non-negative value.

On error it returns a value of EOF.

Example

```
#include <stdio.h>
int main(void)
{
   /* write a string to standard output */
   fputs("Hello world\n", stdout);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
fputs	+	+	+	+
fputws		+	+	+

3.1.4.28.32 fread

Header File

stdio.h

Category

Input/output Routines

Prototype

```
size_t fread(void *ptr, size_t size, size_t n, FILE *stream);
```

Description

Reads data from a stream.

fread reads n items of data each of length size bytes from the given input stream into a block pointed to by ptr.

The total number of bytes read is (n * size).

Return Value

On success fread returns the number of items (not bytes) actually read.

On end-of-file or error it returns a short count (possibly 0).

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   FILE *stream;
   char msg[] = "this is a test";
   char buf[20];
   if ((stream = fopen("DUMMY.FIL", "w+"))
       == NULL)
   {
      fprintf(stderr, "Cannot open output file.\n");
      return 1;
   }
   /* write some data to the file */
   fwrite(msg, strlen(msg)+1, 1, stream);
   /* seek to the beginning of the file */
   fseek(stream, SEEK_SET, 0);
   /* read the data and display it */
   fread(buf, strlen(msg)+1, 1, stream);
   printf("%s\n", buf);
   fclose(stream);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.33 freopen, _wfreopen

Header File

stdio.h

Category

Input/output Routines

Prototype

```
FILE *freopen(const char *filename, const char *mode, FILE *stream);
```

```
FILE *_wfreopen(const wchar_t *filename, const wchar_t *mode, FILE *stream);
```

Description

Associates a new file with an open stream.

freopen substitutes the named file in place of the open stream. It closes stream regardless of whether the open succeeds. freopen is useful for changing the file attached to stdin, stdout, or stderr.

The mode string used in calls to fopen is one of the following values:

r	Open for reading only.
w	Create for writing. .

a	Append; open for writing at end-of-file or create for writing if the file does not exist.
r+	Open an existing file for update (reading and writing).
w+	Create a new file for update (reading and writing).
a+	Open for append; open (or create if the file does not exist) for update at the end of the file.

To specify that a given file is being opened or created in text mode append a t to the mode string (rt w+t and so on); similarly to specify binary mode append a b to the mode string (wb a+b and so on).

If a t or b is not given in the mode string the mode is governed by the global variable _fmode. If _fmode is set to O_BINARY files are opened in binary mode. If _fmode is set to O_TEXT they are opened in text mode. These O_... constants are defined in fcntl.h.

When a file is opened for update, both input and output can be done on the resulting stream; however,

- output cannot be directly followed by input without an intervening fseek or rewind
- input cannot be directly followed by output without an intervening fseek, rewind, or an input that encounters end-of-file

Return Value

On successful completion freopen returns the argument stream.

On error it returns NULL.

Example

```
#include <stdio.h>
int main(void)
{
   /* redirect standard output to a file */
   if (freopen("OUTPUT.FIL", "w", stdout)
       == NULL)
      fprintf(stderr, "error redirecting stdout\n");
   /* this output will go to a file */
   printf("This will go into a file.");
   /* close the standard output stream */
   fclose(stdout);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
freopen	+	+	+	+
_wfreopen		NT only		

3.1.4.28.34 fscanf, fwscanf

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fscanf(FILE *stream, const char *format[, address, ...]);
```

```
int fwscanf(FILE *stream, const wchar_t *format[, address, ...]);
```

Description

Scans and formats input from a stream.

fscanf scans a series of input fields one character at a time reading from a stream. Then each field is formatted according to a format specifier passed to fscanf in the format string pointed to by format. Finally fscanf stores the formatted input at an address passed to it as an argument following format. The number of format specifiers and addresses must be the same as the number of input fields.

Note: For details on format specifiers, see scanf Format Specifiers.

fscanf can stop scanning a particular field before it reaches the normal end-of-field character (whitespace) or it can terminate entirely for a number of reasons. See scanf for a discussion of possible causes.

Return Value

fscanf returns the number of input fields successfully scanned, converted and stored. The return value does not include scanned fields that were not stored.

If fscanf attempts to read at end-of-file, the return value is EOF. If no fields were stored, the return value is 0.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   int i;
   printf("Input an integer: ");
   /* read an integer from the
      standard input stream */
   if (fscanf(stdin, "%d", &i))
      printf("The integer read was: %i\n", i);
   else
   {
      fprintf(stderr, "Error reading an integer from stdin.\n");
      exit(1);
   }
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.35 fseek

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fseek(FILE *stream, long offset, int whence);
```

Description

Repositions a file pointer on a stream.

fseek sets the file pointer associated with stream to a new position that is offset bytes from the file location given by whence. For text mode streams offset should be 0 or a value returned by ftell.

whence must be one of the values 0. 1, or 2 which represent three symbolic constants (defined in stdio.h) as follows:

fseek discards any character pushed back using ungetc. fseek is used with stream I/O; for file handle I/O use lseek.

After fseek the next operation on an update file can be either input or output.

Return Value

fseek returns 0 if the pointer is successfully moved and nonzero on failure.

fseek might return a 0 indicating that the pointer has been moved successfully when in fact it has not been. This is because DOS, which actually resets the pointer, does not verify the setting. fseek returns an error code only on an unopened file or device.

In the event of an error return the global variable errno is set to one of the following values:

EBADF	Bad file pointer
EINVAL	Invalid argument
ESPIPE	Illegal seek on device

Example

```
#include <stdio.h>
long filesize(FILE *stream);
int main(void)
{
   FILE *stream;
   stream = fopen("MYFILE.TXT", "w+");
   fprintf(stream, "This is a test");
   printf("Filesize of MYFILE.TXT is %ld bytes\n", filesize(stream));
   fclose(stream);
   return 0;
}
long filesize(FILE *stream)
{
   long curpos, length;
   curpos = ftell(stream);
   fseek(stream, 0L, SEEK_END);
   length = ftell(stream);
   fseek(stream, curpos, SEEK_SET);
   return length;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.36 fsetpos

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int fsetpos(FILE *stream, const fpos_t *pos);
```

Description

Positions the file pointer of a stream.

fsetpos sets the file pointer associated with stream to a new position. The new position is the value obtained by a previous call to fgetpos on that stream. It also clears the end-of-file indicator on the file that stream points to and undoes any effects of ungetc on that file. After a call to fsetpos the next operation on the file can be input or output.

Return Value

On success fsetpos returns 0.

On failure it returns a nonzero value and also sets the global variable errno to a nonzero value.

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.37 ftell

Header File

stdio.h

Category

Input/output Routines

Prototype

```
long int ftell(FILE *stream);
```

Description

Returns the current file pointer.

ftell returns the current file pointer for stream. The offset is measured in bytes from the beginning of the file (if the file is binary). The value returned by ftell can be used in a subsequent call to fseek.

Return Value

ftell returns the current file pointer position on success. It returns -1L on error and sets the global variable errno to a positive value.

In the event of an error return the global variable errno is set to one of the following values:

EBADF	Bad file pointer
ESPIPE	Illegal seek on device

Example

```
#include <stdio.h>
int main(void)
{
   FILE *stream;
   stream = fopen("MYFILE.TXT", "w+");
   fprintf(stream, "This is a test");
   printf("The file pointer is at byte %ld\n", ftell(stream));
   fclose(stream);
```

```
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.38 fwrite

Header File

stdio.h

Category

Input/output Routines

Prototype

```
size_t fwrite(const void *ptr, size_t size, size_t n, FILE *stream);
```

Description

Writes to a stream.

fwrite appends n items of data each of length size bytes to the given output file. The data written begins at ptr. The total number of bytes written is (n x size). ptr in the declarations is a pointer to any object.

Return Value

On successful completion fwrite returns the number of items (not bytes) actually written.

On error it returns a short count.

Example

```
#include <stdio.h>
struct mystruct
{
  int i;
  char ch;
};
int main(void)
{
   FILE *stream;
   struct mystruct s;
   if ((stream = fopen("TEST.$$$", "wb")) == NULL) /* open file TEST.$$$ */
   {
      fprintf(stderr, "Cannot open output file.\n");
      return 1;
   }
   s.i = 0;
   s.ch = 'A';
   fwrite(&s, sizeof(s), 1, stream); /* write struct s to file */
   fclose(stream); /* close file */
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.39 getc, getwc

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int getc(FILE *stream);
```

```
wint_t getwc(FILE *stream);
```

Description

Gets character from stream.

getc returns the next character on the given input stream and increments the stream's file pointer to point to the next character.

Note: For Win32 GUI applications, stdin must be redirected.

Return Value

On success, getc returns the character read, after converting it to an **int** without sign extension.

On end-of-file or error, it returns EOF.

Example

```
#include <stdio.h>
int main(void)
{
   char ch;
   printf("Input a character:");
/* read a character from the
standard input stream */
   ch = getc(stdin);
   printf("The character input was: '%c'\n", ch);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
getc	+	+	+	+
getwc		+	+	+

3.1.4.28.40 getchar, getwchar

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
int getchar(void);
wint_t getwchar(void);
```

Description

Gets character from stdin.

getchar is a macro that returns the next character on the named input stream stdin. It is defined to be getc(stdin).

Note: Do not use this function in Win32 GUI applications.

Return Value

On success, getchar returns the character read, after converting it to an **int** without sign extension.

On end-of-file or error, it returns EOF.

Example

```
#include <stdio.h>
int main(void)
{
   int c;
/*
Note that getchar reads from stdin and is line buffered; this means it will not return until
you press ENTER.
 */
   while ((c = getchar()) != '\n')
      printf("%c", c);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
getchar	+	+	+	+
getwchar		+	+	+

3.1.4.28.41 gets, _getws

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
char *gets(char *s);
wchar_t *_getws(wchar_t *s); // Unicode version
```

Description

Gets a string from stdin.

gets collects a string of characters terminated by a new line from the standard input stream stdin and puts it into s. The new line is replaced by a null character (\0) in s.

gets allows input strings to contain certain whitespace characters (spaces, tabs). gets returns when it encounters a new line; everything up to the new line is copied into s.

The gets function is not length-terminated. If the input string is sufficiently large, data can be overwritten and corrupted. The fgets function provides better control of input strings.

Note: For Win32 GUI applications, stdin must be redirected.

Return Value

On success, gets returns the string argument s.

On end-of-file or error, it returns NULL

Example

```
#include <stdio.h>
int main(void)
{
   char string[80];
   printf("Input a string:");
   gets(string);
   printf("The string input was: %s\n", string);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
gets	+	+	+	+
_getws		+		

3.1.4.28.42 _getw

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int _getw(FILE *stream);
```

Description

Gets an integer from stream.

_getw returns the next integer in the named input stream. It assumes no special alignment in the file.

_getw should not be used when the stream is opened in text mode.

Return Value

_getw returns the next integer on the input stream.

On end-of-file or error, _getw returns EOF.

Note: Because EOF is a legitimate value for _getw to return, feof or ferror should be used to detect end-of-file or error.

Example

```
#include <stdio.h>
#include <stdlib.h>
#define FNAME "test.$$$"
```

```
int main(void)
{
FILE *fp;
int word;
/* place the word in a file */
fp = fopen(FNAME, "wb");
if (fp == NULL)
{
printf("Error opening file %s\n", FNAME);
      exit(1);
   }
   word = 94;
   putw(word,fp);
   if (ferror(fp))
       printf("Error writing to file\n");
   else
       printf("Successful write\n");
   fclose(fp);
   /* reopen the file */
   fp = fopen(FNAME, "rb");
   if (fp == NULL)
   {
      printf("Error opening file %s\n", FNAME);
      exit(1);
   }
   /* extract the word */
   word = getw(fp);
   if (ferror(fp))
       printf("Error reading file\n");
   else
       printf("Successful read: word = %d\n", word);
   /* clean up */
   fclose(fp);
   unlink(FNAME);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.28.43 printf, wprintf

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
int printf(const char *format[, argument, ...]);
```

```
int wprintf(const wchar_t *format[, argument, ...]);
```

Description

Writes formatted output to stdout.

The printf function:

- Accepts a series of arguments
- Applies to each argument a format specifier contained in the format string *format
- Outputs the formatted data (to the screen, a stream, stdout, or a string)

There must be enough arguments for the format. If there are not, the results will be unpredictable and likely disastrous. Excess arguments (more than required by the format) are merely ignored.

Note: For Win32 GUI applications, stdout must be redirected.

Return Value

On success, printf returns the number of bytes output.

On error, printf returns EOF.

More About printf

Example

```
#include <stdio.h>
#include <string.h>
#define I 555
#define R 5.5
int main(void)
{
   int i,j,k,l;
   char buf[7];
   char *prefix = buf;
   char tp[20];
   printf("prefix  6d      6o      8x        10.2e        "
          "10.2f\n");
   strcpy(prefix,"%");
   for (i = 0; i < 2; i++)
   {
      for (j = 0; j < 2; j++)
         for (k = 0; k < 2; k++)
            for (l = 0; l < 2; l++)
            {
               if (i==0)  strcat(prefix,"-");
               if (j==0)  strcat(prefix,"+");
               if (k==0)  strcat(prefix,"#");
               if (l==0)  strcat(prefix,"0");
               printf("%5s |",prefix);
               strcpy(tp,prefix);
               strcat(tp,"6d |");
               printf(tp,I);
               strcpy(tp,"");
               strcpy(tp,prefix);
               strcat(tp,"6o |");
               printf(tp,I);
               strcpy(tp,"");
               strcpy(tp,prefix);
               strcat(tp,"8x |");
               printf(tp,I);
               strcpy(tp,"");
               strcpy(tp,prefix);
               strcat(tp,"10.2e |");
               printf(tp,R);
               strcpy(tp,prefix);
               strcat(tp,"10.2f |");
               printf(tp,R);
               printf("  \n");
               strcpy(prefix,"%");
            }
       }
   return 0;
}
```

printf	+	+	+	+
_wprintf		+		

3.1.4.28.44 putc, putwc

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int putc(int c, FILE *stream);
wint_t putwc(wint_t c, FILE *stream);
```

Description

Outputs a character to a stream.

putc is a macro that outputs the character c to the stream given by stream.

Return Value

On success, putc returns the character printed, c.

On error, putc returns EOF.

Example

```
#include <stdio.h>
int main(void)
{
   char msg[] = "Hello world\n";
   int i = 0;
   while (msg[i])
      putc(msg[i++], stdout);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
putc	+	+	+	+
putwc		+	+	+

3.1.4.28.45 putchar, putwchar

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
int putchar(int c);

wint_t putwchar(wint_t c);
```

Description

putchar is a macro defined to be putc(c, stdout).

Note: For Win32 GUI applications, stdout must be redirected.

Return Value

On success, putchar returns the character c. On error, putchar returns EOF.

Example

```
#include <stdio.h>
/* define some box-drawing characters */
#define LEFT_TOP  0xDA
#define RIGHT_TOP 0xBF
#define HORIZ     0xC4
#define VERT      0xB3
#define LEFT_BOT  0xC0
#define RIGHT_BOT 0xD9
int main(void)
{
   char i, j;
   /* draw the top of the box */
   putchar(LEFT_TOP);
   for (i=0; i<10; i++)
      putchar(HORIZ);
   putchar(RIGHT_TOP);
   putchar('\n');
   /* draw the middle */
   for (i=0; i<4; i++)
   {
      putchar(VERT);
      for (j=0; j<10; j++)
         putchar(' ');
      putchar(VERT);
      putchar('\n');
   }
   /* draw the bottom */
   putchar(LEFT_BOT);
   for (i=0; i<10; i++)
      putchar(HORIZ);
   putchar(RIGHT_BOT);
   putchar('\n');
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
putchar	+	+	+	+
putwchar		+	+	+

3.1.4.28.46 puts, _putws

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
int puts(const char *s);
int _putws(const wchar_t *s);
```

Description

Outputs a string to stdout.

puts copies the null-terminated string s to the standard output stream stdout and appends a newline character.

Note: For Win32 GUI applications, stdout must be redirected.

Return Value

On successful completion, puts returns a nonnegative value. Otherwise, it returns a value of EOF.

Example

```
#include <stdio.h>
int main(void)
{
   char string[] = "This is an example output string\n";
   puts(string);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
puts	+	+	+	+
_putws		+		

3.1.4.28.47 _putw

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int _putw(int w, FILE *stream);
```

Description

Writes an integer on a stream.

_putw outputs the integer w to the given stream. _putw neither expects nor causes special alignment in the file.

Return Value

On success, _putw returns the integer w. On error, _putw returns EOF. Because EOF is a legitimate integer, use ferror to detect errors with _putw.

Example

```
#include <stdio.h>
#include <stdlib.h>
#define FNAME "test.$$$"
int main(void)
{
   FILE *fp;
   int word;
   /* place the word in a file */
   fp = fopen(FNAME, "wb");
   if (fp == NULL)
   {
      printf("Error opening file %s\n", FNAME);
      exit(1);
   }
   word = 94;
   putw(word,fp);
   if (ferror(fp))
       printf("Error writing to file\n");
   else
       printf("Successful write\n");
   fclose(fp);
   /* reopen the file */
   fp = fopen(FNAME, "rb");
   if (fp == NULL)
   {
      printf("Error opening file %s\n", FNAME);
      exit(1);
   }
   /* extract the word */
   word = getw(fp);
   if (ferror(fp))
       printf("Error reading file\n");
   else
       printf("Successful read: word = %d\n", word);
   /* clean up */
   fclose(fp);
   unlink(FNAME);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.28.48 remove, _wremove

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int remove(const char *filename);
```

```
int _wremove(const wchar_t *filename);
```

Description

Removes a file.

remove deletes the file specified by filename. It is a macro that simply translates its call to a call to unlink. If your file is open, be sure to close it before removing it.

The filename string can include a full path.

Return Value

On successful completion, remove returns 0. On error, it returns -1, and the global variable errno is set to one of the following values:

EACCES	Permission denied
ENOENT	No such file or directory

Example

```
#include <stdio.h>
int main(void)
{
    char file[80];
    /* prompt for file name to delete */
    printf("File to delete: ");
    gets(file);
    /* delete the file */
    if (remove(file) == 0)
       printf("Removed %s.\n",file);
    else
       perror("remove");
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
remove	+	+	+	+
_wremove		NT only		

3.1.4.28.49 rename, _wrename

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int rename(const char *oldname, const char *newname);
```

```
int _wrename(const wchar_t *oldname, const wchar_t *newname);
```

Description

Renames a file.

rename changes the name of a file from oldname to newname. If a drive specifier is given in newname, the specifier must be the same as that given in oldname.

Directories in oldname and newname need not be the same, so rename can be used to move a file from one directory to another. Wildcards are not allowed.

This function will fail (EEXIST) if either file is currently open in any process.

Return Value

On success, rename returns 0.

On error (if the file cannot be renamed), it returns -1 and the global variable errno is set to one of the following values:

EEXIST	Permission denied: file already exists.
ENOENT	No such file or directory
ENOTSAM	Not same device

Example

```
#include <stdio.h>
int main(void)
{
    char oldname[80], newname[80];
    /* prompt for file to rename and new name */
    printf("File to rename: ");
    gets(oldname);
    printf("New name: ");
    gets(newname);
    /* Rename the file */
    if (rename(oldname, newname) == 0)
       printf("Renamed %s to %s.\n", oldname, newname);
    else
       perror("rename");
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
rename	+	+	+	+
_wrename		NT only		

3.1.4.28.50 rewind

Header File

stdio.h

Category

Input/output Routines

Prototype

```
void rewind(FILE *stream);
```

Description

Repositions a file pointer to the beginning of a stream.

rewind(stream) is equivalent to fseek(stream, 0L, SEEK_SET), except that rewind clears the end-of-file and error indicators, while fseek clears the end-of-file indicator only.

After rewind, the next operation on an update file can be either input or output.

Return Value

None.

Example

```
#include <stdio.h>
#include <dir.h>
int main(void)
{
    FILE *fp;
    char *fname = "TXXXXXX", *newname, first;
    newname = mktemp(fname);
    fp = fopen(newname,"w+");
    fprintf(fp,"abcdefghijklmnopqrstuvwxyz");
    rewind(fp);
    fscanf(fp,"%c",&first);
    printf("The first character is: %c\n",first);
    fclose(fp);
    remove(newname);
    return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.51 _rmtmp

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int _rmtmp(void);
```

Description

Removes temporary files.

The _rmtmp function closes and deletes all open temporary file streams which were previously created with tmpfile. The current directory must the same as when the files were created, or the files will not be deleted.

Return Value

_rmtmp returns the total number of temporary files it closed and deleted.

Example

```
#include <stdio.h>
#include <process.h>

void main()
{
   FILE *stream;
   int i;

   /* Create temporary files */
   for (i = 1; i <= 10; i++)
   {
     if ((stream = tmpfile()) == NULL)
       perror("Could not open temporary file\n");
     else
       printf("Temporary file %d created\n", i);
   }
   /* Remove temporary files */
   if (stream != NULL)
     printf("%d temporary files deleted\n", rmtmp());
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.28.52 scanf, wscanf

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
int scanf(const char *format[, address, ...]);
```

```
int wscanf(const wchar_t *format[, address, ...]);
```

Description

Scans and formats input from the stdin stream.

Note: For Win32 GUI applications, stdin must be redirected.

The scanf function:

- scans a series of input fields one character at a time
- formats each field according to a corresponding format specifier passed in the format string *format.
- vsscanf scans and formats input from a string, using an argument list

There must be one format specifier and address for each input field.

scanf might stop scanning a particular field before it reaches the normal end-of-field (whitespace) character, or it might terminate entirely. For details about why this might happen, see When ...scanf Stops Scanning.

Note: scanf often leads to unexpected results if you diverge from an expected pattern. You must provide information that tells scanf how to synchronize at the end of a line.

The combination of gets or fgets followed by sscanf is safe and easy, and therefore recommended over scanf.

Return Value

On success, scanf returns the number of input fields successfully scanned, converted, and stored. The return value does not include scanned fields that were not stored.

On error:

- if no fields were stored, scanf returns 0.
- if scanf attempts to read at end-of-file or at end-of-string, it returns EOF.

More About scanf

Example

```
#include <stdio.h>
int main(void)
{
   char label[20];
   char name[20];
   int entries = 0;
   int loop, age;
   double salary;
   struct Entry_struct
   {
      char  name[20];
      int   age;
      float salary;
   } entry[20];
/* Input a label as a string of characters restricting to 20 characters */
   printf("\n\nPlease enter a label for the chart: ");
   scanf("%20s", label);
   fflush(stdin);  /* flush the input stream in case of bad input */
/* Input number of entries as an integer */
  printf("How many entries will there be? (less than 20) ");
  scanf("%d", &entries);
  fflush(stdin);   /* flush the input stream in case of bad input */
/* input a name restricting input to only letters upper or lower case */
   for (loop=0;loop<entries;++loop)
   {
      printf("Entry %d\n", loop);
      printf("  Name   : ");
      scanf("%[A-Za-z]", entry[loop].name);
      fflush(stdin);  /* flush the input stream in case of bad input */
/* input an age as an integer */
      printf("  Age    : ");
      scanf("%d", &entry[loop].age);
      fflush(stdin);  /* flush the input stream in case of bad input */
/* input a salary as a float */
      printf("  Salary : ");
      scanf("%f", &entry[loop].salary);
      fflush(stdin); /* flush the input stream in case of bad input */
   }
/* Input a name, age and salary as a string, integer, and double */
   printf("\nPlease enter your name, age and salary\n");
   scanf("%20s %d %lf", name, &age, &salary);
/* Print out the data that was input */
   printf("\n\nTable %s\n",label);
   printf("Compiled by %s  age %d  $%15.2lf\n", name, age, salary);
   printf("-----------------------------------------------------\n");
   for (loop=0;loop<entries;++loop)
      printf("%4d | %-20s | %5d | %15.2lf\n",
         loop + 1,
         entry[loop].name,
         entry[loop].age,
         entry[loop].salary);
   printf("-----------------------------------------------------\n");
   return 0;
```

```
}
```

3.1.4.28.53 setbuf

Header File

stdio.h

Category

Input/output Routines

Prototype

```
void setbuf(FILE *stream, char *buf);
```

Description

Assigns buffering to a stream.

setbuf causes the buffer buf to be used for I/O buffering instead of an automatically allocated buffer. It is used after stream has been opened.

If buf is null, I/O will be unbuffered; otherwise, it will be fully buffered. The buffer must be BUFSIZ bytes long (specified in stdio.h).

stdin and stdout are unbuffered if they are not redirected; otherwise, they are fully buffered. setbuf can be used to change the buffering style used.

Unbuffered means that characters written to a stream are immediately output to the file or device, while buffered means that the characters are accumulated and written as a block.

setbuf produces unpredictable results unless it is called immediately after opening stream or after a call to fseek. Calling setbuf after stream has been unbuffered is legal and will not cause problems.

A common cause for error is to allocate the buffer as an automatic (local) variable and then fail to close the file before returning from the function where the buffer was declared.

Return Value

None.

Example

```
#include <stdio.h>
/* BUFSIZ is defined in stdio.h */
char outbuf[BUFSIZ];
int main(void)
{
   /* attach a buffer to the standard output stream */
   setbuf(stdout, outbuf);
   /* put some characters into the buffer */
   puts("This is a test of buffered output.\n\n");
   puts("This output will go into outbuf\n");
   puts("and won't appear until the buffer\n");
   puts("fills up or we flush the stream.\n");
   /* flush the output buffer */
   fflush(stdout);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.54 setvbuf

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int setvbuf(FILE *stream, char *buf, int type, size_t size);
```

Description

Assigns buffering to a stream.

setvbuf causes the buffer buf to be used for I/O buffering instead of an automatically allocated buffer. It is used after the given stream is opened.

If buf is null, a buffer will be allocated using malloc; the buffer will use size as the amount allocated. The buffer will be automatically freed on close. The size parameter specifies the buffer size and must be greater than zero.

The parameter size is limited by the constant UINT_MAX as defined in limits.h.

stdin and stdout are unbuffered if they are not redirected; otherwise, they are fully buffered. Unbuffered means that characters written to a stream are immediately output to the file or device, while buffered means that the characters are accumulated and written as a block.

- The type parameter is one of the following:

_IOFBF	fully buffered file. When a buffer is empty, the next input operation will attempt to fill the entire buffer. On output, the buffer will be completely filled before any data is written to the file.
_IOLBF	line buffered file. When a buffer is empty, the next input operation will still attempt to fill the entire buffer. On output, however, the buffer will be flushed whenever a newline character is written to the file.
_IONBF	unbuffered file. The buf and size parameters are ignored. Each input operation will read directly from the file, and each output operation will immediately write the data to the file.

A common cause for error is to allocate the buffer as an automatic (local) variable and then fail to close the file before returning from the function where the buffer was declared.

Return Value

On success, setvbuf returns 0.

On error (if an invalid value is given for type or size, or if there is not enough space to allocate a buffer), it returns nonzero.

Example

```
#include <stdio.h>
int main(void)
{
   FILE *input, *output;
   char bufr[512];
   input = fopen("file.in", "r+b");
   output = fopen("file.out", "w");
   /* set up input stream for minimal disk access,
      using our own character buffer */
```

```
if (setvbuf(input, bufr, _IOFBF, 512) != 0)
      printf("failed to set up buffer for input file\n");
   else
      printf("buffer set up for input file\n");
   /* set up output stream for line buffering using space that
      will be obtained through an indirect call to malloc */
   if (setvbuf(output, NULL, _IOLBF, 132) != 0)
      printf("failed to set up buffer for output file\n");
   else
      printf("buffer set up for output file\n");
   /* perform file I/O here */
   /* close files */
   fclose(input);
   fclose(output);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++

3.1.4.28.55 snprintf;snwprintf

Header File

stdio.h

Category

Memory and String Manipulation Routines

Prototype

```
int snprintf(char* buffer, size_t nsize, const char* fmt, ...);
```

```
int snwprintf(wchar_t* buffer, size_t nsize, const wchar_t* fmt, ...);
```

Description

Sends formatted output to a buffer of a maximum length specified by nsize.

If the number of bytes to output is:

- < nsize, then all of the characters have been written, including the terminating '\0' character.
- == nsize, then nsize characters are written, with no terminating '\0' character.

> nsize, then only nsize characters are written, with no terminating '\0' character.

If nsize is 0, then the string will not be written to (and may be NULL).

Return Value

Number of bytes output, or, if nsize is 0, the number of bytes needed, not including the terminating '\0' character.

3.1.4.28.56 sprintf, swprintf

Header File

stdio.h

Category

Memory and String Manipulation Routines

Prototype

```
int sprintf(char *buffer, const char *format[, argument, ...]);
int swprintf(wchar_t *buffer, const wchar_t *format[, argument, ...]);
```

Description

Writes formatted output to a string.

Note: For details on format specifiers, see printf.

sprintf accepts a series of arguments, applies to each a format specifier contained in the format string pointed to by format, and outputs the formatted data to a string.

sprintf applies the first format specifier to the first argument, the second to the second, and so on. There must be the same number of format specifiers as arguments.

Return Value

On success, sprintf returns the number of bytes output. The return value does not include the terminating null byte in the count.

On error, sprintf returns EOF.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   char buffer[80];
   sprintf(buffer, "An approximation of Pi is %f\n", M_PI);
   puts(buffer);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
sprintf	+	+	+	+
swprintf		+	+	+

3.1.4.28.57 sscanf, swscanf

Header File

stdio.h

Category

Memory and String Manipulation Routines

Syntax

```
int sscanf(const char *buffer, const char *format[, address, ...]);
int swscanf(const wchar_t *buffer, const wchar_t *format[, address, ...]);
```

Description

Scans and formats input from a string.

Note: For details on format specifiers, see scanf.

sscanf scans a series of input fields, one character at a time, reading from a string. Then each field is formatted according to a format specifier passed to sscanf in the format string pointed to by format. Finally, sscanf stores the formatted input at an address passed to it as an argument following format. There must be the same number of format specifiers and addresses as there are input fields.

sscanf might stop scanning a particular field before it reaches the normal end-of-field (whitespace) character, or it might terminate entirely, for a number of reasons. See scanf for a discussion of possible causes.

Return Value

On success, sscanf returns the number of input fields successfully scanned, converted, and stored; the return value does not include scanned fields that were not stored.

If sscanf attempts to read at end-of-string, it returns EOF.

On error (If no fields were stored), it returns 0.

Example

```
#include <stdio.h>
#include <stdlib.h>
char *names[4] = {"Peter", "Mike", "Shea", "Jerry"};
#define NUMITEMS 4
int main(void)
{
   int   loop;
   char  temp[4][80];
   char  name[20];
   int   age;
   long  salary;
/* create name, age and salary data */
   for (loop=0; loop < NUMITEMS; ++loop)
      sprintf(temp[loop], "%s %d %ld", names[loop], random(10) + 20, random(5000) + 27500L);
/* print title bar */
   printf("%4s | %-20s | %5s | %15s\n", "#", "Name", "Age", "Salary");
   printf("   ------------------------------------------------\n");
/* input a name, age and salary data */
   for (loop=0; loop < NUMITEMS; ++loop)
      {
      sscanf(temp[loop],"%s %d %ld", &name, &age, &salary);
      printf("%4d | %-20s | %5d | %15ld\n", loop + 1, name, age, salary);
      }
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
sscanf	+	+	+	+
swscanf		+	+	+

3.1.4.28.58 stderr, stdin, stdout

Header File

stdio.h

Description

Predefined streams automatically opened when the program is started.

Name	Meaning
stdin	Standard input device
stdout	Standard output device
stderr	Standard error output device

3.1.4.28.59 _tempnam, _wtempnam

Header File

stdio.h

Category

Input/output Routines

Prototype

```
char *_tempnam(char *dir, char *prefix)
```

```
wchar_t *_wtempnam(wchar_t *dir, wchar_t *prefix)
```

Description

Creates a unique file name in specified directory.

The _tempnam function accepts single-byte or multibyte string arguments.

The _tempnam function creates a unique file name in arbitrary directories. The unique file is not actually created; _tempnam only verifies that it does not currently exist. It attempts to use the following directories, in the order shown, when creating the file name:

- The directory specified by the TMP environment variable.
- The dir argument to _tempnam.
- The P_tmpdir definition in stdio.h. If you edit stdio.h and change this definition, _tempnam will not use the new definition.
- The current working directory.

If any of these directories is NULL, or undefined, or does not exist, it is skipped.

The prefix argument specifies the first part of the file name; it cannot be longer than 5 characters, and cannot contain a period (.). A unique file name is created by concatenating the directory name, the prefix, and 6 unique characters. Space for the resulting file name is allocated with malloc; when this file name is no longer needed, the caller should call free to free it.

If you do create a temporary file using the name constructed by _tempnam, it is your responsibility to delete the file name (for example, with a call to remove). It is not deleted automatically. (tmpfile does delete the file name.)

Return Value

If _tempnam is successful, it returns a pointer to the unique temporary file name, which the caller can pass to free when it is no longer needed. Otherwise, if _tempnam cannot create a unique file name, it returns NULL.

Example

```
#include <stdio.h>
#include <stdlib.h>
void main(void)
{
  FILE *stream;
  int i;
  char *name;
  for (i = 1; i <= 10; i++) {
    if ((name = tempnam("\\tmp","wow")) == NULL)
      perror("tempnam couldn't create name");
```

```
    else {
      printf("Creating %s\n",name);
      if ((stream = fopen(name,"wb")) == NULL)
        perror("Could not open temporary file\n");
      else
        fclose(stream);
    }
    free(name);
  }
  printf("Warning: temp files not deleted.\n");
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_tempnam		+		
_wtempnam		+		

3.1.4.28.60 tmpfile

Header File

stdio.h

Category

Input/output Routines

Prototype

```
FILE *tmpfile(void);
```

Description

Opens a “scratch” file in binary mode.

tmpfile creates a temporary binary file and opens it for update (w + b). If you do not change the directory after creating the temporary file, the file is automatically removed when it’s closed or when your program terminates.

Return Value

tmpfile returns a pointer to the stream of the temporary file created. If the file can’t be created, tmpfile returns NULL.

Example

```
#include <stdio.h>
#include <process.h>
int main(void)
{
   FILE *tempfp;
   tempfp = tmpfile();
   if (tempfp)
      printf("Temporary file created\n");
   else
   {
      printf("Unable to create temporary file\n");
      exit(1);
   }
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.28.61 tmpnam, _wtmpnam

Header File

stdio.h

Category

Input/output Routines

Prototype

```
char *tmpnam(char *s);
```

```
wchar_t *_wtmpnam(wchar_t *s);
```

Description

Creates a unique file name.

tmpnam creates a unique file name, which can safely be used as the name of a temporary file. tmpnam generates a different string each time you call it, up to TMP_MAX times. TMP_MAX is defined in stdio.h as 65,535.

The parameter to tmpnam, s, is either null or a pointer to an array of at least L_tmpnam characters. L_tmpnam is defined in stdio.h. If s is NULL, tmpnam leaves the generated temporary file name in an internal static object and returns a pointer to that object. If s is not NULL, tmpnam overwrites the internal static object and places its result in the pointed-to array, which must be at least L_tmpnam characters long, and returns s.

If you do create such a temporary file with tmpnam, it is your responsibility to delete the file name (for example, with a call to remove). It is not deleted automatically. (tmpfile does delete the file name.)

Return Value

If s is null, tmpnam returns a pointer to an internal static object. Otherwise, tmpnam returns s.

Example

```
#include <stdio.h>
int main(void)
{
   char name[13];
   tmpnam(name);
   printf("Temporary name: %s\n", name);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
tmpnam	+	+	+	+
_wtmpnam		+		

3.1.4.28.62 ungetc, ungetwc

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int ungetc(int c, FILE *stream);
```

```
wint_t ungetwc(wint_t c, FILE *stream);
```

Description

Pushes a character back into input stream.

Note: Do not use this function in Win32 GUI applications.

ungetc pushes the character c back onto the named input stream, which must be open for reading. This character will be returned on the next call to getc or fread for that stream. One character can be pushed back in all situations. A second call to ungetc without a call to getc will force the previous character to be forgotten. A call to fflush, fseek, fsetpos, or rewind erases all memory of any pushed-back characters.

Return Value

On success, ungetc returns the character pushed back.

On error, it returns EOF.

Example

```
#include <stdio.h>
#include <ctype.h>
int main( void )
{
   int i=0;
   char ch;
   puts("Input an integer followed by a char:");
   /* read chars until non digit or EOF */
   while((ch = getchar()) != EOF && isdigit(ch))
      i = 10 * i + ch - 48; /* convert ASCII into int value */
   /* if non digit char was read, push it back into input buffer */
   if (ch != EOF)
      ungetc(ch, stdin);
   printf("i = %d, next char in buffer = %c\n", i, getchar());
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
ungetc	+	+	+	+
ungetwc		+	+	+

3.1.4.28.63 vfprintf, vfwprintf

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int vfprintf(FILE *stream, const char *format, va_list arglist);

int vfwprintf(FILE *stream, const wchar_t *format, va_list arglist);
```

Description

Writes formatted output to a stream.

The v...printf functions are known as alternate entry points for the ...printf functions. They behave exactly like their ...printf counterparts, but they accept a pointer to a list of arguments instead of an argument list.

For details on format specifiers, see Printf Format Specifiers.

vfprintf accepts a pointer to a series of arguments, applies to each argument a format specifier contained in the format string pointed to by format, and outputs the formatted data to a stream. There must be the same number of format specifiers as arguments.

Return Value

On success, vfprintf returns the number of bytes output.

On error, it returns EOF.

Example

```
#include <stdio.h>
#include <stdlib.h>
#include <stdarg.h>
FILE *fp;
int vfpf(char *fmt, ...)
{
   va_list argptr;
   int cnt;
   va_start(argptr, fmt);
   cnt = vfprintf(fp, fmt, argptr);
   va_end(argptr);
   return(cnt);
}
int main(void)
{
   int inumber = 30;
   float fnumber = 90.0;
   char string[4] = "abc";
   fp = tmpfile();
   if (fp == NULL)
   {
      perror("tmpfile() call");
      exit(1);
   }
   vfpf("%d %f %s", inumber, fnumber, string);
   rewind(fp);
   fscanf(fp,"%d %f %s", &inumber, &fnumber, string);
   printf("%d %f %s\n", inumber, fnumber, string);
   fclose(fp);
   return 0;
}
```

Portability

3.1.4.28.64 vfscanf

Header File

stdio.h

Category

Input/output Routines

Prototype

```
int vfscanf(FILE *stream, const char *format,va_list arglist);
```

Description

Scans and formats input from a stream.

The v...scanf functions are known as alternate entry points for the ...scanf functions. They behave exactly like their ...scanf counterparts but they accept a pointer to a list of arguments instead of an argument list.

For details on format specifiers, see Scanf Format Specifiers.

vfscanf scans a series of input fields one character at a time reading from a stream. Then each field is formatted according to a format specifier passed to vfscanf in the format string pointed to by format. Finally vfscanf stores the formatted input at an address passed to it as an argument following format. There must be the same number of format specifiers and addresses as there are input fields. vfscanf might stop scanning a particular field before it reaches the normal end-of-field (whitespace) character or it might terminate entirely for a number of reasons. See scanf for a discussion of possible causes.

Return Value

vfscanf returns the number of input fields successfully scanned converted and stored; the return value does not include scanned fields that were not stored. If no fields were stored the return value is 0.

If vfscanf attempts to read at end-of-file the return value is EOF.

Example

```
#include <stdio.h>
#include <stdlib.h>
#include <stdarg.h>
FILE *fp;
int vfsf(char *fmt, ...)
{
   va_list  argptr;
   int cnt;
   va_start(argptr, fmt);
   cnt = vfscanf(fp, fmt, argptr);
   va_end(argptr);
   return(cnt);
}
int main(void)
{
   int inumber = 30;
   float fnumber = 90.0;
         char string[4] = "abc";
   fp = tmpfile();
   if (fp == NULL)
   {
      perror("tmpfile() call");
      exit(1);
   }
   fprintf(fp,"%d %f %s\n",inumber,fnumber,string);
   rewind(fp);
```

```
   vfsf("%d %f %s",&inumber,&fnumber,string);
   printf("%d %f %s\n",inumber,fnumber,string);
   fclose(fp);
   return 0;
}
```

	+	+	+

3.1.4.28.65 vprintf, vwprintf

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
int vprintf(const char *format, va_list arglist);
```

```
int vwprintf(const wchar_t * format, va_list arglist);
```

Description

Writes formatted output to stdout.

Note: Do not use this function in Win32 GUI applications.

The v...printf functions are known as alternate entry points for the ...printf functions. They behave exactly like their ...printf counterparts, but they accept a pointer to a list of arguments instead of an argument list.

Note: For details on format specifiers, see Printf Format Specifiers.

vprintf accepts a pointer to a series of arguments, applies to each a format specifier contained in the format string pointed to by format, and outputs the formatted data to stdout. There must be the same number of format specifiers as arguments.

Return Value

vprint returns the number of bytes output. In the event of error, vprint returns EOF.

Example

```
#include <stdio.h>
#include <stdarg.h>
int vpf(char *fmt, ...)
{
   va_list argptr;
   int cnt;
   va_start(argptr, fmt);
   cnt = vprintf(fmt, argptr);
   va_end(argptr);
   return(cnt);
}
int main(void)
{
   int inumber = 30;
   float fnumber = 90.0;
   char *string = "abc";

3.1.4.28.66 vscanf

Header File

stdio.h

Category

Console I/O Routines

Prototype

```
int vscanf(const char *format, va_list arglist);
```

Description

Scans and formats input from stdin.

Note: Do not use this function in Win32 GUI applications.

The v...scanf functions are known as alternate entry points for the ...scanf functions. They behave exactly like their ...scanf counterparts, but they accept a pointer to a list of arguments instead of an argument list.

Note: For details on format specifiers, see Scanf Format Specifiers.

vscanf scans a series of input fields, one character at a time, reading from stdin. Then each field is formatted according to a format specifier passed to vscanf in the format string pointed to by format. Finally, vscanf stores the formatted input at an address passed to it as an argument following format. There must be the same number of format specifiers and addresses as there are input fields.

vscanf might stop scanning a particular field before it reaches the normal end-of-field (whitespace) character, or it might terminate entirely, for a number of reasons. See scanf for a discussion of possible causes.

Return Value

vscanf returns the number of input fields successfully scanned, converted, and stored; the return value does not include scanned fields that were not stored. If no fields were stored, the return value is 0.

If vscanf attempts to read at end-of-file, the return value is EOF.

Example

```
#include <stdio.h>
#include <stdarg.h>
int vscnf(char *fmt, ...)
{
   va_list argptr;
   int cnt;
   printf("Enter an integer, a float, and a string (e.g. i,f,s,)\n");
   va_start(argptr, fmt);
   cnt = vscanf(fmt, argptr);
   va_end(argptr);
   return(cnt);
```

```
}
int main(void)
{
   int inumber;
   float fnumber;
   char string[80];
   vscnf("%d, %f, %s", &inumber, &fnumber, string);
   printf("%d %f %s\n", inumber, fnumber, string);
   return 0;
}
```

3.1.4.28.67 vsnprintf;vsnwprintf

Header File

stdio.h

Category

Memory and String Manipulation Routines

Prototype

```
int vsnprintf(char* buffer, size_t nsize, const char* format, va_list param);
```

```
int vsnwprintf(wchar_t* buffer, size_t nsize, const wchar_t* format, va_list param);
```

Description

Sends formatted output to a buffer of maximum length specified by nsize.

If the number of bytes to output is:

- < nsize, then all of the characters have been written, including the terminating ‘\0’ character.
- == nsize, then nsize characters are written, with no terminating ‘\0’ character.

> nsize, then only nsize characters are written, with no terminating ‘\0’ character.

If nsize is 0, then the string will not be written to (and may be NULL).

Return Value

Number of bytes output, or, if nsize is 0, the number of bytes needed, not including the terminating ‘\0’ character.

3.1.4.28.68 vsprintf, vswprintf

Header File

stdio.h

Category

Memory and String Manipulation Routines

Prototype

```
int vsprintf(char *buffer, const char *format, va_list arglist);
```

```
int vswprintf(wchar_t *buffer, const wchar_t *format, va_list arglist);
```

Description

Writes formatted output to a string.

The v...printf functions are known as alternate entry points for the ...printf functions. They behave exactly like their ...printf counterparts, but they accept a pointer to a list of arguments instead of an argument list.

vsprintf accepts a pointer to a series of arguments, applies to each a format specifier contained in the format string pointed to by format, and outputs the formatted data to a string. There must be the same number of format specifiers as arguments.

Return Value

vsprintf returns the number of bytes output. In the event of error, vsprintf returns EOF.

Example

```
#include <stdio.h>
#include <conio.h>
#include <stdarg.h>
char buffer[80];
int vspf(char *fmt, ...)
{
   va_list argptr;
   int cnt;
   va_start(argptr, fmt);
   cnt = vsprintf(buffer, fmt, argptr);
   va_end(argptr);
   return(cnt);
}
int main(void)
{
   int inumber = 30;
   float fnumber = 90.0;
   char string[4] = "abc";
   vspf("%d %f %s", inumber, fnumber, string);
   printf("%s\n", buffer);
   return 0;
}
```

3.1.4.29 stdlib.h

The following functions, macros, and classes are provided in `stdlib.h`:

Topics

Name	Description
EXIT_xxxx #defines (see page 1095)	**Header File** stdlib.h **Description** Constants defining exit conditions for calls to the exit function.
RAND_MAX #define (see page 1095)	**Header File** stdlib.h **Syntax** **Description** Maximum value returned by rand function.

_argc (see page 1095)	**Header File** stdlib.h **Syntax** `extern int _argc;` **Description** _argc has the same value as argc (passed to main) when the program starts. This variable holds the number of arguments passed to the program. The value includes the name of the program itself, so _argc and argc are always at least 1.

_argv, _wargv (see page 1095)	**Header File**
	stdlib.h
	Syntax
	`extern char **_argv;`
	`extern wchar_t ** _wargv`
	Description
	_argv points to an array containing the original command-line arguments (the elements of argv[]) passed to main when the program starts.
	_wargv is the Unicode version of _argv.
	Portability

_atoi64, _wtoi64 (see page 1096)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`__int64 _atoi64(const char *s);`
	`__int64 _wtoi64(const wchar_t *s);`
	Description
	Converts a string to an **__int64**.
	The syntax of the string must be:
	`__int64 ::= [isspace]* [sign] digit [digit]*`
	Only decimal integers are acceptable.
	_wtoi64 is the wide-character version. It converts a wide-character string to an **__int64**.
	In this function, the first unrecognized character ends the conversion. There are no provisions for overflow in atoi (results are undefined). There is no defined method to return an error indication to the caller. The result is undefined if the input string... more (see page 1096)

_crotl, _crotr (see page 1096)	**Header File**
	stdlib.h
	Category
	Math Routines
	Prototype
	`unsigned char _crotl(unsigned char val, int count);`
	`unsigned char _crotr(unsigned char val, int count);`
	Description
	Rotates an unsigned char left or right.
	_crotl rotates the given val to the left count bits. _crotr rotates the given val to the right count bits.
	The argument val is an **unsigned char**, or its equivalent in decimal or hexadecimal form.
	Return Value
	• The functions return the rotated byte:
	• _crotl returns the value of val left-rotated count bits.
	• _crotr returns the value of val right-rotated count bits.
	Portability

_exit (see page 1097)	**Header File** stdlib.h **Category** Process Control Routines **Prototype** `void _exit(int status);` **Description** Terminates program. _exit terminates execution without closing any files, flushing any output, or calling any exit functions. The calling process uses status as the exit status of the process. Typically a value of 0 is used to indicate a normal exit, and a nonzero value indicates some error. **Return Value** None. **Example**

_fullpath, _wfullpath (see page 1098)	**Header File**
	stdlib.h
	Category
	Directory Control Routines
	Prototype
	`char * _fullpath(char *buffer, const char *path, int buflen);`
	`wchar_t * _wfullpath(wchar_t *buffer, const wchar_t *path, int buflen);`
	Description
	Converts a path name from relative to absolute.
	_fullpath converts the relative path name in path to an absolute path name that is stored in the array of characters pointed to by buffer. The maximum number of characters that can be stored at buffer is buflen. The function returns NULL if the buffer isn't big enough to store the absolute path name or if the path contains an invalid drive letter.
	If buffer... more (see page 1098)

_lrand (see page 1099)	**Header File** stdlib.h **Category** Math Routines **Prototype** `long _lrand(void);` **Description** _lrand is the long random number generator function. _rand uses a multiplicative congruential random number generator with period 2^64 to return successive pseudo-random numbers in the range from 0 to 2^31 - 1. The generator is reinitialized by calling srand with an argument value of 1. It can be set to a new starting point by calling srand with a given seed number.

_lrotl, _lrotr (see page 1099)	**Header File**
	stdlib.h
	Category
	Math Routines
	Prototype
	`unsigned long _lrotl(unsigned long val, int count);`
	`unsigned long _lrotr(unsigned long val, int count);`
	Description
	Rotates an **unsigned long** integer value to the left or right.
	_lrotlrotates the given val to the left count bits. _lrotr rotates the given val to the right count bits.
	Return Value
	The functions return the rotated integer:
	• _lrotl returns the value of val left-rotated count bits.
	• _lrotr returns the value of val right-rotated count bits.
	Example

_makepath, _wmakepath (see page 1100)	**Header File**
	stdlib.h
	Category
	Directory Control Routines
	Prototype
	`void _makepath(char *path, const char *drive, const char *dir, const char *name, const char *ext);`
	`void _wmakepath(wchar_t *path, const wchar_t *drive, const wchar_t *dir, const wchar_t *name, const wchar_t *ext);`
	Description
	Builds a path from component parts.
	_makepath makes a path name from its components. The new path name is
	`X:\DIR\SUBDIR\NAME.EXT`
	where

_rotl, _rotr (see page 1102)	**Header File**
	stdlib.h
	Category
	Math Routines
	Prototype
	`unsigned short _rotl(unsigned short value, int count);`
	`unsigned short _rotr(unsigned short value, int count);`
	Description
	Bit-rotates an **unsigned** short integer value to the left or right.
	_rotl rotates the given value to the left count bits.
	_rotr rotates the given value to the right count bits.
	Return Value
	_rotl, and _rotr return the rotated integer:
	• _rotl returns the value of value left-rotated count bits.
	• _rotr returns the value of value right-rotated count bits.
	Example

_searchenv, _wsearchenv (see page 1103)	**Header File**
	stdlib.h
	Category
	Miscellaneous Routines
	Prototype
	`char *_searchenv(const char *file, const char *varname, char *buf);`
	`char *_wsearchenv(const wchar_t *file, const wchar_t *varname, wchar_t *buf);`
	Description
	Looks for a file, using an environment variable as the search path.
	_searchenv attempts to locate file, searching along the path specified by the operating system environment variable varname. Typical environment variables that contain paths are PATH, LIB, and INCLUDE.
	_searchenv searches for the file in the current directory of the current drive first. If the file is not found there, the environment variable varname is fetched, and each directory in the path it... more (see page 1103)

_searchstr, _wsearchstr (see page 1104)	**Header File**
	stdlib.h
	Category
	Miscellaneous Routines
	Prototype
	`void _searchstr(const char *file, const char *ipath, char *buf);`
	`void _wsearchstr(const wchar_t *file, const wchar_t *ipath,wchar_t *pathname);`
	Description
	Searches a list of directories for a file.
	_searchstr attempts to locate file, searching along the path specified by the string ipath.
	_searchstr searches for the file in the current directory of the current drive first. If the file is not found there, each directory in ipath is searched in turn until the file is found, or the path is exhausted. The directories in ipath must be separated by semicolons.
	When the file is located,... more (see page 1104)

_splitpath, _wsplitpath (see page 1105)	**Header File**
	stdlib.h
	Category
	Directory Control Routines
	Prototype
	`void _splitpath(const char *path, char *drive, char *dir, char *name, char *ext);`
	`void _wsplitpath(const wchar_t *path, wchar_t *drive, wchar_t *dir, wchar_t *name, wchar_t *ext);`
	Description
	Splits a full path name into its components.
	_splitpath takes a file's full path name (path) as a string in the form
	X:\DIR\SUBDIR\NAME.EXT
	and splits path into its four components. It then stores those components in the strings pointed to by drive, dir, name, and ext. (All five components must be passed, but any of them can be a null, which means the corresponding component will be... more (see page 1105)

_ui64toa, _ui64tow (see page 1106)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`char *_ui64toa(unsigned __int64 value, char *string, int radix);`
	`wchar_t *_ui64tow(unsigned __int64 value, wchar_t *string, int radix);`
	Description
	_ui64toa converts an unsigned **__int64** to a string.
	_ui64tow is the unicode version. _ui64tow converts an unsigned **__int64** to a wide-character string.
	These functions convert value to a null-terminated string and store the result in string. value is an **__int64**.
	radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. If value is negative and radix is 10, the first character of string is... more (see page 1106)

abort (see page 1107)	**Header File** stdlib.h **Category** Process Control Routines **Prototype** `void abort(void);` **Description** Abnormally terminates a program. abort causes an abnormal program termination by calling raise(SIGABRT). If there is no signal handler for SIGABRT, then abort writes a termination message (Abnormal program termination) on stderr, then aborts the program by a call to _exit with exit code 3. **Return Value** abort returns the exit code 3 to the parent process or to the operating system command processor. **Example**
atexit (see page 1107)	**Header File** stdlib.h **Category** Process Control Routines **Prototype** `int atexit(void (_USERENTRY * func)(void));` **Description** Registers termination function. atexit registers the function pointed to by func as an exit function. Upon normal termination of the program, exit calls func just before returning to the operating system. fcmp must be used with the _USERENTRY calling convention. Each call to atexit registers another exit function. Up to 32 functions can be registered. They are executed on a last-in, first-out basis (that is, the last function registered is the first to be executed). **Return Value** atexit returns 0 on success and nonzero on failure... more (see page 1107)

atoi, _wtoi (see page 1108)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`int atoi(const char *s);`
	`int _wtoi(const wchar_t *s);`
	Description
	Converts a string to an integer.
	• atoi converts a string pointed to by s to **int**; atoi recognizes (in the following order)
	• An optional string of tabs and spaces
	• An optional sign
	• A string of digits
	The characters must match this generic format:
	[ws] [sn] [ddd]
	In this function, the first unrecognized character ends the conversion. There are no provisions for overflow in atoi (results are undefined).
	Return Value
	atoi returns the converted value of the input string. If the... more (see page 1108)

atol, _wtol (see page 1109)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`long atol(const char *s);`
	`long _wtol(const wchar_t *s);`
	Description
	Converts a string to a long.
	• atol converts the string pointed to by s to **long**. atol recognizes (in the following order)
	• An optional string of tabs and spaces
	• An optional sign
	• A string of digits
	The characters must match this generic format:
	`[ws] [sn] [ddd]`
	In this function, the first unrecognized character ends the conversion. There are no provisions for overflow in atol (results are undefined).
	Return Value
	atol returns the converted value of the input string. If the... more (see page 1109)

bsearch (see page 1110)	**Header File** stdlib.h **Category** Memory and String Manipulation Routines **Prototype** `void *bsearch(const void *key, const void *base, size_t nelem, size_t width, int (_USERENTRY *fcmp)(const void *, const void *));` **Description** Binary search of an array. bsearch searches a table (array) of nelem elements in memory, and returns the address of the first entry in the table that matches the search key. The array must be in order. If no match is found, bsearch returns 0. **Note:** Because this is a binary search, the first matching entry is not necessarily the first entry in the table. The type size_t is defined... more (see page 1110)

div (see page 1111)	**Header File**
	stdlib.h
	Category
	Math Routines
	Prototype
	`div_t div(int numer, int denom);`
	Description
	Divides two integers, returning quotient and remainder.
	div divides two integers and returns both the quotient and the remainder as a div_t type. numer and denom are the numerator and denominator, respectively. The div_t type is a structure of integers defined (with **typedef**) in stdlib.h as follows:
	`typedef struct {`
	`int quot; /* quotient */`
	`int rem; /* remainder */`
	`} div_t;`
	Return Value
	div returns a structure whose elements are quot (the quotient) and rem (the remainder).
	Example

ecvt (see page 1112)	**Header File** stdlib.h **Category** Conversion Routines, Math Routines **Prototype** `char *ecvt(double value, int ndig, int *dec, int *sign);` **Description** Converts a floating-point number to a string. ecvt converts value to a null-terminated string of ndig digits, starting with the leftmost significant digit, and returns a pointer to the string. The position of the decimal point relative to the beginning of the string is stored indirectly through dec (a negative value for dec means that the decimal lies to the left of the returned digits). There is no decimal point in the string itself. If the sign of value is... more (see page 1112)

_environ, _wenviron (see page 1113)	**Header File**
	stdlib.h
	Syntax
	`extern char ** _environ;`
	`extern wchar_t ** _wenviron`
	Description
	_environ is an array of pointers to strings; it is used to access and alter the operating system environment variables. Each string is of the form:
	`envvar = varvalue`
	where envvar is the name of an environment variable (such as PATH), and varvalue is the string value to which envvar is set (such as C:\Utils;C:\MyPrograms). The string varvalue can be empty.
	When a program begins execution, the operating system environment settings are passed directly to the program. Note that env, the third argument to main, is equal... more (see page 1113)

exit (see page 1114)	**Header File** stdlib.h **Category** Process Control Routines **Prototype** `void exit(int status);` **Description** Terminates program. exit terminates the calling process. Before termination, all files are closed, buffered output (waiting to be output) is written, and any registered "exit functions" (posted with atexit) are called. status is provided for the calling process as the exit status of the process. Typically a value of 0 is used to indicate a normal exit, and a nonzero value indicates some error. It can be, but is not required, to be set with one of the following:
fcvt (see page 1114)	**Header File** stdlib.h **Category** Conversion Routines, Math Routines **Prototype** `char *fcvt(double value, int ndig, int *dec, int *sign);` **Description** Converts a floating-point number to a string. fcvt converts value to a null-terminated string digit starting with the leftmost significant digit with ndig digits to the right of the decimal point. fcvt then returns a pointer to the string. The position of the decimal point relative to the beginning of the string is stored indirectly through dec (a negative value for dec means to the left of the returned digits). There is no decimal point in the string itself. If... more (see page 1114)

gcvt (see page 1115)	**Header File** stdlib.h **Category** Conversion Routines, Math Routines **Prototype** `char *gcvt(double value, int ndec, char *buf);` **Description** Converts floating-point number to a string. gcvt converts value to a null-terminated ASCII string and stores the string in buf. It produces ndec significant digits in FORTRAN F format, if possible; otherwise, it returns the value in the printf E format (ready for printing). It might suppress trailing zeros. **Return Value** gcvt returns the address of the string pointed to by buf. **Example**

getenv, _wgetenv (see page 1116)	**Header File**
	stdlib.h
	Category
	Process Control Routines
	Prototype
	`char *getenv(const char *name);`
	`wchar_t *_wgetenv(const wchar_t *name);`
	Description
	Find or delete an environment variable from the system environment.
	The environment consists of a series of entries that are of the form name=string\0.
	getenv returns the value of a specified variable. name can be either uppercase or lowercase. name must not include the equal sign (**=**). If the specified environment variable does not exist, getenv returns a NULL pointer.
	To delete the variable from the environment, use getenv("name=").
	Note: Environment entries must not be changed directly. If you want to... more (see page 1116)

itoa, _itow (see page 1117)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`char *itoa(int value, char *string, int radix);`
	`wchar_t *_itow(int value, wchar_t *string, int radix);`
	Description
	Converts an integer to a string.
	itoa converts value to a null-terminated string and stores the result in string. With itoa, value is an integer. _itow is the unicode version of the function. It converts an integer to a wide-character string.
	radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. If value is negative and radix is 10, the first character of string is the minus... more (see page 1117)

labs (see page 1118)	**Header File** stdlib.h **Category** Math Routines **Prototype** `long labs(long int x);` **Description** Gives long absolute value. labs computes the absolute value of the parameter x. **Return Value** labs returns the absolute value of x. **Example**

lfind (see page 1119)	**Header File** stdlib.h **Category** Memory and String Manipulation Routines **Prototype** `void *lfind(const void *key, const void *base, size_t *num, size_t width, int (_USERENTRY *fcmp)(const void *, const void *));` **Description** Performs a linear search. lfind makes a linear search for the value of key in an array of sequential records. It uses a user-defined comparison routine fcmp. The fcmp function must be used with the _USERENTRY calling convention. The array is described as having *num records that are width bytes wide, and begins at the memory location pointed to by base. **Return Value** lfind returns the address of the first... more (see page 1119)
lsearch (see page 1120)	**Header File** stdlib.h **Category** Memory and String Manipulation Routines **Prototype** `void *lsearch(const void *key, void *base, size_t *num, size_t width, int (_USERENTRY *fcmp)(const void *, const void *));` **Description** Performs a linear search. lsearch searches a table for information. Because this is a linear search, the table entries do not need to be sorted before a call to lsearch. If the item that key points to is not in the table, lsearch appends that item to the table. • base points to the base (0th element) of the search table. • num points to an integer containing the number of entries in... more (see page 1120)

ltoa, _ltoa, _ltow (see page 1121)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`char * ltoa(long value, char * string, int radix);`
	`char *_ltoa(long value, char *string, int radix);`
	`wchar_t *_ltow(long value, wchar_t *string, int radix);`
	Description
	Converts a **long** to a string. _ltow is the unicode version. It converts a **long** to a wide-charater string.
	Converts value to a null-terminated string and stores the result in string. value is a **long**.
	radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. If value is negative and radix is 10, the first character of... more (see page 1121)

max (see page 1122)	**Header File**
	stdlib.h
	Category
	C++ Prototyped Routines
	Prototype
	`(type) max(a, b);`
	`template <class T> T max( T t1, T t2 ); // C++ only`
	Description
	Returns the larger of two values.
	The C macro and the C++ template function compare two values and return the larger of the two. Both arguments and the routine declaration must be of the same type.
	Return Value
	max returns the larger of two values.
	Portability

mblen (see page 1122)	**Header File** stdlib.h **Category** Memory and String Manipulation Routines **Prototype** `int mblen(const char *s, size_t n);` **Description** Determines the length of a multibyte character. If s is not null, mblen determines the number of bytes in the multibyte character pointed to by s. The maximum number of bytes examined is specified by n. The behavior of mblen is affected by the setting of LC_CTYPE category of the current locale. **Return Value** If s is null, mblen returns a nonzero value if multibyte characters have state-dependent encodings. Otherwise, mblen returns 0. If s is not null, mblen returns 0 if s... more (see page 1122)
mbstowcs (see page 1123)	**Header File** stdlib.h **Category** Conversion Routines, Memory and String Manipulation Routines **Prototype** `size_t mbstowcs(wchar_t *pwcs, const char *s, size_t n);` **Description** Converts a multibyte string to a **wchar_t** array. The function converts the multibyte string s into the array pointed to by pwcs. No more than n values are stored in the array. If an invalid multibyte sequence is encountered, mbstowcs returns (size_t) -1. The pwcs array will not be terminated with a zero value if mbstowcs returns n. **Return Value** If an invalid multibyte sequence is encountered, mbstowcs returns (size_t) -1. Otherwise, the function returns the number of array... more (see page 1123)
mbtowc (see page 1124)	**Header File** stdlib.h **Category** Conversion Routines, Memory and String Manipulation Routines **Prototype** `int mbtowc(wchar_t *pwc, const char *s, size_t n);` **Description** Converts a multibyte character to **wchar_t** code. If s is not null, mbtowc determines the number of bytes that comprise the multibyte character pointed to by s. Next, mbtowc determines the value of the type **wchar_t** that corresponds to that multibyte character. If there is a successful match between **wchar_t** and the multibyte character, and pwc is not null, the **wchar_t** value is stored in the array pointed to by pwc. At most n characters are examined. **Return Value... more (see page 1124)**

min (see page 1125)	**Header File**
	stdlib.h
	Category
	C++ Prototyped Routines
	Prototype
	`(type) min(a, b); /* macro version */`
	`template <class T> T min( T t1, T t2 );// C++ only`
	Description
	Returns the smaller of two values.
	The C macro and the C++ template function compare two values and return the smaller of the two. Both arguments and the routine declaration must be of the same type.
	Return Value
	min returns the smaller of two values.

putenv, _wputenv (see page 1126)	**Header File**
	stdlib.h
	Category
	Process Control Routines
	Prototype
	`int putenv(const char *name);`
	`int _wputenv(const wchar_t *name);`
	Description
	Adds string to current environment.
	putenv accepts the string name and adds it to the environment of the current process. For example,
	`putenv("PATH=C:\\BC");`
	putenv can also be used to modify an existing name. name can be either uppercase or lowercase. name must not include the equal sign (=). You can set a variable to an empty value by specifying an empty string on the right side of the '=' sign.
	putenv can be used only to modify the current program's _environment.... more (see page 1126)

qsort (see page 1127)	**Header File** stdlib.h **Category** Memory and String Manipulation Routines **Prototype** `void qsort(void *base, size_t nelem, size_t width, int (_USERENTRY *fcmp)(const void *, const void *));` **Description** Sorts using the quicksort algorithm. qsort is an implementation of the "median of three" variant of the quicksort algorithm. qsort sorts the entries in a table by repeatedly calling the user-defined comparison function pointed to by fcmp. • base points to the base (0th element) of the table to be sorted. • nelem is the number of entries in the table. • width is the size of each entry in the table, in bytes. fcmp, the comparison... more (see page 1127)
rand (see page 1128)	**Header File** stdlib.h **Category** Math Routines **Prototype** `int rand(void);` **Description** Random number generator. rand uses a multiplicative congruential random number generator with period 2 to the 32nd power to return successive pseudo-random numbers in the range from 0 to RAND_MAX. The symbolic constant RAND_MAX is defined in stdlib.h. **Return Value** rand returns the generated pseudo-random number. **Example**

random (see page 1128)	**Header File** stdlib.h **Category** Math Routines **Prototype** `int random(int num);` **Description** Random number generator. random returns a random number between 0 and (num-1). random(num) is a macro defined in stdlib.h. Both num and the random number returned are integers. **Return Value** random returns a number between 0 and (num-1). **Example**
randomize (see page 1129)	**Header File** stdlib.h, time.h **Category** Math Routines **Prototype** `void randomize(void);` **Description** Initializes random number generator. randomize initializes the random number generator with a random value. **Return Value** None. **Example**
srand (see page 1130)	**Header File** stdlib.h **Category** Math Routines **Prototype** `void srand(unsigned seed);` **Description** Initializes random number generator. The random number generator is reinitialized by calling srand with an argument value of 1. It can be set to a new starting point by calling srand with a given seed number. **Return Value** None. **Example**

strlen, _mbslen, wcslen, _mbstrlen (see page 1131)	**Header File**
	string.h, mbstring.h, stdlib.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`size_t strlen(const char *s);`
	`size_t wcslen(const wchar_t *s);`
	`size_t _mbslen(const unsigned char *s);`
	`size_t _mbstrlen(const char *s)`
	Description
	Calculates the length of a string.
	strlen calculates the length of s.
	_mbslen and _mbstrlen test the string argument to determine the number of multibyte characters they contain.
	_mbstrlen is affected by the LC_CTYPE category setting as determined by the setlocale function. The function tests to determine whether the string argument is a valid multibyte string.
	_mbslen is affected by the code page that is in use. This... more (see page 1131)

strtod, _strtold, wcstod, _wcstold (see page 1131)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`double strtod(const char *s, char **endptr);`
	`double wcstod(const wchar_t *s, wchar_t **endptr);`
	`long double _strtold(const char *s, char **endptr);`
	`long double _wcstold(const wchar_t *s, wchar_t **endptr);`
	Description
	Convert a string to a **double** or **long double** value.
	strtod converts a character string, s, to a **double** value. s is a sequence of characters that can be interpreted as a **double** value; the characters must match this generic format:
	`[ws] [sn] [ddd] [.] [ddd] [fmt[sn]ddd]`
	where:

strtol, wcstol (see page 1133)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`long strtol(const char *s, char **endptr, int radix);`
	`long wcstol(const wchar_t *s, wchar_t **endptr, int radix);`
	Description
	Converts a string to a **long** value.
	strtol converts a character string, s, to a **long** integer value. s is a sequence of characters that can be interpreted as a **long** value; the characters must match this generic format:
	`[ws] [sn] [0] [x] [ddd]`
	where:

strtoul, wcstoul (see page 1134)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`unsigned long strtoul(const char *s, char **endptr, int radix);`
	`unsigned long wcstoul(const wchar_t *s, wchar_t **endptr, int radix);`
	Description
	Converts a string to an **unsigned long** in the given radix.
	strtoul operates the same as strtol, except that it converts a string str to an **unsigned long** value (where strtol converts to a **long**). Refer to the entry for strtol for more information.
	Return Value
	strtoul returns the converted value, an **unsigned long**, or 0 on error.
	Example

swab (see page 1135)	**Header File** stdlib.h **Category** Memory and String Manipulation Routines **Prototype** `void swab(char *from, char *to, int nbytes);` **Description** Swaps bytes. swab copies nbytes bytes from the from string to the to string. Adjacent even- and odd-byte positions are swapped. This is useful for moving data from one machine to another machine with a different byte order. nbytes should be even. **Return Value** None. **Example**

system, _wsystem (see page 1136)	**Header File**
	stdlib.h
	Category
	Process Control Routines
	Prototype
	`int system(const char *command);`
	`int _wsystem(const wchar_t *command);`
	Description
	Issues an operating system command.
	system invokes the operating system command processor to execute an operating system command, batch file, or other program named by the string command, from inside an executing C program.
	To be located and executed, the program must be in the current directory or in one of the directories listed in the PATH string in the environment.
	The COMSPEC environment variable is used to find the command processor program, so it need not be in the current directory.
	Return... more (see page 1136)

ultoa, _ultow (see page 1137)	**Header File**
	stdlib.h
	Category
	Conversion Routines, Math Routines
	Prototype
	`char *ultoa(unsigned long value, char *string, int radix);`
	`wchar_t *_ultow(unsigned long value, wchar_t *string, int radix);`
	Description
	Converts an **unsigned long** to a string.
	ultoa converts value to a null-terminated string and stores the result in string. value is an **unsigned long**.
	radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. ultoa performs no overflow checking, and if value is negative and radix equals 10, it does not set the minus sign.
	Note: The space allocated for string must be... more (see page 1137)

wcstombs (see page 1137)	**Header File** stdlib.h **Category** Conversion Routines, Memory and String Manipulation Routines **Prototype** `size_t wcstombs(char *s, const wchar_t *pwcs, size_t n);` **Description** Converts a **wchar_t** array into a multibyte string. wcstombs converts the type **wchar_t** elements contained in pwcs into a multibyte character string s. The process terminates if either a null character or an invalid multibyte character is encountered. No more than n bytes are modified. If n number of bytes are processed before a null character is reached, the array s is not null terminated. The behavior of wcstombs is affected by the setting of LC_CTYPE category of the... more (see page 1137)
wctomb (see page 1138)	**Header File** stdlib.h **Category** Conversion Routines, Memory and String Manipulation Routines **Prototype** `int wctomb(char *s, wchar_t wc);` **Description** Converts **wchar_t** code to a multibyte character. If s is not null, wctomb determines the number of bytes needed to represent the multibyte character corresponding to wc (including any change in shift state). The multibyte character is stored in s. At most MB_CUR_MAX characters are stored. If the value of wc is zero, wctomb is left in the initial state. The behavior of wctomb is affected by the setting of LC_CTYPE category of the current locale. **Return Value** If s is a... more (see page 1138)

3.1.4.29.1 EXIT_xxxx #defines

Header File

stdlib.h

Description

Constants defining exit conditions for calls to the exit function.

Name	Meaning
EXIT_SUCCESS	Normal program termination
EXIT_FAILURE	Abnormal program termination

3.1.4.29.2 RAND_MAX #define

Header File

stdlib.h

Syntax

Description

Maximum value returned by rand function.

3.1.4.29.3 _argc

Header File

stdlib.h

Syntax

```
extern int _argc;
```

Description

_argc has the same value as argc (passed to main) when the program starts. This variable holds the number of arguments passed to the program. The value includes the name of the program itself, so _argc and argc are always at least 1.

3.1.4.29.4 _argv, _wargv

Header File

stdlib.h

Syntax

```
extern char **_argv;
extern wchar_t ** _wargv
```

Description

_argv points to an array containing the original command-line arguments (the elements of argv[]) passed to main when the program starts.

_wargv is the Unicode version of _argv.

Portability

	POSIX	Win32	ANSI C	ANSI C++
_argv		+		
_wargv		NT only		

3.1.4.29.5 _atoi64, _wtoi64

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
__int64 _atoi64(const char *s);
__int64 _wtoi64(const wchar_t *s);
```

Description

Converts a string to an __**int64**.

The syntax of the string must be:

```
__int64 ::= [isspace]* [sign] digit [digit]*
```

Only decimal integers are acceptable.

_wtoi64 is the wide-character version. It converts a wide-character string to an __**int64**.

In this function, the first unrecognized character ends the conversion. There are no provisions for overflow in atoi (results are undefined). There is no defined method to return an error indication to the caller. The result is undefined if the input string is invalid.

Return Value

Returns the converted value of the input string. If the string cannot be converted to a __**int64**, the return value is 0.

Portability

	POSIX	Win32	ANSI C	ANSI C++
_atoi64		+		
_wtoi64		+		

3.1.4.29.6 _crotl, _crotr

Header File

stdlib.h

Category

Math Routines

Prototype

```
unsigned char _crotl(unsigned char val, int count);
unsigned char _crotr(unsigned char val, int count);
```

Description

Rotates an unsigned char left or right.

_crotl rotates the given val to the left count bits. _crotr rotates the given val to the right count bits.

The argument val is an **unsigned char**, or its equivalent in decimal or hexadecimal form.

Return Value

- The functions return the rotated byte:
- _crotl returns the value of val left-rotated count bits.
- _crotr returns the value of val right-rotated count bits.

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.7 _exit

Header File

stdlib.h

Category

Process Control Routines

Prototype

```
void _exit(int status);
```

Description

Terminates program.

_exit terminates execution without closing any files, flushing any output, or calling any exit functions.

The calling process uses status as the exit status of the process. Typically a value of 0 is used to indicate a normal exit, and a nonzero value indicates some error.

Return Value

None.

Example

```
#include   <stdlib.h>
#include   <stdio.h>
void done(void);
int main(void)
{
   atexit(done);
   _exit(0);
   return 0;
}
void done()
```

```
{
   printf("hello\n");
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+		

3.1.4.29.8 _fullpath, _wfullpath

Header File

stdlib.h

Category

Directory Control Routines

Prototype

```
char * _fullpath(char *buffer, const char *path, int buflen);
```

```
wchar_t * _wfullpath(wchar_t *buffer, const wchar_t *path, int buflen);
```

Description

Converts a path name from relative to absolute.

_fullpath converts the relative path name in path to an absolute path name that is stored in the array of characters pointed to by buffer. The maximum number of characters that can be stored at buffer is buflen. The function returns NULL if the buffer isn't big enough to store the absolute path name or if the path contains an invalid drive letter.

If buffer is NULL, _fullpath allocates a buffer of up to _MAX_PATH characters. This buffer should be freed using free when it is no longer needed. _MAX_PATH is defined in stdlib.h.

Return Value

If successful the _fullpath function returns a pointer to the buffer containing the absolute path name.

On error, this function returns NULL.

Example

```
#include <stdio.h>
#include <stdlib.h>
char buf[_MAX_PATH];
void main(int argc, char *argv[])
{
  for ( ; argc; argv++, argc--)
  {
    if (_fullpath(buf, argv[0], _MAX_PATH) == NULL)
      printf("Unable to obtain full path of %s\n",argv[0]);
    else
      printf("Full path of %s is %s\n",argv[0],buf);
  }
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_fullpath		+		

_wfullpath		NT only		

3.1.4.29.9 _lrand

Header File

stdlib.h

Category

Math Routines

Prototype

```
long _lrand(void);
```

Description

_lrand is the long random number generator function. _rand uses a multiplicative congruential random number generator with period 2^64 to return successive pseudo-random numbers in the range from 0 to 2^31 - 1.

The generator is reinitialized by calling srand with an argument value of 1. It can be set to a new starting point by calling srand with a given seed number.

3.1.4.29.10 _lrotl, _lrotr

Header File

stdlib.h

Category

Math Routines

Prototype

```
unsigned long _lrotl(unsigned long val, int count);
unsigned long _lrotr(unsigned long val, int count);
```

Description

Rotates an **unsigned long** integer value to the left or right.

_lrotlrotates the given val to the left count bits. _lrotr rotates the given val to the right count bits.

Return Value

The functions return the rotated integer:

- _lrotl returns the value of val left-rotated count bits.
- _lrotr returns the value of val right-rotated count bits.

Example

```
#include <stdlib.h>
#include <stdio.h>
/* function prototypes */
int lrotl_example(void);
int lrotr_example(void);
/* lrotl example */
int lrotl_example(void)
```

```
{
   unsigned long result;
   unsigned long value = 100;
   result = _lrotl(value,1);
   printf("The value %lu rotated left one bit is: %lu\n", value, result);
   return 0;
}
/* lrotr example */
int lrotr_example(void)
{
   unsigned long result;
   unsigned long value = 100;
   result = _lrotr(value,1);
   printf("The value %lu rotated right one bit is: %lu\n", value, result);
   return 0;
}
int main(void)
{
   lrotl_example();
   lrotr_example();
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.11 _makepath, _wmakepath

Header File

stdlib.h

Category

Directory Control Routines

Prototype

```
void _makepath(char *path, const char *drive, const char *dir, const char *name, const char *ext);
```

```
void _wmakepath(wchar_t *path, const wchar_t *drive, const wchar_t *dir, const wchar_t *name, const wchar_t *ext);
```

Description

Builds a path from component parts.

_makepath makes a path name from its components. The new path name is

```
X:\DIR\SUBDIR\NAME.EXT
```

where

drive	=	X:
dir	=	\DIR\SUBDIR\
name	=	NAME
ext	=	.EXT

If drive is empty or NULL, no drive is inserted in the path name. If it is missing a trailing colon (:), a colon is inserted in the path name.		
If dir is empty or NULL, no directory is inserted in the path name. If it is missing a trailing slash (\ or /), a backslash is inserted in the path name.		
If name is empty or NULL, no file name is inserted in the path name.		
If ext is empty or NULL, no extension is inserted in the path name. If it is missing a leading period (.), a period is inserted in the path name.		
_makepath assumes there is enough space in path for the constructed path name. The maximum constructed length is _MAX_PATH. _MAX_PATH is defined in stdlib.h.		
_makepath and _splitpath are invertible; if you split a given path with _splitpath, then merge the resultant components with _makepath, you end up with path.		

If drive is empty or NULL, no drive is inserted in the path name. If it is missing a trailing colon (:), a colon is inserted in the path name.

If dir is empty or NULL, no directory is inserted in the path name. If it is missing a trailing slash (\ or /), a backslash is inserted in the path name.

If name is empty or NULL, no file name is inserted in the path name.

If ext is empty or NULL, no extension is inserted in the path name. If it is missing a leading period (.), a period is inserted in the path name.

_makepath assumes there is enough space in path for the constructed path name. The maximum constructed length is _MAX_PATH. _MAX_PATH is defined in stdlib.h.

_makepath and _splitpath are invertible; if you split a given path with _splitpath, then merge the resultant components with _makepath, you end up with path.

Return Value

Example

```
#include <dir.h>
#include <string.h>
#include <stdio.h>
#include <stdlib.h>
int main(void)
{
  char s[_MAX_PATH];
  char drive[_MAX_DRIVE];
  char dir[_MAX_DIR];
  char file[_MAX_FNAME];
  char ext[_MAX_EXT];
  getcwd(s,_MAX_PATH);           /* get current working directory */
 if (s[strlen(s)-1] != '\\')
     strcat(s,"\\");             /* append a trailing \ character */
  _splitpath(s,drive,dir,file,ext); /* split the string to separate
    elems */
  strcpy(file,"DATA");
  strcpy(ext,".TXT");
  _makepath(s,drive,dir,file,ext); /* merge everything into one string */
  puts(s);                       /* display resulting string */
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_makepath		+		
_wmakepath		+		

3.1.4.29.12 _rotl, _rotr

Header File

stdlib.h

Category

Math Routines

Prototype

```
unsigned short _rotl(unsigned short value, int count);
unsigned short _rotr(unsigned short value, int count);
```

Description

Bit-rotates an **unsigned** short integer value to the left or right.

_rotl rotates the given value to the left count bits.

_rotr rotates the given value to the right count bits.

Return Value

_rotl, and _rotr return the rotated integer:

- _rotl returns the value of value left-rotated count bits.
- _rotr returns the value of value right-rotated count bits.

Example

```
#include <stdlib.h>
#include <stdio.h>
/* rotl example */
int rotl_example(void)
{
   unsigned value, result;
   value = 32767;
   result = _rotl(value, 1);
   printf("The value %u rotated left one bit is: %u\n", value, result);
   return 0;
}
/* rotr example */
int rotr_example(void)
{
   unsigned value, result;
   value = 32767;
   result = _rotr(value, 1);
   printf("The value %u rotated right one bit is: %u\n", value, result);
   return 0;
}
int main(void)
{
   rotl_example();
   rotr_example();
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_rotl		+		
_rotr				

3.1.4.29.13 _searchenv, _wsearchenv

Header File

stdlib.h

Category

Miscellaneous Routines

Prototype

```
char *_searchenv(const char *file, const char *varname, char *buf);
```

```
char *_wsearchenv(const wchar_t *file, const wchar_t *varname, wchar_t *buf);
```

Description

Looks for a file, using an environment variable as the search path.

_searchenv attempts to locate file, searching along the path specified by the operating system environment variable varname. Typical environment variables that contain paths are PATH, LIB, and INCLUDE.

_searchenv searches for the file in the current directory of the current drive first. If the file is not found there, the environment variable varname is fetched, and each directory in the path it specifies is searched in turn until the file is found, or the path is exhausted.

When the file is located, the full path name is stored in the buffer pointed to by buf. This string can be used in a call to access the file (for example, with fopen or exec...). The buffer is assumed to be large enough to store any possible file name. If the file cannot be successfully located, an empty string (consisting of only a null character) will be stored at buf.

Return Value

None.

Example

```
#include <stdio.h>
#include <stdlib.h>

char buf[_MAX_PATH];

int main(void)
{
  /* ILINK32 will be found in your installation directory */
  _searchenv("ILINK32.EXE","PATH",buf);
  if (buf[0] == '\0')
    printf("ILINK32.EXE not found\n");
  else
    printf("ILINK32.EXE found in %s\n", buf);

  /* looks for nonexistent file */
  _searchenv("NOTEXIST.FIL","PATH",buf);
  if (buf[0] == '\0')
    printf("NOTEXIST.FIL not found\n");
  else
```

```
    printf("NOTEXIST.FIL found in %s\n", buf);
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_searchenv		+		
_wsearchenv		NT only		

3.1.4.29.14 _searchstr, _wsearchstr

Header File

stdlib.h

Category

Miscellaneous Routines

Prototype

```
void _searchstr(const char *file, const char *ipath, char *buf);
```

```
void _wsearchstr(const wchar_t *file, const wchar_t *ipath,wchar_t *pathname);
```

Description

Searches a list of directories for a file.

_searchstr attempts to locate file, searching along the path specified by the string ipath.

_searchstr searches for the file in the current directory of the current drive first. If the file is not found there, each directory in ipath is searched in turn until the file is found, or the path is exhausted. The directories in ipath must be separated by semicolons.

When the file is located, the full path name is stored in the buffer pointed by by buf. This string can be used in a call to access the file (for example, with fopen or exec...). The buffer is assumed to be large enough to store any possible file name. The constant _MAX_PATH defined in stdlib.h, is the size of the largest file name. If the file cannot be successfully located, an empty string (consisting of only a null character) will be stored at buf.

Return Value

None.

Example

```
#include <stdio.h>
#include <stdlib.h>
char buf[_MAX_PATH];
int main(void)
{
  /* look for ILINK32.EXE */
  _searchstr("ILINK32.EXE", "PATH", buf);
  if (buf[0] == '\0')
  printf ("ILINK32.EXE not found\n");
  else
  printf ("ILINK32.EXE found in %s\n", buf);
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_searchstr		+		
_wsearchstr		NT only		

3.1.4.29.15 _splitpath, _wsplitpath

Header File

stdlib.h

Category

Directory Control Routines

Prototype

```
void _splitpath(const char *path, char *drive, char *dir, char *name, char *ext);
```

```
void _wsplitpath(const wchar_t *path, wchar_t *drive, wchar_t *dir, wchar_t *name, wchar_t *ext);
```

Description

Splits a full path name into its components.

_splitpath takes a file's full path name (path) as a string in the form

X:\DIR\SUBDIR\NAME.EXT

and splits path into its four components. It then stores those components in the strings pointed to by drive, dir, name, and ext. (All five components must be passed, but any of them can be a null, which means the corresponding component will be parsed but not stored.) The maximum sizes for these strings are given by the constants _MAX_DRIVE, _MAX_DIR, _MAX_PATH, _MAX_FNAME, and _MAX_EXT (defined in stdlib.h), and each size includes space for the null-terminator. These constants are defined in stdlib.h.

_MAX_PATH	path
_MAX_DRIVE	drive; includes colon (:)
_MAX_DIR	dir; includes leading and trailing backslashes (\)
_MAX_FNAME	name
_MAX_EXT	ext; includes leading dot (.)

_splitpath assumes that there is enough space to store each non-null component.

When _splitpath splits path, it treats the punctuation as follows:

- drive includes the colon (C:, A:, and so on).
- dir includes the leading and trailing backslashes (\BC\include\, \source\, and so on).
- name includes the file name.
- ext includes the dot preceding the extension (.C, .EXE, and so on).

_makepath and _splitpath are invertible; if you split a given path with _splitpath, then merge the resultant components with _makepath, you end up with path.

Return Value

None.

Example

```
#include <dir.h>
#include <string.h>
#include <stdio.h>
#include <stdlib.h>
int main(void)
{
  char s[_MAX_PATH];
  char drive[_MAX_DRIVE];
  char dir[_MAX_DIR];
  char file[_MAX_FNAME];
  char ext[_MAX_EXT];
  /* get current working directory */
  getcwd(s,_MAX_PATH);
  if (s[strlen(s)-1] != '\\')
  /* append a trailing \ character */
    strcat(s,"\\");
  /* split the string to separate elems */
  _splitpath(s,drive,dir,file,ext);
  strcpy(file,"DATA");
  strcpy(ext,".TXT");
  /* merge everything into one string */
  _makepath(s,drive,dir,file,ext);
  /* display resulting string */
  puts(s);
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_splitpath		+		
_wsplitpath		+		

3.1.4.29.16 _ui64toa, _ui64tow

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
char *_ui64toa(unsigned __int64 value, char *string, int radix);
```

```
wchar_t *_ui64tow(unsigned __int64 value, wchar_t *string, int radix);
```

Description

_ui64toa converts an unsigned __**int64** to a string.

_ui64tow is the unicode version. _ui64tow converts an unsigned __**int64** to a wide-character string.

These functions convert value to a null-terminated string and store the result in string. value is an __**int64**.

radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. If value is negative and radix is 10, the first character of string is the minus sign (**-**).

Note: The space allocated for string must be large enough to hold the returned string, including the terminating null character

(\0). Can return up to 33 bytes.

Return Value

Returns a pointer to string.

Portability

	POSIX	Win32	ANSI C	ANSI C++
_ui64toa				
_ui64tow		+		

3.1.4.29.17 abort

Header File

stdlib.h

Category

Process Control Routines

Prototype

```
void abort(void);
```

Description

Abnormally terminates a program.

abort causes an abnormal program termination by calling raise(SIGABRT). If there is no signal handler for SIGABRT, then abort writes a termination message (Abnormal program termination) on stderr, then aborts the program by a call to _exit with exit code 3.

Return Value

abort returns the exit code 3 to the parent process or to the operating system command processor.

Example

```
#include <stdio.h>
#include <stdlib.h>
 int main(void)
 {
   printf("Calling abort()\n");
   abort();
   return 0; /* This is never reached */
 }
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.18 atexit

Header File

stdlib.h

Category

Process Control Routines

Prototype

```
int atexit(void (_USERENTRY * func)(void));
```

Description

Registers termination function.

atexit registers the function pointed to by func as an exit function. Upon normal termination of the program, exit calls func just before returning to the operating system. fcmp must be used with the _USERENTRY calling convention.

Each call to atexit registers another exit function. Up to 32 functions can be registered. They are executed on a last-in, first-out basis (that is, the last function registered is the first to be executed).

Return Value

atexit returns 0 on success and nonzero on failure (no space left to register the function).

Example

```
#include <stdio.h>
#include <stdlib.h>
void exit_fn1(void)
{
   printf("Exit function #1 called\n");
}
void exit_fn2(void)
{
   printf("Exit function #2 called\n");
}
int main(void)
{
   /* post exit function #1 */
   atexit(exit_fn1);
   /* post exit function #2 */
   atexit(exit_fn2);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.19 atoi, _wtoi

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
int atoi(const char *s);
```

```
int _wtoi(const wchar_t *s);
```

Description

Converts a string to an integer.

- atoi converts a string pointed to by s to **int**; atoi recognizes (in the following order)
- An optional string of tabs and spaces
- An optional sign
- A string of digits

The characters must match this generic format:

[ws] [sn] [ddd]

In this function, the first unrecognized character ends the conversion. There are no provisions for overflow in atoi (results are undefined).

Return Value

atoi returns the converted value of the input string. If the string cannot be converted to a number of the corresponding type (**int**), atoi returns 0.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   int n;
   char *str = "12345.67";
   n = atoi(str);
   printf("string = %s integer = %d\n", str, n);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
atoi	+	+	+	+
_wtoi		+		

3.1.4.29.20 atol, _wtol

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
long atol(const char *s);
```

```
long _wtol(const wchar_t *s);
```

Description

Converts a string to a long.

- atol converts the string pointed to by s to **long**. atol recognizes (in the following order)
- An optional string of tabs and spaces

- An optional sign
- A string of digits

The characters must match this generic format:

```
[ws] [sn] [ddd]
```

In this function, the first unrecognized character ends the conversion. There are no provisions for overflow in atol (results are undefined).

Return Value

atol returns the converted value of the input string. If the string cannot be converted to a number of the corresponding type (b), atol returns 0.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   long l;
   char *lstr = "98765432";
   l = atol(lstr);
   printf("string = %s integer = %ld\n", lstr, l);
   return(0);
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
atol	+	+	+	+
_wtol		+		

3.1.4.29.21 bsearch

Header File

stdlib.h

Category

Memory and String Manipulation Routines

Prototype

```
void *bsearch(const void *key, const void *base, size_t nelem, size_t width, int (_USERENTRY *fcmp)(const void *, const void *));
```

Description

Binary search of an array.

bsearch searches a table (array) of nelem elements in memory, and returns the address of the first entry in the table that matches the search key. The array must be in order. If no match is found, bsearch returns 0.

Note: Because this is a binary search, the first matching entry is not necessarily the first entry in the table.

The type size_t is defined in stddef.h header file.

- nelem gives the number of elements in the table.
- width specifies the number of bytes in each table entry.

The comparison routine fcmp must be used with the _USERENTRY calling convention.

fcmp is called with two arguments: elem1 and elem2. Each argument points to an item to be compared. The comparison function compares each of the pointed-to items (*elem1 and *elem2), and returns an integer based on the results of the comparison.

- For bsearch, the fcmp return value is
- < 0 if *elem1 < *elem2
- == 0 if *elem1 == *elem2
- > 0 if *elem1 > *elem2

Return Value

bsearch returns the address of the first entry in the table that matches the search key. If no match is found, bsearch returns 0.

Example

```
#include <stdlib.h>
#include <stdio.h>
typedef int (*fptr)(const void*, const void*);
#define NELEMS(arr) (sizeof(arr) / sizeof(arr[0]))
int numarray[] = {123, 145, 512, 627, 800, 933};
int numeric (const int *p1, const int *p2)
{
   return(*p1 - *p2);
}
#pragma argsused
int lookup(int key)
{
   int  *itemptr;
   /* The cast of (int(*)(const void *,const void*))
      is needed to avoid a type mismatch error at
      compile time */
   itemptr = (int *) bsearch (&key, numarray, NELEMS(numarray),
      sizeof(int), (fptr)numeric);
   return (itemptr != NULL);
}
int main(void)
{
   if (lookup(512))
      printf("512 is in the table.\n");
   else
      printf("512 isn't in the table.\n");
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.22 div

Header File

stdlib.h

Category

Math Routines

Prototype

```
div_t div(int numer, int denom);
```

Description

Divides two integers, returning quotient and remainder.

div divides two integers and returns both the quotient and the remainder as a div_t type. numer and denom are the numerator and denominator, respectively. The div_t type is a structure of integers defined (with **typedef**) in stdlib.h as follows:

```
typedef struct {
int quot; /* quotient */
int rem; /* remainder */
} div_t;
```

Return Value

div returns a structure whose elements are quot (the quotient) and rem (the remainder).

Example

```
/* div example */
#include <stdlib.h>
#include <stdio.h>
div_t x;
int main(void)
{
   x = div(10,3);
   printf("10 div 3 = %d remainder %d\n",
   x.quot, x.rem);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.23 ecvt

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
char *ecvt(double value, int ndig, int *dec, int *sign);
```

Description

Converts a floating-point number to a string.

ecvt converts value to a null-terminated string of ndig digits, starting with the leftmost significant digit, and returns a pointer to the string. The position of the decimal point relative to the beginning of the string is stored indirectly through dec (a negative value for dec means that the decimal lies to the left of the returned digits). There is no decimal point in the string itself. If the sign of value is negative, the word pointed to by sign is nonzero; otherwise, it's 0. The low-order digit is rounded.

Return Value

The return value of ecvt points to static data for the string of digits whose content is overwritten by each call to ecvt and fcvt.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   char *string;
   double value;
   int dec, sign;
   int ndig = 10;
   value = 9.876;
   string = ecvt(value, ndig, &dec, &sign);
   printf("string = %s      dec = %d sign = %d\n", string, dec, sign);
   value = -123.45;
   ndig= 15;
   string = ecvt(value,ndig,&dec,&sign);
   printf("string = %s dec = %d sign = %d\n", string, dec, sign);
   value = 0.6789e5; /* scientific notation */
   ndig = 5;
   string = ecvt(value,ndig,&dec,&sign);
   printf("string = %s         dec = %d sign = %d\n", string, dec, sign);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.24 _environ, _wenviron

Header File

stdlib.h

Syntax

```
extern char ** _environ;
```

```
extern wchar_t ** _wenviron
```

Description

_environ is an array of pointers to strings; it is used to access and alter the operating system environment variables. Each string is of the form:

```
envvar = varvalue
```

where envvar is the name of an environment variable (such as PATH), and varvalue is the string value to which envvar is set (such as C:\Utils;C:\MyPrograms). The string varvalue can be empty.

When a program begins execution, the operating system environment settings are passed directly to the program. Note that env, the third argument to main, is equal to the initial setting of _environ.

The _environ array can be accessed by getenv; however, the putenv function is the only routine that should be used to add, change or delete the _environ array entries. This is because modification can resize and relocate the process environment array, but _environ is automatically adjusted so that it always points to the array.

Portability

	POSIX	Win32	ANSI C	ANSI C++
_environ		+		
_wenviron		NT only		

3.1.4.29.25 exit

Header File

stdlib.h

Category

Process Control Routines

Prototype

```
void exit(int status);
```

Description

Terminates program.

exit terminates the calling process. Before termination, all files are closed, buffered output (waiting to be output) is written, and any registered "exit functions" (posted with atexit) are called.

status is provided for the calling process as the exit status of the process. Typically a value of 0 is used to indicate a normal exit, and a nonzero value indicates some error. It can be, but is not required, to be set with one of the following:

EXIT_FAILURE	Abnormal program termination; signal to operating system that program has terminated with an error
EXIT_SUCCESS	Normal program termination

Return Value

None.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   int status;
   printf("Enter either 1 or 2\n");
   status = getchar();
   exit(status - '0');
/* Note: this line is never reached */
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.26 fcvt

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
char *fcvt(double value, int ndig, int *dec, int *sign);
```

Description

Converts a floating-point number to a string.

fcvt converts value to a null-terminated string digit starting with the leftmost significant digit with ndig digits to the right of the decimal point. fcvt then returns a pointer to the string. The position of the decimal point relative to the beginning of the string is stored indirectly through dec (a negative value for dec means to the left of the returned digits). There is no decimal point in the string itself. If the sign of value is negative the word pointed to by sign is nonzero; otherwise it is 0.

The correct digit has been rounded for the number of digits to the right of the decimal point specified by ndig.

Return Value

The return value of fcvt points to static data whose content is overwritten by each call to fcvt and ecvt.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
  char *str;
  double num;
  int dec, sign, ndig = 5;
  /* a regular number */
  num = 9.876;
  str = fcvt(num, ndig, &dec, &sign);
  printf("string = %10s decimal place = %d sign = %d\n", str, dec, sign);
  /* a negative number */
  num = -123.45;
  str = fcvt(num, ndig, &dec, &sign);
  printf("string = %10s decimal place = %d sign = %d\n", str, dec, sign);
  /* scientific notation */
  num = 0.678e5;
  str = fcvt(num, ndig, &dec, &sign);
  printf("string = %10s  decimal place= %d  sign = %d\n", str, dec, sign);
  return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.27 gcvt

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
char *gcvt(double value, int ndec, char *buf);
```

Description

Converts floating-point number to a string.

gcvt converts value to a null-terminated ASCII string and stores the string in buf. It produces ndec significant digits in FORTRAN F format, if possible; otherwise, it returns the value in the printf E format (ready for printing). It might suppress trailing zeros.

Return Value

gcvt returns the address of the string pointed to by buf.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   char str[25];
   double num;
   int sig = 5; /* significant digits */
   /* a regular number */
   num = 9.876;
   gcvt(num, sig, str);
   printf("string = %s\n", str);
   /* a negative number */
   num = -123.4567;
   gcvt(num, sig, str);
   printf("string = %s\n", str);
   /* scientific notation */
   num = 0.678e5;
   gcvt(num, sig, str);
   printf("string = %s\n", str);
   return(0);
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.28 getenv, _wgetenv

Header File

stdlib.h

Category

Process Control Routines

Prototype

```
char *getenv(const char *name);
```

```
wchar_t *_wgetenv(const wchar_t *name);
```

Description

Find or delete an environment variable from the system environment.

The environment consists of a series of entries that are of the form name=string\0.

getenv returns the value of a specified variable. name can be either uppercase or lowercase. name must not include the equal sign (**=**). If the specified environment variable does not exist, getenv returns a NULL pointer.

To delete the variable from the environment, use getenv("name=").

Note: Environment entries must not be changed directly. If you want to change an environment value, you must use putenv.

Return Value

On success, getenv returns the value associated with name.

If the specified name is not defined in the environment, getenv returns a NULL pointer.

Example

```
#include <stdio.h>
#include <stdlib.h>
#include <alloc.h>
#include <string.h>
int main(void)
{
   char *path, *ptr;
   int i = 0;
   /* get the current path environment */
   ptr = getenv("PATH");
   /* set up new path */
   path = (char *) malloc(strlen(ptr)+15);
   strcpy(path,"PATH=");
   strcat(path,ptr);
   strcat(path,";c:\\temp");
   /* replace the current path and display current environment */
   putenv(path);
   while (_environ[i])
       printf("%s\n",_environ[i++]);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
getenv	+	+	+	+
_wgetenv		+		

3.1.4.29.29 itoa, _itow

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
char *itoa(int value, char *string, int radix);
```

```
wchar_t *_itow(int value, wchar_t *string, int radix);
```

Description

Converts an integer to a string.

itoa converts value to a null-terminated string and stores the result in string. With itoa, value is an integer. _itow is the unicode version of the function. It converts an integer to a wide-character string.

radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. If value is negative and radix is 10, the first character of string is the minus sign (-).

Note: The space allocated for string must be large enough to hold the returned string, including the terminating null character (\0). itoa can return up to 33 bytes.

Return Value

itoa returns a pointer to string.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   int number = 12345;
   char string[25];
   itoa(number, string, 10);
   printf("integer = %d string = %s\n", number, string);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.30 labs

Header File

stdlib.h

Category

Math Routines

Prototype

```
long labs(long int x);
```

Description

Gives long absolute value.

labs computes the absolute value of the parameter x.

Return Value

labs returns the absolute value of x.

Example

```
#include <stdio.h>
#include <math.h>
int main(void)
{
   long result;
   long x = -12345678L;
   result= labs(x);
   printf("number: %ld abs value: %ld\n", x, result);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.31 lfind

Header File

stdlib.h

Category

Memory and String Manipulation Routines

Prototype

```
void *lfind(const void *key, const void *base, size_t *num, size_t width, int (_USERENTRY *fcmp)(const void *, const void *));
```

Description

Performs a linear search.

lfind makes a linear search for the value of key in an array of sequential records. It uses a user-defined comparison routine fcmp. The fcmp function must be used with the _USERENTRY calling convention.

The array is described as having *num records that are width bytes wide, and begins at the memory location pointed to by base.

Return Value

lfind returns the address of the first entry in the table that matches the search key. If no match is found, lfind returns NULL. The comparison routine must return 0 if *elem1 == *elem2, and nonzero otherwise (elem1 and elem2 are its two parameters).

Example

```
#include <stdio.h>
#include <stdlib.h>
int compare(int *x, int *y)
{
   return( *x - *y );
}
int main(void)
{
   int array[5] = {35, 87, 46, 99, 12};
   size_t nelem = 5;
   int key;
   int *result;
   key = 99;
   result = (int *) lfind(&key, array, &nelem,
      sizeof(int), (int(*)(const void *,const void *))compare);
   if (result)
      printf("Number %d found\n",key);
   else
      printf("Number %d not found\n",key);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.32 lsearch

Header File

stdlib.h

Category

Memory and String Manipulation Routines

Prototype

```
void *lsearch(const void *key, void *base, size_t *num, size_t width, int (_USERENTRY *fcmp)(const void *, const void *));
```

Description

Performs a linear search.

lsearch searches a table for information. Because this is a linear search, the table entries do not need to be sorted before a call to lsearch. If the item that key points to is not in the table, lsearch appends that item to the table.

- base points to the base (0th element) of the search table.
- num points to an integer containing the number of entries in the table.
- width contains the number of bytes in each entry.
- key points to the item to be searched for (the search key).

The function fcmp must be used with the _USERENTRY calling convention.

The argument fcmp points to a user-written comparison routine, that compares two items and returns a value based on the comparison.

To search the table, lsearch makes repeated calls to the routine whose address is passed in fcmp.

On each call to the comparison routine, lsearch passes two arguments:

key	a pointer to the item being searched for
elem	pointer to the element of base being compared.

fcmp is free to interpret the search key and the table entries in any way.

Return Value

lsearch returns the address of the first entry in the table that matches the search key.

If the search key is not identical to *elem, fcmp returns a nonzero integer. If the search key is identical to *elem, fcmp returns 0.

Example

```
#include <stdlib.h>
#include <stdio.h>
#include <string.h>     /* for strcmp declaration */
/* initialize number of colors */
char *colors[10] = { "Red", "Blue", "Green" };
int ncolors = 3;
int colorscmp(char **arg1, char **arg2)
{
   return(strcmp(*arg1, *arg2));
}
int addelem(char **key)
{
   int oldn = ncolors;
   lsearch(key, colors, (size_t *)&ncolors, sizeof(char *),
```

```
      (int(*)(const void *,const void *))colorscmp);
   return(ncolors == oldn);
}
int main(void)
{
   int i;
   char *key = "Purple";
   if (addelem(&key))
      printf("%s already in colors table\n", key);
   else
   {
      printf("%s added to colors table\n", key);
   }
   printf("The colors:\n");
   for (i = 0; i < ncolors; i++)
      printf("%s\n", colors[i]);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.33 ltoa, _ltoa, _ltow

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
char * ltoa(long value, char * string, int radix);
```

```
char *_ltoa(long value, char *string, int radix);
```

```
wchar_t *_ltow(long value, wchar_t *string, int radix);
```

Description

Converts a **long** to a string. _ltow is the unicode version. It converts a **long** to a wide-charater string.

Converts value to a null-terminated string and stores the result in string. value is a **long**.

radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. If value is negative and radix is 10, the first character of string is the minus sign (**-**).

Note: The space allocated for string must be large enough to hold the returned string, including the terminating null character (\0). Can return up to 33 bytes.

Return Value

Returns a pointer to string.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
```

```
    char string[25];
    long value = 123456789L;
    ltoa(value,string,10);
    printf("number = %ld  string = %s\n", value, string);
    return 0;
}
```

3.1.4.29.34 max

Header File

stdlib.h

Category

C++ Prototyped Routines

Prototype

```
(type) max(a, b);
```

```
template <class T> T max( T t1, T t2 ); // C++ only
```

Description

Returns the larger of two values.

The C macro and the C++ template function compare two values and return the larger of the two. Both arguments and the routine declaration must be of the same type.

Return Value

max returns the larger of two values.

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.35 mblen

Header File

stdlib.h

Category

Memory and String Manipulation Routines

Prototype

```
int mblen(const char *s, size_t n);
```

Description

Determines the length of a multibyte character.

If s is not null, mblen determines the number of bytes in the multibyte character pointed to by s. The maximum number of bytes examined is specified by n.

The behavior of mblen is affected by the setting of LC_CTYPE category of the current locale.

Return Value

If s is null, mblen returns a nonzero value if multibyte characters have state-dependent encodings. Otherwise, mblen returns 0.

If s is not null, mblen returns 0 if s points to the null character, and -1 if the next n bytes do not comprise a valid multibyte character; the number of bytes that comprise a valid multibyte character.

Example

```
#include <stdlib.h>
#include <stdio.h>
void main (void)
{
  int i ;
  char *mulbc = (char *)malloc( sizeof( char) );
  wchar_t widec = L'a';
  printf (" convert a wide character to multibyte character:\n" );
  i = wctomb (mulbc, widec);
  printf( "\tCharacters converted: %u\n", i);
  printf( "\tMultibyte character: %x\n\n", mulbc);
  printf( " Find length--in byte-- of multibyte character:\n");
  i = mblen( mulbc, MB_CUR_MAX);
  printf("\tLength--in bytes--if multiple character: %u\n",i);
  printf("\tWide character: %x\n\n", mulbc);
  printf( " Attempt to find length of a Wide character Null:\n");
  widec = L'\0';
  wctomb(mulbc, widec);
  i = mblen( mulbc, MB_CUR_MAX);
  printf("\tLength--in bytes--if multiple character: %u\n",i);
  printf("\tWide character: %x\n\n", mulbc);
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.36 mbstowcs

Header File

stdlib.h

Category

Conversion Routines, Memory and String Manipulation Routines

Prototype

```
size_t mbstowcs(wchar_t *pwcs, const char *s, size_t n);
```

Description

Converts a multibyte string to a **wchar_t** array.

The function converts the multibyte string s into the array pointed to by pwcs. No more than n values are stored in the array. If an invalid multibyte sequence is encountered, mbstowcs returns (size_t) -1.

The pwcs array will not be terminated with a zero value if mbstowcs returns n.

Return Value

If an invalid multibyte sequence is encountered, mbstowcs returns (size_t) -1. Otherwise, the function returns the number of array elements modified, not including the terminating code, if any.

Example

```
#include <stdio.h>
#include <stdlib.h>
void main(void)
{
  int x;
  char    *mbst = (char *)malloc(MB_CUR_MAX);
  wchar_t *pwst = L"Hi";
  wchar_t *pwc      = (wchar_t *)malloc(sizeof( wchar_t));
  printf ("Convert to multibyte string:\n");
  x = wcstombs (mbst, pwst, MB_CUR_MAX);
  printf ("\tCharacters converted %u\n",x);
  printf ("\tHEx value of first");
  printf (" multibyte character: %#.4x\n\n", mbst);
  printf ("Convert back to wide character string:\n");
  x = mbstowcs(pwc, mbst, MB_CUR_MAX);
  printf( "\tCharacters converted: %u\n",x);
  printf( "\tHex value of first");
  printf( "wide character: %#.4x\n\n", pwc);
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.37 mbtowc

Header File

stdlib.h

Category

Conversion Routines, Memory and String Manipulation Routines

Prototype

```
int mbtowc(wchar_t *pwc, const char *s, size_t n);
```

Description

Converts a multibyte character to **wchar_t** code.

If s is not null, mbtowc determines the number of bytes that comprise the multibyte character pointed to by s. Next, mbtowc determines the value of the type **wchar_t** that corresponds to that multibyte character. If there is a successful match between **wchar_t** and the multibyte character, and pwc is not null, the **wchar_t** value is stored in the array pointed to by pwc. At most n characters are examined.

Return Value

When s points to an invalid multibyte character, -1 is returned. When s points to the null character, 0 is returned. Otherwise,

mbtowc returns the number of bytes that comprise the converted multibyte character.

The return value never exceeds MB_CUR_MAX or the value of n.

Example

```
#include <stdlib.h>
#include<stdio.h>
void main(void)
{
  int     x;
  char     *mbchar    = (char *)calloc(1, sizeof( char));
  wchar_t  wchar      = L'a';
  wchar_t   *pwcnull = NULL;
  wchar_t  *pwchar    = (wchar_t *)calloc(1,  sizeof( wchar_t ));
  printf ("Convert a wide character to multibyte character:\n");
  x = wctomb( mbchar, wchar);
  printf( "\tCharacters converted: %u\n", x);
  printf( "\tMultibyte character: %x\n\n", mbchar);
  printf ("Convert multibyte character back to a wide character:\n");
  x = mbtowc( pwchar, mbchar, MB_CUR_MAX );
  printf( "\tBytes converted: %u\n", x);
  printf( "\tWide character: %x\n\n", pwchar);
  printf ("Atempt to convert when target is NULL\n" );
  printf (" returns the length of the multibyte character:\n" );
  x = mbtowc (pwcnull, mbchar, MB_CUR_MAX );
  printf ( "\tlength of multibyte character:%u\n\n", x );
  printf ("Attempt to convert a NULL pointer to a" );
  printf (" wide character:\n" );
  mbchar = NULL;
  x = mbtowc (pwchar, mbchar, MB_CUR_MAX);
  printf( "\tBytes converted: %u\n", x );
  }
```

Portability

POSIX	Win32	ANSI C	ANSI C++

3.1.4.29.38 min

Header File

stdlib.h

Category

C++ Prototyped Routines

Prototype

```
(type) min(a, b); /* macro version */
```

```
template <class T> T min( T t1, T t2 );// C++ only
```

Description

Returns the smaller of two values.

The C macro and the C++ template function compare two values and return the smaller of the two. Both arguments and the routine declaration must be of the same type.

Return Value

min returns the smaller of two values.

3.1.4.29.39 putenv, _wputenv

Header File

stdlib.h

Category

Process Control Routines

Prototype

```
int putenv(const char *name);
```

```
int _wputenv(const wchar_t *name);
```

Description

Adds string to current environment.

putenv accepts the string name and adds it to the environment of the current process. For example,

```
putenv(“PATH=C:\\BC”);
```

putenv can also be used to modify an existing name. name can be either uppercase or lowercase. name must not include the equal sign (**=**). You can set a variable to an empty value by specifying an empty string on the right side of the ‘=’ sign.

putenv can be used only to modify the current program’s _environment. Once the program ends, the old _environment is restored. The _environment of the current process is passed to child processes, including any changes made by putenv.

Note that the string given to putenv must be static or global. Unpredictable results will occur if a local or dynamic string given to putenv is used after the string memory is released.

Return Value

On success, putenv returns 0; on failure, -1.

Example

```
#include <stdio.h>
#include <stdlib.h>
#include <alloc.h>
#include <string.h>
int main(void)
{
   char *path, *ptr;
   int i = 0;
   /* get the current path environment */
   ptr = getenv("PATH");
   /* set up new path */
   path = (char *) malloc(strlen(ptr)+15);
   strcpy(path,"PATH=");
   strcat(path,ptr);
   strcat(path,";c:\\temp");
   /* replace the current path and display current environment */
   putenv(path);
   while (_environ[i])
       printf("%s\n",_environ[i++]);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
putenv		+		
_wputenv		NT only		

3.1.4.29.40 qsort

Header File

stdlib.h

Category

Memory and String Manipulation Routines

Prototype

```
void qsort(void *base, size_t nelem, size_t width, int (_USERENTRY *fcmp)(const void *, const void *));
```

Description

Sorts using the quicksort algorithm.

qsort is an implementation of the “median of three” variant of the quicksort algorithm. qsort sorts the entries in a table by repeatedly calling the user-defined comparison function pointed to by fcmp.

- base points to the base (0th element) of the table to be sorted.
- nelem is the number of entries in the table.
- width is the size of each entry in the table, in bytes.

fcmp, the comparison function, must be used with the _USERENTRY calling convention.

- fcmp accepts two arguments, elem1 and elem2, each a pointer to an entry in the table. The comparison function compares each of the pointed-to items (*elem1 and *elem2), and returns an integer based on the result of the comparison.
- *elem1 < *elem2 fcmp returns an integer < 0
- *elem1 == *elem2 fcmp returns 0
- *elem1 > *elem2 fcmp returns an integer > 0

In the comparison, the less-than symbol (<) means the left element should appear before the right element in the final, sorted sequence. Similarly, the greater-than (>) symbol means the left element should appear after the right element in the final, sorted sequence.

Return Value

None.

Example

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
int sort_function( const void *a, const void *b);
char list[5][4] = { "cat", "car", "cab", "cap", "can" };
int main(void)
{
   int  x;
   qsort((void *)list, 5, sizeof(list[0]), sort_function);
   for (x = 0; x < 5; x++)
      printf("%s\n", list[x]);
   return 0;
```

```
}
int sort_function( const void *a, const void *b)
{
   return( strcmp((char *)a,(char *)b) );
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.41 rand

Header File

stdlib.h

Category

Math Routines

Prototype

```
int rand(void);
```

Description

Random number generator.

rand uses a multiplicative congruential random number generator with period 2 to the 32nd power to return successive pseudo-random numbers in the range from 0 to RAND_MAX. The symbolic constant RAND_MAX is defined in stdlib.h.

Return Value

rand returns the generated pseudo-random number.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
    int i;
    randomize();
    printf("Ten random numbers from 0 to 99\n\n");
    for(i=0; i<10; i++)
       printf("%d\n", rand() % 100);
    return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.42 random

Header File

stdlib.h

Category

Math Routines

Prototype

```
int random(int num);
```

Description

Random number generator.

random returns a random number between 0 and (num-1). random(num) is a macro defined in stdlib.h. Both num and the random number returned are integers.

Return Value

random returns a number between 0 and (num-1).

Example

```
#include <stdlib.h>
#include <stdio.h>
#include <time.h>
/* prints a random number in the range 0 to 99 */
int main(void)
 {
    randomize();
    printf("Random number in the 0-99 range: %d\n", random (100));
    return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.43 randomize

Header File

stdlib.h, time.h

Category

Math Routines

Prototype

```
void randomize(void);
```

Description

Initializes random number generator.

randomize initializes the random number generator with a random value.

Return Value

None.

Example

```
#include <stdlib.h>
#include <stdio.h>
```

```
#include <time.h>
int main(void)
{
    int i;
    randomize();
    printf("Ten random numbers from 0 to 99\n\n");
    for(i=0; i<10; i++)
        printf("%d\n", rand() % 100);
    return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.29.44 srand

Header File

stdlib.h

Category

Math Routines

Prototype

```
void srand(unsigned seed);
```

Description

Initializes random number generator.

The random number generator is reinitialized by calling srand with an argument value of 1. It can be set to a new starting point by calling srand with a given seed number.

Return Value

None.

Example

```
#include <stdlib.h>
#include <stdio.h>
#include <time.h>
int main(void)
{
   int i;
   time_t t;
   srand((unsigned) time(&t));
   printf("Ten random numbers from 0 to 99\n\n");
   for(i=0; i<10; i++)
       printf("%d\n", rand() % 100);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.45 strlen, _mbslen, wcslen, _mbstrlen

Header File

string.h, mbstring.h, stdlib.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
size_t strlen(const char *s);
size_t wcslen(const wchar_t *s);
size_t _mbslen(const unsigned char *s);
size_t _mbstrlen(const char *s)
```

Description

Calculates the length of a string.

strlen calculates the length of s.

_mbslen and _mbstrlen test the string argument to determine the number of multibyte characters they contain.

_mbstrlen is affected by the LC_CTYPE category setting as determined by the setlocale function. The function tests to determine whether the string argument is a valid multibyte string.

_mbslen is affected by the code page that is in use. This function doesn't test for multibyte validity.

Return Value

strlen returns the number of characters in s, not counting the null-terminating character.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *string = "CodeGear";
   printf("%d\n", strlen(string));
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strlen	+	+	+	+
_mbslen		+		
wcslen		+	+	+
_mbstrlen		+		

3.1.4.29.46 strtod, _strtold, wcstod, _wcstold

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
double strtod(const char *s, char **endptr);
double wcstod(const wchar_t *s, wchar_t **endptr);
long double _strtold(const char *s, char **endptr);
long double _wcstold(const wchar_t *s, wchar_t **endptr);
```

Description

Convert a string to a **double** or **long double** value.

strtod converts a character string, s, to a **double** value. s is a sequence of characters that can be interpreted as a **double** value; the characters must match this generic format:

```
[ws] [sn] [ddd] [.] [ddd] [fmt[sn]ddd]
```

where:

[ws]	=	optional whitespace
[sn]	=	optional sign (+ or -)
[ddd]	=	optional digits
[fmt]	=	optional e or E
[.]	=	optional decimal point

strtod also recognizes +INF and -INF for plus and minus infinity, and +NAN and -NAN for not-a-number.

For example, here are some character strings that strtod can convert to **double**:

```
+ 1231.1981 e-1
502.85E2
+ 2010.952
```

strtod stops reading the string at the first character that cannot be interpreted as an appropriate part of a **double** value.

If endptr is not null, strtod sets *endptr to point to the character that stopped the scan (*endptr = &stopper). endptr is useful for error detection.

_strtold is the l**ong double** version; it converts a string to a **long double** value.

Return Value

These functions return the value of s as a **double** (strtod) or a **long double** (_strtold). In case of overflow, they return plus or minus HUGE_VAL (strtod) or _LHUGE_VAL (_strtold).

Example

```
#include <stdio.h>
#include <stdlib.h>
int main(void)
{
   char input[80], *endptr;
   double value;
   printf("Enter a floating point number:");
   gets(input);
   value = strtod(input, &endptr);
```

```
   printf("The string is %s the number is %lf\n", input, value);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strtod	+	+	+	+
_strtold		+		
wcstod		+	+	+
_wcstold		+		

3.1.4.29.47 strtol, wcstol

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
long strtol(const char *s, char **endptr, int radix);
```

```
long wcstol(const wchar_t *s, wchar_t **endptr, int radix);
```

Description

Converts a string to a **long** value.

strtol converts a character string, s, to a **long** integer value. s is a sequence of characters that can be interpreted as a **long** value; the characters must match this generic format:

```
[ws] [sn] [0] [x] [ddd]
```

where:

[ws]	=	optional whitespace
[sn]	=	optional sign (+ or -)
[0]	=	optional zero (0)
[x]	=	optional x or X
[ddd]	=	optional digits

strtol stops reading the string at the first character it doesn't recognize.

If radix is between 2 and 36, the long integer is expressed in base radix. If radix is 0, the first few characters of s determine the base of the value being converted.

If radix is 1, it is considered to be an invalid value. If radix is less than 0 or greater than 36, it is considered to be an invalid value.

Any invalid value for radix causes the result to be 0 and sets the next character pointer *endptr to the starting string pointer.

If the value in s is meant to be interpreted as octal, any character other than 0 to 7 will be unrecognized.

If the value in s is meant to be interpreted as decimal, any character other than 0 to 9 will be unrecognized.

If the value in s is meant to be interpreted as a number in any other base, then only the numerals and letters used to represent numbers in that base will be recognized. (For example, if radix equals 5, only 0 to 4 will be recognized; if radix equals 20, only 0 to 9 and A to J will be recognized.)

If endptr is not null, strtol sets *endptr to point to the character that stopped the scan (*endptr = &stopper).

Return Value

strtol returns the value of the converted string, or 0 on error.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   char *string = "87654321", *endptr;
   long lnumber;
   /* strtol converts string to long integer  */
   lnumber = strtol(string, &endptr, 10);
   printf("string = %s  long = %ld\n", string, lnumber);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strtol	+	+	+	+
wcstol		+	+	+

3.1.4.29.48 strtoul, wcstoul

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
unsigned long strtoul(const char *s, char **endptr, int radix);
```

```
unsigned long wcstoul(const wchar_t *s, wchar_t **endptr, int radix);
```

Description

Converts a string to an **unsigned long** in the given radix.

strtoul operates the same as strtol, except that it converts a string str to an **unsigned long** value (where strtol converts to a **long**). Refer to the entry for strtol for more information.

Return Value

strtoul returns the converted value, an **unsigned long**, or 0 on error.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
```

```
    char *string = "87654321", *endptr;
    unsigned long lnumber;
    lnumber = strtoul(string, &endptr, 10);
    printf("string = %s  long = %lu\n",
    string, lnumber);
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strtoul	+	+	+	+
wcstoul		+	+	+

3.1.4.29.49 swab

Header File

stdlib.h

Category

Memory and String Manipulation Routines

Prototype

```
void swab(char *from, char *to, int nbytes);
```

Description

Swaps bytes.

swab copies nbytes bytes from the from string to the to string. Adjacent even- and odd-byte positions are swapped. This is useful for moving data from one machine to another machine with a different byte order. nbytes should be even.

Return Value

None.

Example

```
#include <stdlib.h>
#include <stdio.h>
#include <string.h>
char source[15] = "rFna koBlrna d";
char target[15];
int main(void)
{
    swab(source, target, strlen(source));
    printf("This is target: %s\n", target);
    return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+		

3.1.4.29.50 system, _wsystem

Header File

stdlib.h

Category

Process Control Routines

Prototype

```
int system(const char *command);
```

```
int _wsystem(const wchar_t *command);
```

Description

Issues an operating system command.

system invokes the operating system command processor to execute an operating system command, batch file, or other program named by the string command, from inside an executing C program.

To be located and executed, the program must be in the current directory or in one of the directories listed in the PATH string in the environment.

The COMSPEC environment variable is used to find the command processor program, so it need not be in the current directory.

Return Value

If command is a NULL pointer, system returns nonzero if a command processor is available.

If command is not a NULL pointer, system returns 0 if the command processor was successfully started.

If an error occurred, a -1 is returned and errno is set to one of the following:

ENOENT	Path or file function not found
ENOEXEC	Exec format error
ENOMEM	Not enough memory

Example

```
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   printf("About to spawn a command-line program.\n");
   system("dir");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
system	+	+		
_wsystem		NT only		

3.1.4.29.51 ultoa, _ultow

Header File

stdlib.h

Category

Conversion Routines, Math Routines

Prototype

```
char *ultoa(unsigned long value, char *string, int radix);
```

```
wchar_t *_ultow(unsigned long value, wchar_t *string, int radix);
```

Description

Converts an **unsigned long** to a string.

ultoa converts value to a null-terminated string and stores the result in string. value is an **unsigned long**.

radix specifies the base to be used in converting value; it must be between 2 and 36, inclusive. ultoa performs no overflow checking, and if value is negative and radix equals 10, it does not set the minus sign.

Note: The space allocated for string must be large enough to hold the returned string, including the terminating null character (\0). ultoa can return up to 33 bytes.

Return Value

ultoa returns string.

Example

```
#include <stdlib.h>
#include <stdio.h>
int main( void )
{
   unsigned long lnumber = 3123456789L;
   char string[25];
   ultoa(lnumber,string,10);
   printf("string = %s  unsigned long = %lu\n",string,lnumber);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
ultoa		+		
_ultow		+		

3.1.4.29.52 wcstombs

Header File

stdlib.h

Category

Conversion Routines, Memory and String Manipulation Routines

Prototype

```
size_t wcstombs(char *s, const wchar_t *pwcs, size_t n);
```

Description

Converts a **wchar_t** array into a multibyte string.

wcstombs converts the type **wchar_t** elements contained in pwcs into a multibyte character string s. The process terminates if either a null character or an invalid multibyte character is encountered.

No more than n bytes are modified. If n number of bytes are processed before a null character is reached, the array s is not null terminated.

The behavior of wcstombs is affected by the setting of LC_CTYPE category of the current locale.

Return Value

If an invalid multibyte character is encountered, wcstombs returns (size_t) -1. Otherwise, the function returns the number of bytes modified, not including the terminating code, if any.

Example

```
#include <stdio.h>
#include <stdlib.h>
void main(void)
{
  int x;
  char *pbuf = (char*)malloc( MB_CUR_MAX);
  wchar_t *pwcsEOL = L'\0';
  char *pwchi= L"Hi there!";

  printf (" Convert entire wchar string into a multibyte string:\n");
  x = wcstombs( pbuf, pwchi,MB_CUR_MAX);
  printf ("Character converted: %u\n", x);
  printf ("Multibyte string character: %1s\n\n",pbuf);
  printf (" Convert when target is NULL\n");
  x = wcstombs( pbuf, pwcsEOL, MB_CUR_MAX);
  printf ("Character converted: %u\n",x);
  printf ("Multibyte string: %1s\n\n",pbuf);

}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.29.53 wctomb

Header File

stdlib.h

Category

Conversion Routines, Memory and String Manipulation Routines

Prototype

```
int wctomb(char *s, wchar_t wc);
```

Description

Converts **wchar_t** code to a multibyte character.

If s is not null, wctomb determines the number of bytes needed to represent the multibyte character corresponding to wc (including any change in shift state). The multibyte character is stored in s. At most MB_CUR_MAX characters are stored. If the value of wc is zero, wctomb is left in the initial state.

The behavior of wctomb is affected by the setting of LC_CTYPE category of the current locale.

Return Value

If s is a NULL pointer, wctomb returns a nonzero value if multibyte character encodings do have state-dependent encodings, and a zero value if they do not.

If s is not a NULL pointer, wctomb returns -1 if the wc value does not represent a valid multibyte character. Otherwise, wctomb returns the number of bytes that are contained in the multibyte character corresponding to wc. In no case will the return value be greater than the value of MB_CUR_MAX macro.

Example

```
#include <stdio.h>
#include <stdlib.h>
void main(void)
{
  int x;
  wchar_t wc = L'a';
  char *pmbNULL = NULL;
  char *pmb = (char *)malloc(sizeof( char ));
  printf (" Convert a wchar_t array into a multibyte string:\n");
  x = wctomb( pmb, wc);
  printf ("Character converted: %u\n", x);
  printf ("Multibyte string: %1s\n\n",pmb);
  printf (" Convert when target is NULL\n");
  x = wctomb( pmbNULL, wc);
  printf ("Character converted: %u\n",x);
  printf ("Multibyte stri ng: %1s\n\n",pmbNULL);

}
```

Portability

POSIX	Win32	ANSI C	ANSI C++

3.1.4.30 string.h

The following functions, macros, and classes are provided in `string.h`:

Topics

Name	Description

_ismbblead, _ismbbtrail (see page 1152)	**Header File**
	mbstring.h
	Category
	Classification Routines
	Prototype
	`int _ismbblead(unsigned int c);`
	`int _ismbbtrail(unsigned int c);`
	Description
	_ismbblead and _ismbbtrail are used to test whether the argument c is the first or the second byte of a multibyte character.
	_ismbblead and _ismbbtrail are affected by the code page in use. You can set the code page by using the _setlocale function.
	Return Value
	If c is in the lead byte of a multibyte character, _ismbblead returns true.
	If c is in the trail byte of a multibyte character, _ismbbtrail returns a nonzero value.

_ismbclegal (see page 1153)	**Header File** mbstring.h **Category** Classification Routines **Prototype** `int _ismbclegal(unsigned int c);` **Description** _ismbclegal tests whether each byte of the c argument is in the code page that is currently in use. **Return Value** _ismbclegal returns a nonzero value if the argument c is a valid multibyte character on the current code page. Otherwise, the function returns zero.

_ismbslead, _ismbstrail (see page 1153)	**Header File**
	mbstring.h
	Category
	Classification Routines
	Prototype
	`int _ismbslead(const unsigned char *s1, const unsigned char *s2);`
	`int _ismbstrail(const unsigned char *s1, const unsigned char *s2);`
	Description
	The _ismbslead and _ismbstrail functions test the s1 argument to determine whether the s2 argument is a pointer to the lead byte or the trail byte. The test is case-sensitive.
	Return Value
	The _ismbslead and _ismbstrail routines return -1 if s2 points to a lead byte or a trail byte, respectively. If the test is false, the routines return zero.

_mbbtype (see page 1154)	**Header File** mbstring.h **Category** Classification Routines **Prototype** `int _mbbtype(unsigned char ch, int mode);` **Description** The _mbbtype function inspects the multibyte argument, character ch, to determine whether it is a single-byte character, or whether ch is the leadbyte or trailing byte in a multibyte character. The _mbbtype function can determine whether ch is an invalid character. **Return Value** The value that _mbbtype returns is one of the following manifest constants, defined in mbctype.h. The return value depends on the value of ch and the test which you want performed on ch.

_mbccpy (see page 1154)	**Header File** mbstring.h **Category** Memory and String Manipulation Routines **Prototype** `void _mbccpy(unsigned char *dest, unsigned char *src);` **Description** The _mbccpy function copies a multibyte character from src to dest. The _mbccpy function makes an implicit call to _ismbblead so that the src pointer references a lead byte. If src doesn't reference a lead byte, no copy is performed. **Return Value** None.
_mbsbtype (see page 1154)	**Header File** mbstring.h **Category** Classification Routines **Prototype** `int _mbsbtype(const unsigned char *str, size_t nbyte);` **Description** The nbyte argument specifies the number of bytes from the start of the zero-based string. The _mbsbtype function inspects the argument str to determine whether the byte at the position specified by nbyte is a single-byte character, or whether it is the leadbyte or trailing byte in a multibyte character. The _mbsbtype function can determine whether the byte pointed at is an invalid character or a NULL byte. Any invalid bytes in str before nbyte are ignored. **Return Value** The value that _mbsbtype returns is... more (see page 1154)
_mbsnbcmp (see page 1155)	**Header File** mbstring.h **Category** Memory and String Manipulation Routines **Prototype** `int _mbsnbcmp(const unsigned char *s1, const unsigned char s2, size_t maxlen);` **Description** _mbsnbcmp makes an case-sensitive comparison of s1 and s2 for no more than maxlen bytes. It starts with the first byte in each string and continues with subsequent bytes until the corresponding bytes differ or until it has examined maxlen bytes. _mbsnbcmp is case sensitive. _mbsnbcmp is not affected by locale. _mbsnbcmp compares bytes based on the current multibyte code page. **Return Value** • _mbsnbcmp returns an integer value based on the result of comparing s1 (or part of... more (see page 1155)

_mbsnbcnt, _mbsnccnt, _strncnt, _wcsncnt (see page 1155)	**Header File**
	mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`size_t _mbsnbcnt(const unsigned char * str, size_t nmbc);`
	`size_t _mbsnccnt(const unsigned char * str, size_t nbyte);`
	Description
	If _MBCS is defined:
	_mbsnbcnt is mapped to the portable macro _tcsnbcnt
	_mbsnccnt is mapped to the portable macro _tcsnccnt If _UNICODE is defined:
	both _mbsnbcnt and _mbsnccnt are mapped to the _wcsncnt macro
	If neither _MBCS nor _UNICODE are defined.
	_tcsnbcnt and _tcsnccnt are mapped to the _strncnt macro _strncnt is the single-byte version of these functions. _wcsncnt is the wide-character version of these functions.
	_strncnt and _wcsncnt are available only for... more (see page 1155)

_mbsnbcoll, _mbsnbicoll (see page 1156)	**Header File**
	mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int _mbsnbcoll(const unsigned char *s1, const unsigned char *s2, maxlen);`
	`int _mbsnbicoll(const unsigned char *s1, const unsigned char *s2, maxlen);`
	Description
	_mbsnbicoll is the case-insensitive version of _mbsnbcoll.
	These functions collate the strings specified by arguments s1 and s2. The collation order is determined by lexicographic order as specified by the current multibyte code page. At most, maxlen number of bytes are collated.
	Note: Note:
	The lexicographic order is not always the same as the order of characters in the character set.If the last byte in s1 or s2 is... more (see page 1156)

_mbsnbcpy (see page 1157)	**Header File** mbstring.h **Category** Memory and String Manipulation Routines **Prototype** `unsigned char *_mbsnbcpy(unsigned char *dest, unsigned char *src, size_t maxlen);` **Description** The _mbsnbcpy function copies at most maxlen number of characters from the src buffer to the dest buffer. The dest buffer is null terminated after the copy. It is the user's responsibility to be sure that dest is large enough to allow the copy. An improper buffer size can result in memory corruption. **Return Value** The function returns dest.
_mbsnbicmp (see page 1157)	**Header File** mbstring.h **Category** Memory and String Manipulation Routines **Prototype** `int _mbsnbicmp(const unsigned char *s1, const unsigned char s2, size_t maxlen);` **Description** _mbsnbicmp ignores case while making a comparison of s1 and s2 for no more than maxlen bytes. It starts with the first byte in each string and continues with subsequent bytes until the corresponding bytes differ or until it has examined maxlen bytes. _mbsnbicmp is not case sensitive. _mbsnbicmp is not affected by locale. _mbsnbicmp compares bytes based on the current multibyte code page. **Return Value** • _mbsnbicmp returns an integer value based on the result of comparing s1... more (see page 1157)
_mbsnbset (see page 1158)	**Header File** mbstring.h **Category** Memory and String Manipulation Routines **Prototype** `unsigned char *_mbsnbset(unsigned char str, unsigned int ch, size_t maxlen);` **Description** _mbsnbset sets at most maxlen number of bytes in the string str to the character ch. The argument ch can be a single or multibyte character. The function quits if the terminating null character is found before maxlen is reached. If ch is a multibyte character that cannot be accomodated at the end of str, the last character in str is set to a blank character. **Return Value** strset returns str.

_mbsninc, _strninc, _wcsninc (see page 1158)	**Header File** mbstring.h **Category** Memory and String Manipulation Routines **Prototype** `unsigned char *_mbsninc(const unsigned char *str, size_t num);` **Description** The functions increment the character array str by num number of characters. These functions should be accessed through the portable macro, _tcsninc, defined in tchar.h. **Return value** The functions return a pointer to the resized character string specified by the argument str.
_mbsspnp, _strspnp, _wcsspnp (see page 1158)	**Header File** mbstring.h **Category** Memory and String Manipulation Routines **Prototype** `unsigned char *_mbsspnp(const unsigned char *s1, const unsigned char *s2);` **Description** Each of these functions search for the first character in s1 that is not contained in s2. Use the portable macro, _tcsspnp, defined in tchar.h, to access these functions. **Return Value** The functions return a pointer to the first character in s1 that is not found in the character set for s2. If every character from s1 is found in s2, each of the functions return NULL.

_strdec, mbsdec, _wcsdec (see page 1159)	**Header File**
	mbstring.h, tchar.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`unsigned char *_mbsdec(const unsigned char *s, const unsigned char *p);`
	`inline char *_strdec(const char * s1, const char * s2) { return (char *)(s1,(s2-1));`
	`// From tchar.h`
	`#define _tcsdec _strdec`
	`#define _tcsdec _wcsdec`
	Description
	_mbsdec returns a pointer p indicating the character in string s back to 1 byte backward. If there are no more characters before string p (it is the same position as s), _mbsdec returns a **null** pointer.
	_strdec is the single-byte version of this function.
	_wcsdec is the wide-character version of this function.
	Return Value... more (see page 1159)

_strerror (see page 1159)	**Header File** string.h, stdio.h **Category** Memory and String Manipulation Routines **Prototype** `char *_strerror(const char *s);` **Description** Builds a customized error message. _strerror lets you generate customized error messages; it returns a pointer to a null-terminated string containing an error message. • If s is null, the return value points to the most recent error message. • If s is not null, the return value contains s (your customized error message), a colon, a space, the most-recently generated system error message, and a new line. s should be 94 characters or less. **Return Value** _strerror returns a pointer to a constructed error string.... more (see page 1159)

_strinc, mbsinc, _wcsinc (see page 1160)	**Header File**
	mbstring.h, tchar.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`unsigned char *_mbsinc(const unsigned char *p);`
	`// From tchar.h`
	`#define _tcsinc _strinc`
	`#define _tcsinc _wcsinc`
	`inline char * strinc(const char * s) { return (char *)(s+1); }`
	Description
	_mbsinc increments a string pointer by one byte.
	_strdec is the single-byte version of this function.
	_wcsdec is the wide-character version of this function.
	Return Value
	Returns a pointer that is forwarded by 1 byte.

_strnextc,_mbsnextc,_wcsnextc (see page 1161)	**Header File**
	tchar.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`unsigned int _strnextc(const char *str);`
	`unsigned int _mbsnextc (const unsigned char *str);`
	Description
	These routines should be accessed by using the portable _tcsnextc function. The functions inspect the current character in str. The pointer to str is not advanced.
	Return Value
	The functions return the integer value of the character pointed to by str.
	Example

stpcpy, _wstpcpy, _stpcpy (see page 1161)	**Header File**
	string.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`char *stpcpy(char *dest, const char *src);`
	`wchar * _wcspcpy(wchar *dest, const wchar *src);`
	Description
	Copies one string into another.
	_stpcpy copies the string src to dest, stopping after the terminating null character of src has been reached.
	Return Value
	stpcpy returns a pointer to the terminating null character of dest.
	If UNICODE is defined, _wcspcpy returns a pointer to the terminating null character of the **wchar_t** dest string.
	Example

strcat, _mbscat, wcscat (see page 1162)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`char *strcat(char *dest, const char *src);`
	`wchar_t *wcscat(wchar_t *dest, const wchar_t *src);`
	`unsigned char *_mbscat(unsigned char *dest, const unsigned char *src);`
	Description
	Appends one string to another.
	strcat appends a copy of src to the end of dest. The length of the resulting string is strlen(dest) + strlen(src).
	Return Value
	strcat returns a pointer to the concatenated strings.
	Example

strchr, _mbschr, wcschr (see page 1163)	**Header File**
	string.h
	Category
	Memory and String Manipulation Routines, Inline Routines, C++ Prototyped Routines
	Prototype
	`char *strchr(const char *s, int c);/* C only */`
	`const char *strchr(const char *s, int c);// C++ only`
	`char *strchr( char *s, int c);// C++ only`
	`wchar_t *wcschr(const wchar_t *s, int c);`
	`unsigned char * _mbschr(const unsigned char *s, unsigned int c);`
	Description
	Scans a string for the first occurrence of a given character.
	strchr scans a string in the forward direction, looking for a specific character. strchr finds the first occurrence of the character c in the string s. The null-terminator is considered to... more (see page 1163)

strcmp, _mbscmp, wcscmp (see page 1164)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`int strcmp(const char *s1, const char *s2);`
	`int wcscmp(const wchar_t *s1, const wchar_t *s2);`
	`int _mbscmp(const unsigned char *s1, const unsigned char *s2);`
	Description
	Compares one string to another.
	strcmp performs an unsigned comparison of s1 to s2, starting with the first character in each string and continuing with subsequent characters until the corresponding characters differ or until the end of the strings is reached.
	Return Value

strcmpi (see page 1165)	**Header File**
	string.h, wchar.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int strcmpi(const char *s1, const char *s2);`
	`int _wcscmpi(const wchar_t *s1, const wchar_t *s2);`
	Description
	Compares one string to another, without case sensitivity.
	strcmpi performs an unsigned comparison of s1 to s2, without case sensitivity (same as stricmp--implemented as a macro).
	It returns a value (< 0, 0, or > 0) based on the result of comparing s1 (or part of it) to s2 (or part of it).
	The routine strcmpi is the same as stricmp. strcmpi is implemented through a macro in string.h and translates calls from strcmpi... more (see page 1165)

strcoll,_stricoll, _mbscoll, _mbsicoll, wcscoll, _wcsicoll (see page 1166)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int strcoll(const char *s1, const char *s2);`
	`int wcscoll(const wchar_t *s1, const wchar_t *s2);`
	`int _stricoll(const char *s1, const char *s2);`
	`int _wcsicoll(const wchar_t *s1, wconst_t char *s2);`
	`int _mbscoll(const unsigned char *s1, const unsigned char *s2);`
	`int _mbsicoll(const unsigned char *s1, const unsigned char *s2);`
	Description
	Compares two strings.
	strcoll compares the string pointed to by s1 to the string pointed to by s2, according to the current locale's LC_COLLATE category.
	_stricoll performs like strcoll but is not case sensitive.
	Note: Note
	_stricoll does not compare string according... more (see page 1166)

strcpy (see page 1167)	**Header File**
	string.h, wchar.h, mbstring.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`char *strcpy(char *dest, const char *src);`
	`wchar_t *wcscpy(wchar_t *dest, const wchar_t *src);`
	`unsigned char *_mbscpy(unsigned char *dest, const unsigned char *src);`
	Description
	Copies one string into another.
	Copies string src to dest, stopping after the terminating null character has been moved.
	Return Value
	strcpy returns dest.
	Example

strcspn, _mbscspn, wcscspn (see page 1168)	**Header File**
	string.h, wchar.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`size_t strcspn(const char *s1, const char *s2);`
	`size_t wcscspn(const wchar_t *s1, const wchar_t *s2);`
	`size_t _mbscspn(const unsigned char *s1, const unsigned char *s2);`
	Description
	Scans a string for the initial segment not containing any subset of a given set of characters.
	The strcspn functions search s1 until any one of the characters contained in s2 is found. The number of characters which were read in s1 is the return value. The string termination character is not counted. Neither string is altered during the search.
	Return Value
	strcspn returns... more (see page 1168)

strdup, _mbsdup, _wcsdup (see page 1169)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`char *strdup(const char *s);`
	`wchar_t *_wcsdup(const wchar_t *s);`
	`unsigned char *_mbsdup(const wchar_t *s);`
	Description
	Copies a string into a newly created location.
	strdup makes a duplicate of string s, obtaining space with a call to malloc. The allocated space is (strlen(s) + 1) bytes long. The user is responsible for freeing the space allocated by strdup when it is no longer needed.
	Return Value
	strdup returns a pointer to the storage location containing the duplicated string, or returns null if space could not be allocated.
	Example

strerror (see page 1170)	**Header File** string.h **Category** Memory and String Manipulation Routines **Prototype** `char *strerror(int errnum);` **Description** Returns a pointer to an error message string. strerror takes an **int** parameter errnum, an error number, and returns a pointer to an error message string associated with errnum. **Return Value** strerror returns a pointer to a constructed error string. The error message string is constructed in a static buffer that is overwritten with each call to strerror. **Example**

stricmp, _mbsicmp, _wcsicmp (see page 1170)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int stricmp(const char *s1, const char *s2);`
	`int _wcsicmp(const wchar_t *s1, const wchar_t *s2);`
	`int _mbsicmp(const unsigned char *s1, const unsigned char *s2);`
	Description
	Compares one string to another, without case sensitivity.
	stricmp performs an unsigned comparison of s1 to s2, starting with the first character in each string and continuing with subsequent characters until the corresponding characters differ or until the end of the strings is reached. The comparison is not case sensitive.
	It returns a value (< 0, 0, or > 0) based on the result of... more (see page 1170)

strlwr, _mbslwr, _wcslwr (see page 1171)	**Header File**
	string.h, mbstring.h
	Category
	Conversion Routines, Memory and String Manipulation Routines
	Prototype
	`char *strlwr(char *s);`
	`wchar_t *_wcslwr(wchar_t *s);`
	`unsigned char *_mbslwr(unsigned char *s);`
	Description
	Converts uppercase letters in a string to lowercase.
	strlwr converts uppercase letters in string s to lowercase according to the current locale's LC_CTYPE category. For the C locale, the conversion is from uppercase letters (A to Z) to lowercase letters (a to z). No other characters are changed.
	Return Value
	strlwr returns a pointer to the string s.
	Example

strncat (see page 1172)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`char *strncat(char *dest, const char *src, size_t maxlen);`
	`wchar_t *wcsncat(wchar_t *dest, const wchar_t *src, size_t maxlen);`
	`unsigned char *_mbsncat(unsigned char *dest, const unsigned char *src, size_t maxlen);`
	`unsigned char *_mbsnbcat(unsigned char *__dest, const unsigned char *__src, _SIZE_T __maxlen);`
	Description
	Appends a portion of one string to another.
	strncat copies at most maxlen characters of src to the end of dest and then appends a null character. The maximum length of the resulting string is strlen(dest) + maxlen.
	For _mbsnbcat, if the second byte of 2-bytes character is... more (see page 1172)

strncmp, _mbsncmp, wcsncmp (see page 1173)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`int strncmp(const char *s1, const char *s2, size_t maxlen);`
	`int wcsncmp(const wchar_t *s1, const wchar_t *s2, size_t maxlen);`
	`int _mbsncmp(const unsigned char *s1, const unsigned char *s2, size_t maxlen);`
	`#define _mbccmp(__s1, __s2) _mbsncmp((__s1),(__s2),1)`
	Description
	Compares a portion of one string to a portion of another.
	strncmp makes the same unsigned comparison as strcmp, but looks at no more than maxlen characters. It starts with the first character in each string and continues with subsequent characters until the corresponding characters differ or until it has examined maxlen characters.... more (see page 1173)

strncmpi, wcsncmpi (see page 1174)	**Header File**
	string.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int strncmpi(const char *s1, const char *s2, size_t n);`
	`int wcsncmpi(const wchar_t *s1, const wchar_t *s2, size_t n);`
	Description
	Compares a portion of one string to a portion of another, without case sensitivity.
	strncmpi performs a signed comparison of s1 to s2, for a maximum length of n bytes, starting with the first character in each string and continuing with subsequent characters until the corresponding characters differ or until n characters have been examined. The comparison is not case sensitive. (strncmpi is the same as strnicmp--implemented as a macro). It... more (see page 1174)

strncoll, strnicoll, _mbsncoll, _mbsnicoll, _wcsncoll, _wcsnicoll (see page 1175)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int _strncoll(const char *s1, const char *s2, size_t n);`
	`int _wcsncoll(const wchar_t *s1, const wchar_t *s2, size_t n);`
	`int _strnicoll(const char *s1, const char *s2, size_t n);`
	`int _wcsnicoll(const wchar_t *s1, const wchar_t *s2, size_t n);`
	`int _mbsncoll(const unsigned char *s1, const unsigned char *s2, size_t n);`
	`int _mbsnicoll(const unsigned char *s1, const unsigned char *s2, size_t n);`
	Description
	_strncoll compares n number of elements from the string pointed to by s1 to the string pointed to by s2, according to the current locale's LC_COLLATE category.
	_strnicoll performs like... more (see page 1175)

strncpy, _mbsncpy, wcsncpy (see page 1176)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`char *strncpy(char *dest, const char *src, size_t maxlen);`
	`wchar_t *wcsncpy(wchar_t *dest, const wchar_t *src, size_t maxlen);`
	`unsigned char *_mbsncpy(unsigned char *dest, const unsigned char *src, size_t maxlen);`
	Description
	Copies a given number of bytes from one string into another, truncating or padding as necessary.
	strncpy copies up to maxlen characters from src into dest, truncating or null-padding dest. The target string, dest, might not be null-terminated if the length of src is maxlen or more.
	Return Value
	strncpy returns dest.
	Example

strnicmp, _mbsnicmp, _wcsnicmp (see page 1176)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`int strnicmp(const char *s1, const char *s2, size_t maxlen);`
	`int _wcsnicmp(const wchar_t *s1, const wchar_t *s2, size_t maxlen);`
	`int _mbsnicmp(const unsigned char *s1, const unsigned char *s2, size_t maxlen);`
	Description
	Compares a portion of one string to a portion of another, without case sensitivity.
	strnicmp performs a signed comparison of s1 to s2, for a maximum length of maxlen bytes, starting with the first character in each string and continuing with subsequent characters until the corresponding characters differ or until the end of the strings is reached. The comparison... more (see page 1176)

strnset, _mbsnset, _wcsnset (see page 1177)	**Header File**
	string.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`char *strnset(char *s, int ch, size_t n);`
	`wchar_t *_wcsnset(wchar_t *s, wchar_t ch, size_t n);`
	`unsigned char *_mbsnset(unsigned char *s, unsigned int ch, size_t n);`
	Description
	Sets a specified number of characters in a string to a given character.
	strnset copies the character ch into the first n bytes of the string s. If n > strlen(s), then strlen(s) replaces n. It stops when n characters have been set, or when a null character is found.
	Return Value
	Each of these functions return s.
	Example

strpbrk, _mbspbrk, wcspbrk (see page 1178)	**Header File**
	string.h, mbstring.h
	Category
	C++ Prototyped Routines, Memory and String Manipulation Routines
	Prototype
	`char *strpbrk(const char *s1, const char *s2); /* C only */`
	`const char *strpbrk(const char *s1, const char *s2); // C++ only`
	`char *strpbrk(char *s1, const char *s2); // C++ only`
	`wchar_t * wcspbrk(const wchar_t *s1, const wchar_t *s2);`
	`unsigned char *_mbspbrk(const unsigned char *s1, const unsigned char *s2);`
	Description
	Scans a string for the first occurrence of any character from a given set.
	strpbrk scans a string, s1, for the first occurrence of any character appearing in s2.
	Return Value
	strpbrk returns a pointer to... more (see page 1178)

strrchr, _mbsrchr, wcsrchr (see page 1179)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines, Inline Routines, C++ Prototyped Routines
	Prototype
	`char *strrchr(const char *s, int c); /* C only */`
	`const char *strrchr(const char *s, int c); // C++ only`
	`char *strrchr(char *s, int c); // C++ only`
	`wchar_t *wcsrchr(const wchar_t *s, wchar_t c);`
	`unsigned char * _mbsrchr(const unsigned char *s, unsigned int c);`
	Description
	Scans a string for the last occurrence of a given character.
	strrchr scans a string in the reverse direction, looking for a specific character. strrchr finds the last occurrence of the character c in the string s. The null-terminator... more (see page 1179)

strrev, _mbsrev, _wcsrev (see page 1180)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`char *strrev(char *s);`
	`wchar_t *_wcsrev(wchar_t *s);`
	`unsigned char *_mbsrev(unsigned char *s);`
	Description
	Reverses a string.
	strrev changes all characters in a string to reverse order, except the terminating null character. (For example, it would change string\0 to gnirts\0.)
	Return Value
	strrev returns a pointer to the reversed string.
	Example

strset, _mbsset, _wcsset (see page 1181)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines, Inline Routines
	Prototype
	`char *strset(char *s, int ch);`
	`wchar_t *_wcsset(wchar_t *s, wchar_t ch);`
	`unsigned char *_mbsset(unsigned char *s, unsigned int ch);`
	Description
	Sets all characters in a string to a given character.
	strset sets all characters in the string s to the character ch. It quits when the terminating null character is found.
	Return Value
	strset returns s.
	Example

strspn, _mbsspn, wcsspn (see page 1182)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`size_t strspn(const char *s1, const char *s2);`
	`size_t wcsspn(const wchar_t *s1, const wchar_t *s2);`
	`size_t _mbsspn(const unsigned char *s1, const unsigned char *s2);`
	Description
	Scans a string for the first segment that is a subset of a given set of characters.
	strspn finds the initial segment of string s1 that consists entirely of characters from string s2.
	Return Value
	strspn returns the length of the initial segment of s1 that consists entirely of characters from s2.
	Example

strstr, _mbsstr, wcsstr (see page 1182)	**Header File**
	string.h
	Category
	C++ Prototyped Routines, Memory and String Manipulation Routines
	Prototype
	`char *strstr(const char *s1, const char *s2); /* C only */`
	`const char *strstr(const char *s1, const char *s2); // C++ only`
	`char *strstr(char *s1, const char *s2); // C++ only`
	`wchar_t * wcsstr(const wchar_t *s1, const wchar_t *s2);`
	`unsigned char * _mbsstr(const unsigned char *s1, const unsigned char *s2);`
	Description
	Scans a string for the occurrence of a given substring.
	strstr scans s1 for the first occurrence of the substring s2.
	Return Value
	strstr returns a pointer to the element in s1, where s2 begins (points... more (see page 1182)

strtok, _mbstok, wcstok (see page 1183)	**Header File**
	string.h, mbstring.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`char *strtok(char *s1, const char *s2);`
	`wchar_t *wcstok(wchar_t *s1, const wchar_t *s2);`
	`unsigned char *_mbstok(unsigned char *s1, const unsigned char *s2);`
	Description
	Searches one string for tokens, which are separated by delimiters defined in a second string.
	strtok considers the string s1 to consist of a sequence of zero or more text tokens, separated by spans of one or more characters from the separator string s2.
	The first call to strtok returns a pointer to the first character of the first token in s1 and writes a null character... more (see page 1183)

strupr, _mbsupr, _wcsupr (see page 1184)	**Header File**
	string.h, mbstring.h
	Category
	Conversion Routines, Memory and String Manipulation Routines
	Prototype
	`char *strupr(char *s);`
	`wchar_t *_wcsupr(wchar_t *s);`
	`unsigned char *_mbsupr(unsigned char *s);`
	Description
	Converts lowercase letters in a string to uppercase.
	strupr converts lowercase letters in string s to uppercase according to the current locale's LC_CTYPE category. For the default C locale, the conversion is from lowercase letters (a to z) to uppercase letters (A to Z). No other characters are changed.
	Return Value
	strupr returns s.
	Example

strxfrm, wcsxfrm (see page 1185)	**Header File**
	string.h
	Category
	Memory and String Manipulation Routines
	Prototype
	`size_t strxfrm(char *target, const char *source, size_t n);`
	`size_t wcsxfrm(wchar_t *target, const wchar_t *source, size_t n);`
	Description
	Transforms a portion of a string to a specified collation.
	strxfrm transforms the string pointed to by source into the string target for no more than n characters. The transformation is such that if the strcmp function is applied to the resulting strings, its return corresponds with the return values of the strcoll function.
	No more than n characters, including the terminating null character, are copied to target.
	strxfrm transforms a character string... more (see page 1185)

3.1.4.30.1 _ismbblead, _ismbbtrail

Header File

mbstring.h

Category

Classification Routines

Prototype

```
int _ismbblead(unsigned int c);
```

```
int _ismbbtrail(unsigned int c);
```

Description

_ismbblead and _ismbbtrail are used to test whether the argument c is the first or the second byte of a multibyte character.

_ismbblead and _ismbbtrail are affected by the code page in use. You can set the code page by using the _setlocale function.

Return Value

If c is in the lead byte of a multibyte character, _ismbblead returns true.

If c is in the trail byte of a multibyte character, _ismbbtrail returns a nonzero value.

3.1.4.30.2 _ismbclegal

Header File

mbstring.h

Category

Classification Routines

Prototype

```
int _ismbclegal(unsigned int c);
```

Description

_ismbclegal tests whether each byte of the c argument is in the code page that is currently in use.

Return Value

_ismbclegal returns a nonzero value if the argument c is a valid multibyte character on the current code page. Otherwise, the function returns zero.

3.1.4.30.3 _ismbslead, _ismbstrail

Header File

mbstring.h

Category

Classification Routines

Prototype

```
int _ismbslead(const unsigned char *s1, const unsigned char *s2);
int _ismbstrail(const unsigned char *s1, const unsigned char *s2);
```

Description

The _ismbslead and _ismbstrail functions test the s1 argument to determine whether the s2 argument is a pointer to the lead byte or the trail byte. The test is case-sensitive.

Return Value

The _ismbslead and _ismbstrail routines return -1 if s2 points to a lead byte or a trail byte, respectively. If the test is false, the routines return zero.

3.1.4.30.4 _mbbtype

Header File

mbstring.h

Category

Classification Routines

Prototype

```
int _mbbtype(unsigned char ch, int mode);
```

Description

The _mbbtype function inspects the multibyte argument, character ch, to determine whether it is a single-byte character, or whether ch is the leadbyte or trailing byte in a multibyte character. The _mbbtype function can determine whether ch is an invalid character.

Return Value

The value that _mbbtype returns is one of the following manifest constants, defined in mbctype.h. The return value depends on the value of ch and the test which you want performed on ch.

3.1.4.30.5 _mbccpy

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
void _mbccpy(unsigned char *dest, unsigned char *src);
```

Description

The _mbccpy function copies a multibyte character from src to dest. The _mbccpy function makes an implicit call to _ismbblead so that the src pointer references a lead byte. If src doesn't reference a lead byte, no copy is performed.

Return Value

None.

3.1.4.30.6 _mbsbtype

Header File

mbstring.h

Category

Classification Routines

Prototype

```
int _mbsbtype(const unsigned char *str, size_t nbyte);
```

Description

The nbyte argument specifies the number of bytes from the start of the zero-based string.

The _mbsbtype function inspects the argument str to determine whether the byte at the position specified by nbyte is a single-byte character, or whether it is the leadbyte or trailing byte in a multibyte character. The _mbsbtype function can determine whether the byte pointed at is an invalid character or a NULL byte.

Any invalid bytes in str before nbyte are ignored.

Return Value

The value that _mbsbtype returns is one of the following manifest constants, defined in mbctype.h.

3.1.4.30.7 _mbsnbcmp

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
int _mbsnbcmp(const unsigned char *s1, const unsigned char s2, size_t maxlen);
```

Description

_mbsnbcmp makes an case-sensitive comparison of s1 and s2 for no more than maxlen bytes. It starts with the first byte in each string and continues with subsequent bytes until the corresponding bytes differ or until it has examined maxlen bytes.

_mbsnbcmp is case sensitive.

_mbsnbcmp is not affected by locale.

_mbsnbcmp compares bytes based on the current multibyte code page.

Return Value

- _mbsnbcmp returns an integer value based on the result of comparing s1 (or part of it) to s2 (or part of it):
- < 0 if s1 is less than s2
- == 0 if s1 is the same as s2
- > 0 if s1 is greater than s2

3.1.4.30.8 _mbsnbcnt, _mbsnccnt, _strncnt, _wcsncnt

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
size_t _mbsnbcnt(const unsigned char * str, size_t nmbc);
size_t _mbsnccnt(const unsigned char * str, size_t nbyte);
```

Description

If _MBCS is defined:

_mbsnbcnt is mapped to the portable macro _tcsnbcnt

_mbsnccnt is mapped to the portable macro _tcsnccnt If _UNICODE is defined:

both _mbsnbcnt and _mbsnccnt are mapped to the _wcsncnt macro

If neither _MBCS nor _UNICODE are defined.

_tcsnbcnt and _tcsnccnt are mapped to the _strncnt macro _strncnt is the single-byte version of these functions. _wcsncnt is the wide-character version of these functions.

_strncnt and _wcsncnt are available only for generic-text mappings. They should not be used directly.

_mbsnbcnt examines the first nmbc multibyte characters of the str argument. The function returns the number of bytes found in the those characters.

_mbsnccnt examines the first nmbc bytes of the str argument. The function returns the number of characters found in those bytes. If NULL is encountered in the second byte of a multibyte character, the whole character is considered NULL and will not be included in the return value.

Each of the functions ends its examination of the str argument if NULL is reached before the specified number of characters or bytes is examined.

If str has fewer than the specified number of characters or bytes, the function return the number of characters or bytes found in str.

Return Value

_mbsnbcnt returns the number of bytes found.

_mbsnccnt returns the number of characters found.

If nmbc or nbyte are less than zero, the functions return 0.

3.1.4.30.9 _mbsnbcoll, _mbsnbicoll

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
int _mbsnbcoll(const unsigned char *s1, const unsigned char *s2, maxlen);
int _mbsnbicoll(const unsigned char *s1, const unsigned char *s2, maxlen);
```

Description

_mbsnbicoll is the case-insensitive version of _mbsnbcoll.

These functions collate the strings specified by arguments s1 and s2. The collation order is determined by lexicographic order as specified by the current multibyte code page. At most, maxlen number of bytes are collated.

Note: Note:

The lexicographic order is not always the same as the order of characters in the character set.If the last byte in s1 or s2 is a

leadbyte, it is not compared.

Return Value

- Each of these functions return an integer value based on the result of comparing s1 (or part of it) to s2 (or part of it):
- < 0 if s1 is less than s2
- == 0 if s1 is the same as s2
- > 0 if s1 is greater than s2

On error, each of these functions returns _**NLSCMPERROR**.

3.1.4.30.10 _mbsnbcpy

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
unsigned char *_mbsnbcpy(unsigned char *dest, unsigned char *src, size_t maxlen);
```

Description

The _mbsnbcpy function copies at most maxlen number of characters from the src buffer to the dest buffer. The dest buffer is null terminated after the copy.

It is the user's responsibility to be sure that dest is large enough to allow the copy. An improper buffer size can result in memory corruption.

Return Value

The function returns dest.

3.1.4.30.11 _mbsnbicmp

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
int _mbsnbicmp(const unsigned char *s1, const unsigned char s2, size_t maxlen);
```

Description

_mbsnbicmp ignores case while making a comparison of s1 and s2 for no more than maxlen bytes. It starts with the first byte in each string and continues with subsequent bytes until the corresponding bytes differ or until it has examined maxlen bytes.

_mbsnbicmp is not case sensitive.

_mbsnbicmp is not affected by locale.

_mbsnbicmp compares bytes based on the current multibyte code page.

Return Value

- _mbsnbicmp returns an integer value based on the result of comparing s1 (or part of it) to s2 (or part of it):
- < 0 if s1 is less than s2
- == 0 if s1 is the same as s2
- > 0 if s1 is greater than s2

3.1.4.30.12 _mbsnbset

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
unsigned char *_mbsnbset(unsigned char str, unsigned int ch, size_t maxlen);
```

Description

_mbsnbset sets at most maxlen number of bytes in the string str to the character ch. The argument ch can be a single or multibyte character.

The function quits if the terminating null character is found before maxlen is reached. If ch is a multibyte character that cannot be accomodated at the end of str, the last character in str is set to a blank character.

Return Value

strset returns str.

3.1.4.30.13 _mbsninc, _strninc, _wcsninc

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
unsigned char *_mbsninc(const unsigned char *str, size_t num);
```

Description

The functions increment the character array str by num number of characters.

These functions should be accessed through the portable macro, _tcsninc, defined in tchar.h.

Return value

The functions return a pointer to the resized character string specified by the argument str.

3.1.4.30.14 _mbsspnp, _strspnp, _wcsspnp

Header File

mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
unsigned char *_mbsspnp(const unsigned char *s1, const unsigned char *s2);
```

Description

Each of these functions search for the first character in s1 that is not contained in s2.

Use the portable macro, _tcsspnp, defined in tchar.h, to access these functions.

Return Value

The functions return a pointer to the first character in s1 that is not found in the character set for s2.

If every character from s1 is found in s2, each of the functions return NULL.

3.1.4.30.15 _strdec, mbsdec, _wcsdec

Header File

mbstring.h, tchar.h

Category

Memory and String Manipulation Routines

Prototype

```
unsigned char *_mbsdec(const unsigned char *s, const unsigned char *p);
inline char *_strdec(const char * s1, const char * s2) { return (char *)(s1,(s2-1));
// From tchar.h
#define _tcsdec _strdec
#define _tcsdec _wcsdec
```

Description

_mbsdec returns a pointer p indicating the character in string s back to 1 byte backward. If there are no more characters before string p (it is the same position as s), _mbsdec returns a **null** pointer.

_strdec is the single-byte version of this function.

_wcsdec is the wide-character version of this function.

Return Value

Returns a pointer back to 1 byte, or **null** pointer if there is no character before p.

3.1.4.30.16 _strerror

Header File

string.h, stdio.h

Category

Memory and String Manipulation Routines

Prototype

```
char *_strerror(const char *s);
```

Description

Builds a customized error message.

_strerror lets you generate customized error messages; it returns a pointer to a null-terminated string containing an error message.

- If s is null, the return value points to the most recent error message.
- If s is not null, the return value contains s (your customized error message), a colon, a space, the most-recently generated system error message, and a new line. s should be 94 characters or less.

Return Value

_strerror returns a pointer to a constructed error string. The error message string is constructed in a static buffer that is overwritten with each call to _strerror.

Example

```
#include <stdio.h>
#include <errno.h>
int main(void)
{
   char *buffer;
   buffer = strerror(errno);
   printf("Error: %s\n", buffer);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.30.17 _strinc, mbsinc, _wcsinc

Header File

mbstring.h, tchar.h

Category

Memory and String Manipulation Routines

Prototype

```
unsigned char *_mbsinc(const unsigned char *p);

// From tchar.h

#define _tcsinc _strinc

#define _tcsinc _wcsinc

inline char * strinc(const char * s) { return (char *)(s+1); }
```

Description

_mbsinc increments a string pointer by one byte.

_strdec is the single-byte version of this function.

_wcsdec is the wide-character version of this function.

Return Value

Returns a pointer that is forwarded by 1 byte.

3.1.4.30.18 _strnextc,_mbsnextc,_wcsnextc

Header File

tchar.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
unsigned int _strnextc(const char *str);
```

```
unsigned int _mbsnextc (const unsigned char *str);
```

Description

These routines should be accessed by using the portable _tcsnextc function. The functions inspect the current character in str. The pointer to str is not advanced.

Return Value

The functions return the integer value of the character pointed to by str.

Example

```
#include <tchar.h>
#include <stdio.h>
int main()
{
   unsigned int retval = 0;
   const unsigned char *string = "ABC";
   retval = _strnextc(string);
   printf("The starting character:%c", retval);
   retval = _strnextc(++string);
   printf("\nThe next character:%c", retval);
   return 0;
}
/***
The starting character:A
The next character:B
***/
```

3.1.4.30.19 stpcpy, _wstpcpy, _stpcpy

Header File

string.h

Category

Memory and String Manipulation Routines

Prototype

```
char *stpcpy(char *dest, const char *src);
```

```
wchar * _wcspcpy(wchar *dest, const wchar *src);
```

Description

Copies one string into another.

_stpcpy copies the string src to dest, stopping after the terminating null character of src has been reached.

Return Value

stpcpy returns a pointer to the terminating null character of dest.

If UNICODE is defined, _wcspcpy returns a pointer to the terminating null character of the **wchar_t** dest string.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char string[10];
   char *str1 = "abcdefghi";
   stpcpy(string, str1);
   printf("%s\n", string);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_stpcpy		+		
_wcspcpy		+		

3.1.4.30.20 strcat, _mbscat, wcscat

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
char *strcat(char *dest, const char *src);
wchar_t *wcscat(wchar_t *dest, const wchar_t *src);
unsigned char *_mbscat(unsigned char *dest, const unsigned char *src);
```

Description

Appends one string to another.

strcat appends a copy of src to the end of dest. The length of the resulting string is strlen(dest) + strlen(src).

Return Value

strcat returns a pointer to the concatenated strings.

Example

```
#include <string.h>
#include <stdio.h>
```

```
int main(void)
{
   char destination[25];
   char *blank = " ", *c = "C++", *CodeGear = "CodeGear";
   strcpy(destination, CodeGear);
   strcat(destination, blank);
   strcat(destination, c);
   printf("%s\n", destination);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strcat	+	+	+	+
_mbscat		+		
wcscat		+	+	+

3.1.4.30.21 strchr, _mbschr, wcschr

Header File

string.h

Category

Memory and String Manipulation Routines, Inline Routines, C++ Prototyped Routines

Prototype

```
char *strchr(const char *s, int c);/* C only */
```

```
const char *strchr(const char *s, int c);// C++ only
```

```
char *strchr( char *s, int c);// C++ only
```

```
wchar_t *wcschr(const wchar_t *s, int c);
```

```
unsigned char * _mbschr(const unsigned char *s, unsigned int c);
```

Description

Scans a string for the first occurrence of a given character.

strchr scans a string in the forward direction, looking for a specific character. strchr finds the first occurrence of the character c in the string s. The null-terminator is considered to be part of the string.

For example:

```
strchr(strs,0)
```

returns a pointer to the terminating null character of the string strs.

Return Value

strchr returns a pointer to the first occurrence of the character c in s; if c does not occur in s, strchr returns null.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   char string[15];
```

```
    char *ptr, c = 'r';
    strcpy(string, "This is a string");
    ptr = strchr(string, c);
    if (ptr)
       printf("The character %c is at position: %d\n", c, ptr-string);
    else
       printf("The character was not found\n");
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strchr	+	+	+	+
_mbschr		+		
wcschr		+	+	+

3.1.4.30.22 strcmp, _mbscmp, wcscmp

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
int strcmp(const char *s1, const char *s2);
```

```
int wcscmp(const wchar_t *s1, const wchar_t *s2);
```

```
int _mbscmp(const unsigned char *s1, const unsigned char *s2);
```

Description

Compares one string to another.

strcmp performs an unsigned comparison of s1 to s2, starting with the first character in each string and continuing with subsequent characters until the corresponding characters differ or until the end of the strings is reached.

Return Value

less than s2	< 0
the same as s2	== 0
greater than s2	> 0

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
char *buf1 = "aaa", *buf2 = "bbb", *buf3 = "ccc";
int ptr;
ptr = strcmp(buf2, buf1);
if (ptr > 0)
      printf("buffer 2 is greater than buffer 1\n");
   else
      printf("buffer 2 is less than buffer 1\n");
```

```
   ptr = strcmp(buf2, buf3);
   if (ptr > 0)
      printf("buffer 2 is greater than buffer 3\n");
   else
      printf("buffer 2 is less than buffer 3\n");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strcmp	+	+	+	+
_mbscmp		+		
wcscmp		+	+	+

3.1.4.30.23 strcmpi

Header File

string.h, wchar.h

Category

Memory and String Manipulation Routines

Prototype

```
int strcmpi(const char *s1, const char *s2);
```

```
int _wcscmpi(const wchar_t *s1, const wchar_t *s2);
```

Description

Compares one string to another, without case sensitivity.

strcmpi performs an unsigned comparison of s1 to s2, without case sensitivity (same as stricmp--implemented as a macro).

It returns a value (< 0, 0, or > 0) based on the result of comparing s1 (or part of it) to s2 (or part of it).

The routine strcmpi is the same as stricmp. strcmpi is implemented through a macro in string.h and translates calls from strcmpi to stricmp. Therefore, in order to use strcmpi, you must include the header file string.h for the macro to be available. This macro is provided for compatibility with other C compilers.

Return Value

less than s2	< 0
the same as s2	== 0
greater than s2	> 0

Example

```
/* strncmpi example */
#include <string.h>
#include <stdio.h>
int main(void)
{
   char *buf1 = "BBB", *buf2 = "bbb";
   int ptr;
   ptr = strcmpi(buf2, buf1);
   if (ptr > 0)
```

```
      printf("buffer 2 is greater than buffer 1\n");
   if (ptr < 0)
      printf("buffer 2 is less than buffer 1\n");
   if (ptr == 0)
      printf("buffer 2 equals buffer 1\n");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strcmpi		+		
_wcscmpi		+		

3.1.4.30.24 strcoll,_stricoll, _mbscoll, _mbsicoll, wcscoll, _wcsicoll

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
int strcoll(const char *s1, const char *s2);
int wcscoll(const wchar_t *s1, const wchar_t *s2);
int _stricoll(const char *s1, const char *s2);
int _wcsicoll(const wchar_t *s1, wconst_t char *s2);
int _mbscoll(const unsigned char *s1, const unsigned char *s2);
int _mbsicoll(const unsigned char *s1, const unsigned char *s2);
```

Description

Compares two strings.

strcoll compares the string pointed to by s1 to the string pointed to by s2, according to the current locale's LC_COLLATE category.

_stricoll performs like strcoll but is not case sensitive.

Note: Note

_stricoll does not compare string according to the current locale's LC_COLLATE category. _stricoll gives you a stricmp. The required collation is obtained by calling _lstricoll, or just plain stricoll (which maps to _lstricoll).

The real collation (_lstricoll) returns -1, 0 or 1, whereas _stricoll does a codepoint comparison, and returns < 0, 0 or > 0.

Return Value

less than s2	< 0
the same as s2	== 0
greater than s2	> 0

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *two = "International";
   char *one = "Borland";
   int check;
   check = strcoll(one, two);
   if (check == 0)
      printf("The strings are equal\n");
   if (check <  0)
      printf("%s comes before %s\n", one, two);
   if (check >  0)
      printf("%s comes before %s\n", two, one);
   return 0;
}
```

Portability

3.1.4.30.25 strcpy

Header File

string.h, wchar.h, mbstring.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
char *strcpy(char *dest, const char *src);
```

```
wchar_t *wcscpy(wchar_t *dest, const wchar_t *src);
```

```
unsigned char *_mbscpy(unsigned char *dest, const unsigned char *src);
```

Description

Copies one string into another.

Copies string src to dest, stopping after the terminating null character has been moved.

Return Value

strcpy returns dest.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
```

```
    char string[10];
    char *str1 = "abcdefghi";
    strcpy(string, str1);
    printf("%s\n", string);
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++

_mbscpy		+		
wcscpy		+	+	+

3.1.4.30.26 strcspn, _mbscspn, wcscspn

Header File

string.h, wchar.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
size_t strcspn(const char *s1, const char *s2);
```

```
size_t wcscspn(const wchar_t *s1, const wchar_t *s2);
```

```
size_t _mbscspn(const unsigned char *s1, const unsigned char *s2);
```

Description

Scans a string for the initial segment not containing any subset of a given set of characters.

The strcspn functions search s1 until any one of the characters contained in s2 is found. The number of characters which were read in s1 is the return value. The string termination character is not counted. Neither string is altered during the search.

Return Value

strcspn returns the length of the initial segment of string s1 that consists entirely of characters not from string s2.

Example

```
#include <stdio.h>
#include <string.h>
#include <alloc.h>
int main(void)
{
    char *string1 = "1234567890";
    char *string2 = "747DC8";
    int length;
    length = strcspn(string1, string2);
    printf("Character where strings intersect is at position %d\n",
           length);
    return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strcspn	+	+	+	+
_mbscspn		+		
wcscspn		+	+	+

3.1.4.30.27 strdup, _mbsdup, _wcsdup

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
char *strdup(const char *s);
```

```
wchar_t *_wcsdup(const wchar_t *s);
```

```
unsigned char *_mbsdup(const wchar_t *s);
```

Description

Copies a string into a newly created location.

strdup makes a duplicate of string s, obtaining space with a call to malloc. The allocated space is (strlen(s) + 1) bytes long. The user is responsible for freeing the space allocated by strdup when it is no longer needed.

Return Value

strdup returns a pointer to the storage location containing the duplicated string, or returns null if space could not be allocated.

Example

```
#include <stdio.h>
#include <string.h>
#include <alloc.h>
int main(void)
{
   char *dup_str, *string = "abcde";
   dup_str = strdup(string);
   printf("%s\n", dup_str);
   free(dup_str);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strdup		+		
_mbsdup		+		
_wcsdup		+		

3.1.4.30.28 strerror

Header File

string.h

Category

Memory and String Manipulation Routines

Prototype

```
char *strerror(int errnum);
```

Description

Returns a pointer to an error message string.

strerror takes an **int** parameter errnum, an error number, and returns a pointer to an error message string associated with errnum.

Return Value

strerror returns a pointer to a constructed error string. The error message string is constructed in a static buffer that is overwritten with each call to strerror.

Example

```
#include <stdio.h>
#include <errno.h>
int main(void)
{
  char *buffer;
  buffer = strerror(errno);
  printf("Error: %s\n", buffer);
  return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.30.29 stricmp, _mbsicmp, _wcsicmp

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
int stricmp(const char *s1, const char *s2);
```

```
int _wcsicmp(const wchar_t *s1, const wchar_t *s2);
```

```
int _mbsicmp(const unsigned char *s1, const unsigned char *s2);
```

Description

Compares one string to another, without case sensitivity.

stricmp performs an unsigned comparison of s1 to s2, starting with the first character in each string and continuing with subsequent characters until the corresponding characters differ or until the end of the strings is reached. The comparison is not case sensitive.

It returns a value (< 0, 0, or > 0) based on the result of comparing s1 (or part of it) to s2 (or part of it).

The routines stricmp and strcmpi are the same; strcmpi is implemented through a macro in string.h that translates calls from strcmpi to stricmp. Therefore, in order to use stricmp, you must include the header file string.h for the macro to be available.

Return Value

less than s2	< 0
the same as s2	== 0
greater than s2	> 0

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   char *buf1 = "BBB", *buf2 = "bbb";
   int ptr;
   ptr = stricmp(buf2, buf1);
   if (ptr > 0)
      printf("buffer 2 is greater than buffer 1\n");
   if (ptr < 0)
      printf("buffer 2 is less than buffer 1\n");
   if (ptr == 0)
      printf("buffer 2 equals buffer 1\n");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
stricmp		+	+	+
_mbsicmp		+		
_wcsicmp		+		

3.1.4.30.30 strlwr, _mbslwr, _wcslwr

Header File

string.h, mbstring.h

Category

Conversion Routines, Memory and String Manipulation Routines

Prototype

```
char *strlwr(char *s);
```

```
wchar_t *_wcslwr(wchar_t *s);
```

```
unsigned char *_mbslwr(unsigned char *s);
```

Description

Converts uppercase letters in a string to lowercase.

strlwr converts uppercase letters in string s to lowercase according to the current locale's LC_CTYPE category. For the C locale, the conversion is from uppercase letters (A to Z) to lowercase letters (a to z). No other characters are changed.

Return Value

strlwr returns a pointer to the string s.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *string = "CodeGear";
   printf("string prior to strlwr: %s\n", string);
   strlwr(string);
   printf("string after strlwr:    %s\n", string);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strlwr		+		
_mbslwr		+		
_wcslwr		+		

3.1.4.30.31 strncat

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
char *strncat(char *dest, const char *src, size_t maxlen);
wchar_t *wcsncat(wchar_t *dest, const wchar_t *src, size_t maxlen);
unsigned char *_mbsncat(unsigned char *dest, const unsigned char *src, size_t maxlen);
unsigned char *_mbsnbcat(unsigned char *__dest, const unsigned char *__src, _SIZE_T __maxlen);
```

Description

Appends a portion of one string to another.

strncat copies at most maxlen characters of src to the end of dest and then appends a null character. The maximum length of the resulting string is strlen(dest) + maxlen.

For _mbsnbcat, if the second byte of 2-bytes character is null, the first byte of this character is regarded as null.

These four functions behave identically and differ only with respect to the type of arguments and return types.

Return Value

strncat returns dest.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   char destination[25];
   char *source = " States";
   strcpy(destination, "United");
   strncat(destination, source, 7);
   printf("%s\n", destination);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strncat	+	+	+	+
_mbsncat		+		
_mbsnbcat		+		
_wcsncat		+		

3.1.4.30.32 strncmp, _mbsncmp, wcsncmp

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
int strncmp(const char *s1, const char *s2, size_t maxlen);
int wcsncmp(const wchar_t *s1, const wchar_t *s2, size_t maxlen);
int _mbsncmp(const unsigned char *s1, const unsigned char *s2, size_t maxlen);
#define _mbccmp(__s1, __s2) _mbsncmp((__s1),(__s2),1)
```

Description

Compares a portion of one string to a portion of another.

strncmp makes the same unsigned comparison as strcmp, but looks at no more than maxlen characters. It starts with the first character in each string and continues with subsequent characters until the corresponding characters differ or until it has examined maxlen characters.

Return Value

- strncmp returns an int value based on the result of comparing s1 (or part of it) to s2 (or part of it):
- < 0 if s1 is less than s2
- == 0 if s1 is the same as s2
- > 0 if s1 is greater than s2

Example

```
#include <string.h>
#include <stdio.h>
int  main(void)
{
   char *buf1 = "aaabbb", *buf2 = "bbbccc", *buf3 = "ccc";
   int ptr;
   ptr = strncmp(buf2,buf1,3);
   if (ptr > 0)
      printf("buffer 2 is greater than buffer 1\n");
   else
      printf("buffer 2 is less than buffer 1\n");
   ptr = strncmp(buf2,buf3,3);
   if (ptr > 0)
      printf("buffer 2 is greater than buffer 3\n");
   else
      printf("buffer 2 is less than buffer 3\n");
   return(0);
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strncmp	+	+	+	+
_mbsncmp		+		
_mbccmp		+		
wcsncmp		+	+	+

3.1.4.30.33 strncmpi, wcsncmpi

Header File

string.h

Category

Memory and String Manipulation Routines

Prototype

```
int strncmpi(const char *s1, const char *s2, size_t n);

int wcsncmpi(const wchar_t *s1, const wchar_t *s2, size_t n);
```

Description

Compares a portion of one string to a portion of another, without case sensitivity.

strncmpi performs a signed comparison of s1 to s2, for a maximum length of n bytes, starting with the first character in each string and continuing with subsequent characters until the corresponding characters differ or until n characters have been examined. The comparison is not case sensitive. (strncmpi is the same as strnicmp--implemented as a macro). It returns a value (< 0, 0, or > 0) based on the result of comparing s1 (or part of it) to s2 (or part of it).

The routines strnicmp and strncmpi are the same; strncmpi is implemented through a macro in string.h that translates calls from strncmpi to strnicmp. Therefore, in order to use strncmpi, you must include the header file string.h for the macro to be available. This macro is provided for compatibility with other C compilers.

Return Value

less than s2	< 0
the same as s2	== 0
greater than s2	> 0

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   char *buf1 = "BBBccc", *buf2 = "bbbccc";
   int ptr;
   ptr = strncmpi(buf2,buf1,3);
   if (ptr > 0)
      printf("buffer 2 is greater than buffer 1\n");
   if (ptr < 0)
      printf("buffer 2 is less than buffer 1\n");
   if (ptr == 0)
      printf("buffer 2 equals buffer 1\n");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strncmpi		+		
wcsncmpi		+		

3.1.4.30.34 strncoll, strnicoll, _mbsncoll, _mbsnicoll, _wcsncoll, _wcsnicoll

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
int _strncoll(const char *s1, const char *s2, size_t n);
int _wcsncoll(const wchar_t *s1, const wchar_t *s2, size_t n);
int _strnicoll(const char *s1, const char *s2, size_t n);
int _wcsnicoll(const wchar_t *s1, const wchar_t *s2, size_t n);
int _mbsncoll(const unsigned char *s1, const unsigned char *s2, size_t n);
int _mbsnicoll(const unsigned char *s1, const unsigned char *s2, size_t n);
```

Description

_strncoll compares n number of elements from the string pointed to by s1 to the string pointed to by s2, according to the current locale's LC_COLLATE category.

_strnicoll performs like _strncoll but is not case sensitive.

Return Value

less than s2	< 0
the same as s2	== 0
greater than s2	> 0

3.1.4.30.35 strncpy, _mbsncpy, wcsncpy

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
char *strncpy(char *dest, const char *src, size_t maxlen);
wchar_t *wcsncpy(wchar_t *dest, const wchar_t *src, size_t maxlen);
unsigned char *_mbsncpy(unsigned char *dest, const unsigned char *src, size_t maxlen);
```

Description

Copies a given number of bytes from one string into another, truncating or padding as necessary.

strncpy copies up to maxlen characters from src into dest, truncating or null-padding dest. The target string, dest, might not be null-terminated if the length of src is maxlen or more.

Return Value

strncpy returns dest.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char string[10];
   char *str1 = "abcdefghi";
   strncpy(string, str1, 3);
   string[3] = '\0';
   printf("%s\n", string);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strncpy	+	+	+	+
_mbsncpy		+		
wcsncpy		+	+	+

3.1.4.30.36 strnicmp, _mbsnicmp, _wcsnicmp

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
int strnicmp(const char *s1, const char *s2, size_t maxlen);
int _wcsnicmp(const wchar_t *s1, const wchar_t *s2, size_t maxlen);
int _mbsnicmp(const unsigned char *s1, const unsigned char *s2, size_t maxlen);
```

Description

Compares a portion of one string to a portion of another, without case sensitivity.

strnicmp performs a signed comparison of s1 to s2, for a maximum length of maxlen bytes, starting with the first character in each string and continuing with subsequent characters until the corresponding characters differ or until the end of the strings is reached. The comparison is not case sensitive.

It returns a value (< 0, 0, or > 0) based on the result of comparing s1 (or part of it) to s2 (or part of it).

Return Value

less than s2	< 0
the same as s2	== 0
greater than s2	> 0

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   char *buf1 = "BBBccc", *buf2 = "bbbccc";
   int ptr;
   ptr = strnicmp(buf2, buf1, 3);
   if (ptr > 0)
      printf("buffer 2 is greater than buffer 1\n");
   if (ptr < 0)
      printf("buffer 2 is less than buffer 1\n");
   if (ptr == 0)
      printf("buffer 2 equals buffer 1\n");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strnicmp		+		
_mbsnicmp		+		
_wcsnicmp		+		

3.1.4.30.37 strnset, _mbsnset, _wcsnset

Header File

string.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
char *strnset(char *s, int ch, size_t n);
wchar_t *_wcsnset(wchar_t *s, wchar_t ch, size_t n);
unsigned char *_mbsnset(unsigned char *s, unsigned int ch, size_t n);
```

Description

Sets a specified number of characters in a string to a given character.

strnset copies the character ch into the first n bytes of the string s. If n > strlen(s), then strlen(s) replaces n. It stops when n characters have been set, or when a null character is found.

Return Value

Each of these functions return s.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *string = "abcdefghijklmnopqrstuvwxyz";
   char letter = 'x';
   printf("string before strnset: %s\n", string);
   strnset(string, letter, 13);
   printf("string after  strnset: %s\n", string);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strnset		+		
_mbsnset		+		
_wcsnset		+		

3.1.4.30.38 strpbrk, _mbspbrk, wcspbrk

Header File

string.h, mbstring.h

Category

C++ Prototyped Routines, Memory and String Manipulation Routines

Prototype

```
char *strpbrk(const char *s1, const char *s2); /* C only */
const char *strpbrk(const char *s1, const char *s2); // C++ only
char *strpbrk(char *s1, const char *s2); // C++ only
wchar_t * wcspbrk(const wchar_t *s1, const wchar_t *s2);
```

```
unsigned char *_mbspbrk(const unsigned char *s1, const unsigned char *s2);
```

Description

Scans a string for the first occurrence of any character from a given set.

strpbrk scans a string, s1, for the first occurrence of any character appearing in s2.

Return Value

strpbrk returns a pointer to the first occurrence of any of the characters in s2. If none of the s2 characters occur in s1, strpbrk returns null.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *string1 = "abcdefghijklmnopqrstuvwxyz";
   char *string2 = "onm";
   char *ptr;
   ptr = strpbrk(string1, string2);
   if (ptr)
      printf("strpbrk found first character: %c\n", *ptr);
   else
      printf("strpbrk didn't find character in set\n");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strpbrk	+	+	+	+
_mbspbrk		+		
wcspbrk		+	+	+

3.1.4.30.39 strrchr, _mbsrchr, wcsrchr

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines, Inline Routines, C++ Prototyped Routines

Prototype

```
char *strrchr(const char *s, int c); /* C only */
const char *strrchr(const char *s, int c); // C++ only
char *strrchr(char *s, int c); // C++ only
wchar_t *wcsrchr(const wchar_t *s, wchar_t c);
unsigned char * _mbsrchr(const unsigned char *s, unsigned int c);
```

Description

Scans a string for the last occurrence of a given character.

strrchr scans a string in the reverse direction, looking for a specific character. strrchr finds the last occurrence of the character c

in the string s. The null-terminator is considered to be part of the string.

Return Value

strrchr returns a pointer to the last occurrence of the character c. If c does not occur in s, strrchr returns null.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   char string[15];
   char *ptr, c = 'r';
   strcpy(string, "This is a string");
   ptr = strrchr(string, c);
   if (ptr)
      printf("The character %c is at position: %d\n", c, ptr-string);
   else
      printf("The character was not found\n");
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strrchr	+	+	+	+
_mbsrchr		+		
wcsrchr		+	+	+

3.1.4.30.40 strrev, _mbsrev, _wcsrev

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
char *strrev(char *s);
```

```
wchar_t *_wcsrev(wchar_t *s);
```

```
unsigned char *_mbsrev(unsigned char *s);
```

Description

Reverses a string.

strrev changes all characters in a string to reverse order, except the terminating null character. (For example, it would change string\0 to gnirts\0.)

Return Value

strrev returns a pointer to the reversed string.

Example

```
#include <string.h>
#include <stdio.h>
```

```
int main(void)
{
   char *forward = "string";
   printf("Before strrev(): %s\n", forward);
   strrev(forward);
   printf("After strrev():  %s\n", forward);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strrev		+		
_mbsrev		+		
_wcsrev		+		

3.1.4.30.41 strset, _mbsset, _wcsset

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines, Inline Routines

Prototype

```
char *strset(char *s, int ch);
```

```
wchar_t *_wcsset(wchar_t *s, wchar_t ch);
```

```
unsigned char *_mbsset(unsigned char *s, unsigned int ch);
```

Description

Sets all characters in a string to a given character.

strset sets all characters in the string s to the character ch. It quits when the terminating null character is found.

Return Value

strset returns s.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char string[10] = "123456789";
   char symbol = 'c';
   printf("Before strset(): %s\n", string);
   strset(string, symbol);
   printf("After strset():  %s\n", string);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strset		+		

_mbsset		+		
_wcsset		+		

3.1.4.30.42 strspn, _mbsspn, wcsspn

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
size_t strspn(const char *s1, const char *s2);
size_t wcsspn(const wchar_t *s1, const wchar_t *s2);
size_t _mbsspn(const unsigned char *s1, const unsigned char *s2);
```

Description

Scans a string for the first segment that is a subset of a given set of characters.

strspn finds the initial segment of string s1 that consists entirely of characters from string s2.

Return Value

strspn returns the length of the initial segment of s1 that consists entirely of characters from s2.

Example

```
#include <stdio.h>
#include <string.h>
#include <alloc.h>
int main(void)
{
   char *string1 = "1234567890";
   char *string2 = "123DC8";
   int length;
   length = strspn(string1, string2);
   printf("Character where strings differ is at position %d\n", length);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strspn	+	+	+	+
_mbsspn		+		
wcsspn		+	+	+

3.1.4.30.43 strstr, _mbsstr, wcsstr

Header File

string.h

Category

C++ Prototyped Routines, Memory and String Manipulation Routines

Prototype

```
char *strstr(const char *s1, const char *s2); /* C only */
const char *strstr(const char *s1, const char *s2); // C++ only
char *strstr(char *s1, const char *s2); // C++ only
wchar_t * wcsstr(const wchar_t *s1, const wchar_t *s2);
unsigned char * _mbsstr(const unsigned char *s1, const unsigned char *s2);
```

Description

Scans a string for the occurrence of a given substring.

strstr scans s1 for the first occurrence of the substring s2.

Return Value

strstr returns a pointer to the element in s1, where s2 begins (points to s2 in s1). If s2 does not occur in s1, strstr returns null.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *str1 = "CodeGear", *str2 = "nation", *ptr;
   ptr = strstr(str1, str2);
   printf("The substring is: %s\n", ptr);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strstr	+	+	+	+
_mbsstr		+		
wcsstr		+	+	+

3.1.4.30.44 strtok, _mbstok, wcstok

Header File

string.h, mbstring.h

Category

Memory and String Manipulation Routines

Prototype

```
char *strtok(char *s1, const char *s2);
wchar_t *wcstok(wchar_t *s1, const wchar_t *s2);
unsigned char *_mbstok(unsigned char *s1, const unsigned char *s2);
```

Description

Searches one string for tokens, which are separated by delimiters defined in a second string.

strtok considers the string s1 to consist of a sequence of zero or more text tokens, separated by spans of one or more characters from the separator string s2.

The first call to strtok returns a pointer to the first character of the first token in s1 and writes a null character into s1 immediately following the returned token. Subsequent calls with null for the first argument will work through the string s1 in this way, until no tokens remain.

The separator string, s2, can be different from call to call.

Note: Calls to strtok cannot be nested with a function call that also uses strtok. Doing so will causes an endless loop.

Return Value

strtok returns a pointer to the token found in s1. A NULL pointer is returned when there are no more tokens.

Example

```
#include <string.h>
#include <stdio.h>
int main(void)
{
   char input[16] = "abc,d";
   char *p;
   /* strtok places a NULL terminator
   in front of the token, if found */
   p = strtok(input, ",");
   if (p)   printf("%s\n", p);
   /* A second call to strtok using a NULL
   as the first parameter returns a pointer
   to the character following the token  */
   p = strtok(NULL, ",");
   if (p)   printf("%s\n", p);
   return 0;
}

3.1.4.30.45 strupr, _mbsupr, _wcsupr

Header File

string.h, mbstring.h

Category

Conversion Routines, Memory and String Manipulation Routines

Prototype

```
char *strupr(char *s);

wchar_t *_wcsupr(wchar_t *s);

unsigned char *_mbsupr(unsigned char *s);
```

Description

Converts lowercase letters in a string to uppercase.

strupr converts lowercase letters in string s to uppercase according to the current locale's LC_CTYPE category. For the default C locale, the conversion is from lowercase letters (a to z) to uppercase letters (A to Z). No other characters are changed.

Return Value

strupr returns s.

Example

```
#include <stdio.h>
#include <string.h>
int main(void)
{
   char *string = "abcdefghijklmnopqrstuvwxyz", *ptr;
   /* converts string to upper case characters */
   ptr = strupr(string);
   printf("%s\n", ptr);
   return 0;
}
```

3.1.4.30.46 strxfrm, wcsxfrm

Header File

string.h

Category

Memory and String Manipulation Routines

Prototype

```
size_t strxfrm(char *target, const char *source, size_t n);
```

```
size_t wcsxfrm(wchar_t *target, const wchar_t *source, size_t n);
```

Description

Transforms a portion of a string to a specified collation.

strxfrm transforms the string pointed to by source into the string target for no more than n characters. The transformation is such that if the strcmp function is applied to the resulting strings, its return corresponds with the return values of the strcoll function.

No more than n characters, including the terminating null character, are copied to target.

strxfrm transforms a character string into a special string according to the current locale's LC_COLLATE category. The special string that is built can be compared with another of the same type, byte for byte, to achieve a locale-correct collation result. These special strings, which can be thought of as keys or tokenized strings, are not compatible across the different locales.

The tokens in the tokenized strings are built from the collation weights used by strcoll from the active locale's collation tables.

Processing stops only after all levels have been processed for the character string or the length of the tokenized string is equal to the maxlen parameter.

All redundant tokens are removed from each level's set of tokens.

The tokenized string buffer must be large enough to contain the resulting tokenized string. The length of this buffer depends on the size of the character string, the number of collation levels, the rules for each level and whether there are any special characters in the character string. Certain special characters can cause extra character processing of the string resulting in more space requirements. For example, the French character "oe" will take double the space for itself because in some locales, it expands to collation weights for each level. Substrings that have substitutions will also cause extra space requirements.

There is no safe formula to determine the required string buffer size, but at least (levels * string length) are required.

Return Value

Number of characters copied not including the terminating null character. If the value returned is greater than or equal to n, the content of target is indeterminate.

Example

```
#include <stdio.h>
#include <string.h>
#include <alloc.h>
int main(void)
{
   char *target;
   char *source = "Frank Borland";
   int length;
   /* allocate space for the target string */
   target = (char *) calloc(80, sizeof(char));
   /* copy the source over to the target and get the length */
   length = strxfrm(target, source, 80);
   /* print out the results */
   printf("%s has the length %d\n", target, length);
   return 0;
}
```

	Prototype
	`int fstat(int handle, struct stat *statbuf);`
	`int stat(const char *path, struct stat *statbuf);`
	`int _wstat(const wchar_t *path, struct stat *statbuf);`
	Description
	Gets open file information.
	fstat stores information in the stat structure about the file or directory associated with handle.
	stat stores information about a given file or directory in the stat structure. The name of the file is path.
	statbuf points to the stat structure (defined in sys\stat.h). That structure contains the following fields:

3.1.4.31.1 S_Ixxxx #defines

Header File

sys\stat.h

Description

Definitions used for file status and directory functions.

Name	Meaning
S_IFMT	File type mask
S_IFDIR	Directory
S_IFIFO	FIFO special
S_IFCHR	Character special
S_IFBLK	Block special
S_IFREG	Regular file

S_IREAD	Owner can read
S_IWRITE	Owner can write
S_IEXEC	Owner can execute

3.1.4.31.2 _stati64, _tstati64, stati64, _wstati64

Header File

sys\stat.h, tchar.h

Category

Directory Control Routines

Prototype

```
int stati64(const char *pathname, struct stati64 *buff);
int _stati64(const char *__path, struct stati64 *__statbuf);
int _wstati64(const wchar_t *pathname, struct stati64 *buff);
// From tchar.h
#define _tstati64 _stati64
```

Description

Gather statistics about the file named by *pathP and place them in the buffer *bufP.

The statistics fields are set thus:

st_devset to -1 if S_IFCHR, else set to drive holding the file.

st_ino0

st_modeUnix-style bit-set for file access rights

st_nlink1

st_uid0

st_gid0

st_rdevsame as st_dev

st_sizefile size (0 if S_IFDIR or S_IFCHR)

st_atimetime file last changed (seconds since 1970)

st_mtimesame as st_atime

st_ctimesame as st_atime

The file access rights bit-set may contain S_IFCHR, S_IFDIR, S_IFREG, S_IREAD, S_IWRITE, or S_IEXEC.

If the name is for a device, the time fields will be zero and the size field is undefined.

Return Value

The return value is 0 if the call was successful, otherwise -1 is returned and errno contains the reason. The buffer is not touched unless the call is successful.

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.31.3 fstat, stat, _wstat

Header File

sys\stat.h

Category

Input/output Routines

Prototype

```
int fstat(int handle, struct stat *statbuf);
int stat(const char *path, struct stat *statbuf);
int _wstat(const wchar_t *path, struct stat *statbuf);
```

Description

Gets open file information.

fstat stores information in the stat structure about the file or directory associated with handle.

stat stores information about a given file or directory in the stat structure. The name of the file is path.

statbuf points to the stat structure (defined in sys\stat.h). That structure contains the following fields:

st_mode	Bit mask giving information about the file's mode
st_dev	Drive number of disk containing the file or file handle if the file is on a device
st_rdev	Same as st_dev
st_nlink	Set to the integer constant 1
st_size	Size of the file in bytes
st_atime	Most recent access (Windows) or last time modified (DOS)
st_mtime	Same as st_atime
st_ctime	Same as st_atime

The stat structure contains three more fields not mentioned here. They contain values that are meaningful only in UNIX.

The st_mode bit mask that gives information about the mode of the open file includes the following bits:

One of the following bits will be set:

S_IFCHR	If handle refers to a device.
S_IFREG	If an ordinary file is referred to by handle.

One or both of the following bits will be set:

S_IWRITE	If user has permission to write to file.
S_IREAD	If user has permission to read to file.

The HPFS and NTFS file-management systems make the following distinctions:

st_atime	Most recent access
st_mtime	Most recent modify
st_ctime	Creation time

Return Value

fstat and stat return 0 if they successfully retrieved the information about the open file.

On error (failure to get the information) these functions return -1 and set the global variable errno to

EBADF	Bad file handle

Example

```
#include <sys\stat.h>
#include <stdio.h>
#include <time.h>
int main(void)
{
   struct stat statbuf;
   FILE *stream;
   /* open a file for update */
   if ((stream = fopen("DUMMY.FIL", "w+"))
       == NULL)
   {
      fprintf(stderr, "Cannot open output file.\n");
      return(1);
   }
   fprintf(stream, "This is a test");
   fflush(stream);
   /* get information about the file */
   fstat(fileno(stream), &statbuf);
   fclose(stream);
   /* display the information returned */
   if (statbuf.st_mode & S_IFCHR)
      printf("Handle refers to a device.\n");
   if (statbuf.st_mode & S_IFREG)
      printf("Handle refers to an ordinary file.\n");
   if (statbuf.st_mode & S_IREAD)
      printf("User has read permission on file.\n");
   if (statbuf.st_mode & S_IWRITE)
      printf("User has write permission on file.\n");
   printf("Drive letter of file: %c\n", 'A'+statbuf.st_dev);
   printf("Size of file in bytes: %ld\n", statbuf.st_size);
   printf("Time file last opened: %s\n", ctime(&statbuf.st_ctime));
   return 0;
}
```

3.1.4.32 sys\timeb.h

The following functions, macros, and classes are provided in `sys\timeb.h`:

Topics

Name	Description

ftime (see page 1191)	**Header File**
	sys\timeb.h
	Category
	Time and Date Routines
	Prototype
	`void ftime(struct timeb *buf)`
	Description
	Stores current time in timeb structure.
	On UNIX platforms ftime is available only on System V systems.
	ftime determines the current time and fills in the fields in the timeb structure pointed to by buf. The timeb structure contains four fields: time, millitm, _timezone, and dstflag:
	`struct timeb {`
	`long time ;`
	`short millitm ;`
	`short _timezone ;`
	`short dstflag ;`
	`};`
	• timeprovides the time in seconds since 00:00:00 Greenwich mean time (GMT) January 1 1970.
	• millitmis the fractional part of a second in milliseconds.... more (see page 1191)

3.1.4.32.1 ftime

Header File

sys\timeb.h

Category

Time and Date Routines

Prototype

```
void ftime(struct timeb *buf)
```

Description

Stores current time in timeb structure.

On UNIX platforms ftime is available only on System V systems.

ftime determines the current time and fills in the fields in the timeb structure pointed to by buf. The timeb structure contains four fields: time, millitm, _timezone, and dstflag:

```
struct timeb {
long time ;
short millitm ;
short _timezone ;
short dstflag ;
};
```

- timeprovides the time in seconds since 00:00:00 Greenwich mean time (GMT) January 1 1970.
- millitmis the fractional part of a second in milliseconds.

- _timezoneis the difference in minutes between GMT and the local time. This value is computed going west from GMT. ftime gets this field from the global variable _timezone which is set by tzset.
- dstflagis set to nonzero if daylight saving time is taken into account during time calculations.

  Note: ftime calls tzset. Therefore it isn't necessary to call tzset explicitly when you use ftime.

  Return Value

  None.

  Example

```
#include <stdio.h>
#include <stdlib.h>
#include <time.h>
#include <sys\timeb.h>
/* pacific standard & daylight savings */
char *tzstr = "TZ=PST8PDT";
int main(void)
{
   struct timeb t;
   putenv(tzstr);
   tzset();
   ftime(&t);
   printf("Seconds since 1/1/1970 GMT: %ld\n", t.time);
   printf("Thousandths of a second: %d\n", t.millitm);
   printf("Difference between local time and GMT: %d\n", t._timezone);
   printf("Daylight savings in effect (1) not (0): %d\n", t.dstflag);
   return 0;
}
```

3.1.4.33 sys\types.h

The following functions, macros, and classes are provided in `sys\types.h`:

Topics

Name	Description
time_t (see page 1192)	**Header File** sys\types.h time.h **Syntax** `typedef long time_t;` **Description** Defines the value used by the time functions declared in time.h.

3.1.4.33.1 time_t

Header File

sys\types.h

time.h

Syntax

```
typedef long time_t;
```

Description

Defines the value used by the time functions declared in time.h.

3.1.4.34 time.h

The following functions, macros, and classes are provided in `time.h`:

Topics

Name	Description

_strdate, _wstrdate (see page 1197)	**Header File**
	time.h
	Category
	Conversion Routines, Time and Date Routines
	Prototype
	`char *_strdate(char *buf);`
	`wchar_t *_wstrdate(wchar_t *buf);`
	Description
	Converts current date to string.
	_strdate converts the current date to a string, storing the string in the buffer buf. The buffer must be at least 9 characters long.
	The string has the form MM/DD/YY where MM, DD, and YY are all two-digit numbers representing the month, day, and year. The string is terminated by a null character.
	Return Value
	_strdate returns buf, the address of the date string.
	Example

_strtime, _wstrtime (see page 1198)	**Header File**
	time.h
	Category
	Time and Date Routines
	Prototype
	`char *_strtime(char *buf);`
	`wchar_t *_wstrtime(wchar_t *buf);`
	Description
	Converts current time to string.
	_strtime converts the current time to a string, storing the string in the buffer buf. The buffer must be at least 9 characters long.
	The string has the following form:
	`HH:MM:SS`
	where HH, MM, and SS are all two-digit numbers representing the hour, minute, and second, respectively. The string is terminated by a null character.
	Return Value
	_strtime returns buf, the address of the time string.
	Example

asctime (see page 1199)	**Header File**
	time.h
	Category
	Time and Date Routines
	Prototype
	`char *asctime(const struct tm *tblock);`
	`wchar_t *_wasctime(const struct tm *tblock);`
	Description
	asctime converts date and time to ASCII.
	_wasctime converts date and time to a **wchar_t** string.
	asctime and _wasctime convert a time stored as a structure to a 26 (wide) character string in the following form:
	Mon Nov 21 11:31:54 1983\n\0
	All the fields have a constant width. The output string day-of-the-week and month correspond to the following:
	tm parameterValid value rangeOutput
	tm.mon (month)0-110=Jan, 1=Feb, and so on
	tm.day (day-of-the-week)0-60=Sun, 1=Mon, and so on
	Return Value
	asctime and _wasctime return... more (see page 1199)

clock (see page 1200)	**Header File** time.h **Category** Time and Date Routines **Prototype** `clock_t clock(void);` **Description** Determines processor time. clock can be used to determine the time interval between two events. To determine the time in seconds, the value returned by clock should be divided by the value of the macro CLK_TCK. **Return Value** On success, clock returns the processor time elapsed since the beginning of the program invocation. On error (if the processor time is not available or its value cannot be represented), clock returns -1. **Example**
clock_t (see page 1201)	**Header File** time.h **Syntax** `typedef long clock_t;` **Description** Defines the data type returned by the clock function. **Portability**

ctime, _wctime (see page 1201)	**Header File**
	time.h
	Category
	Time and Date Routines
	Prototype
	`char *ctime(const time_t *time);`
	`wchar_t *_wctime(const time_t *time);`
	Description
	Converts date and time to a string.
	ctime converts a time value pointed to by time (the value returned by the function time) into a 26-character string in the following form, terminating with a newline character and a null character:
	`Mon Nov 21 11:31:54 1983\n\0`
	All the fields have constant width.
	The global long variable _timezone contains the difference in seconds between GMT and local standard time (in PST, _timezone is 8*60*60). The global variable _daylight is used to tell the RTL's... more (see page 1201)

_daylight (see page 1202)	**Header File** time.h **Syntax** `extern int _daylight;` **Description** _daylight is used by the time and date functions. It is used to tell the RTL's functions (mktime & localtime) whether they should take daylight saving time into account if it runs into a date that would normally fall into that category. _daylight is initialized from the values specified in the TZ environment variable and is set to 1 if the daylight savings time conversion should be applied. If TZ is not set, the value of _daylight is obtained from the operating system.
difftime (see page 1202)	**Header File** time.h **Category** Time and Date Routines **Prototype** `double difftime(time_t time2, time_t time1);` **Description** Computes the difference between two times. difftime calculates the elapsed time in seconds, from time1 to time2. **Return Value** difftime returns the result of its calculation as a **double**. **Example**
gmtime (see page 1203)	**Header File** time.h **Category** Time and Date Routines **Prototype** `struct tm *gmtime(const time_t *timer);` **Description** Converts date and time to Greenwich mean time (GMT). gmtime accepts the address of a value returned by time and returns a pointer to the structure of type tm containing the time elements. gmtime converts directly to GMT. The global long variable _timezone should be set to the difference in seconds between GMT and local standard time (in PST _timezone is 8 x 60 x 60). The global variable _daylight should be set to nonzero only if the standard U.S. daylight saving time conversion should... more (see page 1203)
localtime (see page 1204)	**Header File** time.h **Category** Time and Date Routines **Prototype** `struct tm *localtime(const time_t *timer);` **Description** Converts date and time to a structure. localtime accepts the address of a value returned by time and returns a pointer to the structure of type tm containing the time elements. It corrects for the time zone and possible daylight saving time. The global long variable _timezone contains the difference in seconds between GMT and local standard time (in PST, _timezone is 8 x 60 x 60). The global variable _daylight is used to tell the RTL's functions (mktime & localtime) whether they should take... more (see page 1204)

mktime (see page 1206)	**Header File** time.h **Category** Time and Date Routines **Prototype** `time_t mktime(struct tm *t);` **Description** Converts time to calendar format. Converts the time in the structure pointed to by t into a calendar time with the same format used by the time function. The original values of the fields tm_sec, tm_min, tm_hour, tm_mday, and tm_mon are not restricted to the ranges described in the tm structure. If the fields are not in their proper ranges, they are adjusted. Values for fields tm_wday and tm_yday are computed after the other fields have been adjusted. The tm_isdst (Daylight Savings Time) field is adjusted... more (see page 1206)
stime (see page 1207)	**Header File** time.h **Category** Time and Date Routines **Prototype** `int stime(time_t *tp);` **Description** Sets system date and time. stime sets the system time and date. tp points to the value of the time as measured in seconds from 00:00:00 GMT, January 1, 1970. **Return Value** stime returns a value of 0. **Example**

strftime, wcsftime (see page 1207)	**Header File**
	time.h
	Category
	Time and Date Routines
	Prototype
	`size_t strftime(char *s, size_t maxsize, const char *fmt, const struct tm *t);`
	`size_t wcsftime(wchar_t *s, size_t maxsize, const wchar_t *fmt, const struct tm *t);`
	Description
	Formats time for output.
	strftime formats the time in the argument t into the array pointed to by the argument s according to the fmt specifications. All ordinary characters are copied unchanged. No more than maxsize characters are placed in s.
	The time is formatted according to the current locale's LC_TIME category.
	Return Value
	On success, strftime returns the number of characters placed into s.
	On... more (see page 1207)

time (see page 1208)	**Header File** time.h **Category** Time and Date Routines **Prototype** `time_t time(time_t *timer);` **Description** Gets time of day. time gives the current time, in seconds, elapsed since 00:00:00 GMT, January 1, 1970, and stores that value in the location pointed to by timer, provided that timer is not a NULL pointer. **Return Value** time returns the elapsed time in seconds. **Example**

_timezone (see page 1209)	**Header File** time.h **Syntax** `extern long _timezone;` **Description** _timezone is used by the time-and-date functions. It is calculated by the tzset function; it is assigned a long value that is the difference, in seconds, between the current local time and Greenwich mean time. On Win32, the value of _timezone is obtained from the operating system.

tm (see page 1209)	**Header File**
	time.h
	Syntax
	`struct tm {`
	`int tm_sec; /* Seconds */`
	`int tm_min; /* Minutes */`
	`int tm_hour; /* Hour (0--23) */`
	`int tm_mday; /* Day of month (1--31) */`
	`int tm_mon; /* Month (0--11) */`
	`int tm_year; /* Year (calendar year minus 1900) */`
	`int tm_wday; /* Weekday (0--6; Sunday = 0) */`
	`int tm_yday; /* Day of year (0--365) */`
	`int tm_isdst; /* 0 if daylight savings time is not in effect) */`
	`};`
	Description
	A structure defining the time, broken down into increments.
	tm is used by the functions asctime, gmtime, localtime, mktime, and strftime.
	Example... more (see page 1209)

_tzname,_wtzname (see page 1210)	**Header File**
	time.h
	Syntax
	`extern char * _tzname[2]`
	`extern wchar_t *const _wtzname[2]`
	Description
	The global variable _tzname is an array of pointers to strings containing abbreviations for time zone names. _tzname[0] points to a three-character string with the value of the time zone name from the TZ environment string. The global variable _tzname[1] points to a three-character string with the value of the daylight saving time zone name from the TZ environment string. If no daylight saving name is present, _tzname[1] points to a null string.
	On Win32, the value of _tzname is obtained from the operating system.

_tzset, _wtzset (see page 1210)	**Header File**
	time.h
	Category
	Time and Date Routines
	Prototype
	`void _tzset(void)`
	`void _wtzset(void)`
	Description
	Sets value of global variables _daylight, _timezone, and _tzname.
	_tzset is available on XENIX systems.
	_tzset sets the _daylight, _timezone, and _tzname global variables based on the environment variable TZ. _wtzset sets the _daylight, _timezone, and _wtzname global variables. The library functions ftime and localtime use these global variables to adjust Greenwich Mean Time (GMT) to the local time zone. The format of the TZ environment string is:
	`TZ = zzz[+/-]d[d][lll]`
	where zzz is a three-character string representing the name of the current time zone. All... more (see page 1210)

3.1.4.34.1 _strdate, _wstrdate

Header File

time.h

Category

Conversion Routines, Time and Date Routines

Prototype

```
char *_strdate(char *buf);
```

```
wchar_t *_wstrdate(wchar_t *buf);
```

Description

Converts current date to string.

_strdate converts the current date to a string, storing the string in the buffer buf. The buffer must be at least 9 characters long.

The string has the form MM/DD/YY where MM, DD, and YY are all two-digit numbers representing the month, day, and year. The string is terminated by a null character.

Return Value

_strdate returns buf, the address of the date string.

Example

```
#include <time.h>
#include <stdio.h>
void main(void)
{
  char datebuf[9];
  char timebuf[9];
  _strdate(datebuf);
  _strtime(timebuf);
  printf("Date: %s  Time: %s\n",datebuf,timebuf);
}
```

Portability

strdate		+		
_wstrdate		+		

3.1.4.34.2 _strtime, _wstrtime

Header File

time.h

Category

Time and Date Routines

Prototype

```
char *_strtime(char *buf);
```

```
wchar_t *_wstrtime(wchar_t *buf);
```

Description

Converts current time to string.

_strtime converts the current time to a string, storing the string in the buffer buf. The buffer must be at least 9 characters long.

The string has the following form:

`HH:MM:SS`

where HH, MM, and SS are all two-digit numbers representing the hour, minute, and second, respectively. The string is terminated by a null character.

Return Value

_strtime returns buf, the address of the time string.

Example

```
#include <time.h>
#include <stdio.h>
void main(void)
{
  char datebuf[9];
  char timebuf[9];
  _strdate(datebuf);
  _strtime(timebuf);
  printf("Date: %s  Time: %s\n",datebuf,timebuf);
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
_strtime		+		
_wstrtime		+		

3.1.4.34.3 asctime

Header File

time.h

Category

Time and Date Routines

Prototype

```
char *asctime(const struct tm *tblock);
```

```
wchar_t *_wasctime(const struct tm *tblock);
```

Description

asctime converts date and time to ASCII.

_wasctime converts date and time to a **wchar_t** string.

asctime and _wasctime convert a time stored as a structure to a 26 (wide) character string in the following form:

Mon Nov 21 11:31:54 1983\n\0

All the fields have a constant width. The output string day-of-the-week and month correspond to the following:

tm parameterValid value rangeOutput

tm.mon (month)0-110=Jan, 1=Feb, and so on

tm.day (day-of-the-week)0-60=Sun, 1=Mon, and so on

Return Value

asctime and _wasctime return a pointer to the (wide) character string containing the date and time. This string is a static which is overwritten with each call. asctime converts a time stored as a structure in *tblock to a 26-character string of the same form as the ctime string:

```
Sun Sep 16 01:03:52 1973\n\0
```

Example

```
#include <string.h>
#include <time.h>
#include <stdio.h>
int main(void)
{
  struct tm t;
  char str[80];
  /* sample loading of tm structure  */
  t.tm_sec    = 1;  /* Seconds */
  t.tm_min    = 30; /* Minutes */
  t.tm_hour   = 9;  /* Hour */
  t.tm_mday   = 22; /* Day of the Month  */
  t.tm_mon    = 11; /* Month */
  t.tm_year   = 56; /* Year - does not include century */
  t.tm_wday   = 4;  /* Day of the week  */
  t.tm_yday   = 0;  /* Does not show in asctime */
  t.tm_isdst  = 0;  /* Is Daylight SavTime; does not show in asctime */
  /* converts structure to null terminated string */
  strcpy(str, asctime(&t));
  printf("%s\n", str);
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
asctime	+	+	+	+
_wasctime		+		

3.1.4.34.4 clock

Header File

time.h

Category

Time and Date Routines

Prototype

```
clock_t clock(void);
```

Description

Determines processor time.

clock can be used to determine the time interval between two events. To determine the time in seconds, the value returned by clock should be divided by the value of the macro CLK_TCK.

Return Value

On success, clock returns the processor time elapsed since the beginning of the program invocation.

On error (if the processor time is not available or its value cannot be represented), clock returns -1.

Example

```
#include <time.h>
#include <stdio.h>
#include <dos.h>
int main(void)
{
   clock_t start, end;
   start = clock();
   delay(2000);
   end = clock();
   printf("The time was: %f\n", (end - start) / CLK_TCK);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.34.5 clock_t

Header File

time.h

Syntax

```
typedef long clock_t;
```

Description

Defines the data type returned by the clock function.

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.34.6 ctime, _wctime

Header File

time.h

Category

Time and Date Routines

Prototype

```
char *ctime(const time_t *time);
```

```
wchar_t *_wctime(const time_t *time);
```

Description

Converts date and time to a string.

ctime converts a time value pointed to by time (the value returned by the function time) into a 26-character string in the following form, terminating with a newline character and a null character:

```
Mon Nov 21 11:31:54 1983\n\0
```

All the fields have constant width.

The global long variable _timezone contains the difference in seconds between GMT and local standard time (in PST, _timezone is 8*60*60). The global variable _daylight is used to tell the RTL's functions (mktime & localtime) whether they should take daylight saving time into account if it runs into a date that would normally fall into that category. It is set to 1 if the daylight savings time conversion should be applied.. These variables are set by the tzset function, not by the user program directly.

Return Value

ctime returns a pointer to the character string containing the date and time. The return value points to static data that is overwritten with each call to ctime.

Example

```
#include <stdio.h>
#include <time.h>
int main(void)
{
  time_t t;
  time(&t);
  printf("Today's date and time: %s\n", ctime(&t));
  return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
ctime	+	+	+	+
_wctime		+		

3.1.4.34.7 _daylight

Header File

time.h

Syntax

```
extern int _daylight;
```

Description

_daylight is used by the time and date functions. It is used to tell the RTL's functions (mktime & localtime) whether they should take daylight saving time into account if it runs into a date that would normally fall into that category. _daylight is initialized from the values specified in the TZ environment variable and is set to 1 if the daylight savings time conversion should be applied. If TZ is not set, the value of _daylight is obtained from the operating system.

3.1.4.34.8 difftime

Header File

time.h

Category

Time and Date Routines

Prototype

```
double difftime(time_t time2, time_t time1);
```

Description

Computes the difference between two times.

difftime calculates the elapsed time in seconds, from time1 to time2.

Return Value

difftime returns the result of its calculation as a **double**.

Example

```
#include <time.h>
#include <stdio.h>
#include <dos.h>
#include <conio.h>
int main(void)
{
   time_t first, second;
   clrscr();
   first = time(NULL);  /* Gets system
                           time */
   delay(2000);         /* Waits 2 secs */
   second = time(NULL); /* Gets system time
                           again */
   printf("The difference is: %f seconds\n",difftime(second,first));
   getch();
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.34.9 gmtime

Header File

time.h

Category

Time and Date Routines

Prototype

```
struct tm *gmtime(const time_t *timer);
```

Description

Converts date and time to Greenwich mean time (GMT).

gmtime accepts the address of a value returned by time and returns a pointer to the structure of type tm containing the time elements. gmtime converts directly to GMT.

The global long variable _timezone should be set to the difference in seconds between GMT and local standard time (in PST _timezone is 8 x 60 x 60). The global variable _daylight should be set to nonzero only if the standard U.S. daylight saving time

conversion should be applied.

This is the tm structure declaration from the time.h header file:

```
struct tm {
int tm_sec; /* Seconds */
int tm_min; /* Minutes */
int tm_hour; /* Hour (0 - 23) */
int tm_mday; /* Day of month (1 - 31) */
int tm_mon; /* Month (0 - 11) */
int tm_year; /* Year (calendar year minus 1900) */
int tm_wday; /* Weekday (0 - 6; Sunday is 0) */
int tm_yday; /* Day of year (0 -365) */
int tm_isdst; /* Nonzero if daylight saving time is in effect. */
};
```

These quantities give the time on a 24-hour clock, day of month (1 to 31), month (0 to 11), weekday (Sunday equals 0), year - 1900, day of year (0 to 365), and a flag that is nonzero if daylight saving time is in effect.

Return Value

gmtime returns a pointer to the structure containing the time elements. This structure is a static that is overwritten with each call.

Example

```
#include <stdio.h>
#include <stdlib.h>
#include <time.h>
/* Pacific Standard Time & Daylight Savings */
char *tzstr = "TZ=PST8PDT";
int main(void)
{
   time_t t;
   struct tm *gmt, *area;
   putenv(tzstr);
   tzset();
   t = time(NULL);
   area = localtime(&t);
   printf("Local time is: %s", asctime(area));
   gmt = gmtime(&t);
   printf("GMT is:        %s", asctime(gmt));
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.34.10 localtime

Header File

time.h

Category

Time and Date Routines

Prototype

```
struct tm *localtime(const time_t *timer);
```

Description

Converts date and time to a structure.

localtime accepts the address of a value returned by time and returns a pointer to the structure of type tm containing the time elements. It corrects for the time zone and possible daylight saving time.

The global long variable _timezone contains the difference in seconds between GMT and local standard time (in PST, _timezone is 8 x 60 x 60). The global variable _daylight is used to tell the RTL's functions (mktime & localtime) whether they should take daylight saving time into account if it runs into a date that would normally fall into that category. It is set to 1 if the daylight savings time conversion should be applied. These values are set by tzset, not by the user program directly.

This is the **tm** structure declaration from the time.h header file:

```
struct tm {
int tm_sec;
int tm_min;
int tm_hour;
int tm_mday;
int tm_mon;
int tm_year;
int tm_wday;
int tm_yday;
int tm_isdst;
};
```

These quantities give the time on a 24-hour clock, day of month (1 to 31), month (0 to 11), weekday (Sunday equals 0), year - 1900, day of year (0 to 365), and a flag that is nonzero if the daylight saving time conversion should be applied.

Return Value

localtime returns a pointer to the structure containing the time elements. This structure is a static that is overwritten with each call.

Example

```
#include <time.h>
#include <stdio.h>
int main(void)
{
   time_t timer;
   struct tm *tblock;
   /* gets time of day */
   timer = time(NULL);
   /* converts date/time to a structure */
   tblock = localtime(&timer);
   printf("Local time is: %s", asctime(tblock));
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.34.11 mktime

Header File

time.h

Category

Time and Date Routines

Prototype

```
time_t mktime(struct tm *t);
```

Description

Converts time to calendar format.

Converts the time in the structure pointed to by t into a calendar time with the same format used by the time function. The original values of the fields tm_sec, tm_min, tm_hour, tm_mday, and tm_mon are not restricted to the ranges described in the tm structure. If the fields are not in their proper ranges, they are adjusted. Values for fields tm_wday and tm_yday are computed after the other fields have been adjusted.

The tm_isdst (Daylight Savings Time) field is adjusted with the correct value after calling the function mktime. Also, tm_isdst is used for adusting the value of tm_hour. For example, if the value of tm_isdst is 1, but the current date is not DST, mktime updates tm_hour (tm_hour = tm_hour - 1) and sets tm_isdst to 0.

The allowable range of calendar times is Jan 1 1970 00:00:00 to Jan 19 2038 03:14:07.

Return Value

On success, mktime returns calendar time as described above.

On error (if the calendar time cannot be represented), mktime returns -1.

Example

```
#include <stdio.h> #include <time.h>
        char *wday[] = {"Sunday", "Monday", "Tuesday", "Wednesday", "Thursday", "Friday",
        "Saturday", "Unknown"}; int main(void) { struct tm time_check; int year, month, day; /*
        Input a year, month and day to find the weekday for */ printf("Year: "); scanf("%d",
        &year); printf("Month: "); scanf("%d", &month); printf("Day: "); scanf("%d",
        &day); /* load the time_check structure with the data */ time_check.tm_year = year -
        1900; time_check.tm_mon = month - 1; time_check.tm_mday = day; time_check.tm_hour = 0;
        time_check.tm_min = 0; time_check.tm_sec = 1; time_check.tm_isdst = -1; /* call mktime
to
        fill in the weekday field of the structure */ if (mktime(&time_check) == -1)
        time_check.tm_wday = 7; /* print out the day of the week */ printf("That day is a
%s\n",
        wday[time_check.tm_wday]); return 0; }
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.34.12 stime

Header File

time.h

Category

Time and Date Routines

Prototype

```
int stime(time_t *tp);
```

Description

Sets system date and time.

stime sets the system time and date. tp points to the value of the time as measured in seconds from 00:00:00 GMT, January 1, 1970.

Return Value

stime returns a value of 0.

Example

```
#include <stdio.h>
#include <time.h>
int main(void)
{
  time_t t;
  t = time(NULL);
  printf("Current date is %s", ctime(&t));
  t -= 24L*60L*60L;  /* Back up to same time previous day */
  stime(&t);
  printf("\nNew date is %s", ctime(&t));
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
	+		

3.1.4.34.13 strftime, wcsftime

Header File

time.h

Category

Time and Date Routines

Prototype

```
size_t strftime(char *s, size_t maxsize, const char *fmt, const struct tm *t);
```

```
size_t wcsftime(wchar_t *s, size_t maxsize, const wchar_t *fmt, const struct tm *t);
```

Description

Formats time for output.

strftime formats the time in the argument t into the array pointed to by the argument s according to the fmt specifications. All ordinary characters are copied unchanged. No more than maxsize characters are placed in s.

The time is formatted according to the current locale's LC_TIME category.

Return Value

On success, strftime returns the number of characters placed into s.

On error (if the number of characters required is greater than maxsize), strftime returns 0.

More about strftime

Example

```
#include <stdio.h>
#include <time.h>
#include <dos.h>
int main(void)
{
   struct tm *time_now;
   time_t secs_now;
   char str[80];
   tzset();
   time(&secs_now);
   time_now = localtime(&secs_now);
   strftime(str, 80,
            "It is %M minutes after %I o'clock (%Z)  %A, %B %d 19%y",
            time_now);
   printf("%s\n",str);
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++
strftime	+	+	+	+
wcsftime		+	+	+

3.1.4.34.14 time

Header File

time.h

Category

Time and Date Routines

Prototype

```
time_t time(time_t *timer);
```

Description

Gets time of day.

time gives the current time, in seconds, elapsed since 00:00:00 GMT, January 1, 1970, and stores that value in the location pointed to by timer, provided that timer is not a NULL pointer.

Return Value

time returns the elapsed time in seconds.

Example

```
#include <time.h>
#include <stdio.h>
int main(void)
{
   time_t t;
   t = time(NULL);
   printf("The number of seconds since January 1, 1970 is %ld",t);
   return 0;
}
```

Portability

POSIX	Win32	ANSI C	ANSI C++
+	+	+	+

3.1.4.34.15 _timezone

Header File

time.h

Syntax

```
extern long _timezone;
```

Description

_timezone is used by the time-and-date functions. It is calculated by the tzset function; it is assigned a long value that is the difference, in seconds, between the current local time and Greenwich mean time.

On Win32, the value of _timezone is obtained from the operating system.

3.1.4.34.16 tm

Header File

time.h

Syntax

```
struct tm {
int tm_sec; /* Seconds */
int tm_min; /* Minutes */
int tm_hour; /* Hour (0--23) */
int tm_mday; /* Day of month (1--31) */
int tm_mon; /* Month (0--11) */
int tm_year; /* Year (calendar year minus 1900) */
int tm_wday; /* Weekday (0--6; Sunday = 0) */
int tm_yday; /* Day of year (0--365) */
int tm_isdst; /* 0 if daylight savings time is not in effect) */
```

```
};
```

Description

A structure defining the time, broken down into increments.

tm is used by the functions asctime, gmtime, localtime, mktime, and strftime.

Example

3.1.4.34.17 _tzname,_wtzname

Header File

time.h

Syntax

```
extern char * _tzname[2]
```

```
extern wchar_t *const _wtzname[2]
```

Description

The global variable _tzname is an array of pointers to strings containing abbreviations for time zone names. _tzname[0] points to a three-character string with the value of the time zone name from the TZ environment string. The global variable _tzname[1] points to a three-character string with the value of the daylight saving time zone name from the TZ environment string. If no daylight saving name is present, _tzname[1] points to a null string.

On Win32, the value of _tzname is obtained from the operating system.

3.1.4.34.18 _tzset, _wtzset

Header File

time.h

Category

Time and Date Routines

Prototype

```
void _tzset(void)
```

```
void _wtzset(void)
```

Description

Sets value of global variables _daylight, _timezone, and _tzname.

_tzset is available on XENIX systems.

_tzset sets the _daylight, _timezone, and _tzname global variables based on the environment variable TZ. _wtzset sets the _daylight, _timezone, and _wtzname global variables. The library functions ftime and localtime use these global variables to adjust Greenwich Mean Time (GMT) to the local time zone. The format of the TZ environment string is:

```
TZ = zzz[+/-]d[d][lll]
```

where zzz is a three-character string representing the name of the current time zone. All three characters are required. For example, the string “PST” could be used to represent Pacific standard time.

[+/-]d[d] is a required field containing an optionally signed number with 1 or more digits. This number is the local time zone’s

difference from GMT in hours. Positive numbers adjust westward from GMT. Negative numbers adjust eastward from GMT. For example, the number 5 = EST, +8 = PST, and -1 = continental Europe. This number is used in the calculation of the global variable _timezone. _timezone is the difference in seconds between GMT and the local time zone.

lll is an optional three-character field that represents the local time zone, daylight saving time. For example, the string “PDT” could be used to represent pacific daylight saving time. If this field is present, it causes the global variable _daylight to be set nonzero. If this field is absent, _daylight is set to zero.

If the TZ environment string isn’t present or isn’t in the preceding form, a default TZ = “EST5EDT” is presumed for the purposes of assigning values to the global variables _daylight, _timezone, and _tzname. On a Win32 system, none of these global variables are set if TZ is null.

The global variables _tzname[0] and _wtzname[1] point to a three-character string with the value of the time-zone name from the TZ environment string. _tzname[1] and _wtzname[1] point to a three-character string with the value of the daylight saving time-zone name from the TZ environment string. If no daylight saving name is present, _tzname[1] and _wtzname[1] point to a null string.

Return Value

None.

Example

```
#include <time.h>
#include <stdlib.h>
#include <stdio.h>
int main(void)
{
   time_t td;
   putenv("TZ=PST8PDT");
   tzset();
   time(&td);
   printf("Current time = %s\n", asctime(localtime(&td)));
   return 0;
}
```

Portability

	POSIX	Win32	ANSI C	ANSI C++

_wtzset		+		

3.1.4.35 typeinfo.h

The following functions, macros, and classes are provided in `typeinfo.h`:

Topics

Name	Description
bad_cast class (see page 1212)	**Header File** typeinfo.h **Description** When dynamic_cast fails to make a cast to reference, the expression can throw bad_cast. Note that when dynamic_cast fails to make a cast to pointer type, the result is the null pointer.

bad_typeid class (see page 1212)	**Header File** typeinfo.h **Description** When the operand of typeid is a dereferenced null pointer, the **typeid** operator can throw bad_typeid.
type_info class (see page 1212)	**Header File** typeinfo.h **Description** Provides information about a type. **Constructor** Only a private constructor is provided. You cannot create type_info objects. By declaring your objects to be _ _rtti types, or by using the -RT compiler switch, the compiler provides your objects with the elements of type_info. type_info references are generated by the typeid operator. **Public Member Functions** **Operators**

3.1.4.35.1 bad_cast class

Header File

typeinfo.h

Description

When dynamic_cast fails to make a cast to reference, the expression can throw bad_cast. Note that when dynamic_cast fails to make a cast to pointer type, the result is the null pointer.

3.1.4.35.2 bad_typeid class

Header File

typeinfo.h

Description

When the operand of typeid is a dereferenced null pointer, the **typeid** operator can throw bad_typeid.

3.1.4.35.3 type_info class

Header File

typeinfo.h

Description

Provides information about a type.

Constructor

Only a private constructor is provided. You cannot create type_info objects. By declaring your objects to be _ _rtti types, or by using the -RT compiler switch, the compiler provides your objects with the elements of type_info. type_info references are generated by the typeid operator.

Public Member Functions

Operators

3.1.4.36 utime.h

The following functions, macros, and classes are provided in `utime.h`:

Topics

Name	Description

_utime, _wutime (see page 1213)	**Header File**
	utime.h
	Category
	Input/output Routines
	Prototype
	`int _utime(char *path, struct utimbuf *times);`
	`int _wutime(wchar_t *path, struct _utimbuf *times);`
	Description
	Sets file time and date.
	_utime sets the modification time for the file path. The modification time is contained in the utimbuf structure pointed to by times. This structure is defined in utime.h, and has the following format:
	`struct utimbuf {`
	`time_t actime; /* access time */`
	`time_t modtime; /* modification time */`
	`};`
	The FAT (file allocation table) file system supports only a modification time; therefore, on FAT file systems _utime ignores actime and uses only modtime to set... more (see page 1213)

3.1.4.36.1 _utime, _wutime

Header File

utime.h

Category

Input/output Routines

Prototype

```
int _utime(char *path, struct utimbuf *times);
int _wutime(wchar_t *path, struct _utimbuf *times);
```

Description

Sets file time and date.

_utime sets the modification time for the file path. The modification time is contained in the utimbuf structure pointed to by times. This structure is defined in utime.h, and has the following format:

```
struct utimbuf {
time_t actime; /* access time */
time_t modtime; /* modification time */
};
```

The FAT (file allocation table) file system supports only a modification time; therefore, on FAT file systems _utime ignores actime and uses only modtime to set the file's modification time.

If times is NULL, the file's modification time is set to the current time.

_wutime is the Unicode version of _utime. The Unicode version accepts a filename that is a wchar_t character string. Otherwise,

the functions perform identically.

Return Value

On success, _utime returns 0.

On error, it returns -1, and sets the global variable errno to one of the following values:

EACCES	Permission denied
EMFILE	Too many open files
ENOENT	Path or file name not found

Example

```
/* Copy timestamp from one file to another */
#include <sys\stat.h>
#include <utime.h>
#include <stdio.h>

int main( int argc, char *argv[] )
{
  struct stat src_stat;
  struct utimbuf times;
  if(argc != 3) {
    printf( "Usage: copytime <source file> <dest file>\n" );
    return 1;
  }

  if (stat(argv[1],&src_stat) != 0) {
    perror("Unable to get status of source file");
    return 1;
  }

  times.modtime = times.actime = src_stat.st_mtime;
  if (utime(argv[2],&times) != 0) {
    perror("Unable to set time of destination file");
    return 1;
  }
  return 0;
}
```

3.1.4.37 values.h

The following functions, macros, and classes are provided in `values.h`:

Topics

Name	Description
BITSPERBYTE #define (see page 1215)	**Header File** values.h **Description** Number of bits in a byte.

HIBITx #defines (see page 1215)	**Header File** values.h **Description** Bit mask for the high (sign) bit of standard integer types.
MAXxxxx #defines (integer data types) (see page 1215)	**Header File** values.h **Description** Maximum values for integer data types
Float and Double Limits (see page 1216)	**Header File** values.h **Description** **UNIX System V compatible:**

3.1.4.37.1 BITSPERBYTE #define

Header File

values.h

Description

Number of bits in a byte.

3.1.4.37.2 HIBITx #defines

Header File

values.h

Description

Bit mask for the high (sign) bit of standard integer types.

Name	Meaning
HIBITS	For type short
HIBITI	For type int
HIBITL	For type long

3.1.4.37.3 MAXxxxx #defines (integer data types)

Header File

values.h

Description

Maximum values for integer data types

Name	Meaning
MAXSHORT	Largest short
MAXINT	Largest int
MAXLONG	Largest long

3.1.4.37.4 Float and Double Limits

Header File

values.h

Description

UNIX System V compatible:

_LENBASE	Base to which exponent applies

Limits for double float values

_DEXPLEN	Number of bits in exponent
DMAXEXP	Maximum exponent allowed
DMAXPOWTWO	Largest power of two allowed
DMINEXP	Minimum exponent allowed
DSIGNIF	Number of significant bits
MAXDOUBLE	Largest magnitude double value
MINDOUBLE	Smallest magnitude double value

Limits for float values

_FEXPLEN	Number of bits in exponent
FMAXEXP	Maximum exponent allowed
FMAXPOWTWO	Largest power of two allowed
FMINEXP	Minimum exponent allowed
FSIGNIF	Number of significant bits
MAXFLOAT	Largest magnitude float value
MINFLOAT	Smallest magnitude float value

3.2 Win32 Developer's Guide

This section contains the Win32 Developer's Guide topics for the Delphi Win32 personality in RAD Studio.

Topics

Name	Description
Component Writer's Guide (see page 1217)	The Component Writer's Guide covers all the information relating to creating VCL components in the Delphi personality.
Developing COM-based Applications (see page 1381)	Contains the Developer's Guide topics for creating COM-based applications in Delphi.
Developing Database Applications (see page 1469)	The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress. Contains the Developer's Guide topics for programming database applications.
Programming with Delphi (see page 1879)	Contains the Developer's Guide topics for programming with Delphi.
Writing Internet Applications (see page 2243)	Contains the Developer's Guide topics for writing internet applications in Delphi.

3.2.1 Component Writer's Guide

The Component Writer's Guide covers all the information relating to creating VCL components in the Delphi personality.

Topics

Name	Description
Creating a graphic component (see page 1218)	
Creating events (see page 1231)	
Creating methods (see page 1241)	
Creating properties (see page 1245)	
Customizing a grid (see page 1258)	
Extending the IDE (see page 1276)	
Handling messages (see page 1298)	
Introduction to component creation (see page 1310)	
Making a control data aware (see page 1325)	
Making components available at design time (see page 1339)	
Making a dialog box a component (see page 1358)	
Modifying an existing component (see page 1363)	
Object-oriented programming for component writers (see page 1367)	
Using graphics in components (see page 1376)	

3.2.1.1 Creating a graphic component

Topics

Name	Description
Adding Graphic Capabilities (see page 1219)	Once you have declared your graphic component and published any inherited properties you want to make available, you can add the graphic capabilities that distinguish your component. You have two tasks to perform when creating a graphic control: 1. Determining what to draw. (see page 1223) 2. Drawing the component image. (see page 1224) In addition, for the shape control example, you will add some properties that enable application developers to customize the appearance of the shape at design time.
Creating a Graphic Component (see page 1220)	A graphic control is a simple kind of component. Because a purely graphic control never receives focus, it does not have or need its own window handle. Users can still manipulate the control with the mouse, but there is no keyboard interface. The graphic control presented in the following topics is *TShape*, the shape component on the Additional page of the Tool palette. Although the component created is identical to the standard shape component, you need to call it something different to avoid duplicate identifiers. The following topics use the name *TSampleShape* and show you all the steps involved... more (see page 1220)
Creating and Registering the Graphic Component (see page 1220)	You create every component in the same way: create a unit, derive a component class, register it, compile it, and install it on the Tool palette. This process is outlined in Creating a new component. (see page 1317)
Declaring the Access Properties (see page 1221)	You can provide access to the owned objects of a component by declaring properties of the type of the objects. That gives developers a way to access the objects at design time or runtime. Usually, the read part of the property just references the class field, but the write part calls a method that enables the component to react to changes in the owned object. To the shape control, add properties that provide access to the pen and brush fields. You will also declare methods for reacting to changes to the pen or brush.
Declaring the Class Fields (see page 1222)	Each class a component owns must have a class field declared for it in the component. The class field ensures that the component always has a pointer to the owned object so that it can destroy the class before destroying itself. In general, a component initializes owned objects in its constructor and destroys them in its destructor. Fields for owned objects are nearly always declared as private. If applications (or other components) need access to the owned objects, you can declare **published** or **public** properties for this purpose. Add fields for a pen and brush to the shape control:
Declaring the Property (see page 1222)	When you declare a property, you usually need to declare a private field to store the data for the property, then specify methods for reading and writing the property value. Often, you don't need to use a method to read the value, but can just point to the stored data instead. For the shape control, you will declare a field that holds the current shape, then declare a property that reads that field and writes to it through a method call. Add the following declarations to *TSampleShape*:
Declaring the Property Type (see page 1223)	When you declare a property of a user-defined type, you must declare the type first, before the class that includes the property. The most common sort of user-defined type for properties is enumerated. For the shape control, you need an enumerated type with an element for each kind of shape the control can draw. Add the following type definition above the shape control class's declaration.
Determining What to Draw (see page 1223)	A graphic control can change its appearance to reflect a dynamic condition, including user input. A graphic control that always looks the same should probably not be a component at all. If you want a static image, you can import the image instead of using a control. In general, the appearance of a graphic control depends on some combination of its properties. The gauge control, for example, has properties that determine its shape and orientation and whether it shows its progress numerically as well as graphically. Similarly, the shape control has a property that determines what kind of shape it... more (see page 1223)

Drawing the Component Image (see page 1224)	The essential element of a graphic control is the way it paints its image on the screen. The abstract type *TGraphicControl* defines a method called *Paint* that you override to paint the image you want on your control. The *Paint* method for the shape control needs to do several things: • Use the pen and brush selected by the user. • Use the selected shape. • Adjust coordinates so that squares and circles use the same width and height.
Initializing Owned Classes (see page 1225)	If you add classes to your component, the component's constructor must initialize them so that the user can interact with the objects at runtime. Similarly, the component's destructor must also destroy the owned objects before destroying the component itself.
Overriding the Constructor and Destructor (see page 1226)	To change default property values and initialize owned classes for your component, you must override the inherited constructor and destructor. In both cases, remember always to call the inherited method in your new constructor or destructor.
Publishing Inherited Properties (Graphic) (see page 1227)	Once you derive a component type, you can decide which of the properties and events declared in the protected parts of the ancestor class you want to surface in the new component. *TGraphicControl* already publishes all the properties that enable the component to function as a control, so all you need to publish is the ability to respond to mouse events and handle drag-and-drop. Publishing inherited properties and events is explained in Publishing inherited properties (see page 1250) and Making events visible. (see page 1238) Both processes involve redeclaring just the name of the properties in the published part of the class declaration. For the shape... more (see page 1227)
Publishing the Pen and Brush (see page 1228)	By default, a canvas has a thin black pen and a solid white brush. To let developers change the pen and brush, you must provide classes for them to manipulate at design time, then copy the classes into the canvas during painting. Classes such as an auxiliary pen or brush are called *owned classes* because the component owns them and is responsible for creating and destroying them. Managing owned classes requires: 1. Declaring the class fields. (see page 1222) 2. Declaring the access properties. (see page 1221) 3. Initializing owned classes. (see page 1225) 4. Setting owned classes' properties. (see page 1229)
Refining the Shape Drawing (see page 1228)	The standard shape control does one more thing that your sample shape control does not yet do: it handles squares and circles as well as rectangles and ellipses. To do that, you need to write code that finds the shortest side and centers the image. Here is a refined *Paint* method that adjusts for squares and ellipses:
Setting Owned Classes' Properties (see page 1229)	As the final step in handling the pen and brush classes, you need to make sure that changes in the pen and brush cause the shape control to repaint itself. Both pen and brush classes have *OnChange* events, so you can create a method in the shape control and point both *OnChange* events to it. Add the following method to the shape control, and update the component's constructor to set the pen and brush events to the new method:
Writing the Implementation Method (see page 1230)	When the **read** or **write** part of a property definition uses a method instead of directly accessing the stored property data, you need to implement the method. Add the implementation of the *SetShape* method to the **implementation** part of the unit:

3.2.1.1.1 Adding Graphic Capabilities

Once you have declared your graphic component and published any inherited properties you want to make available, you can add the graphic capabilities that distinguish your component. You have two tasks to perform when creating a graphic control:

1. Determining what to draw. (see page 1223)
2. Drawing the component image. (see page 1224)

In addition, for the shape control example, you will add some properties that enable application developers to customize the

appearance of the shape at design time.

3.2.1.1.2 Creating a Graphic Component

A graphic control is a simple kind of component. Because a purely graphic control never receives focus, it does not have or need its own window handle. Users can still manipulate the control with the mouse, but there is no keyboard interface.

The graphic control presented in the following topics is *TShape*, the shape component on the Additional page of the Tool palette. Although the component created is identical to the standard shape component, you need to call it something different to avoid duplicate identifiers. The following topics use the name *TSampleShape* and show you all the steps involved in creating the shape component:

- Creating and registering the component (see page 1363).
- Publishing inherited properties (see page 1227).
- Adding graphic capabilities (see page 1219).

3.2.1.1.3 Creating and Registering the Graphic Component

You create every component in the same way: create a unit, derive a component class, register it, compile it, and install it on the Tool palette. This process is outlined in Creating a new component. (see page 1317)

For this example, follow the general procedure for creating a component, with these specifics:

1. Call the component's unit *Shapes*.
2. Derive a new component type called *TSampleShape*, descended from *TGraphicControl*.
3. Register *TSampleShape* on the Samples category of the Tool palette.

The resulting unit should look like this:

```
unit Shapes;
interface
uses SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls, Forms;
type
  TSampleShape = class(TGraphicControl)
  end;
procedure Register;
implementation
procedure Register;
begin
  RegisterComponent('Samples', [TSampleShape]);
end;
end.
//---------------------------------------------------------------------------
#include <vcl.h>
#pragma hdrstop
#include "Shapes.h"
//---------------------------------------------------------------------------
#pragma package(smart_init);
//---------------------------------------------------------------------------
// ValidCtrCheck is used to assure that the components created do not have
// any pure virtual functions.
//
static inline void ValidCtrCheck(TSampleShape *)
{
  new TSampleShape(NULL);
}
//---------------------------------------------------------------------------
__fastcall TSampleShape::TGraphicControl(TComponent* Owner)
: TGraphicControl(Owner)
```

```
{
}
//---------------------------------------------------------------------------
namespace Shapes
{
  void __fastcall PACKAGE Register()
  {
    TComponentClass classes[1] = {__classid(TSampleShape)};
    RegisterComponents("Samples", classes, 0);
  }
}
//---------------------------------------------------------------------------
#ifndef ShapesH
#define ShapesH
//---------------------------------------------------------------------------
#include <sysutils.hpp>
#include <controls.hpp>
#include <classes.hpp>
#include <forms.hpp>
//---------------------------------------------------------------------------
class PACKAGE TSampleShape : public TGraphicControl
{
private:
protected:
public:
__published:
};
//---------------------------------------------------------------------------
#endif
```

3.2.1.1.4 Declaring the Access Properties

You can provide access to the owned objects of a component by declaring properties of the type of the objects. That gives developers a way to access the objects at design time or runtime. Usually, the read part of the property just references the class field, but the write part calls a method that enables the component to react to changes in the owned object.

To the shape control, add properties that provide access to the pen and brush fields. You will also declare methods for reacting to changes to the pen or brush.

```
type
  TSampleShape = class(TGraphicControl)
  .
  .
  .
  private                                              { these methods should be private }
    procedure SetBrush(Value: TBrush);
    procedure SetPen(Value: TPen);
  published                                          { make these available at design time }
    property Brush: TBrush read FBrush write SetBrush;
    property Pen: TPen read FPen write SetPen;
  end;
class PACKAGE TSampleShape : public TGraphicControl
{
  .
  .
  .
private:
    TPen *FPen;
    TBrush *FBrush;
    void __fastcall SetBrush(TBrush *Value);
    void __fastcall SetPen(TPen *Value);
    .
    .
    .
__published:
```

```
    __property TBrush* Brush = {read=FBrush, write=SetBrush, nodefault};
    __property TPen* Pen = {read=FPen, write=SetPen, nodefault};
};
```

Then, write the *SetBrush* and *SetPen* methods in the implementation part of the unit:

```
procedure TSampleShape.SetBrush(Value: TBrush);
begin
  FBrush.Assign(Value);                          { replace existing brush with parameter }
end;
procedure TSampleShape.SetPen(Value: TPen);
begin
  FPen.Assign(Value);                             { replace existing pen with parameter }
end;
void __fastcall TSampleShape::SetBrush( TBrush* Value)
{
  FBrush->Assign(Value);
}
void __fastcall TSampleShape::SetPen( TPen* Value)
{
  FPen->Assign(Value);
}
```

To directly assign the contents of *Value* to *FBrush*-

```
  FBrush := Value;
  FBrush = Value;
```

- would overwrite the internal pointer for *FBrush*, lose memory, and create a number of ownership problems.

3.2.1.1.5 Declaring the Class Fields

Each class a component owns must have a class field declared for it in the component. The class field ensures that the component always has a pointer to the owned object so that it can destroy the class before destroying itself. In general, a component initializes owned objects in its constructor and destroys them in its destructor.

Fields for owned objects are nearly always declared as private. If applications (or other components) need access to the owned objects, you can declare **published** or **public** properties for this purpose.

Add fields for a pen and brush to the shape control:

```
type
  TSampleShape = class(TGraphicControl)
  private            { fields are nearly always private }
    FPen: TPen;      { a field for the pen object }
    FBrush: TBrush;  { a field for the brush object }
    .
    .
    .
  end;
class PACKAGE TSampleShape : public TGraphicControl
{
private:               // data members are always private
    TPen *FPen;        // a data member for the pen object
    TBrush *FBrush;    // a data member for the brush object
    .
    .
    .
};
```

3.2.1.1.6 Declaring the Property

When you declare a property, you usually need to declare a private field to store the data for the property, then specify methods for reading and writing the property value. Often, you don't need to use a method to read the value, but can just point to the

stored data instead.

For the shape control, you will declare a field that holds the current shape, then declare a property that reads that field and writes to it through a method call.

Add the following declarations to *TSampleShape*:

```
type
  TSampleShape = class(TGraphicControl)
  private
    FShape: TSampleShapeType;  { field to hold property value }
    procedure SetShape(Value: TSampleShapeType);
  published
    property Shape: TSampleShapeType read FShape write SetShape;
  end;
```

```
class PACKAGE TSampleShape : public TGraphicControl
{
private:
    TSampleShapeType FShape;
    void __fastcall SetShape(TSampleShapeType Value);
__published:
    __property TSampleShapeType Shape = {read=FShape, write=SetShape, nodefault};
};
```

Now all that remains is to add the implementation of *SetShape*.

3.2.1.1.7 Declaring the Property Type

When you declare a property of a user-defined type, you must declare the type first, before the class that includes the property. The most common sort of user-defined type for properties is enumerated.

For the shape control, you need an enumerated type with an element for each kind of shape the control can draw.

Add the following type definition above the shape control class's declaration.

```
type
  TSampleShapeType = (sstRectangle, sstSquare, sstRoundRect, sstRoundSquare,
    sstEllipse, sstCircle);
  TSampleShape = class(TGraphicControl) { this is already there }
```

```
enum TSampleShapeType { sstRectangle, sstSquare, sstRoundRect, sstRoundSquare, sstEllipse,
sstCircle };
class PACKAGE TSampleShape : public TGraphicControl         // this is already there
```

You can now use this type to declare a new property in the class.

3.2.1.1.8 Determining What to Draw

A graphic control can change its appearance to reflect a dynamic condition, including user input. A graphic control that always looks the same should probably not be a component at all. If you want a static image, you can import the image instead of using a control.

In general, the appearance of a graphic control depends on some combination of its properties. The gauge control, for example, has properties that determine its shape and orientation and whether it shows its progress numerically as well as graphically. Similarly, the shape control has a property that determines what kind of shape it should draw.

To give your control a property that determines the shape it draws, add a property called *Shape*. This requires

1. Declaring the property type. (see page 1223)
2. Declaring the property. (see page 1222)
3. Writing the implementation method. (see page 1230)

Creating properties is explained in more detail in Creating properties (see page 1249).

3.2.1.1.9 Drawing the Component Image

The essential element of a graphic control is the way it paints its image on the screen. The abstract type *TGraphicControl* defines a method called *Paint* that you override to paint the image you want on your control.

The *Paint* method for the shape control needs to do several things:

- Use the pen and brush selected by the user.
- Use the selected shape.
- Adjust coordinates so that squares and circles use the same width and height.

Overriding the Paint method requires two steps:

1. Add *Paint* to the component's declaration.
2. Write the *Paint* method in the **implementation** part of the unit.

For the shape control, add the following declaration to the class declaration:

```
type
  TSampleShape = class(TGraphicControl)
  .
  .
  .
  protected
    procedure Paint; override;
  .
  .
  .
  end;
class PACKAGE TSampleShape : public TGraphicControl
{
  .
  .
  .
protected:
    virtual void __fastcall Paint();
    .
    .
    .
};
```

Then write the method in the **implementation** part of the unit:

```
procedure TSampleShape.Paint;
begin
  with Canvas do
  begin
    Pen := FPen;                                          { copy the component's pen }
    Brush := FBrush;                                    { copy the component's brush }
    case FShape of
      sstRectangle, sstSquare:
        Rectangle(0, 0, Width, Height);                 { draw rectangles and squares }
      sstRoundRect, sstRoundSquare:
        RoundRect(0, 0, Width, Height, Width div 4, Height div 4); { draw rounded shapes }
      sstCircle, sstEllipse:
        Ellipse(0, 0, Width, Height);                         { draw round shapes }
    end;
  end;
end;
void __fastcall TSampleShape::Paint()
{
  int X,Y,W,H,S;
```

```
  Canvas->Pen = FPen;                                   // copy the component's pen
  Canvas->Brush = FBrush;                               // copy the component's brush
  W=Width;                                              // use the component width
  H=Height;                                             // use the component height
  X=Y=0;                                                // save smallest for circles/squares
  if( W<H )
    S=W;
  else
    S=H;
  switch(FShape)
  {
    case sstRectangle:                                   // draw rectangles and squares
    case sstSquare:
      Canvas->Rectangle(X,Y,X+W,Y+H);
      break;
    case sstRoundRect:                                   // draw rounded rectangles and squares
    case sstRoundSquare:
      Canvas->RoundRect(X,Y,X+W,Y+H,S/4,S/4);
      break;
    case sstCircle:                                      // draw circles and ellipses
    case sstEllipse:
      Canvas->Ellipse(X,Y,X+W,Y+H);
      break;
    default:
      break;
  }
}
```

Paint is called whenever the control needs to update its image. Controls are painted when they first appear or when a window in front of them goes away. In addition, you can force repainting by calling *Invalidate*, as the *StyleChanged* method does.

3.2.1.1.10 Initializing Owned Classes

If you add classes to your component, the component's constructor must initialize them so that the user can interact with the objects at runtime. Similarly, the component's destructor must also destroy the owned objects before destroying the component itself.

Because you have added a pen and a brush to the shape control, you need to initialize them in the shape control's constructor and destroy them in the control's destructor:

1. Construct the pen and brush in the shape control constructor:

```
constructor TSampleShape.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                        { always call the inherited constructor }
  Width := 65;
  Height := 65;
  FPen := TPen.Create;                                                  { construct the pen }
  FBrush := TBrush.Create;                                            { construct the brush }
end;
__fastcall TSampleShape::TSampleShape(TComponent* Owner) : TGraphicControl(Owner)
{
  Width = 65;
  Height = 65;
  FBrush = new TBrush();                             // construct the pen
  FPen = new TPen();                                 // construct the brush
}
```

2. Add the overridden destructor to the declaration of the component class:

```
type
  TSampleShape = class(TGraphicControl)
  public                                                  { destructors are always public}
    constructor Create(AOwner: TComponent); override;
    destructor Destroy; override;                          { remember override directive }
```

```
  end;
class PACKAGE TSampleShape : public TGraphicControl
{
  .
  .
  .
public:                                                  // destructors are always public
    virtual __fastcall TSampleShape(TComponent* Owner);
    __fastcall ~TSampleShape();                          // the destructor
    .
    .
    .
};
```

3. Write the new destructor in the **implementation** part of the unit:

```
destructor TSampleShape.Destroy;
begin
  FPen.Free;                                                  { destroy the pen object }
  FBrush.Free;                                               { destroy the brush object }
  inherited Destroy;                          { always call the inherited destructor, too }
end;
__fastcall TSampleShape::~TSampleShape()
{
  delete FPen;                                           // delete the pen object
  delete FBrush;                                         // delete the brush object
}
```

3.2.1.1.11 Overriding the Constructor and Destructor

To change default property values and initialize owned classes for your component, you must override the inherited constructor and destructor. In both cases, remember always to call the inherited method in your new constructor or destructor.

Changing default property values

The default size of a graphic control is fairly small, so you can change the width and height in the constructor. Changing default property values is explained in more detail in Modifying an existing component (see page 1365).

In this example, the shape control sets its size to a square 65 pixels on each side.

1. Add the overridden constructor to the declaration of the component class:

```
type
  TSampleShape = class(TGraphicControl)
  public                                                  { constructors are always public }
    constructor Create(AOwner: TComponent); override        { remember override directive }
  end;
class PACKAGE TSampleShape : public TGraphicControl
{
public:
    virtual __fastcall TSampleShape(TComponent *Owner);
};
```

2. Redeclare the *Height* and *Width* properties with their new default values:

```
type
  TSampleShape = class(TGraphicControl)
  .
  .
  .
  published
    property Height default 65;
    property Width default 65;
  end;
class PACKAGE TSampleShape : public TGraphicControl
{
  .
```

```
  .
  .
__published:
    __property Height;
    __property Width;
}
```

3. Write the new constructor in the **implementation** part of the unit:

```
constructor TSampleShape.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);  { always call the inherited constructor }
  Width := 65;
  Height := 65;
end;
__fastcall TSampleShape::TSampleShape(TComponent* Owner) : TGraphicControl(Owner)
{
  Width = 65;
  Height = 65;
}
```

3.2.1.1.12 Publishing Inherited Properties (Graphic)

Once you derive a component type, you can decide which of the properties and events declared in the protected parts of the ancestor class you want to surface in the new component. *TGraphicControl* already publishes all the properties that enable the component to function as a control, so all you need to publish is the ability to respond to mouse events and handle drag-and-drop.

Publishing inherited properties and events is explained in Publishing inherited properties (see page 1250) and Making events visible. (see page 1238) Both processes involve redeclaring just the name of the properties in the published part of the class declaration.

For the shape control, you can publish the three mouse events, the three drag-and-drop events, and the two drag-and-drop properties:

```
type
  TSampleShape = class(TGraphicControl)
  published
    property DragCursor;        { drag-and-drop properties }
    property DragMode;
    property OnDragDrop;        { drag-and-drop events }
    property OnDragOver;
    property OnEndDrag;
    property OnMouseDown;       { mouse events }
    property OnMouseMove;
    property OnMouseUp;
  end;
class PACKAGE TSampleShape : public TGraphicControl
{
private:
__published:
    __property DragCursor ;
    __property DragMode ;
    __property OnDragDrop ;
    __property OnDragOver ;
    __property OnEndDrag ;
    __property OnMouseDown ;
    __property OnMouseMove ;
    __property OnMouseUp ;
};
```

The sample shape control now makes mouse and drag-and-drop interactions available to its users.

3.2.1.1.13 Publishing the Pen and Brush

By default, a canvas has a thin black pen and a solid white brush. To let developers change the pen and brush, you must provide classes for them to manipulate at design time, then copy the classes into the canvas during painting. Classes such as an auxiliary pen or brush are called *owned classes* because the component owns them and is responsible for creating and destroying them.

Managing owned classes requires:

1. Declaring the class fields. (see page 1222)
2. Declaring the access properties. (see page 1221)
3. Initializing owned classes. (see page 1225)
4. Setting owned classes' properties. (see page 1229)

3.2.1.1.14 Refining the Shape Drawing

The standard shape control does one more thing that your sample shape control does not yet do: it handles squares and circles as well as rectangles and ellipses. To do that, you need to write code that finds the shortest side and centers the image.

Here is a refined *Paint* method that adjusts for squares and ellipses:

```
procedure TSampleShape.Paint;
var
  X, Y, W, H, S: Integer;
begin  with Canvas do
  begin
    Pen := FPen;                                          { copy the component's pen }
    Brush := FBrush;                                    { copy the component's brush }
    W := Width;                                            { use the component width }
    H := Height;                                         { use the component height }
    if W < H then S := W else S := H;                 { save smallest for circles/squares }
    case FShape of                                    { adjust height, width and position }
      sstRectangle, sstRoundRect, sstEllipse:
        begin
          X := 0;                                  { origin is top-left for these shapes }
          Y := 0;
        end;
      sstSquare, sstRoundSquare, sstCircle:
        begin
          X := (W - S) div 2;                             { center these horizontally... }
          Y := (H - S) div 2;                                       { ...and vertically }
          W := S;                                  { use shortest dimension for width... }
          H := S;                                               { ...and for height }
        end;
    end;
    case FShape of
      sstRectangle, sstSquare:
        Rectangle(X, Y, X + W, Y + H);                    { draw rectangles and squares }
      sstRoundRect, sstRoundSquare:
        RoundRect(X, Y, X + W, Y + H, S div 4, S div 4);           { draw rounded shapes }
      sstCircle, sstEllipse:
        Ellipse(X, Y, X + W, Y + H);                                 { draw round shapes }
    end;
  end;
end;
void __fastcall TSampleShape::Paint(void)
{
  int X,Y,W,H,S;
  Canvas->Pen = FPen;                        // copy the component's pen
  Canvas->Brush = FBrush;                    // copy the component's brush
```

```
  W=Width;                                    // use the component width
  H=Height;                                   // use the component height
  X=Y=0;                                      // save smallest for circles/squares
  if( W<H )
    S=W;
  else
    S=H;
  switch(FShape)                               // adjust height, width and position
  {
    case sstRectangle:
    case sstRoundRect:
    case sstEllipse:
      Y=X=0;                                 // origin is top-left for these shapes
      break;
    case sstSquare:
    case sstRoundSquare:
    case sstCircle:
      X= (W-S)/2;                             // center these horizontally
      Y= (H-S)/2;                             // and vertically
      break;
    default:
    break;
  }
  switch(FShape)
  {
    case sstSquare:                           // draw rectangles and squares
      W=H=S;                                  // use shortest dimension for width and height
    case sstRectangle:
      Canvas->Rectangle(X,Y,X+W,Y+H);
      break;
    case sstRoundSquare:                      // draw rounded rectangles and squares
      W=H=S;
    case sstRoundRect:
      Canvas->RoundRect(X,Y,X+W,Y+H,S/4,S/4);
      break;
    case sstCircle:                           // draw circles and ellipses
      W=H=S;
    case sstEllipse:
      Canvas->Ellipse(X,Y,X+W,Y+H);
      break;
    default:
      break;
  }
}
```

3.2.1.1.15 Setting Owned Classes' Properties

As the final step in handling the pen and brush classes, you need to make sure that changes in the pen and brush cause the shape control to repaint itself. Both pen and brush classes have *OnChange* events, so you can create a method in the shape control and point both *OnChange* events to it.

Add the following method to the shape control, and update the component's constructor to set the pen and brush events to the new method:

```
type
  TSampleShape = class(TGraphicControl)
  published
    procedure StyleChanged(Sender: TObject);
  end;
.
.
.
implementation
.
.
```

```
.
constructor TSampleShape.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                      { always call the inherited constructor }
  Width := 65;
  Height := 65;
  FPen := TPen.Create;                                                { construct the pen }
  FPen.OnChange := StyleChanged;                    { assign method to OnChange event }
  FBrush := TBrush.Create;                                        { construct the brush }
  FBrush.OnChange := StyleChanged;                  { assign method to OnChange event }
end;
procedure TSampleShape.StyleChanged(Sender: TObject);
begin
  Invalidate;                                    { erase and repaint the component }
end;
//header file
class PACKAGE TSampleShape : public TGraphicControl
{
  .
  .
  .
public:
    void __fastcall StyleChanged(TObject* Owner);
    .
    .
    .
};
//implmentation file
__fastcall TSampleShape::TSampleShape(TComponent* Owner) : TGraphicControl(Owner)
{
  Width = 65;
  Height = 65;
  FBrush = new TBrush();
  FBrush->OnChange = StyleChanged;
  FPen = new TPen();
  FPen->OnChange = StyleChanged;
}
//also include StyleChanged method in the implementation file
void __fastcall TSampleShape::StyleChanged( TObject* Sender)
{
  Invalidate();         // repaints the component
}
```

With these changes, the component redraws to reflect changes to either the pen or the brush.

3.2.1.1.16 Writing the Implementation Method

When the **read** or **write** part of a property definition uses a method instead of directly accessing the stored property data, you need to implement the method.

Add the implementation of the *SetShape* method to the **implementation** part of the unit:

```
procedure TSampleShape.SetShape(Value: TSampleShapeType);
begin
  if FShape <> Value then                          { ignore if this isn"t a change }
  begin
    FShape := Value;                               { store the new value }
    Invalidate;                                    { force a repaint with the new shape }
  end;
end;
void __fastcall TSampleShape::SetShape(TSampleShapeType Value)
{
  if (FShape != Value)             // ignore if this isn't a change
  {
     FShape = Value;               // store the new value
```

```
      Invalidate();                // force a repaint with the new shape
    }
  }
```

3.2.1.2 Creating events

Topics

Name	Description
Creating Events: Overview (see page 1233)	An event is a link between an occurrence in the system (such as a user action or a change in focus) and a piece of code that responds to that occurrence. The responding code is an *event handler*, and is nearly always written by the application developer. Events let application developers customize the behavior of components without having to change the classes themselves. This is known as *delegation*. Events for the most common user actions (such as mouse actions) are built into all the standard components, but you can also define new events. To create events in a... more (see page 1233)
What Are Events? (see page 1234)	An event is a mechanism that links an occurrence to some code. More specifically, an event is a method pointer that points to a method in a specific class instance. From the application developer's perspective, an event is just a name related to a system occurrence, such as *OnClick*, to which specific code can be attached. For example, a push button called *Button1* has an *OnClick* method. By default, when you assign a value to the *OnClick* event, the Form Designer generates an event handler called *Button1Click* in the form that contains the button and assigns it to *OnClick... more (see page 1234)*
Events Are closures (C++) (see page 1234)	Closures are used to implement events. A closure is a special pointer type that points to a specific method in a specific class instance. As a component writer, you can treat the closure as a place holder: your code detects that an event occurs, so you call the method (if any) specified by the user for that event. Closures maintain a hidden pointer to a class instance. When the user assigns a handler to a component's event, the assignment is not just to a method with a particular name, but rather to a specific method of a specific class instance.... more (see page 1234)
Events Are Method Pointers (see page 1234)	Delphi uses method pointers to implement events. A method pointer is a special pointer type that points to a specific method in a specific class instance. As a component writer, you can treat the method pointer as a placeholder: When your code detects that an event occurs, you call the method (if any) specified by the user for that event. Method pointers work just like any other procedural type, but they maintain a hidden pointer to a class instance. When the application developer assigns a handler to a component's event, the assignment is not just to a method with a... more (see page 1234)
Calling the Click-event Handler (see page 1235)	All controls, for example, inherit a dynamic method called *Click* for handling click events:
Events Are Properties (see page 1235)	Components use properties to implement their events. Unlike most other properties, events do not use methods to implement their read and write parts. Instead, event properties use a private class field of the same type as the property. By convention, the field's name is the name of the property preceded by the letter *F*. For example, the *OnClick* method's pointer is stored in a field called *FOnClick* of type *TNotifyEvent*, and the declaration of the *OnClick* event property looks like this:
Event Types Are Method-pointer Types (see page 1235)	Because an event is a pointer to an event handler, the type of the event property must be a method-pointer type. Similarly, any code to be used as an event handler must be an appropriately typed method of a class. All event-handler methods are procedures. To be compatible with an event of a given type, an event-handler method must have the same number and type of parameters, in the same order, passed in the same way. Delphi defines method types for all its standard events. When you create your own events, you can use an existing type if that is... more (see page 1235)

Event Handler Types Are Procedures (see page 1236)	Although the compiler allows you to declare method-pointer types that are functions, you should never do so for handling events. Because an empty function returns an undefined result, an empty event handler that was a function might not always be valid. For this reason, all your events and their associated event handlers should be procedures. Although an event handler cannot be a function, you can still get information from the application developer's code using **var** parameters. When doing this, make sure you assign a valid value to the parameter before calling the handler so you don't require the user's code... more (see page 1236)
Event Handlers Have A Return Type of void (C++) (see page 1236)	Event handlers must have a return type of **void**. Even though the handler can return only **void**, you can still get information back from the user's code by passing arguments by reference. When you do this, make sure you assign a valid value to the argument before calling the handler so you do not require the user's code to change the value. An example of passing arguments by reference to an event handler is the key-pressed event, of type `TKeyPressEvent`. `TKeyPressEvent` defines two arguments: one to indicate which object generated the event, and one to indicate which... more (see page 1236)
Event Types Are closure Types (C++) (see page 1236)	Because an event is a pointer to an event handler, the type of the event property must be a closure type. Similarly, any code to be used as an event handler must be an appropriately typed method of a class. To be compatible with an event of a given type, an event-handler method must have the same number and type of parameters, in the same order, passed in the same way. C++Builder defines closures for all its standard events. When you create your own events, you can use an existing closure if that is appropriate, or define one of your... more (see page 1236)
Event Handlers Are Optional (see page 1237)	When creating events, remember that developers using your components may not attach handlers to them. This means that your component should not fail or generate errors simply because there is no handler attached to a particular event. (The mechanics of calling handlers and dealing with events that have no attached handler are explained in Calling the event (see page 1240).) Events happen almost constantly in a GUI application. Just moving the mouse pointer across a visual component sends numerous mouse-move messages, which the component translates into *OnMouseMove* events. In most cases, developers do not want to handle the mouse-move events, and this... more (see page 1237)
Implementing the Standard Events (see page 1237)	The controls that come with the component library inherit events for the most common occurrences. These are called the *standard events*. Although all these events are built into the controls, they are often **protected**, meaning developers cannot attach handlers to them. When you create a control, you can choose to make events visible to users of your control. There are three things you need to consider when incorporating the standard events into your controls: • Identifying standard events (see page 1237) • Making events visible (see page 1238) • Changing the standard event handling (see page 1238)
Identifying Standard Events (see page 1237)	There are two categories of standard events: those defined for all controls and those defined only for the standard windowed controls.
Making Events Visible (see page 1238)	The declarations of the standard events in *TControl* and *TWinControl* are protected, as are the methods that correspond to them. If you are inheriting from one of these abstract classes and want to make their events accessible at runtime or design time, you need to redeclare the events as either **public** or **published**. Redeclaring a property without specifying its implementation keeps the same implementation methods, but changes the protection level. You can, therefore, take an event that is defined in *TControl* but not made visible, and surface it by declaring it as public or published.
Changing the Standard Event Handling (see page 1238)	If you want to change the way your component responds to a certain kind of event, you might be tempted to write some code and assign it to the event. As an application developer, that is exactly what you would do. But when you are creating a component, you must keep the event available for developers who use the component. This is the reason for the protected implementation methods associated with each of the standard events. By overriding the implementation method, you can modify the internal event handling; and by calling the inherited method you can maintain the standard handling,... more (see page 1238)

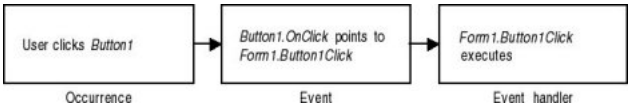
Defining Your Own Events (see page 1238)	Defining entirely new events is relatively unusual. There are times, however, when a component introduces behavior that is entirely different from that of any other component, so you will need to define an event for it. There are the issues you will need to consider when defining an event: • Triggering the event (see page 1239) • Defining the handler type (see page 1239) • Declaring the event (see page 1240) • Calling the event (see page 1240)
Triggering the Event (see page 1239)	You need to know what triggers the event. For some events, the answer is obvious. For example, a mouse-down event occurs when the user presses the left button on the mouse and Windows sends a *WM_LBUTTONDOWN* message to the application. Upon receiving that message, a component calls its *MouseDown* method, which in turn calls any code the user has attached to the *OnMouseDown* event. However, some events are less clearly tied to specific external occurrences. For example, a scroll bar has an *OnChange* event, which is triggered by several kinds of occurrence, including keystrokes, mouse clicks, and changes in other... more (see page 1239)
Two Kinds of Events (see page 1239)	There are two kinds of occurrence you might need to provide events for: user interactions and state changes. User-interaction events are nearly always triggered by a message from Windows, indicating that the user did something your component may need to respond to. State-change events may also be related to messages from Windows (focus changes or enabling, for example), but they can also occur through changes in properties or other code. You have total control over the triggering of the events you define. Define the events with care so that developers are able to understand and use them.
Defining the Handler Type (see page 1239)	Once you determine when the event occurs, you must define how you want the event handled. This means determining the type of the event handler. In most cases, handlers for events you define yourself are either simple notifications or event-specific types. It is also possible to get information back from the handler.
Declaring the Event (see page 1240)	Once you have determined the type of your event handler, you are ready to declare the method pointer and the property for the event. Be sure to give the event a meaningful and descriptive name so that users can understand what the event does. Try to be consistent with names of similar properties in other components.
Calling the Event (see page 1240)	You should centralize calls to an event. That is, create a virtual method in your component that calls the application's event handler (if it assigns one) and provides any default handling. Putting all the event calls in one place ensures that someone deriving a new component from yours can customize event handling by overriding a single method, rather than searching through your code for places where you call the event. There are two other considerations when calling the event: • Empty handlers must be valid. (see page 1240) • Users can override default handling. (see page 1240)
Empty Handlers Must Be Valid (see page 1240)	You should never create a situation in which an empty event handler causes an error, nor should the proper functioning of your component depend on a particular response from the application's event-handling code.
Users Can Override Default Handling (see page 1240)	For some kinds of events, developers may want to replace the default handling or even suppress all responses. To allow this, you need to pass an argument by reference to the handler and check for a certain value when the handler returns. This is in keeping with the rule that an empty handler should have the same effect as no handler at all. Because an empty handler will not change the values of arguments passed by reference, the default handling always takes place after calling the empty handler.

3.2.1.2.1 Creating Events: Overview

An event is a link between an occurrence in the system (such as a user action or a change in focus) and a piece of code that responds to that occurrence. The responding code is an *event handler*, and is nearly always written by the application developer. Events let application developers customize the behavior of components without having to change the classes themselves. This is known as *delegation*.

Events for the most common user actions (such as mouse actions) are built into all the standard components, but you can also define new events. To create events in a component, you need to understand the following:

- What are events? (see page 1234)
- Implementing the standard events (see page 1237)
- Defining your own events (see page 1238)



Events are implemented as properties, so you should already be familiar with the material in Creating properties (see page 1249) before you attempt to create or change a component's events.

3.2.1.2.2 What Are Events?

An event is a mechanism that links an occurrence to some code. More specifically, an event is a method pointer that points to a method in a specific class instance.

From the application developer's perspective, an event is just a name related to a system occurrence, such as *OnClick*, to which specific code can be attached. For example, a push button called *Button1* has an *OnClick* method. By default, when you assign a value to the *OnClick* event, the Form Designer generates an event handler called *Button1Click* in the form that contains the button and assigns it to *OnClick*. When a click event occurs in the button, the button calls the method assigned to *OnClick*, in this case, *Button1Click*.

To write an event, you need to understand the following:

- Events are method pointers (see page 1234).
- Events are properties (see page 1235).
- Event types are method-pointer types (see page 1235).
- Event-handler types are procedures (see page 1236).
- Event handlers are optional (see page 1237).

3.2.1.2.3 Events Are closures (C++)

Closures are used to implement events. A closure is a special pointer type that points to a specific method in a specific class instance. As a component writer, you can treat the closure as a place holder: your code detects that an event occurs, so you call the method (if any) specified by the user for that event.

Closures maintain a hidden pointer to a class instance. When the user assigns a handler to a component's event, the assignment is not just to a method with a particular name, but rather to a specific method of a specific class instance. That instance is usually the form that contains the component, but it need not be.

3.2.1.2.4 Events Are Method Pointers

Delphi uses method pointers to implement events. A method pointer is a special pointer type that points to a specific method in a specific class instance. As a component writer, you can treat the method pointer as a placeholder: When your code detects that an event occurs, you call the method (if any) specified by the user for that event.

Method pointers work just like any other procedural type, but they maintain a hidden pointer to a class instance. When the application developer assigns a handler to a component's event, the assignment is not just to a method with a particular name, but rather to a method of a specific class instance. That instance is usually the form that contains the component, but it need not be.

3.2.1.2.5 Calling the Click-event Handler

All controls, for example, inherit a dynamic method called *Click* for handling click events:

```
procedure Click; dynamic;
virtual void __fastcall Click(void);
```

The implementation of *Click* calls the user's click-event handler, if one exists. If the user has assigned a handler to a control's *OnClick* event, clicking the control results in that method being called. If no handler is assigned, nothing happens.

3.2.1.2.6 Events Are Properties

Components use properties to implement their events. Unlike most other properties, events do not use methods to implement their read and write parts. Instead, event properties use a private class field of the same type as the property.

By convention, the field's name is the name of the property preceded by the letter *F*. For example, the *OnClick* method's pointer is stored in a field called *FOnClick* of type *TNotifyEvent*, and the declaration of the *OnClick* event property looks like this:

```
type
  TControl = class(TComponent)
  private
    FOnClick: TNotifyEvent;                { declare a field to hold the method pointer }
    .
    .
    .
  protected
    property OnClick: TNotifyEvent read FOnClick write FOnClick;
  end;
class PACKAGE TControl : public TComponent
{
private:
    TNotifyEvent FOnClick;
  .
  .
  .
protected:
    __property TNotifyEvent OnClick = {read=FOnClick, write=FOnClick};
  .
  .
  .
};
```

To learn about *TNotifyEvent* and other event types, see the next section, Event types are method-pointer types. (see page 1235)

As with any other property, you can set or change the value of an event at runtime. The main advantage to having events be properties, however, is that component users can assign handlers to events at design time, using the Object Inspector.

3.2.1.2.7 Event Types Are Method-pointer Types

Because an event is a pointer to an event handler, the type of the event property must be a method-pointer type. Similarly, any code to be used as an event handler must be an appropriately typed method of a class.

All event-handler methods are procedures. To be compatible with an event of a given type, an event-handler method must have the same number and type of parameters, in the same order, passed in the same way.

Delphi defines method types for all its standard events. When you create your own events, you can use an existing type if that is appropriate, or define one of your own.

3.2.1.2.8 Event Handler Types Are Procedures

Although the compiler allows you to declare method-pointer types that are functions, you should never do so for handling events. Because an empty function returns an undefined result, an empty event handler that was a function might not always be valid. For this reason, all your events and their associated event handlers should be procedures.

Although an event handler cannot be a function, you can still get information from the application developer's code using **var** parameters. When doing this, make sure you assign a valid value to the parameter before calling the handler so you don't require the user's code to change the value.

An example of passing **var** parameters to an event handler is the *OnKeyPress* event, of type *TKeyPressEvent*. *TKeyPressEvent* defines two parameters, one to indicate which object generated the event, and one to indicate which key was pressed:

```
type
  TKeyPressEvent = procedure(Sender: TObject; var Key: Char) of object;
```

Normally, the *Key* parameter contains the character pressed by the user. Under certain circumstances, however, the user of the component may want to change the character. One example might be to force all characters to uppercase in an editor. In that case, the user could define the following handler for keystrokes:

```
procedure TForm1.Edit1KeyPressed(Sender: TObject; var Key: Char);
begin
  Key := UpCase(Key);
end;
```

You can also use **var** parameters to let the user override the default handling.

3.2.1.2.9 Event Handlers Have A Return Type of void (C++)

Event handlers must have a return type of **void**. Even though the handler can return only **void**, you can still get information back from the user's code by passing arguments by reference. When you do this, make sure you assign a valid value to the argument before calling the handler so you do not require the user's code to change the value.

An example of passing arguments by reference to an event handler is the key-pressed event, of type `TKeyPressEvent`. `TKeyPressEvent` defines two arguments: one to indicate which object generated the event, and one to indicate which key was pressed:

```
typedef void __fastcall (__closure *TKeyPressEvent)(TObject *Sender, Char &Key);
```

Normally, the `Key` parameter contains the character pressed by the user. Under certain circumstances, however, the user of the component might want to change the character. One example might be to force all characters to uppercase in an edit control. In that case, the user could define the following handler for keystrokes:

```
void __fastcall TForm1::Edit1KeyPress(TObject *Sender, Char &Key)
{
  Key = UpCase(Key);
}
```

You can also use arguments passed by reference to let the user override the default handling.

3.2.1.2.10 Event Types Are closure Types (C++)

Because an event is a pointer to an event handler, the type of the event property must be a closure type. Similarly, any code to be used as an event handler must be an appropriately typed method of a class.

To be compatible with an event of a given type, an event-handler method must have the same number and type of parameters, in the same order, passed in the same way.

C++Builder defines closures for all its standard events. When you create your own events, you can use an existing closure if that is appropriate, or define one of your own.

3.2.1.2.11 Event Handlers Are Optional

When creating events, remember that developers using your components may not attach handlers to them. This means that your component should not fail or generate errors simply because there is no handler attached to a particular event. (The mechanics of calling handlers and dealing with events that have no attached handler are explained in Calling the event (see page 1240).)

Events happen almost constantly in a GUI application. Just moving the mouse pointer across a visual component sends numerous mouse-move messages, which the component translates into *OnMouseMove* events. In most cases, developers do not want to handle the mouse-move events, and this should not cause a problem. So the components you create should not require handlers for their events.

Moreover, application developers can write any code they want in an event handler. The components in the class library have events written in such a way as to minimize the chance of an event handler generating errors. Obviously, you cannot protect against logic errors in application code, but you can ensure that data structures are initialized before calling events so that application developers do not try to access invalid data.

3.2.1.2.12 Implementing the Standard Events

The controls that come with the component library inherit events for the most common occurrences. These are called the *standard events*. Although all these events are built into the controls, they are often **protected**, meaning developers cannot attach handlers to them. When you create a control, you can choose to make events visible to users of your control.

There are three things you need to consider when incorporating the standard events into your controls:

- Identifying standard events (see page 1237)
- Making events visible (see page 1238)
- Changing the standard event handling (see page 1238)

3.2.1.2.13 Identifying Standard Events

There are two categories of standard events: those defined for all controls and those defined only for the standard windowed controls.

Standard events for all controls

The most basic events are defined in the class *TControl*. All controls, whether windowed, graphical, or custom, inherit these events. The following events are available in all controls:

- *OnClick*
- *OnDblClick*
- *OnDragDrop*
- *OnDragOver*
- *OnEndDrag*
- *OnMouseMove*
- *OnMouseDown*
- *OnMouseUp*

The standard events have corresponding protected virtual methods declared in *TControl*, with names that correspond to the event names. For example, *OnClick* events call a method named *Click*, and *OnEndDrag* events call a method named

DoEndDrag.

Standard events for standard controls

In addition to the events common to all controls, standard windowed controls (those that descend from *TWinControl*) have the following events:

- *OnEnter*
- *OnKeyPress*
- *OnKeyDown*
- *OnKeyUp*
- *OnExit*

Like the standard events in *TControl*, the windowed control events have corresponding methods. The standard key events listed above respond to all normal keystrokes.

Note: To respond to special keystrokes (such as the Alt

key), however, you must respond to the WM_GETDLGCODE or CM_WANTSPECIALKEYS message from Windows. See Handling messages and system notifications (see page 1308) for information on writing message handlers.

3.2.1.2.14 Making Events Visible

The declarations of the standard events in *TControl* and *TWinControl* are protected, as are the methods that correspond to them. If you are inheriting from one of these abstract classes and want to make their events accessible at runtime or design time, you need to redeclare the events as either **public** or **published**.

Redeclaring a property without specifying its implementation keeps the same implementation methods, but changes the protection level. You can, therefore, take an event that is defined in *TControl* but not made visible, and surface it by declaring it as public or published.

3.2.1.2.15 Changing the Standard Event Handling

If you want to change the way your component responds to a certain kind of event, you might be tempted to write some code and assign it to the event. As an application developer, that is exactly what you would do. But when you are creating a component, you must keep the event available for developers who use the component.

This is the reason for the protected implementation methods associated with each of the standard events. By overriding the implementation method, you can modify the internal event handling; and by calling the inherited method you can maintain the standard handling, including the event for the application developer's code.

The order in which you call the methods is significant. As a rule, call the inherited method first, allowing the application developer's event-handler to execute before your customizations (and in some cases, to keep the customizations from executing). There may be times when you want to execute your code before calling the inherited method, however. For example, if the inherited code is somehow dependent on the status of the component and your code changes that status, you should make the changes and then allow the user's code to respond to them.

3.2.1.2.16 Defining Your Own Events

Defining entirely new events is relatively unusual. There are times, however, when a component introduces behavior that is entirely different from that of any other component, so you will need to define an event for it.

There are the issues you will need to consider when defining an event:

- Triggering the event (see page 1239)

- Defining the handler type (see page 1239)
- Declaring the event (see page 1240)
- Calling the event (see page 1240)

3.2.1.2.17 Triggering the Event

You need to know what triggers the event. For some events, the answer is obvious. For example, a mouse-down event occurs when the user presses the left button on the mouse and Windows sends a *WM_LBUTTONDOWN* message to the application. Upon receiving that message, a component calls its *MouseDown* method, which in turn calls any code the user has attached to the *OnMouseDown* event.

However, some events are less clearly tied to specific external occurrences. For example, a scroll bar has an *OnChange* event, which is triggered by several kinds of occurrence, including keystrokes, mouse clicks, and changes in other controls. When defining your events, you must ensure that all the appropriate occurrences call the proper events.

3.2.1.2.18 Two Kinds of Events

There are two kinds of occurrence you might need to provide events for: user interactions and state changes. User-interaction events are nearly always triggered by a message from Windows, indicating that the user did something your component may need to respond to. State-change events may also be related to messages from Windows (focus changes or enabling, for example), but they can also occur through changes in properties or other code.

You have total control over the triggering of the events you define. Define the events with care so that developers are able to understand and use them.

3.2.1.2.19 Defining the Handler Type

Once you determine when the event occurs, you must define how you want the event handled. This means determining the type of the event handler. In most cases, handlers for events you define yourself are either simple notifications or event-specific types. It is also possible to get information back from the handler.

Simple notifications

A notification event is one that only tells you that the particular event happened, with no specific information about when or where. Notifications use the type *TNotifyEvent*, which carries only one parameter, the sender of the event. All a handler for a notification "knows" about the event is what kind of event it was, and what component the event happened to. For example, click events are notifications. When you write a handler for a click event, all you know is that a click occurred and which component was clicked.

Notification is a one-way process. There is no mechanism to provide feedback or prevent further handling of a notification.

Event-specific handlers

In some cases, it is not enough to know which event happened and what component it happened to. For example, if the event is a key-press event, it is likely that the handler will want to know which key the user pressed. In these cases, you need handler types that include parameters for additional information.

If your event was generated in response to a message, it is likely that the parameters you pass to the event handler come directly from the message parameters.

Returning information from the handler

Because all event handlers are procedures, the only way to pass information back from a handler is through a **var** parameter. Your components can use such information to determine how or whether to process an event after the user's handler executes.

For example, all the key events (*OnKeyDown*, *OnKeyUp*, and *OnKeyPress*) pass by reference the value of the key pressed in a parameter named *Key*. The event handler can change *Key* so that the application sees a different key as being involved in the event. This is a way to force typed characters to uppercase, for example.

3.2.1.2.20 Declaring the Event

Once you have determined the type of your event handler, you are ready to declare the method pointer and the property for the event. Be sure to give the event a meaningful and descriptive name so that users can understand what the event does. Try to be consistent with names of similar properties in other components.

Event names start with "On"

The names of most events in Delphi begin with "On." This is just a convention; the compiler does not enforce it. The Object Inspector determines that a property is an event by looking at the type of the property: all method-pointer properties are assumed to be events and appear on the Events page.

Developers expect to find events in the alphabetical list of names starting with "On." Using other kinds of names is likely to confuse them.

Note: The main exception to this rule is that many events that occur before and after some occurrence begin with "Before" and "After."

3.2.1.2.21 Calling the Event

You should centralize calls to an event. That is, create a virtual method in your component that calls the application's event handler (if it assigns one) and provides any default handling.

Putting all the event calls in one place ensures that someone deriving a new component from yours can customize event handling by overriding a single method, rather than searching through your code for places where you call the event.

There are two other considerations when calling the event:

- Empty handlers must be valid. (see page 1240)
- Users can override default handling. (see page 1240)

3.2.1.2.22 Empty Handlers Must Be Valid

You should never create a situation in which an empty event handler causes an error, nor should the proper functioning of your component depend on a particular response from the application's event-handling code.

3.2.1.2.23 Users Can Override Default Handling

For some kinds of events, developers may want to replace the default handling or even suppress all responses. To allow this, you need to pass an argument by reference to the handler and check for a certain value when the handler returns.

This is in keeping with the rule that an empty handler should have the same effect as no handler at all. Because an empty handler will not change the values of arguments passed by reference, the default handling always takes place after calling the empty handler.

3.2.1.3 Creating methods

Topics

Name	Description
Abstract Methods (see page 1242)	Sometimes a method is declared as **abstract** in a Delphi component. In the component library, abstract methods usually occur in classes whose names begin with "custom," such as *TCustomGrid*. Such classes are themselves abstract, in the sense that they are intended only for deriving descendant classes. While you can create an instance object of a class that contains an abstract member, it is not recommended. Calling the abstract member leads to an *EAbstractError* exception. The **abstract** directive is used to indicate parts of classes that should be surfaced and defined in descendant components; it forces component writers to redeclare... more (see page 1242)
Avoiding Interdependencies (see page 1242)	At all times when writing components, minimize the preconditions imposed on the developer. To the greatest extent possible, developers should be able to do anything they want to a component, whenever they want to do it. There will be times when you cannot accommodate that, but your goal should be to come as close as possible. This list gives you an idea of the kinds of dependencies to avoid: • Methods that the user *must* call to use the component • Methods that must execute in a particular order • Methods that put the component into a state or mode where certain events... more (see page 1242)
Creating Methods: Overview (see page 1243)	Component methods are procedures and functions built into the structure of a class. Although there are essentially no restrictions on what you can do with the methods of a component, Delphi does use some standards you should follow. These guidelines include: • Avoiding dependencies (see page 1242) • Naming methods (see page 1244) • Protecting methods (see page 1245) • Making methods virtual (see page 1245) • Declaring methods (see page 1243) In general, components should not contain many methods and you should minimize the number of methods that an application needs to call. The features you might be inclined to implement as methods are often better encapsulated into properties. Properties provide an interface that suits the Delphi and are... more (see page 1243)
Declaring Methods (see page 1243)	Declaring a method in a component is the same as declaring any class method. To declare a new method in a component, do the following: • Add the declaration to the component's object-type declaration. • Implement the method in the **implementation** part of the component's unit.
Example of Declaring Methods (see page 1243)	The following code shows a component that defines two new methods, one **protected** method and one **public** virtual method.

Methods That Should Be Protected (see page 1244)	Any implementation methods for the component should be **protected** so that applications cannot call them at the wrong time. If you have methods that application code should not call, but that are called in derived classes, declare them as **protected**. For example, suppose you have a method that relies on having certain data set up for it beforehand. If you make that method **public**, there is a chance that applications will call it before setting up the data. On the other hand, by making it **protected**, you ensure that applications cannot call it directly. You can then... more (see page 1244)
Methods That Should Be Public (see page 1244)	Any method that application developers need to call must be declared as **public**. Keep in mind that most method calls occur in event handlers, so methods should avoid tying up system resources or putting the operating system in a state where it cannot respond to the user. **Note:** Constructors and destructors should always be **public**.
Naming Methods (see page 1244)	Delphi imposes no restrictions on what you name methods or their parameters. There are a few conventions that make methods easier for application developers, however. Keep in mind that the nature of a component architecture dictates that many different kinds of people can use your components. If you are accustomed to writing code that only you or a small group of programmers use, you might not think too much about how you name things. It is a good idea to make your method names clear because people unfamiliar with your code (and even unfamiliar with coding) might have to use... more (see page 1244)
Protecting Methods (see page 1245)	All parts of classes, including fields, methods, and properties, have a level of protection or "visibility," as explained in Controlling access. (see page 1371) Choosing the appropriate visibility for a method is simple. Most methods you write in your components are **public** or **protected**. You rarely need to make a method **private**, unless it is truly specific to that type of component, to the point that even derived components should not have access to it.
Making Methods Virtual (see page 1245)	You make methods **virtual** when you want different types to be able to execute different code in response to the same method call. If you create components intended to be used directly by application developers, you can probably make all your methods nonvirtual. On the other hand, if you create abstract components from which other components will be derived, consider making the added methods **virtual**. This way, derived components can override the inherited **virtual** methods.

3.2.1.3.1 Abstract Methods

Sometimes a method is declared as **abstract** in a Delphi component. In the component library, abstract methods usually occur in classes whose names begin with "custom," such as *TCustomGrid*. Such classes are themselves abstract, in the sense that they are intended only for deriving descendant classes.

While you can create an instance object of a class that contains an abstract member, it is not recommended. Calling the abstract member leads to an *EAbstractError* exception.

The **abstract** directive is used to indicate parts of classes that should be surfaced and defined in descendant components; it forces component writers to redeclare the abstract member in descendant classes before actual instances of the class can be created.

3.2.1.3.2 Avoiding Interdependencies

At all times when writing components, minimize the preconditions imposed on the developer. To the greatest extent possible, developers should be able to do anything they want to a component, whenever they want to do it. There will be times when you cannot accommodate that, but your goal should be to come as close as possible.

This list gives you an idea of the kinds of dependencies to avoid:

- Methods that the user *must* call to use the component
- Methods that must execute in a particular order
- Methods that put the component into a state or mode where certain events or methods could be invalid

The best way to handle these situations is to ensure that you provide ways out of them. For example, if calling a method puts your component into a state where calling another method might be invalid, then write that second method so that if an application calls it when the component is in a bad state, the method corrects the state before executing its main code. At a minimum, you should raise an exception in cases when a user calls a method that is invalid.

In other words, if you create a situation where parts of your code depend on each other, the burden should be on *you* to be sure that using the code in incorrect ways does not cause problems. A warning message, for example, is preferable to a system failure if the user does not accommodate your dependencies.

3.2.1.3.3 Creating Methods: Overview

Component methods are procedures and functions built into the structure of a class. Although there are essentially no restrictions on what you can do with the methods of a component, Delphi does use some standards you should follow. These guidelines include:

- Avoiding dependencies (see page 1242)
- Naming methods (see page 1244)
- Protecting methods (see page 1245)
- Making methods virtual (see page 1245)
- Declaring methods (see page 1243)

In general, components should not contain many methods and you should minimize the number of methods that an application needs to call. The features you might be inclined to implement as methods are often better encapsulated into properties. Properties provide an interface that suits the Delphi and are accessible at design time.

3.2.1.3.4 Declaring Methods

Declaring a method in a component is the same as declaring any class method.

To declare a new method in a component, do the following:

- Add the declaration to the component's object-type declaration.
- Implement the method in the **implementation** part of the component's unit.

3.2.1.3.5 Example of Declaring Methods

The following code shows a component that defines two new methods, one **protected** method and one **public** virtual method.

C++

This is the interface definition in the `.H` file:

```
class PACKAGE TSampleComponent : public TControl
{
protected:
    void __fastcall MakeBigger();
public:
    virtual int __fastcall CalculateArea();
  .
  .
  .
};
```

This is the code in the .CPP file of the unit that implements the methods:

```
void __fastcall TSampleComponent::MakeBigger()
{
  Height = Height + 5;
  Width = Width + 5;
```

```
}
int __fastcall TSampleComponent::CalculateArea()
{
  return Width * Height;
}
```

Delphi

```
type
  TSampleComponent = class(TControl)
  protected
    procedure MakeBigger;                                { declare protected static method }
  public
    function CalculateArea: Integer; virtual;            { declare public virtual method }
  end;
.
.
.
implementation
.
.
.
procedure TSampleComponent.MakeBigger;                          { implement first method }
begin
  Height := Height + 5;
  Width := Width + 5;
end;
function TSampleComponent.CalculateArea: Integer;              { implement second method }
begin
  Result := Width * Height;
end;
```

3.2.1.3.6 Methods That Should Be Protected

Any implementation methods for the component should be **protected** so that applications cannot call them at the wrong time. If you have methods that application code should not call, but that are called in derived classes, declare them as **protected**.

For example, suppose you have a method that relies on having certain data set up for it beforehand. If you make that method **public**, there is a chance that applications will call it before setting up the data. On the other hand, by making it **protected**, you ensure that applications cannot call it directly. You can then set up other, **public** methods that ensure that data setup occurs before calling the **protected** method.

Property-implementation methods should be declared as virtual **protected** methods. Methods that are so declared allow the application developers to override the property implementation, either augmenting its functionality or replacing it completely. Such properties are fully polymorphic. Keeping access methods **protected** ensures that developers do not accidentally call them, inadvertently modifying a property.

3.2.1.3.7 Methods That Should Be Public

Any method that application developers need to call must be declared as **public**. Keep in mind that most method calls occur in event handlers, so methods should avoid tying up system resources or putting the operating system in a state where it cannot respond to the user.

Note: Constructors and destructors should always be **public**.

3.2.1.3.8 Naming Methods

Delphi imposes no restrictions on what you name methods or their parameters. There are a few conventions that make methods easier for application developers, however. Keep in mind that the nature of a component architecture dictates that many different

kinds of people can use your components.

If you are accustomed to writing code that only you or a small group of programmers use, you might not think too much about how you name things. It is a good idea to make your method names clear because people unfamiliar with your code (and even unfamiliar with coding) might have to use your components.

Here are some suggestions for making clear method names:

- Make names descriptive. Use meaningful verbs. A name like *PasteFromClipboard* is much more informative than simply *Paste* or *PFC*.
- Function names should reflect the nature of what they return.

Although it might be obvious to you as a programmer that a function named *X* returns the horizontal position of something, a name like *GetHorizontalPosition* is more universally understandable.

As a final consideration, make sure the method really needs to be a method. A good guideline is that method names have verbs in them. If you find that you create a lot of methods that do not have verbs in their names, consider whether those methods ought to be properties.

3.2.1.3.9 Protecting Methods

All parts of classes, including fields, methods, and properties, have a level of protection or "visibility," as explained in Controlling access. (see page 1371) Choosing the appropriate visibility for a method is simple.

Most methods you write in your components are **public** or **protected**. You rarely need to make a method **private**, unless it is truly specific to that type of component, to the point that even derived components should not have access to it.

3.2.1.3.10 Making Methods Virtual

You make methods **virtual** when you want different types to be able to execute different code in response to the same method call.

If you create components intended to be used directly by application developers, you can probably make all your methods nonvirtual. On the other hand, if you create abstract components from which other components will be derived, consider making the added methods **virtual**. This way, derived components can override the inherited **virtual** methods.

3.2.1.4 Creating properties

Topics

Name	Description
Creating Properties: Overview (see page 1249)	Properties are the most visible parts of components. The application developer can see and manipulate them at design time and get immediate feedback as the components react in the Form Designer. Well-designed properties make your components easier for others to use and easier for you to maintain. To make the best use of properties in your components, you should understand the following: • Why create properties? (see page 1249) • Types of properties (see page 1250) • Publishing inherited properties (see page 1250) • Defining properties (see page 1251) • Creating array properties (see page 1253) • Storing and loading properties (see page 1254)

Why Create Properties? (see page 1249)	From the application developer's standpoint, properties look like variables. Developers can set or read the values of properties as if they were fields. (About the only thing you can do with a variable that you cannot do with a property is pass it as a **var** parameter.) Properties provide more power than simple fields because • Application developers can set properties at design time. Unlike methods, which are available only at runtime, properties let the developer customize components before running an application. Properties can appear in the Object Inspector, which simplifies the programmer's job; instead of handling several parameters to construct... more (see page 1249)
Types of Properties (see page 1250)	A property can be of any type. Different types are displayed differently in the Object Inspector, which validates property assignments as they are made at design time. ***How properties appear in the Object Inspector***
Publishing Inherited Properties (see page 1250)	All components inherit properties from their ancestor classes. When you derive a new component from an existing one, your new component inherits all the properties of its immediate ancestor. If you derive from one of the abstract classes, many of the inherited properties are either protected or public, but not published. To make a protected or public property available at design time in the Object Inspector, you must redeclare the property as published. Redeclaring means adding a declaration for the inherited property to the declaration of the descendant class.
Defining Properties (see page 1251)	This section shows how to declare new properties and explains some of the conventions followed in the standard components. Topics include: • Property declarations (see page 1251) • Internal data storage (see page 1251) • Direct access (see page 1251) • Access methods (see page 1252) • Default property values (see page 1253)
Property Declarations (see page 1251)	A property is declared in the declaration of its component class. To declare a property, you specify three things: • The name of the property. • The type of the property. • The methods used to read and write the value of the property. If no write method is declared, the property is read-only. Properties declared in a **published** section of the component's class declaration are editable in the Object Inspector at design time. The value of a published property is saved with the component in the form file. Properties declared in a **public** section are available at runtime and can be read... more (see page 1251)

Internal Data Storage (see page 1251)	There are no restrictions on how you store the data for a property. In general, however, Delphi components follow these conventions: • Property data is stored in class fields. • The fields used to store property data are private and should be accessed only from within the component itself. Derived components should use the inherited property; they do not need direct access to the property's internal data storage. • Identifiers for these fields consist of the letter *F* followed by the name of the property. For example, the raw data for the *Width* property defined in *TControl* is stored in a field called... more (see page 1251)
Direct Access (see page 1251)	The simplest way to make property data available is *direct access*. That is, the **read** and **write** parts of the property declaration specify that assigning or reading the property value goes directly to the internal-storage field without calling an access method. Direct access is useful when you want to make a property available in the Object Inspector but changes to its value trigger no immediate processing. It is common to have direct access for the **read** part of a property declaration but use an access method for the **write** part. This allows the status of the component to be... more (see page 1251)
Access Methods (properties) (see page 1252)	You can specify an access method instead of a field in the **read** and **write** parts of a property declaration. Access methods should be protected, and are usually declared as **virtual**; this allows descendant components to override the property's implementation. Avoid making access methods public. Keeping them protected ensures that application developers do not inadvertently modify a property by calling one of these methods.
The Read Method (see page 1252)	The read method for a property is a function that takes no parameters (except as noted below) and returns a value of the same type as the property. By convention, the function's name is *Get* followed by the name of the property. For example, the read method for a property called *Count* would be *GetCount*. The read method manipulates the internal storage data as needed to produce the value of the property in the appropriate type. The only exceptions to the no-parameters rule are for array properties and properties that use index specifiers (see Creating array properties (see page 1253)), both... more (see page 1252)
The Write Method (see page 1252)	The write method for a property is a procedure that takes a single parameter (except as noted below) of the same type as the property. The parameter can be passed by reference or by value, and can have any name you choose. By convention, the write method's name is *Set* followed by the name of the property. For example, the write method for a property called *Count* would be *SetCount*. The value passed in the parameter becomes the new value of the property; the write method must perform any manipulation needed to put the appropriate data in the property's... more (see page 1252)
Default Property Values (see page 1253)	When you declare a property, you can specify a *default value* for it. The VCL uses the default value to determine whether to store the property in a form file. If you do not specify a default value for a property, the VCL always stores the property. To specify a default value for a property, append the **default** directive to the property's declaration (or redeclaration), followed by the default value. For example,
Specifying No Default Value (see page 1253)	When redeclaring a property, you can specify that the property has no default value, even if the inherited property specified one. To designate a property as having no default value, append the **nodefault** directive to the property's declaration. For example,

Creating Array Properties (see page 1253)	Some properties lend themselves to being indexed like arrays. For example, the *Lines* property of *TMemo* is an indexed list of the strings that make up the text of the memo; you can treat it as an array of strings. *Lines* provides natural access to a particular element (a string) in a larger set of data (the memo text). Array properties are declared like other properties, except that • The declaration includes one or more indexes with specified types. The indexes can be of any type. • The **read** and **write** parts of the property declaration, if specified, must be methods. They... more (see page 1253)
Creating Properties for Interfaces (see page 1253)	You can use an interface as the value of a published property, much as you can use an object. However, the mechanism by which your component receives notifications from the implementation of that interface differs. In Creating properties for subcomponents (see page 1254), the property setter called the *FreeNotification* method of the component that was assigned as the property value. This allowed the component to update itself when the component that was the value of the property was freed. When the value of the property is an interface, however, you don't have access to the component that implements that interface. As a... more (see page 1253)
Creating Properties for Subcomponents (see page 1254)	By default, when a property's value is another component, you assign a value to that property by adding an instance of the other component to the form or data module and then assigning that component as the value of the property. However, it is also possible for your component to create its own instance of the object that implements the property value. Such a dedicated component is called a subcomponent. Subcomponents can be any persistent object (any descendant of *TPersistent*). Unlike separate components that happen to be assigned as the value of a property, the published properties of subcomponents... more (see page 1254)
Storing and Loading Properties (see page 1254)	Delphi stores forms and their components in form (.dfm in VCL applications) files. A form file stores the properties of a form and its components. When Delphi developers add the components you write to their forms, your components must have the ability to write their properties to the form file when saved. Similarly, when loaded into Delphi or executed as part of an application, the components must restore themselves from the form file. Most of the time you will not need to do anything to make your components work with form files because the ability to store a representation... more (see page 1254)
Using the Store-and-load Mechanism (see page 1255)	The description of a form consists of a list of the form's properties, along with similar descriptions of each component on the form. Each component, including the form itself, is responsible for storing and loading its own description. By default, when storing itself, a component writes the values of all its published properties that differ from their default values, in the order of their declaration. When loading itself, a component first constructs itself, setting all properties to their default values, then reads the stored, non-default property values. This default mechanism serves the needs of most components, and requires no action... more (see page 1255)
Specifying Default Values (see page 1255)	Delphi components save their property values only if those values differ from the defaults. If you do not specify otherwise, Delphi assumes a property has no default value, meaning the component always stores the property, whatever its value. To specify a default value for a property, add the **default** directive and the new default value to the end of the property declaration. You can also specify a default value when re-declaring a property. In fact, one reason to re-declare a property is to designate a different default value.
Determining What to Store (see page 1255)	You can control whether Delphi stores each of your components' properties. By default, all properties in the published part of the class declaration are stored. You can choose not to store a given property at all, or you can designate a function that determines dynamically whether to store the property. To control whether Delphi stores a property, add the **stored** directive to the property declaration, followed by *True*, *False*, or the name of a Boolean function.

Initializing After Loading (see page 1256)	After a component reads all its property values from its stored description, it calls a virtual method named *Loaded*, which performs any required initializations. The call to *Loaded* occurs before the form and its controls are shown, so you do not need to worry about initialization causing flicker on the screen. To initialize a component after it loads its property values, override the *Loaded* method. **Note:** The first thing to do in any *Loaded* method is call the inherited *Loaded* method. This ensures that any inherited properties are correctly initialized before you initialize your own component. The following code... more (see page 1256)
Storing and Loading Unpublished Properties (see page 1256)	By default, only published properties are loaded and saved with a component. However, it is possible to load and save unpublished properties. This allows you to have persistent properties that do not appear in the Object Inspector. It also allows components to store and load property values that Delphi does not know how to read or write because the value of the property is too complex. For example, the *TStrings* object can't rely on Delphi's automatic behavior to store and load the strings it represents and must use the following mechanism. You can save unpublished properties by adding code that... more (see page 1256)
Creating Methods to Store and Load Property Values (see page 1256)	To store and load unpublished properties, you must first create a method to store your property value and another to load your property value. You have two choices: • Create a method of type *TWriterProc* to store your property value and a method of type *TReaderProc* to load your property value. This approach lets you take advantage of Delphi's built-in capabilities for saving and loading simple types. If your property value is built out of types that Delphi knows how to save and load, use this approach. • Create two methods of type *TStreamProc*, one to store and one to load... more (see page 1256)
Overriding the DefineProperties Method (see page 1257)	Once you have created methods to store and load your property value, you can override the component's *DefineProperties* method. Delphi calls this method when it loads or stores the component. In the *DefineProperties* method, you must call the *DefineProperty* method or the *DefineBinaryProperty* method of the current filer, passing it the method to use for loading or saving your property value. If your load and store methods are of type *TWriterProc* and type *TReaderProc*, then you call the filer's *DefineProperty* method. If you created methods of type *TStreamProc*, call *DefineBinaryProperty* instead. No matter which method you use to... more (see page 1257)

3.2.1.4.1 Creating Properties: Overview

Properties are the most visible parts of components. The application developer can see and manipulate them at design time and get immediate feedback as the components react in the Form Designer. Well-designed properties make your components easier for others to use and easier for you to maintain.

To make the best use of properties in your components, you should understand the following:

- Why create properties? (see page 1249)
- Types of properties (see page 1250)
- Publishing inherited properties (see page 1250)
- Defining properties (see page 1251)
- Creating array properties (see page 1253)
- Storing and loading properties (see page 1254)

3.2.1.4.2 Why Create Properties?

From the application developer's standpoint, properties look like variables. Developers can set or read the values of properties

as if they were fields. (About the only thing you can do with a variable that you cannot do with a property is pass it as a **var** parameter.)

Properties provide more power than simple fields because

- Application developers can set properties at design time. Unlike methods, which are available only at runtime, properties let the developer customize components before running an application. Properties can appear in the Object Inspector, which simplifies the programmer's job; instead of handling several parameters to construct an object, the Object Inspector supplies the values. The Object Inspector also validates property assignments as soon as they are made.
- Properties can hide implementation details. For example, data stored internally in an encrypted form can appear unencrypted as the value of a property; although the value is a simple number, the component may look up the value in a database or perform complex calculations to arrive at it. Properties let you attach complex effects to outwardly simple assignments; what looks like an assignment to a field can be a call to a method which implements elaborate processing.
- Properties can be virtual. Hence, what looks like a single property to an application developer may be implemented differently in different components.

A simple example is the *Top* property of all controls. Assigning a new value to *Top* does not just change a stored value; it repositions and repaints the control. And the effects of setting a property need not be limited to an individual component; for example, setting the *Down* property of a speed button to *True* sets *Down* property of all other speed buttons in its group to *False*.

3.2.1.4.3 Types of Properties

A property can be of any type. Different types are displayed differently in the Object Inspector, which validates property assignments as they are made at design time.

How properties appear in the Object Inspector

Property type	treatment
Simple	Numeric, character, and string properties appear as numbers, characters, and strings. The application developer can edit the value of the property directly.
Enumerated	Properties of enumerated types (including Boolean) appear as editable strings. The developer can also cycle through the possible values by double-clicking the value column, and there is a drop-down list that shows all possible values.
Set	Properties of set types appear as sets. By double-clicking on the property, the developer can expand the set and treat each element as a Boolean value (true if it is included in the set).
Object	Properties that are themselves classes often have their own property editors, specified in the component's registration procedure. If the class held by a property has its own published properties, the Object Inspector lets the developer to expand the list (by double-clicking) to include these properties and edit them individually. Object properties must descend from *TPersistent*.
Interface	Properties that are interfaces can appear in the Object Inspector as long as the value is an interface that is implemented by a component (a descendant of *TComponent*). Interface properties often have their own property editors.
Array	Array properties must have their own property editors; the Object Inspector has no built-in support for editing them. You can specify a property editor when you register your components.

3.2.1.4.4 Publishing Inherited Properties

All components inherit properties from their ancestor classes. When you derive a new component from an existing one, your new component inherits all the properties of its immediate ancestor. If you derive from one of the abstract classes, many of the inherited properties are either protected or public, but not published.

To make a protected or public property available at design time in the Object Inspector, you must redeclare the property as

published. Redeclaring means adding a declaration for the inherited property to the declaration of the descendant class.

3.2.1.4.5 Defining Properties

This section shows how to declare new properties and explains some of the conventions followed in the standard components. Topics include:

- Property declarations (see page 1251)
- Internal data storage (see page 1251)
- Direct access (see page 1251)
- Access methods (see page 1252)
- Default property values (see page 1253)

3.2.1.4.6 Property Declarations

A property is declared in the declaration of its component class. To declare a property, you specify three things:

- The name of the property.
- The type of the property.
- The methods used to read and write the value of the property. If no write method is declared, the property is read-only.

Properties declared in a **published** section of the component's class declaration are editable in the Object Inspector at design time. The value of a published property is saved with the component in the form file. Properties declared in a **public** section are available at runtime and can be read or set in program code.

3.2.1.4.7 Internal Data Storage

There are no restrictions on how you store the data for a property. In general, however, Delphi components follow these conventions:

- Property data is stored in class fields.
- The fields used to store property data are private and should be accessed only from within the component itself. Derived components should use the inherited property; they do not need direct access to the property's internal data storage.
- Identifiers for these fields consist of the letter *F* followed by the name of the property. For example, the raw data for the *Width* property defined in *TControl* is stored in a field called *FWidth*.

The principle that underlies these conventions is that only the implementation methods for a property should access the data behind it. If a method or another property needs to change that data, it should do so through the property, not by direct access to the stored data. This ensures that the implementation of an inherited property can change without invalidating derived components.

3.2.1.4.8 Direct Access

The simplest way to make property data available is *direct access*. That is, the **read** and **write** parts of the property declaration specify that assigning or reading the property value goes directly to the internal-storage field without calling an access method. Direct access is useful when you want to make a property available in the Object Inspector but changes to its value trigger no immediate processing.

It is common to have direct access for the **read** part of a property declaration but use an access method for the **write** part. This allows the status of the component to be updated when the property value changes.

3.2.1.4.9 Access Methods (properties)

You can specify an access method instead of a field in the **read** and **write** parts of a property declaration. Access methods should be protected, and are usually declared as **virtual**; this allows descendant components to override the property's implementation.

Avoid making access methods public. Keeping them protected ensures that application developers do not inadvertently modify a property by calling one of these methods.

3.2.1.4.10 The Read Method

The read method for a property is a function that takes no parameters (except as noted below) and returns a value of the same type as the property. By convention, the function's name is *Get* followed by the name of the property. For example, the read method for a property called *Count* would be *GetCount*. The read method manipulates the internal storage data as needed to produce the value of the property in the appropriate type.

The only exceptions to the no-parameters rule are for array properties and properties that use index specifiers (see Creating array properties (see page 1253)), both of which pass their index values as parameters. (Use index specifiers to create a single read method that is shared by several properties. For more information about index specifiers, see the *Delphi Language Guide*.)

If you do not declare a read method, the property is write-only. Write-only properties are seldom used.

3.2.1.4.11 The Write Method

The write method for a property is a procedure that takes a single parameter (except as noted below) of the same type as the property. The parameter can be passed by reference or by value, and can have any name you choose. By convention, the write method's name is *Set* followed by the name of the property. For example, the write method for a property called *Count* would be *SetCount*. The value passed in the parameter becomes the new value of the property; the write method must perform any manipulation needed to put the appropriate data in the property's internal storage.

The only exceptions to the single-parameter rule are for array properties and properties that use index specifiers, both of which pass their index values as a second parameter. (Use index specifiers to create a single write method that is shared by several properties. For more information about index specifiers, see the *Delphi Language Guide*.)

If you do not declare a write method, the property is read-only.

Write methods commonly test whether a new value differs from the current value before changing the property. For example, here is a simple write method for an integer property called *Count* that stores its current value in a field called *FCount*.

```
procedure TMyComponent.SetCount(Value: Integer);
begin
  if Value <> FCount then
  begin
    FCount := Value;
    Update;
  end;
end;
```

```
void __fastcall TMyComponent::SetCount( int Value )
{
  if ( Value != FCount )
  {
    FCount = Value;
    Update();
  }
```

3.2.1.4.12 Default Property Values

When you declare a property, you can specify a *default value* for it. The VCL uses the default value to determine whether to store the property in a form file. If you do not specify a default value for a property, the VCL always stores the property.

To specify a default value for a property, append the **default** directive to the property's declaration (or redeclaration), followed by the default value. For example,

```
property Cool Boolean read GetCool write SetCool default True;
__property bool IsTrue = {read=GetIsTrue, write=SetIsTrue, default=true};
```

Note: Declaring a default value does not set the property to that value. The component's constructor method should initialize property values when appropriate. However, since objects always initialize their fields to 0, it is not strictly necessary for the constructor to set integer properties to 0, string properties to null, or Boolean properties to *False*.

3.2.1.4.13 Specifying No Default Value

When redeclaring a property, you can specify that the property has no default value, even if the inherited property specified one.

To designate a property as having no default value, append the **nodefault** directive to the property's declaration. For example,

```
property FavoriteFlavor string nodefault;
__property int NewInteger = {nodefault};
```

When you declare a property for the first time, there is no need to include **nodefault**. The absence of a declared default value means that there is no default.

3.2.1.4.14 Creating Array Properties

Some properties lend themselves to being indexed like arrays. For example, the *Lines* property of *TMemo* is an indexed list of the strings that make up the text of the memo; you can treat it as an array of strings. *Lines* provides natural access to a particular element (a string) in a larger set of data (the memo text).

Array properties are declared like other properties, except that

- The declaration includes one or more indexes with specified types. The indexes can be of any type.
- The **read** and **write** parts of the property declaration, if specified, must be methods. They cannot be fields.

The read and write methods for an array property take additional parameters that correspond to the indexes. The parameters must be in the same order and of the same type as the indexes specified in the declaration.

There are a few important differences between array properties and arrays. Unlike the index of an array, the index of an array property does not have to be an integer type. You can index a property on a string, for example. In addition, you can reference only individual elements of an array property, not the entire range of the property.

3.2.1.4.15 Creating Properties for Interfaces

You can use an interface as the value of a published property, much as you can use an object. However, the mechanism by which your component receives notifications from the implementation of that interface differs. In Creating properties for subcomponents (see page 1254), the property setter called the *FreeNotification* method of the component that was assigned as the property value. This allowed the component to update itself when the component that was the value of the property was freed. When the value of the property is an interface, however, you don't have access to the component that implements that interface. As a result, you can't call its *FreeNotification* method.

To handle this situation, you can call your component's *ReferenceInterface* method:

```
procedure TDemoComponent.SetMyIntfProp(const Value: IMyInterface);
```

```
begin
  ReferenceInterface(FIntfField, opRemove);
  FIntfField := Value;
  ReferenceInterface(FIntfField, opInsert);
end;
```

Calling *ReferenceInterface* with a specified interface does the same thing as calling another component's *FreeNotification* method. Thus, after calling *ReferenceInterface* from the property setter, you can override the *Notification* method to handle the notifications from the implementor of the interface:

```
procedure TDemoComponent.Notification(AComponent: TComponent; Operation: TOperation);
begin
  inherited Notification(AComponent, Operation);
  if (Assigned(MyIntfProp)) and (AComponent.IsImplementorOf(MyInftProp)) then
    MyIntfProp := nil;
end;
```

Note that the *Notification* code assigns **nil** to the *MyIntfProp* property, not to the private field (*FIntfField*). This ensures that *Notification* calls the property setter, which calls *ReferenceInterface* to remove the notification request that was established when the property value was set previously. All assignments to the interface property must be made through the property setter.

3.2.1.4.16 Creating Properties for Subcomponents

By default, when a property's value is another component, you assign a value to that property by adding an instance of the other component to the form or data module and then assigning that component as the value of the property. However, it is also possible for your component to create its own instance of the object that implements the property value. Such a dedicated component is called a subcomponent.

Subcomponents can be any persistent object (any descendant of *TPersistent*). Unlike separate components that happen to be assigned as the value of a property, the published properties of subcomponents are saved with the component that creates them. In order for this to work, however, the following conditions must be met:

- The *Owner* of the subcomponent must be the component that creates it and uses it as the value of a published property. For subcomponents that are descendants of *TComponent*, you can accomplish this by setting the *Owner* property of the subcomponent. For other subcomponents, you must override the *GetOwner* method of the persistent object so that it returns the creating component.
- If the subcomponent is a descendant of *TComponent*, it must indicate that it is a subcomponent by calling the *SetSubComponent* method. Typically, this call is made either by the owner when it creates the subcomponent or by the constructor of the subcomponent.

  Note: When a component that has subcomponents is streamed, the subcomponents will have their csLoading flag set and their Loaded method called. This can create a complication for any subcomponent properties that are writable. If you allow your subcomponent property to be assigned to an external component reference, then you cannot free your subcomponent until it's owner's Loaded method is called. Otherwise, the streaming system will attempt to call the subcomponent's Loaded method after the subcomponent has been freed.

  Typically, properties whose values are subcomponents are read-only. If you allow a property whose value is a subcomponent to be changed, the property setter must free the subcomponent when another component is assigned as the property value. In addition, the component often re-instantiates its subcomponent when the property is set to nil. Otherwise, once the property is changed to another component, the subcomponent can never be restored at design time.

  Note that the property setter above called the *FreeNotification* method of the component that is set as the property value. This call ensures that the component that is the value of the property sends a notification if it is about to be destroyed. It sends this notification by calling the *Notification* method. You handle this call by overriding the *Notification* method.

3.2.1.4.17 Storing and Loading Properties

Delphi stores forms and their components in form (.dfm in VCL applications) files. A form file stores the properties of a form and its components. When Delphi developers add the components you write to their forms, your components must have the ability to

write their properties to the form file when saved. Similarly, when loaded into Delphi or executed as part of an application, the components must restore themselves from the form file.

Most of the time you will not need to do anything to make your components work with form files because the ability to store a representation and load from it are part of the inherited behavior of components. Sometimes, however, you might want to alter the way a component stores itself or the way it initializes when loaded; so you should understand the underlying mechanism.

These are the aspects of property storage you need to understand:

- Using the store-and-load mechanism (see page 1255)
- Specifying default values (see page 1255)
- Determining what to store (see page 1255)
- Initializing after loading (see page 1256)
- Storing and loading unpublished properties (see page 1256)

3.2.1.4.18 Using the Store-and-load Mechanism

The description of a form consists of a list of the form's properties, along with similar descriptions of each component on the form. Each component, including the form itself, is responsible for storing and loading its own description.

By default, when storing itself, a component writes the values of all its published properties that differ from their default values, in the order of their declaration. When loading itself, a component first constructs itself, setting all properties to their default values, then reads the stored, non-default property values.

This default mechanism serves the needs of most components, and requires no action at all on the part of the component writer. There are several ways you can customize the storing and loading process to suit the needs of your particular components, however.

3.2.1.4.19 Specifying Default Values

Delphi components save their property values only if those values differ from the defaults. If you do not specify otherwise, Delphi assumes a property has no default value, meaning the component always stores the property, whatever its value.

To specify a default value for a property, add the **default** directive and the new default value to the end of the property declaration.

You can also specify a default value when re-declaring a property. In fact, one reason to re-declare a property is to designate a different default value.

```
__property Alignment = {default=taCenter};
```

Note: Specifying the default value does not automatically assign that value to the property on creation of the object. You must make sure that the component's constructor assigns the necessary value. A property whose value is not set by a component's constructor assumes a zero value- that is, whatever value the property assumes when its storage memory is set to 0. Thus numeric values default to 0, Boolean values to *False*, pointers to **nil**, and so on. If there is any doubt, assign a value in the constructor method.

3.2.1.4.20 Determining What to Store

You can control whether Delphi stores each of your components' properties. By default, all properties in the published part of the class declaration are stored. You can choose not to store a given property at all, or you can designate a function that determines dynamically whether to store the property.

To control whether Delphi stores a property, add the **stored** directive to the property declaration, followed by *True*, *False*, or the

name of a Boolean function.

3.2.1.4.21 Initializing After Loading

After a component reads all its property values from its stored description, it calls a virtual method named *Loaded*, which performs any required initializations. The call to *Loaded* occurs before the form and its controls are shown, so you do not need to worry about initialization causing flicker on the screen.

To initialize a component after it loads its property values, override the *Loaded* method.

Note: The first thing to do in any *Loaded* method is call the inherited *Loaded* method. This ensures that any inherited properties are correctly initialized before you initialize your own component.

The following code comes from the *TDatabase* component. After loading, the database tries to reestablish any connections that were open at the time it was stored, and specifies how to handle any exceptions that occur while connecting.

```
procedure TDatabase.Loaded;
begin
  inherited Loaded;                                  { call the inherited method first}
  try
    if FStreamedConnected then Open                        { reestablish connections }
    else CheckSessionName(False);
  except
    if csDesigning in ComponentState then                          { at design time... }
      Application.HandleException(Self)              { let Delphi handle the exception }
    else raise;                                                  { otherwise, reraise }
  end;
end;
```

3.2.1.4.22 Storing and Loading Unpublished Properties

By default, only published properties are loaded and saved with a component. However, it is possible to load and save unpublished properties. This allows you to have persistent properties that do not appear in the Object Inspector. It also allows components to store and load property values that Delphi does not know how to read or write because the value of the property is too complex. For example, the *TStrings* object can't rely on Delphi's automatic behavior to store and load the strings it represents and must use the following mechanism.

You can save unpublished properties by adding code that tells Delphi how to load and save your property's value.

To write your own code to load and save properties, use the following steps:

1. Create methods to store and load the property value (see page 1256).
2. Override the DefineProperties method (see page 1257), passing those methods to a filer object.

3.2.1.4.23 Creating Methods to Store and Load Property Values

To store and load unpublished properties, you must first create a method to store your property value and another to load your property value. You have two choices:

- Create a method of type *TWriterProc* to store your property value and a method of type *TReaderProc* to load your property value. This approach lets you take advantage of Delphi's built-in capabilities for saving and loading simple types. If your property value is built out of types that Delphi knows how to save and load, use this approach.
- Create two methods of type *TStreamProc*, one to store and one to load your property's value. *TStreamProc* takes a stream as an argument, and you can use the stream's methods to write and read your property values.

For example, consider a property that represents a component that is created at runtime. Delphi knows how to write this value, but does not do so automatically because the component is not created in the form designer. Because the streaming system can already load and save components, you can use the first approach. The following methods load and store the dynamically

created component that is the value of a property named *MyCompProperty*:

```
procedure TSampleComponent.LoadCompProperty(Reader: TReader);
begin
  if Reader.ReadBoolean then
    MyCompProperty := Reader.ReadComponent(nil);
end;
procedure TSampleComponent.StoreCompProperty(Writer: TWriter);
begin
  Writer.WriteBoolean(MyCompProperty <> nil);
  if MyCompProperty <> nil then
    Writer.WriteComponent(MyCompProperty);
end;
void __fastcall TSampleComponent::LoadCompProperty(TReader *Reader)
{
  if (Reader->ReadBoolean())
    MyCompProperty = Reader->ReadComponent(NULL);
}
void __fastcall TSampleComponent::StoreCompProperty(TWriter *Writer)
{
  if (MyCompProperty)
  {
    Writer->WriteBoolean(true);
    Writer->WriteComponent(MyCompProperty);
  }
  else
    Writer->WriteBoolean(false);
}
```

3.2.1.4.24 Overriding the DefineProperties Method

Once you have created methods to store and load your property value, you can override the component's *DefineProperties* method. Delphi calls this method when it loads or stores the component. In the *DefineProperties* method, you must call the *DefineProperty* method or the *DefineBinaryProperty* method of the current filer, passing it the method to use for loading or saving your property value. If your load and store methods are of type *TWriterProc* and type *TReaderProc*, then you call the filer's *DefineProperty* method. If you created methods of type *TStreamProc*, call *DefineBinaryProperty* instead.

No matter which method you use to define the property, you pass it the methods that store and load your property value as well as a boolean value indicating whether the property value needs to be written. If the value can be inherited or has a default value, you do not need to write it.

For example, given the *LoadCompProperty* method of type *TReaderProc* and the *StoreCompProperty* method of type *TWriterProc*, you would override *DefineProperties* as follows:

```
procedure TSampleComponent.DefineProperties(Filer: TFiler);
  function DoWrite: Boolean;
  begin
    if Filer.Ancestor <> nil then { check Ancestor for an inherited value }
    begin
      if TSampleComponent(Filer.Ancestor).MyCompProperty = nil then
        Result := MyCompProperty <> nil
      else   if (MyCompProperty = nil) or
         (TMy5Comp(Filer.Ancestor).MyCompProperty.Name <> MyCompProperty.Name) then
        Result := True
      else Result := False;
    end
    else { no inherited value -- check for default (nil) value }
      Result := MyCompProperty <> nil;
  end;
begin
  inherited; { allow base classes to define properties }
  Filer.DefineProperty('MyCompProperty', LoadCompProperty, StoreCompProperty, DoWrite);
end;
void __fastcall TSampleComponent::DefineProperties(TFiler *Filer)
```

```
{
  // before we do anything, let the base class define its properties.
  // Note that this example assumes that TSampleComponent derives directly from TComponent
  TComponent::DefineProperties(Filer);
  bool WriteValue;
  if (Filer->Ancestor) // check for inherited value
  {
    if ((TSampleComponent *)Filer->Ancestor)->MyCompProperty == NULL)
      WriteValue = (MyCompProperty != NULL);
    else if ((MyCompProperty == NULL) ||
            (((TSampleComponent *)Filer->Ancestor)->MyCompProperty->Name !=
                                                    MyCompProperty->Name))
      WriteValue = true;
    else WriteValue = false;
  }
  else // no inherited value, write property if not null
    WriteValue = (MyCompProperty != NULL);
  Filer->DefineProperty("MyCompProperty ",LoadCompProperty,StoreCompProperty, WriteValue);
end;
```

3.2.1.5 Customizing a grid

Topics

Name	Description
Accessing the Day, Month, and Year (see page 1260)	An encoded numeric date is fine for applications, but humans prefer to work with days, months, and years. You can provide alternate access to those elements of the stored, encoded date by creating properties. Because each element of the date (day, month, and year) is an integer, and because setting each requires encoding the date when set, you can avoid duplicating the code each time by sharing the implementation methods for all three properties. That is, you can write two methods, one to read an element and one to write one, and use those methods to get and set all... more (see page 1260)
Changing Initial Values (see page 1262)	A calendar is essentially a grid with a fixed number of rows and columns, although not all the rows always contain dates. For this reason, you have not published the grid properties *ColCount* and *RowCount*, because it is highly unlikely that users of the calendar will want to display anything other than seven days per week. You still must set the initial values of those properties so that the week always has seven days, however. To change the initial values of the component's properties, override the constructor to set the desired values. The constructor must be virtual. Remember that... more (see page 1262)
Creating and registering the component (Grid) (see page 1263)	You create every component the same way: create a unit, derive a component class, register it, compile it, and install it on the Tool palette. Creating a new component. (see page 1317)

Customizing a Grid: Overview (see page 1264)	The component library provides abstract components you can use as the basis for customized components. The most important of these are grids and list boxes. The following topics describe how to create a small one month calendar from the basic grid component, *TCustomGrid*: • Creating and registering the component (see page 1263) • Publishing inherited properties (see page 1271) • Changing initial values (see page 1262) • Resizing the cells (see page 1272) • Filling in the cells (see page 1265) • Navigating months and years (see page 1269) • Navigating days (see page 1269) In VCL applications, the resulting component is similar to the *TCalendar* component on the Samples category of the Tool palette. See Specifying the palette page (see page 1356).
Excluding Blank Cells (see page 1265)	As the calendar is written, the user can select a blank cell, but the date does not change. It makes sense, then, to disallow selection of the blank cells. To control whether a given cell is selectable, override the *SelectCell* method of the grid. *SelectCell* is a function that takes a column and row as parameters, and returns a Boolean value indicating whether the specified cell is selectable. You can override *SelectCell* to return *False* if the cell does not contain a valid date:
Filling in the Cells (see page 1265)	A grid control fills in its contents cell-by-cell. In the case of the calendar, that means calculating which date, if any, belongs in each cell. The default drawing for grid cells takes place in a virtual method called *DrawCell*. To fill in the contents of grid cells, override the *DrawCell* method. The easiest part to fill in is the heading cells in the fixed row. The runtime library contains an array with short day names, so for the calendar, use the appropriate one for each column:
Generating the Day Numbers (see page 1266)	Putting numbers into the calendar involves several considerations. The number of days in the month depends on which month it is, and whether the given year is a leap year. In addition, months start on different days of the week, dependent on the month and year. Use the *IsLeapYear* function to determine whether the year is a leap year. Use the *MonthDays* array in the SysUtils unit to get the number of days in the month. Once you have the information on leap years and days per month, you can calculate where in the grid the individual dates go.... more (see page 1266)
Moving the Selection (see page 1268)	The inherited behavior of a grid handles moving the selection in response to either arrow keys or clicks, but if you want to change the selected day, you need to modify that default behavior. To handle movements within the calendar, override the *Click* method of the grid. When you override a method such as *Click* that is tied in with user interactions, you will nearly always include a call to the inherited method, so as not to lose the standard behavior. The following is an overridden *Click* method for the calendar grid. Be sure to add the declaration of *Click... more (see page 1268)*
Navigating Days (see page 1269)	Within a given month, there are two obvious ways to navigate among the days. The first is to use the arrow keys, and the other is to respond to clicks of the mouse. The standard grid component handles both as if they were clicks. That is, an arrow movement is treated like a click on an adjacent cell. The process of navigating days consists of • Moving the selection (see page 1268) • Providing an OnChange event (see page 1270) • Excluding blank cells (see page 1265)

Navigating Months and Years (see page 1269)	Properties are useful for manipulating components, especially at design time. But sometimes there are types of manipulations that are so common or natural, often involving more than one property, that it makes sense to provide methods to handle them. One example of such a natural manipulation is a "next month" feature for a calendar. Handling the wrapping around of months and incrementing of years is simple, but very convenient for the developer using the component. The only drawback to encapsulating common manipulations into methods is that methods are only available at runtime. However, such manipulations are generally only cumbersome when... more (see page 1269)
Providing an OnChange Event (see page 1270)	Now that users of the calendar can change the date within the calendar, it makes sense to allow applications to respond to those changes.
Publishing Inherited Properties (Grid) (see page 1271)	The abstract grid component, *TCustomGrid*, provides a large number of **protected** properties. You can choose which of those properties you want to make available to users of the calendar control. To make inherited protected properties available to users of your components, redeclare the properties in the **published** part of your component's declaration. For the calendar control, publish the following properties and events, as shown here:
Resizing the Cells (see page 1272)	**Note:** When a user or application changes the size of a window or control, Windows sends a message called *WM_SIZE* to the affected window or control so it can adjust any settings needed to later paint its image in the new size. Your VCL component can respond to that message by altering the size of the cells so they all fit inside the boundaries of the control. To respond to the *WM_SIZE* message, you will add a message-handling method to the component. Creating a message-handling method is described in detail in the section Creating new message handlers. (see page 1304) In this case,... more (see page 1272)
Selecting the Current Day (see page 1274)	Now that you have numbers in the calendar cells, it makes sense to move the selection highlighting to the cell containing the current day. By default, the selection starts on the top left cell, so you need to set the *Row* and *Column* properties both when constructing the calendar initially and when the date changes. To set the selection on the current day, change the *UpdateCalendar* method to set *Row* and *Column* before calling *Refresh*:
Storing the Internal Date (see page 1274)	To store the date for the calendar, you need a private field to hold the date and a runtime-only property that provides access to that date.
Tracking the Date (see page 1275)	For the calendar control to be useful, users and applications must have a mechanism for setting the day, month, and year. Delphi stores dates and times in variables of type *TDateTime*. *TDateTime* is an encoded numeric representation of the date and time, which is useful for programmatic manipulation, but not convenient for human use. You can therefore store the date in encoded form, providing runtime access to that value, but also provide *Day*, *Month*, and *Year* properties that users of the calendar component can set at design time. Tracking the date in the calendar consists of the... more (see page 1275)

3.2.1.5.1 Accessing the Day, Month, and Year

An encoded numeric date is fine for applications, but humans prefer to work with days, months, and years. You can provide alternate access to those elements of the stored, encoded date by creating properties.

Because each element of the date (day, month, and year) is an integer, and because setting each requires encoding the date when set, you can avoid duplicating the code each time by sharing the implementation methods for all three properties. That is, you can write two methods, one to read an element and one to write one, and use those methods to get and set all three properties.

To provide design-time access to the day, month, and year, you do the following:

1. Declare the three properties, assigning each a unique **index** number:

```
type
  TSampleCalendar = class(TCustomGrid)
  public
    property Day: Integer index 3 read GetDateElement write SetDateElement;
    property Month: Integer index 2 read GetDateElement write SetDateElement;
```

```
    property Year: Integer index 1 read GetDateElement write SetDateElement;
  .
  .
  .
class PACKAGE TSampleCalendar : public TCustomGrid
{
  .
  .
  .
public:
    __property int Day = {read=GetDateElement, write=SetDateElement, index=3,
      nodefault};
    __property int Month = {read=GetDateElement, write=SetDateElement, index=2,
nodefault};
    __property int Year = {read=GetDateElement, write=SetDateElement, index=1,
nodefault};
};
```

2. Declare and write the implementation methods, setting different elements for each index value:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    function GetDateElement(Index: Integer): Integer;         { note the Index parameter }
    procedure SetDateElement(Index: Integer; Value: Integer);
  .
  .
  .
function TSampleCalendar.GetDateElement(Index: Integer): Integer;
var
  AYear, AMonth, ADay: Word;
begin
  DecodeDate(FDate, AYear, AMonth, ADay);             { break encoded date into elements }
  case Index of
    1: Result := AYear;
    2: Result := AMonth;
    3: Result := ADay;
    else Result := -1;
  end;
end;
procedure TSampleCalendar.SetDateElement(Index: Integer; Value: Integer);
var
  AYear, AMonth, ADay: Word;
begin
  if Value > 0 then                                      { all elements must be positive }
  begin
    DecodeDate(FDate, AYear, AMonth, ADay);                  { get current date elements }
    case Index of                                     { set new element depending on Index }
      1: AYear := Value;
      2: AMonth := Value;
      3: ADay := Value;
      else Exit;
    end;
    FDate := EncodeDate(AYear, AMonth, ADay);                { encode the modified date }
    Refresh;                                            { update the visible calendar }
  end;
end;
// header file
class PACKAGE TSampleCalendar : public TCustomGrid
{
private:
    int __fastcall GetDateElement(int Index);           // note the Index parameter
    void __fastcall SetDateElement(int Index, int Value);
    .
    .
    .
};
```

```
// implementation file
int __fastcall TSampleCalendar::GetDateElement(int Index)
{
  unsigned short AYear, AMonth, ADay;
  int result;
  FDate.DecodeDate(&AYear, &AMonth, &ADay);            // break encoded date into elements
  switch (Index)
  {
    case 1: result = AYear;  break;
    case 2: result = AMonth; break;
    case 3: result = ADay;   break;
    default: result = -1;
  }
  return result;
}
void __fastcall TSampleCalendar::SetDateElement(int Index, int Value)
{
  unsigned short AYear, AMonth, ADay;
  if (Value > 0)                                        // all elements must be positive
  {
    FDate.DecodeDate(&AYear, &AMonth, &ADay);     // get current date elements
    switch (Index)
    {
      case 1: AYear = Value;     break;
      case 2: AMonth = Value;    break;
      case 3: ADay = Value;      break;
      default: return;
    }
  }
  FDate = TDateTime(AYear, AMonth, ADay);         // encode the modified date
  Refresh();                                      // update the visible calendar
}
```

Now you can set the calendar's day, month, and year at design time using the Object Inspector or at runtime using code. Of course, you have not yet added the code to paint the dates into the cells, but now you have the needed data.

3.2.1.5.2 Changing Initial Values

A calendar is essentially a grid with a fixed number of rows and columns, although not all the rows always contain dates. For this reason, you have not published the grid properties *ColCount* and *RowCount*, because it is highly unlikely that users of the calendar will want to display anything other than seven days per week. You still must set the initial values of those properties so that the week always has seven days, however.

To change the initial values of the component's properties, override the constructor to set the desired values. The constructor must be virtual.

Remember that you need to add the constructor to the **public** part of the component's object declaration, then write the new constructor in the **implementation** part of the component's unit. The first statement in the new constructor should always be a call to the inherited constructor. Then add the StdCtrls unit to the **uses** clause.

```
type
  TSampleCalendar = class(TCustomGrid)
  public
    constructor Create(AOwner: TComponent); override;
  .
  .
  .
  end;
.
.
.
constructor TSampleCalendar.Create(AOwner: TComponent);
begin
```

```
  inherited Create(AOwner);                                    { call inherited constructor }
  ColCount := 7;                                                  { always seven days/week }
  RowCount := 7;                                          { always six weeks plus the headings }
  FixedCols := 0;                                                          { no row labels }
  FixedRows := 1;                                                { one row for day names }
  ScrollBars := ssNone;                                             { no need to scroll }
  Options := Options - [goRangeSelect] + [goDrawFocusSelected];  {disable range selection}
end;
//header file
class PACKAGE TSampleCalendar : public TCustomGrid
{
protected:
    virtual void __fastcall DrawCell(int ACol, int ARow, const Windows::TRect &Rect,
      TGridDrawState AState);
    .
    .
    .
public:
    __fastcall TSampleCalendar(TComponent *Owner);   // the added constructor
    .
    .
    .
};
//implementation file
__fastcall TSampleCalendar::TSampleCalendar(TComponent *Owner) : TCustomGrid(Owner)
{
  ColCount = 7;
  RowCount = 7;
  FixedCols = 0;
  FixedRows = 1;
  ScrollBars = ssNone;
  Options = (Options >> goRangeSelect) << goDrawFocusSelected;
}
void __fastcall TSampleCalendar::DrawCell(int ACol, int ARow, const Windows::TRect
  &ARect, TGridDrawState AState)
{
}
```

The calendar now has seven columns and seven rows, with the top row fixed, or nonscrolling.

3.2.1.5.3 Creating and registering the component (Grid)

You create every component the same way: create a unit, derive a component class, register it, compile it, and install it on the Tool palette. Creating a new component. (see page 1317)

For this example, follow the general procedure for creating a component, with these specifics:

1. Save the component's unit as *CalSamp*.
2. Derive a new component type called *TSampleCalendar*, descended from *TCustomGrid*.
3. Register *TSampleCalendar* on the Samples category of the Tool palette.

The resulting unit descending from *TCustomGrid* in a VCL application should look like this:

```
unit CalSamp;
interface
uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs, Grids;
type
  TSampleCalendar = class(TCustomGrid)
  end;
procedure Register;
implementation
procedure Register;
begin
```

```
  RegisterComponents('Samples', [TSampleCalendar]);
end;
end.
#include <vcl\vcl.h>
#pragma hdrstop
#include "CalSamp.h"
//---------------------------------------------------------------------------
#pragma package(smart_init);
//---------------------------------------------------------------------------
static inline TSampleCalendar *ValidCtrCheck()
{
  return new TSampleCalendar(NULL);
}
//---------------------------------------------------------------------------
namespace Calsamp
{
  void __fastcall PACKAGE Register()
  {
    TComponentClass classes[1] = {__classid(TSampleCalendar)};
    RegisterComponents("Samples", classes, 0); //Use a different page in CLX applications
  }
}
#ifndef CalSampH
#define CalSampH
//---------------------------------------------------------------------------
#include <vcl\sysutils.hpp>
#include <vcl\controls.hpp>
#include <vcl\classes.hpp>
#include <vcl\forms.hpp>
#include <vcl\grids.hpp>
//---------------------------------------------------------------------------
class PACKAGE TSampleCalendar : public TCustomGrid
{
private:
protected:
public:
__published:
};
//---------------------------------------------------------------------------
#endif
```

If you install the calendar component now, you will find that it appears on the Samples category. The only properties available are the most basic control properties. The next step is to make some of the more specialized properties available to users of the calendar.

Note: While you can install the sample calendar component you have just compiled, do not try to place it on a form yet. The *TCustomGrid* component has an abstract *DrawCell* method that must be redeclared before instance objects can be created. Overriding the *DrawCell* method is described in Filling in the cells (see page 1265)

3.2.1.5.4 Customizing a Grid: Overview

The component library provides abstract components you can use as the basis for customized components. The most important of these are grids and list boxes. The following topics describe how to create a small one month calendar from the basic grid component, *TCustomGrid*:

- Creating and registering the component (see page 1263)
- Publishing inherited properties (see page 1271)
- Changing initial values (see page 1262)
- Resizing the cells (see page 1272)
- Filling in the cells (see page 1265)

- Navigating months and years (see page 1269)
- Navigating days (see page 1269)

In VCL applications, the resulting component is similar to the *TCalendar* component on the Samples category of the Tool palette. See Specifying the palette page (see page 1356).

3.2.1.5.5 Excluding Blank Cells

As the calendar is written, the user can select a blank cell, but the date does not change. It makes sense, then, to disallow selection of the blank cells.

To control whether a given cell is selectable, override the *SelectCell* method of the grid.

SelectCell is a function that takes a column and row as parameters, and returns a Boolean value indicating whether the specified cell is selectable.

You can override *SelectCell* to return *False* if the cell does not contain a valid date:

```
function TSampleCalendar.SelectCell(ACol, ARow: Longint): Boolean;
begin
  if DayNum(ACol, ARow) = -1 then Result := False            { -1 indicates invalid date }
  else Result := inherited SelectCell(ACol, ARow);      { otherwise, use inherited value }
end;
bool __fastcall TSampleCalendar::SelectCell(int ACol, int ARow)
{
  if (DayNum(ACol,ARow) == -1) return false;          // -1 indicates invalid date
  else return TCustomGrid::SelectCell(ACol, ARow);    // otherwise, use inherited value
}
```

Now if the user clicks a blank cell or tries to move to one with an arrow key, the calendar leaves the current cell selected.

3.2.1.5.6 Filling in the Cells

A grid control fills in its contents cell-by-cell. In the case of the calendar, that means calculating which date, if any, belongs in each cell. The default drawing for grid cells takes place in a virtual method called *DrawCell*.

To fill in the contents of grid cells, override the *DrawCell* method.

The easiest part to fill in is the heading cells in the fixed row. The runtime library contains an array with short day names, so for the calendar, use the appropriate one for each column:

```
type
  TSampleCalendar = class(TCustomGrid)
  protected
    procedure DrawCell(ACol, ARow: Longint; ARect: TRect; AState: TGridDrawState);
      override;
  end;
.
.
.
procedure TSampleCalendar.DrawCell(ACol, ARow: Longint; ARect: TRect;
  AState: TGridDrawState);
begin
  if ARow = 0 then
    Canvas.TextOut(ARect.Left, ARect.Top, ShortDayNames[ACol + 1]);    { use RTL strings }
end;
void __fastcall TSampleCalendar::DrawCell(int ACol, int ARow, const Windows::TRect &ARect,
  TGridDrawState AState)
{
  String TheText;
  int TempDay;
  if (ARow == 0) TheText = ShortDayNames[ACol + 1];
```

```
  else
  {
    TheText = "";
    TempDay = DayNum(ACol, ARow);                    // DayNum is defined later
    if (TempDay != -1) TheText = IntToStr(TempDay);
  }
  Canvas->TextRect(ARect, ARect.Left + (ARect.Right - ARect.Left
   - Canvas->TextWidth(TheText)) / 2,
  ARect.Top + (ARect.Bottom - ARect.Top - Canvas->TextHeight(TheText)) / 2, TheText);
}
```

3.2.1.5.7 Generating the Day Numbers

Putting numbers into the calendar involves several considerations. The number of days in the month depends on which month it is, and whether the given year is a leap year. In addition, months start on different days of the week, dependent on the month and year. Use the *IsLeapYear* function to determine whether the year is a leap year. Use the *MonthDays* array in the SysUtils unit to get the number of days in the month.

Once you have the information on leap years and days per month, you can calculate where in the grid the individual dates go. The calculation is based on the day of the week the month starts on.

Because you will need the month-offset number for each cell you fill in, the best practice is to calculate it once when you change the month or year, then refer to it each time. You can store the value in a class field, then update that field each time the date changes.

To fill in the days in the proper cells, you do the following:

1. Add a month-offset field to the object and a method that updates the field value:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    FMonthOffset: Integer;                                  { storage for the offset }
  .
  .
  .
  protected
    procedure UpdateCalendar; virtual;                    { property for offset access }
  end;
.
.
.
procedure TSampleCalendar.UpdateCalendar;
var
  AYear, AMonth, ADay: Word;
  FirstDate: TDateTime;                              { date of the first day of the month }
begin
  if FDate <> 0 then                               { only calculate offset if date is valid }
  begin
    DecodeDate(FDate, AYear, AMonth, ADay);                      { get elements of date }
    FirstDate := EncodeDate(AYear, AMonth, 1);                     { date of the first }
    FMonthOffset := 2 - DayOfWeek(FirstDate);        { generate the offset into the grid }
  end;
  Refresh;                                                  { always repaint the control }
end;
class PACKAGE TSampleCalendar : public TCustomGrid
{
private:
    int FMonthOffset;                           // storage for the offset
    .
    .
    .
protected:
    virtual void __fastcall UpdateCalendar(void);
```

```
    .
    .
    .
};
void __fastcall TSampleCalendar::UpdateCalendar(void)
{
  unsigned short AYear, AMonth, ADay;
  TDateTime FirstDate;                          // date of first day of the month
  if ((int)FDate != 0)                          // only calculate offset if date is valid
  {
    FDate.DecodeDate(&AYear, &AMonth, &ADay);  // get elements of date
    FirstDate = TDateTime(AYear, AMonth, 1);   // date of the first
    FMonthOffset = 2 - FirstDate.DayOfWeek();  // generate the offset into the grid
  }
  Refresh();                                    // always repaint the control
}
```

2. Add statements to the constructor and the *SetCalendarDate* and *SetDateElement* methods that call the new update method whenever the date changes:

```
constructor TSampleCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                                    { this is already here }
  .                                                          { other initializations here }
  .
  .
  UpdateCalendar;                                                { set proper offset }
end;
procedure TSampleCalendar.SetCalendarDate(Value: TDateTime);
begin  FDate := Value;                                                { this was already here }
  UpdateCalendar;                                       { this previously called Refresh }
end;
procedure TSampleCalendar.SetDateElement(Index: Integer; Value: Integer);
begin
  .
  .
  .
    FDate := EncodeDate(AYear, AMonth, ADay);              { encode the modified date }
    UpdateCalendar;                                     { this previously called Refresh }
  end;
end;
__fastcall TSampleCalendar::TSampleCalendar(TComponent *Owner)
  : TCustomGrid(Owner)
{
  .
  .
  .
  UpdateCalendar();
}
void __fastcall TSampleCalendar::SetCalendarDate(TDateTime Value)
{
  FDate = Value;                                  // this was already here
  UpdateCalendar();                               // this previously called Refresh
}
void __fastcall TSampleCalendar::SetDateElement(int Index, int Value)
{
  .
  .
  .
  FDate = TDateTime(AYear, AMonth, ADay);        // this was already here
  UpdateCalendar();                              // this previously called Refresh
}
```

3. Add a method to the calendar that returns the day number when passed the row and column coordinates of a cell:

```
function TSampleCalendar.DayNum(ACol, ARow: Integer): Integer;
begin
  Result := FMonthOffset + ACol + (ARow - 1) * 7;          { calculate day for this cell }
```

```
  if (Result < 1) or (Result > MonthDays[IsLeapYear(Year), Month]) then
    Result := -1;                                              { return -1 if invalid }
end;
int __fastcall TSampleCalendar::DayNum(int ACol, int ARow)
{
  int result = FMonthOffset + ACol + (ARow - 1) * 7;       // calculate day for this cell
  if ((result < 1)||(result > MonthDays[IsLeapYear(Year)][Month]))
    result = -1;   // return -1 if invalid
  return result;
}
```

Remember to add the declaration of *DayNum* to the component's type declaration.

4. Now that you can calculate where the dates go, you can update *DrawCell* to fill in the dates:

```
procedure TCalendar.DrawCell(ACol, ARow: Longint; ARect: TRect; AState: TGridDrawState);
var
  TheText: string;
  TempDay: Integer;
begin
  if ARow = 0 then                                        { if this is the header row ...}
    TheText := ShortDayNames[ACol + 1]                           { just use the day name }
  else begin
    TheText := '';                                          { blank cell is the default }
    TempDay := DayNum(ACol, ARow);                           { get number for this cell }
    if TempDay <> -1 then TheText := IntToStr(TempDay);       { use the number if valid }
  end;
  with ARect, Canvas do
    TextRect(ARect, Left + (Right - Left - TextWidth(TheText)) div 2,
      Top + (Bottom - Top - TextHeight(TheText)) div 2, TheText);
end;
void __fastcall TSampleCalendar::DrawCell(int ACol, int ARow, const TRect &ARect,
  TGridDrawState AState)
{
  String TheText;
  int TempDay;
  if (ARow == 0)                                    // this is the header row
    TheText = ShortDayNames[ACol + 1];              // just use the day name
  else
  {
    TheText = "";                                   // blank cell is the default
    TempDay = DayNum(ACol, ARow);                   // get number for this cell
    if (TempDay != -1) TheText = IntToStr(TempDay); // use the number if valid
  }
  Canvas->TextRect(ARect, ARect.Left + (ARect.Right - ARect.Left -
    Canvas->TextWidth(TheText)) / 2,
  ARect.Top + (ARect.Bottom - ARect.Top - Canvas->TextHeight(TheText)) / 2, TheText);
}
```

Now if you reinstall the calendar component and place one on a form, you will see the proper information for the current month.

3.2.1.5.8 Moving the Selection

The inherited behavior of a grid handles moving the selection in response to either arrow keys or clicks, but if you want to change the selected day, you need to modify that default behavior.

To handle movements within the calendar, override the *Click* method of the grid.

When you override a method such as *Click* that is tied in with user interactions, you will nearly always include a call to the inherited method, so as not to lose the standard behavior.

The following is an overridden *Click* method for the calendar grid. Be sure to add the declaration of *Click* to *TSampleCalendar*, including the **override** directive afterward.

```
procedure TSampleCalendar.Click;
```

```
var
  TempDay: Integer;
begin
  inherited Click;                          { remember to call the inherited method! }
  TempDay := DayNum(Col, Row);              { get the day number for the clicked cell }
  if TempDay <> -1 then Day := TempDay;                        { change day if valid }
end;
void __fastcall TSampleCalendar::Click()
{
  int TempDay = DayNum(Col, Row);           // get the day number for the clicked cell
  if (TempDay != -1) Day = TempDay;         // change day if valid
}
```

3.2.1.5.9 Navigating Days

Within a given month, there are two obvious ways to navigate among the days. The first is to use the arrow keys, and the other is to respond to clicks of the mouse. The standard grid component handles both as if they were clicks. That is, an arrow movement is treated like a click on an adjacent cell.

The process of navigating days consists of

- Moving the selection (see page 1268)
- Providing an OnChange event (see page 1270)
- Excluding blank cells (see page 1265)

3.2.1.5.10 Navigating Months and Years

Properties are useful for manipulating components, especially at design time. But sometimes there are types of manipulations that are so common or natural, often involving more than one property, that it makes sense to provide methods to handle them. One example of such a natural manipulation is a "next month" feature for a calendar. Handling the wrapping around of months and incrementing of years is simple, but very convenient for the developer using the component.

The only drawback to encapsulating common manipulations into methods is that methods are only available at runtime. However, such manipulations are generally only cumbersome when performed repeatedly, and that is fairly rare at design time.

For the calendar, add the following four methods for next and previous month and year. Each of these methods uses the *IncMonth* function in a slightly different manner to increment or decrement *CalendarDate*, by increments of a month or a year.

```
procedure TCalendar.NextMonth;
begin
  CalendarDate := IncMonth(CalendarDate, 1);
end;
procedure TCalendar.PrevMonth;
begin
  CalendarDate := IncMonth(CalendarDate, -1);
end;
procedure TCalendar.NextYear;
begin
  CalendarDate := IncMonth(CalendarDate, 12);
end;
procedure TCalendar.PrevYear;
begin
  CalendarDate := DecodeDate(IncMonth(CalendarDate, -12);
end;
void __fastcall TSampleCalendar::NextMonth()
{
  CalendarDate = IncMonth(CalendarDate, 1);
}
void __fastcall TSampleCalendar::PrevMonth()
{
  CalendarDate = IncMonth(CalendarDate, -1);
```

```
}
void __fastcall TSampleCalendar::NextYear()
{
  CalendarDate = IncMonth(CalendarDate, 12);
}
void __fastcall TSampleCalendar::PrevYear()
{
  CalendarDate = IncMonth(CalendarDate, -12);
}
```

Be sure to add the declarations of the new methods to the class declaration.

Now when you create an application that uses the calendar component, you can easily implement browsing through months or years.

3.2.1.5.11 Providing an OnChange Event

Now that users of the calendar can change the date within the calendar, it makes sense to allow applications to respond to those changes.

Add an OnChange event to TSampleCalendar.

1. Declare the event, a field to store the event, and a dynamic method to call the event:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    FOnChange: TNotifyEvent;
  protected
    procedure Change; dynamic;
  .
  .
  .
  published
    property OnChange: TNotifyEvent read FOnChange write FOnChange;
  .
  .
  .
class PACKAGE TSampleCalendar : public TCustomGrid
{
private:
    TNotifyEvent FOnChange;
    .
    .
    .
protected:
    virtual void __fastcall Change();
__published:
    __property TNotifyEvent OnChange = {read=FOnChange, write=FOnChange};
    .
    .
    .
}
```

2. Write the *Change* method:

```
procedure TSampleCalendar.Change;
begin
  if Assigned(FOnChange) then FOnChange(Self);
end;
void __fastcall TSampleCalendar::Change()
{
  if(FOnChange != NULL) FOnChange(this);
}
```

3. Add statements calling *Change* to the end of the *SetCalendarDate* and *SetDateElement* methods:

```
procedure TSampleCalendar.SetCalendarDate(Value: TDateTime);
begin
  FDate := Value;
  UpdateCalendar;
  Change;                                                { this is the only new statement }
end;
procedure TSampleCalendar.SetDateElement(Index: Integer; Value: Integer);
begin
    .                                                  { many statements setting element values }
    .
    .
    FDate := EncodeDate(AYear, AMonth, ADay);
    UpdateCalendar;
    Change;                                                                  { this is new }
  end;
end;
void __fastcall TSampleCalendar::SetCalendarDate(TDateTime Value)
{
  FDate = Value;
  UpdateCalendar();
  Change();              // this is the only new statement
}
void __fastcall TSampleCalendar::SetDateElement(int Index, int Value)
{
  .
  .
  .    // many statements setting element values
  FDate = TDateTime(AYear, AMonth, ADay);
  UpdateCalendar();
  Change();              // this is new
}
```

Applications using the calendar component can now respond to changes in the date of the component by attaching handlers to the *OnChange* event.

3.2.1.5.12 Publishing Inherited Properties (Grid)

The abstract grid component, *TCustomGrid*, provides a large number of **protected** properties. You can choose which of those properties you want to make available to users of the calendar control.

To make inherited protected properties available to users of your components, redeclare the properties in the **published** part of your component's declaration.

For the calendar control, publish the following properties and events, as shown here:

```
type
  TSampleCalendar = class(TCustomGrid)
  published
    property Align;  { publish properties }
    property BorderStyle;
    property Color;
    property Font;
    property GridLineWidth;
    property ParentColor;
    property ParentFont;
    property OnClick;  { publish events }
    property OnDblClick;
    property OnDragDrop;
    property OnDragOver;
    property OnEndDrag;
    property OnKeyDown;
    property OnKeyPress;
```

```
    property OnKeyUp;
  end;
class PACKAGE TSampleCalendar : public TCustomGrid
{
.
.
.
__published:
    __property Align ;                    // publish properties
    __property BorderStyle ;
    __property Color ;
    __property Font ;
    __property GridLineWidth ;
    __property ParentColor ;
    __property ParentFont ;
    __property OnClick ;                   // publish events
    __property OnDblClick ;
    __property OnDragDrop ;
    __property OnDragOver ;
    __property OnEndDrag ;
    __property OnKeyDown ;
    __property OnKeyPress ;
    __property OnKeyUp ;
};
```

There are a number of other properties you could also publish, but which do not apply to a calendar, such as the *Options* property that would enable the user to choose which grid lines to draw.

If you install the modified calendar component to the Tool palette and use it in an application, you will find many more properties and events available in the calendar, all fully functional. You can now start adding new capabilities of your own design.

3.2.1.5.13 Resizing the Cells

Note: When a user or application changes the size of a window or control, Windows sends a message called *WM_SIZE* to the affected window or control so it can adjust any settings needed to later paint its image in the new size. Your VCL component can respond to that message by altering the size of the cells so they all fit inside the boundaries of the control. To respond to the *WM_SIZE* message, you will add a message-handling method to the component.

Creating a message-handling method is described in detail in the section Creating new message handlers. (see page 1304)

In this case, the calendar control needs a response to *WM_SIZE*, so add a protected method called *WMSize* to the control indexed to the *WM_SIZE* message, then write the method so that it calculates the proper cell size to allow all cells to be visible in the new size:

```
type
  TSampleCalendar = class(TCustomGrid)
  protected
    procedure WMSize(var Message: TWMSize); message WM_SIZE;
  .
  .
  .
  end;
.
.
.
procedure TSampleCalendar.WMSize(var Message: TWMSize);
var
  GridLines: Integer;                                    { temporary local variable }
begin
  GridLines := 6 * GridLineWidth;                { calculate combined size of all lines }
  DefaultColWidth := (Message.Width - GridLines) div 7;     { set new default cell width }
  DefaultRowHeight := (Message.Height - GridLines) div 7;             { and cell height }
end;
```

```
//header file
class PACKAGE TSampleCalendar : public TCustomGrid
{
.
.
.
protected:
    void __fastcall WMSize(TWMSize &Message);
BEGIN_MESSAGE_MAP
  MESSAGE_HANDLER(WM_SIZE, TWMSize, WMSize)
END_MESSAGE_MAP(TCustomGrid)
};
//implementation file
void __fastcall TSampleCalendar::WMSize(TWMSize &Message)
{
  int GridLines;                                  // temporary local variable
  GridLines = 6 * GridLineWidth;                  // calculated combined size of all lines
  DefaultColWidth = (Message.Width - GridLines) / 7;    // set new default cell width
  DefaultRowHeight = (Message.Height - GridLines) / 7;  // and cell height
}
```

Now when the calendar is resized, it displays all the cells in the largest size that will fit in the control.

In this case, the calendar control needs to override *BoundsChanged* so that it calculates the proper cell size to allow all cells to be visible in the new size:

```
type
  TSampleCalendar = class(TCustomGrid)
  protected
    procedure BoundsChanged; override;
  .
  .
  .
  end;
.
.
.
procedure TSampleCalendar.BoundsChanged;
var
  GridLines: Integer;                                    { temporary local variable }
begin
  GridLines := 6 * GridLineWidth;                 { calculate combined size of all lines }
  DefaultColWidth := (Width - GridLines) div 7;     { set new default cell width }
  DefaultRowHeight := (Height - GridLines) div 7;             { and cell height }
  inherited; {now call the inherited method }
end;
//header file
class PACKAGE TSampleCalendar : public TCustomGrid
{
.
.
.
protected:
    void __fastcall BoundsChanged(void);
};
//implementation file
void __fastcall TSampleCalendar::BoundsChanged(void)
{
  int GridLines;                                  // temporary local variable
  GridLines = 6 * GridLineWidth;                  // calculated combined size of all lines
  DefaultColWidth = (Width - GridLines) / 7;    // set new default cell width
  DefaultRowHeight = (Height - GridLines) / 7;  // and cell height
  TCustomGrid::BoundsChanged(); // now call the inherited method
}
```

3.2.1.5.14 Selecting the Current Day

Now that you have numbers in the calendar cells, it makes sense to move the selection highlighting to the cell containing the current day. By default, the selection starts on the top left cell, so you need to set the *Row* and *Column* properties both when constructing the calendar initially and when the date changes.

To set the selection on the current day, change the *UpdateCalendar* method to set *Row* and *Column* before calling *Refresh*:

```
procedure TSampleCalendar.UpdateCalendar;
begin
  if FDate <> 0 then
  begin
    .  { existing statements to set FMonthOffset }
    .
    .
    Row := (ADay - FMonthOffset) div 7 + 1;
    Col := (ADay - FMonthOffset) mod 7;
  end;
  Refresh; { this is already here }
end;
void __fastcall TSampleCalendar::UpdateCalendar(void)
{
  unsigned short AYear, AMonth, ADay;
  TDateTime FirstDate;
  if ((int) FDate != 0)
  {
  .
  .
  .                                                  // existing statements to set FMonthOffset
    Row = (ADay - FMonthOffset) / 7 + 1;
    Col = (ADay - FMonthOffset) % 7;
  }
  Refresh();                                        // this is already here
}
```

Note that you are now reusing the *ADay* variable previously set by decoding the date.

3.2.1.5.15 Storing the Internal Date

To store the date for the calendar, you need a private field to hold the date and a runtime-only property that provides access to that date.

Adding the internal date to the calendar requires three steps:

1. Declare a private field to hold the date:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    FDate: TDateTime;
  .
  .
  .
class PACKAGE TSampleCalendar : public TCustomGrid
{
public:
    __property TDateTime CalendarDate = {read=FDate, write=SetCalendarDate, nodefault};
    .
    .
    .
};
class PACKAGE TSampleCalendar : public TCustomGrid
```

```
{
private:
    TDateTime FDate;
    .
    .
    .
};
```

2. Initialize the date field in the constructor:

```
constructor TSampleCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);         { this is already here }
  .                                  { other initializations here }
  .
  .
  FDate := Date;                    { get current date from RTL }
end;
__fastcall TSampleCalendar::TSampleCalendar(TComponent *Owner) : TCustomGrid(Owner)
{
  .
  .
  .
  FDate = FDate.CurrentDate();
}
```

3. Declare a runtime property to allow access to the encoded date. You'll need a method for setting the date, because setting the date requires updating the onscreen image of the control:

```
type
  TSampleCalendar = class(TCustomGrid)
  private
    procedure SetCalendarDate(Value: TDateTime);
  public
    property CalendarDate: TDateTime read FDate write SetCalendarDate;
  .
  .
  .
procedure TSampleCalendar.SetCalendarDate(Value: TDateTime);
begin
  FDate := Value;                { set new date value }
  Refresh;                       { update the onscreen image }
end;
class PACKAGE TSampleCalendar : public TCustomGrid
{
private:
    void __fastcall SetCalendarDate(TDateTime Value);
    .
    .
    .
};
void __fastcall TSampleCalendar::SetCalendarDate(TDateTime Value)
{
  FDate = Value;                      // Set the new date value
  Refresh();                          // Update the onscreen image
}
```

3.2.1.5.16 Tracking the Date

For the calendar control to be useful, users and applications must have a mechanism for setting the day, month, and year. Delphi stores dates and times in variables of type *TDateTime*. *TDateTime* is an encoded numeric representation of the date and time, which is useful for programmatic manipulation, but not convenient for human use.

You can therefore store the date in encoded form, providing runtime access to that value, but also provide *Day*, *Month*, and *Year* properties that users of the calendar component can set at design time.

Tracking the date in the calendar consists of the processes:

- Storing the internal date (see page 1274)
- Accessing the day (see page 1260)
- Generating the day numbers (see page 1266)
- Selecting the current day (see page 1274)

3.2.1.6 Extending the IDE

Topics

Name	Description
Adding an Action to the Action List (see page 1278)	The image index obtained in Adding an image to the image list (see page 1279) is used to create an action, as shown below. The wizard uses the *OnExecute* and *OnUpdate* events. A common scenario is for a wizard to use the *OnUpdate* event to enable or disable the action. Be sure the *OnUpdate* event returns quickly, or the user will notice that the IDE becomes sluggish after loading your wizard. The action's *OnExecute* event is similar to the wizard's *Execute* method. If you are using a menu item to invoke a form or project wizard, you might even want to have *OnExecute... more (see page 1278)*
Adding an Image to the Image List (see page 1279)	Suppose you want to add a menu item to invoke your wizard. You also want to enable the user to add a toolbar button that invokes the wizard. The first step is to add an image to the IDE's image list. The index of your image can then be used for the action, which in turn is used by the menu item and toolbar button. Create a resource file that contains a 16 by 16 bitmap resource. Add the following code to your wizard's constructor:
Creating Forms and Projects (see page 1279)	Delphi comes with a number of form and project wizards already installed, and you can write your own. The Object Repository lets you create static templates that can be used in a project, but a wizard offers much more power because it is dynamic. The wizard can prompt the user and create different kinds of files depending on the user's responses. A form or project wizard typically creates one or more new files. Instead of real files, however, it is best to create unnamed, unsaved modules. When the user saves them, the IDE prompts the user for a file name.... more (see page 1279)
Debugging a Wizard (see page 1284)	The Tools API provides you with a lot of flexibility in how your wizard interacts with the IDE. With the flexibility comes responsibility, however. It is easy to wind up with dangling pointers or other access violations. When writing wizards that use the native tools API, you can write code that causes the IDE to crash. It is also possible that you write a wizard that installs but does not act the way you want it to. One of the challenges of working with design-time code is debugging. It's an easy problem to solve, however. Because the wizard is installed... more (see page 1284)
Deleting Toolbar Buttons (see page 1284)	There is no convenient function for removing a button from a toolbar; you must send the CM_CONTROLCHANGE message, where the first parameter is the control to change, and the second parameter is zero to remove it or non-zero to add it to the toolbar. After removing the toolbar buttons, the destructor deletes the action and menu item. Deleting these items automatically removes them from the IDE's ActionList and MainMenu.
Extending the IDE (see page 1285)	You can extend and customize the IDE with your own menu items, tool bar buttons, dynamic form-creation wizards, and more, using the Open Tools API (often shortened to just Tools API). The Tools API is a suite of over 100 interfaces that interact with and control the IDE, including the main menu, the tool bars, the main action list and image list, the source editor's internal buffers, keyboard macros and bindings, forms and their components in the form editor, the debugger and the process being debugged, code completion, the message view, and the To-Do list. Using the Tools API is... more (see page 1285)
Implementing the Wizard Interfaces (see page 1286)	Every wizard class must implement at least *IOTAWizard*, which requires implementing its ancestors, too: *IOTANotifier* and *IInterface*. Form and project wizards must implement all their ancestor interfaces, namely, *IOTARepositoryWizard*, *IOTAWizard*, *IOTANotifier*, and *IInterface*. For C++, to use NotifierObject as a base class you must use multiple inheritance. Your wizard class must inherit from NotifierObject and from the wizard interfaces that you need to implement, such as IOTAWizard. Because IOTAWizard inherits from IOTANotifier and IInterface, there is an ambiguity in the derived class: functions such as AddRef() are declared in every branch of the ancestral... more (see page 1286)

Installing the Wizard Package (see page 1288)	As with any other design-time package, a wizard package must have a *Register* function. (See Registering components (see page 1352) for details about the *Register* function.) In the *Register* function, you can register any number of wizards by calling *RegisterPackageWizard*, and passing a wizard object as the sole argument, as shown below:
Interface Version Numbers (see page 1288)	If you look closely at the declarations of some of the interfaces, such as *IOTAMessageServices*, you will see that they inherit from other interfaces with similar names, such as *IOTAMessageServices50*, which inherits from *IOTAMessageServices40*. This use of version numbers helps insulate your code from changes between releases of Delphi. The Tools API follows the basic principle of COM, namely, that an interface and its GUID never change. If a new release adds features to an interface, the Tools API declares a new interface that inherits from the old one. The GUID remains the same, attached to the... more (see page 1288)
Notifying a Wizard of IDE Events (see page 1289)	An important aspect of writing a well-behaved wizard is to have the wizard respond to IDE events. In particular, any wizard that keeps track of module interfaces must know when the user closes the module, so the wizard can release the interface. To do this, the wizard needs a notifier, which means you must write a notifier class. All notifier classes implement one or more notifier interfaces. The notifier interfaces define callback methods; the wizard registers a notifier object with the Tools API, and the IDE calls back to the notifier when something important happens. Every notifier interface inherits from... more (see page 1289)
Obtaining Tools API Services (see page 1293)	To do anything useful, a wizard needs access to the IDE: its editors, windows, menus, and so on. This is the role of the service interfaces. The Tools API includes many services, such as action services to perform file actions, editor services to access the source code editor, debugger services to access the debugger, and so on. The following table summarizes all the service interfaces. ***Tools API service interfaces***
Overview of the Tools API (see page 1294)	All of the Tools API declarations reside in a single unit, ToolsAPI. To use the Tools API, you typically use the designide package, which means you must build your Tools API add-in as a design-time package or as a DLL that uses runtime packages. For information about package and library issues, see Installing the wizard package (see page 1288). The main interface for writing a Tools API extension is *IOTAWizard*, so most IDE add-ins are called wizards. C++Builder and Delphi wizards are, for the most part, interoperable. You can write and compile a wizard in Delphi, then use it in C++Builder,... more (see page 1294)
Using Editor Interfaces (see page 1295)	Every module has at least one editor interface. Some modules have several editors, such as a source (.pas) file and form description (.dfm) file. All editors implement the *IOTAEditor* interface; cast the editor to a specific type to learn what kind of editor it is. For example, to obtain the form editor interface for a unit, you can do the following:
Using Module Interfaces (see page 1296)	To obtain a module interface, start with the module services (*IOTAModuleServices*). You can query the module services for all open modules, look up a module from a file name or form name, or open a file to obtain its module interface. There are different kinds of modules for different kinds of files, such as projects, resources, and type libraries. Cast a module interface to a specific kind of module interface to learn whether the module is of that type. For example, one way to obtain the current project group interface is as follows:
Using Native IDE Objects (see page 1297)	Wizards have full access to the main menu, tool bars, action list, and image list of the IDE. (Note that the IDE's many context menus are not accessible through the Tools API.) The starting point for working with native IDE objects is the *INTAServices* interface. Use this interface to add an image to the image list, an action to the action list, a menu item to the main menu, and a button to a tool bar. You can tie the action to the menu item and tool button. When the wizard is destroyed, it must clean up the objects it... more (see page 1297)
Working with Files and Editors (see page 1297)	It is important to understand how the Tools API works with files. The main interface is *IOTAModule*. A module represents a set of logically related open files. For example, a single module represents a single unit. The module, in turn, has one or more editors, where each editor represents one file, such as the unit source (.pas) or form (.dfm or .xfm) file. The editor interfaces reflect the internal state of the IDE's editors, so a wizard can see the modified code and forms that the user sees, even if the user has not saved any changes. The following... more (see page 1297)

Writing a Wizard Class (see page 1297)	There are four kinds of wizards, where the wizard kind depends on the interfaces that the wizard class implements. The following table describes the four kinds of wizards. ***The four kinds of wizards***

3.2.1.6.1 Adding an Action to the Action List

The image index obtained in Adding an image to the image list (see page 1279) is used to create an action, as shown below. The wizard uses the *OnExecute* and *OnUpdate* events. A common scenario is for a wizard to use the *OnUpdate* event to enable or disable the action. Be sure the *OnUpdate* event returns quickly, or the user will notice that the IDE becomes sluggish after loading your wizard. The action's *OnExecute* event is similar to the wizard's *Execute* method. If you are using a menu item to invoke a form or project wizard, you might even want to have *OnExecute* call *Execute* directly.

```
NewAction := TAction.Create(nil);
NewAction.ActionList := Services.ActionList;
NewAction.Caption    := GetMenuText();
NewAction.Hint       := 'Display a silly dialog box';
NewAction.ImageIndex := ImageIndex;
NewAction.OnUpdate   := action_update;
NewAction.OnExecute  := action_execute;
action = new TAction(0);
action->ActionList = services->ActionList;
action->Caption    = GetMenuText();
action->Hint       = "Display a silly dialog box";
action->ImageIndex = image;
action->OnUpdate   = action_update;
action->OnExecute  = action_execute;
```

The menu item sets its *Action* property to the newly created action. The tricky part of creating the menu item is knowing where to insert it. The example below looks for theView menu, and inserts the new menu item as the first item in the View menu. (In general, relying on absolute position is not a good idea: you never know when another wizard might insert itself in the menu. Future versions of Delphi are likely to reorder the menu, too. A better approach is to search the menu for a menu item with a specific name. The simplistic approach follows for the sake of clarity.)

```
for I := 0 to Services.MainMenu.Items.Count - 1 do
begin
  with Services.MainMenu.Items[I] do
  begin
    if CompareText(Name, 'ViewsMenu') = 0 then
    begin
      NewItem := TMenuItem.Create(nil);
      NewItem.Action := NewAction;
      Insert(0, NewItem);
    end;
  end;
end;
for (int i = 0; i < services->MainMenu->Items->Count; ++i)
{
TMenuItem* item = services->MainMenu->Items->Items[i];
if (CompareText(item->Name, "ViewsMenu") == 0)
{
menu_item = new TMenuItem(0);
menu_item->Action = action;
item->Insert(0, menu_item);
}
}
```

By adding the action to the IDE's action list, the user can see the action when customizing the toolbars. The user can select the action and add it as a button to any toolbar. This causes a problem when your wizard is unloaded: all the tool buttons end up with dangling pointers to the non-existent action and *OnClick* event handler. To prevent access violations, your wizard must find all tool buttons that refer to its action, and remove those buttons.

3.2.1.6.2 Adding an Image to the Image List

Suppose you want to add a menu item to invoke your wizard. You also want to enable the user to add a toolbar button that invokes the wizard. The first step is to add an image to the IDE's image list. The index of your image can then be used for the action, which in turn is used by the menu item and toolbar button. Create a resource file that contains a 16 by 16 bitmap resource. Add the following code to your wizard's constructor:

```
constructor MyWizard.Create;
var
  Services: INTAServices;
  Bmp: TBitmap;
  ImageIndex: Integer;
begin
  inherited;
  Supports(BorlandIDEServices, INTAServices, Services);
  { Add an image to the image list. }
  Bmp := TBitmap.Create;
  Bmp.LoadFromResourceName(HInstance, 'Bitmap1');
  ImageIndex := Services.AddMasked(Bmp, Bmp.TransparentColor,
                                   'Tempest Software.intro wizard image');
  Bmp.Free;
end;
_di_INTAServices services;
BorlandIDEServices->Supports(services);
// Add an image to the image list.
Graphics::TBitmap* bitmap(new Graphics::TBitmap());
bitmap->LoadFromResourceName(reinterpret_cast<unsigned>(HInstance), "Bitmap1");
int image = services->AddMasked(bitmap, bitmap->TransparentColor,
                                 "Tempest Software.intro wizard image");
delete bitmap;
```

Be sure to load the resource by the name or ID you specify in the resource file. You must choose a color that will be interpreted as the background color for the image. If you don't want a background color, choose a color that does not exist in the bitmap.

3.2.1.6.3 Creating Forms and Projects

Delphi comes with a number of form and project wizards already installed, and you can write your own. The Object Repository lets you create static templates that can be used in a project, but a wizard offers much more power because it is dynamic. The wizard can prompt the user and create different kinds of files depending on the user's responses.

A form or project wizard typically creates one or more new files. Instead of real files, however, it is best to create unnamed, unsaved modules. When the user saves them, the IDE prompts the user for a file name. A wizard uses a creator object to create such modules.

A creator class implements a creator interface, which inherits from *IOTACreator*. The wizard passes a creator object to the module service's *CreateModule* method, and the IDE calls back to the creator object for the parameters it needs to create the module.

For example, a form wizard that creates a new form typically implements *GetExisting* to return *false* and *GetUnnamed* to return *true*. This creates a module that has no name (so the user must pick a name before the file can be saved) and is not backed by an existing file (so the user must save the file even if the user does not make any changes). Other methods of the creator tell the IDE what kind of file is being created (e.g., project, unit, or form), provide the contents of the file, or return the form name, ancestor name, and other important information. Additional callbacks let a wizard add modules to a newly created project, or add components to a newly created form.

To create a new file, which is often required in a form or project wizard, you usually need to provide the contents of the new file. To do so, write a new class that implements the *IOTAFile* interface. If your wizard can make do with the default file contents, you can return **nil** from any function that returns *IOTAFile*.

For example, suppose your organization has a standard comment block that must appear at the top of each source file. You could do this with a static template in the Object Repository, but the comment block would need to be updated manually to reflect the author and creation date. Instead, you can use a creator to dynamically fill in the comment block when the file is created.

The first step is to write a wizard that creates new units and forms. Most of the creator's functions return zero, empty strings, or other default values, which tells the Tools API to use its default behavior for creating a new unit or form. Override *GetCreatorType* to inform the Tools API what kind of module to create: a unit or a form. To create a unit, return sUnit. To create a form, return sForm. To simplify the code, use a single class that takes the creator type as an argument to the constructor. Save the creator type in a data member, so that *GetCreatorType* can return its value. Implement *NewImplSource* and *NewIntfSource* to return the desired file contents.

```
TCreator = class(TInterfacedObject, IOTAModuleCreator)
public
constructor Create(const CreatorType: string);
  { IOTAModuleCreator }
  function GetAncestorName: string;
  function GetImplFileName: string;
  function GetIntfFileName: string;
  function GetFormName: string;
  function GetMainForm: Boolean;
  function GetShowForm: Boolean;
  function GetShowSource: Boolean;
  function NewFormFile(const FormIdent, AncestorIdent: string): IOTAFile;
  function NewImplSource(const ModuleIdent, FormIdent, AncestorIdent: string): IOTAFile;
  function NewIntfSource(const ModuleIdent, FormIdent, AncestorIdent: string): IOTAFile;
  procedure FormCreated(const FormEditor: IOTAFormEditor);
  { IOTACreator }
  function GetCreatorType: string;
  function GetExisting: Boolean;
  function GetFileSystem: string;
  function GetOwner: IOTAModule;
  function GetUnnamed: Boolean;
private
  FCreatorType: string;
end;
class PACKAGE Creator : public IOTAModuleCreator {
public:
__fastcall Creator(const AnsiString creator_type)
: ref_count(0), creator_type(creator_type) {}
virtual __fastcall ~Creator();
// IOTAModuleCreator
virtual AnsiString __fastcall GetAncestorName();
virtual AnsiString __fastcall GetImplFileName();
virtual AnsiString __fastcall GetIntfFileName();
virtual AnsiString __fastcall GetFormName();
virtual bool __fastcall GetMainForm();
virtual bool __fastcall GetShowForm();
virtual bool __fastcall GetShowSource();
virtual _di_IOTAFile __fastcall NewFormFile(
const AnsiString FormIdent, const AnsiString AncestorIdent);
virtual _di_IOTAFile __fastcall NewImplSource(
```

```
const AnsiString ModuleIdent, const AnsiString FormIdent,
const AnsiString AncestorIdent);
virtual _di_IOTAFile __fastcall NewIntfSource(
const AnsiString ModuleIdent, const AnsiString FormIdent,
const AnsiString AncestorIdent);
virtual void __fastcall FormCreated(
const _di_IOTAFormEditor FormEditor);
// IOTACreator
virtual AnsiString __fastcall GetCreatorType();
 virtual bool __fastcall GetExisting();
virtual AnsiString __fastcall GetFileSystem();
virtual _di_IOTAModule __fastcall GetOwner();
virtual bool __fastcall GetUnnamed();
protected:
// IInterface
virtual HRESULT __stdcall QueryInterface(const GUID&, void**);
virtual ULONG __stdcall AddRef();
virtual ULONG __stdcall Release();
private:
long ref_count;
const AnsiString creator_type;
};
```

Most of the members of *T*Creator return zero, **nil**, or empty strings. The boolean methods return *true*, except *GetExisting*, which returns *false*. The most interesting method is *GetOwner*, which returns a pointer to the current project module, or **nil** if there is no project. There is no simple way to discover the current project or the current project group. Instead, *GetOwner* must iterate over all open modules. If a project group is found, it must be the only project group open, so *GetOwner* returns its current project. Otherwise, the function returns the first project module it finds, or **nil** if no projects are open.

```
function TCreator.GetOwner: IOTAModule;
var
  I: Integer;
  Svc: IOTAModuleServices;
  Module: IOTAModule;
  Project: IOTAProject;
  Group: IOTAProjectGroup;
begin
  { Return the current project. }
  Supports(BorlandIDEServices, IOTAModuleServices, Svc);
  Result := nil;
  for I := 0 to Svc.ModuleCount - 1 do
  begin
    Module := Svc.Modules[I];
    if Supports(Module, IOTAProject, Project) then
    begin
      { Remember the first project module}
      if Result = nil then
        Result := Project;
    end
    else if Supports(Module, IOTAProjectGroup, Group) then
    begin
      { Found the project group, so return its active project}
      Result := Group.ActiveProject;
      Exit;
    end;
  end;
end;
_di_IOTAModule __fastcall Creator::GetOwner()
{
// Return the current project.
_di_IOTAProject result = 0;
  _di_IOTAModuleServices svc = interface_cast<IOTAModuleServices>(BorlandIDEServices);
  for (int i = 0; i < svc->ModuleCount; ++i)
  begin
    _di_IOTAModule module = svc->Modules[i];
```

```
_di_IOTAProject project;
_di_IOTAProjectGroup group;
if (module->Supports(project)) {
// Remember the first project module.
if (result == 0)
result = project;
} else if (module->Supports(group)) {
// Found the project group, so return its active project.
result = group->ActiveProject;
break;
}
}
return result;
}
```

The creator returns **nil** from *NewFormSource*, to generate a default form file. The interesting methods are *NewImplSource* and *NewIntfSource*, which create an *IOTAFile* instance that returns the file contents.

The *TFile* class implements the *IOTAFile* interface. It returns -1 as the file age (which means the file does not exist), and returns the file contents as a string. To keep the *TFile* class simple, the creator generates the string, and the *TFile* class simply passes it on.

```
TFile = class(TInterfacedObject, IOTAFile)
public
constructor Create(const Source: string);
  function GetSource: string;
  function GetAge: TDateTime;
private
  FSource: string;
end;
constructor TFile.Create(const Source: string);
begin
  FSource := Source;
end;
  function TFile.GetSource: string;
begin
  Result := FSource;
end;
  function TFile.GetAge: TDateTime;
begin
  Result := TDateTime(-1);
end;
class File : public IOTAFile {
public:
__fastcall File(const AnsiString source);
virtual __fastcall ~File();
AnsiString __fastcall GetSource();
System::TDateTime __fastcall GetAge();
protected:
// IInterface
virtual HRESULT __stdcall QueryInterface(const GUID&, void**);
virtual ULONG __stdcall AddRef();
virtual ULONG __stdcall Release();
private:
long ref_count;
AnsiString source;
};
__fastcall File::File(const AnsiString source)
: ref_count(0), source(source)
{}
AnsiString __fastcall File::GetSource()
{
return source;
}
System::TDateTime __fastcall File::GetAge()
{
```

```
return -1;
}
```

You can store the text for the file contents in a resource to make it easier to modify, but for the sake of simplicity, this example hardcodes the source code in the wizard. The example below generates the source code, assuming there is a form. You can easily add the simpler case of a plain unit. Test *FormIdent*, and if it is empty, create a plain unit; otherwise create a form unit. The basic skeleton for the code is the same as the IDE's default (with the addition of the comments at the top, of course), but you can modify it any way you desire.

```
function TCreator.NewImplSource(
                    const ModuleIdent, FormIdent, AncestorIdent: string): IOTAFile;
var
  FormSource: string;
begin
  FormSource :=
  '{ ------------------------------------------------------------------ ' +   #13#10 +
  '%s - description'+   #13#10 +
  'Copyright ©  %y Your company, inc.'+   #13#10 +
  'Created on %d'+   #13#10 +
  'By %u'+   #13#10 +
  ' ------------------------------------------------------------------ }' +   #13#10 +   #13#10;
  return TFile.Create(Format(FormSource, ModuleIdent, FormIdent,
AncestorIdent));
}
_di_IOTAFile __fastcall Creator::NewImplSource(
const AnsiString ModuleIdent,
const AnsiString FormIdent,
const AnsiString AncestorIdent)
{
const AnsiString form_source =
"/*------------------------------------------------------------------\n"
" %m - description\n"
" Copyright \xa9  %y Your company, inc.\n"
" Created on %d\n"
" By %u\n"
"  ------------------------------------------------------------------*/\n"
"\n"
"#include <vcl.h>\n"
"#pragma hdrstop\n"
"\n"
"#include \"%m.h\"\n"
"//------------------------------------------------------------------\n"
"#pragma package(smart_init)\n"
"#pragma resource \"*.dfm\"\n"
"T%f *%f;\n"
"//------------------------------------------------------------------\n"
"__fastcall T%m::T%m(TComponent* Owner)\n"
"        : T%a(Owner)\n"
"{\n"
"}\n"
"//------------------------------------------------------------------\n";
  return new File(expand(form_source, ModuleIdent, FormIdent,
AncestorIdent));
}
```

The final step is to create two form wizards: one uses sUnit as the creator type, and the other uses sForm. As an added benefit for the user, you can use *INTAServices* to add a menu item to the **File ▸ New** menu to invoke each wizard. The menu item's *OnClick* event handler can call the wizard's *Execute* function.

Some wizards need to enable or disable the menu items, depending on what else is happening in the IDE. For example, a wizard that checks a project into a source code control system should disable its Check In menu item if no files are open in the IDE. You can add this capability to your wizard by using notifiers (see page 1289).

3.2.1.6.4 Debugging a Wizard

The Tools API provides you with a lot of flexibility in how your wizard interacts with the IDE. With the flexibility comes responsibility, however. It is easy to wind up with dangling pointers or other access violations.

When writing wizards that use the native tools API, you can write code that causes the IDE to crash. It is also possible that you write a wizard that installs but does not act the way you want it to. One of the challenges of working with design-time code is debugging. It's an easy problem to solve, however. Because the wizard is installed in Delphi itself, you simply need to set the package's Host Application to the Delphi executable from the **Run ▸ Parameters**... menu item.

When you want (or need) to debug the package, don't install it. Instead, choose **Run ▸ Run** from the menu bar. This starts up a new instance of Delphi. In the new instance, install the already-compiled package by choosing **Components ▸ Install Package**... from the menu bar. Back in the original instance of Delphi, you should now see the telltale blue dots that tell you where you can set breakpoints in the wizard source code. (If not, double-check your compiler options to be sure you enabled debugging; make sure you loaded the right package; and double-check the process modules to make extra sure that you loaded the .bpl file you wanted to load.)

You cannot debug into the VCL or RTL code this way, but you have full debug capabilities for the wizard itself, which might be enough to tell what is going wrong.

Using Native IDE Objects (see page 1297)

3.2.1.6.5 Deleting Toolbar Buttons

There is no convenient function for removing a button from a toolbar; you must send the CM_CONTROLCHANGE message, where the first parameter is the control to change, and the second parameter is zero to remove it or non-zero to add it to the toolbar. After removing the toolbar buttons, the destructor deletes the action and menu item. Deleting these items automatically removes them from the IDE's ActionList and MainMenu.

```
procedure remove_action (Action: TAction; ToolBar: TToolBar);
var
  I: Integer;
  Btn: TToolButton;
begin
  for I := ToolBar.ButtonCount - 1 downto 0 do
  begin
    Btn := ToolBar.Buttons[I];
    if Btn.Action = Action then
    begin
      { Remove "Btn" from "ToolBar" }
      ToolBar.Perform(CM_CONTROLCHANGE, WPARAM(Btn), 0);
      Btn.Free;
    end;
  end;
end;
destructor MyWizard.Destroy;
var
  Services: INTAServices;
  Btn: TToolButton;
begin
  Supports(BorlandIDEServices, INTAServices, Services);
  { Check all the toolbars, and remove any buttons that use this action. }
remove_action(NewAction, Services.ToolBar[sCustomToolBar]);
```

```
remove_action(NewAction, Services.ToolBar[sDesktopToolBar]);
remove_action(NewAction, Services.ToolBar[sStandardToolBar]);
remove_action(NewAction, Services.ToolBar[sDebugToolBar]);
remove_action(NewAction, Services.ToolBar[sViewToolBar]);
remove_action(NewAction, Services.ToolBar[sInternetToolBar]);
  NewItem.Free;
  NewAction.Free;
end;
void __fastcall remove_action (TAction* action, TToolBar* toolbar)
{
for (int i = toolbar->ButtonCount; --i >= 0; )
{
TToolButton* button = toolbar->Buttons[i];
if (button->Action == action)
{
// Remove "button" from "toolbar".
toolbar->Perform(CM_CONTROLCHANGE, WPARAM(button), 0);
delete button;
}
}
}
__fastcall MyWizard::~MyWizard()
{
_di_INTAServices services;
  BorlandIDEServices->Supports(services);
  // Check all the toolbars, and remove any buttons that use
// this action.
remove_action(action, services->ToolBar[sCustomToolBar]);
remove_action(action, services->ToolBar[sDesktopToolBar]);
remove_action(action, services->ToolBar[sStandardToolBar]);
remove_action(action, services->ToolBar[sDebugToolBar]);
remove_action(action, services->ToolBar[sViewToolBar]);
remove_action(action, services->ToolBar[sInternetToolBar]);
  delete menu_item;
delete action;
}
```

3.2.1.6.6 Extending the IDE

You can extend and customize the IDE with your own menu items, tool bar buttons, dynamic form-creation wizards, and more, using the Open Tools API (often shortened to just Tools API). The Tools API is a suite of over 100 interfaces that interact with and control the IDE, including the main menu, the tool bars, the main action list and image list, the source editor's internal buffers, keyboard macros and bindings, forms and their components in the form editor, the debugger and the process being debugged, code completion, the message view, and the To-Do list.

Using the Tools API is simply a matter of writing classes that implement certain interfaces, and calling on services provided by other interfaces. Your Tools API code must be compiled and loaded into the IDE at design-time as a design-time package or in a DLL. Thus, writing a Tools API extension is somewhat like writing a property or component editor. Before tackling this material, make sure you are familiar with the basics of working with packages (see page 2211) and registering components (see page 1350).

Note: To enable the use of the Tools API, you must link with runtime packages and ensure that “designide” is listed as one of the packages you are linking with. In the IDE, you can do this on the Project->Options->Packages

dialog box. If you are building from the command line, make sure that `-LUdesignide` is passed to dcc32.exe. The following topics describe how to use the Tools API:

- Overview of the Tools API (see page 1294)
- Writing a wizard class (see page 1297)
- Obtaining Tools API services (see page 1293)
- Working with files and editors (see page 1297)
- Creating forms and projects (see page 1279)
- Notifying a wizard of IDE events (see page 1289)

3.2.1.6.7 Implementing the Wizard Interfaces

Every wizard class must implement at least *IOTAWizard*, which requires implementing its ancestors, too: *IOTANotifier* and *IInterface*. Form and project wizards must implement all their ancestor interfaces, namely, *IOTARepositoryWizard*, *IOTAWizard*, *IOTANotifier*, and *IInterface*.

For C++, to use NotifierObject as a base class you must use multiple inheritance. Your wizard class must inherit from NotifierObject and from the wizard interfaces that you need to implement, such as IOTAWizard. Because IOTAWizard inherits from IOTANotifier and IInterface, there is an ambiguity in the derived class: functions such as AddRef() are declared in every branch of the ancestral inheritance graph. To resolve this problem, pick one base class as the primary base class and delegate all ambiguous functions to that one class. For example, the class declaration might look as follows:

```
class PACKAGE MyWizard : public NotifierObject, public IOTAMenuWizard {
    typedef NotifierObject inherited;
    public:
        // IOTAWizard
        virtual AnsiString __fastcall GetIDString();
        virtual AnsiString __fastcall GetName();
        virtual TWizardState __fastcall GetState();
        virtual void __fastcall Execute();
        // IOTAMenuWizard
        virtual AnsiString __fastcall GetMenuText();
      void __fastcall AfterSave();
        void __fastcall BeforeSave();
        void __fastcall Destroyed();
        void __fastcall Modified();
    protected:
        // IInterface
        virtual HRESULT __stdcall QueryInterface(const GUID&, void**);
        virtual ULONG __stdcall AddRef();
        virtual ULONG __stdcall Release();
};
// implementation
ULONG __stdcall MyWizard::AddRef()  { return inherited::AddRef(); }
ULONG __stdcall MyWizard::Release() { return inherited::Release(); }
HRESULT __stdcall MyWizard::QueryInterface(const GUID& iid, void** obj)
{
    if (iid == __uuidof(IOTAMenuWizard)) {
        *obj = static_cast<IOTAMenuWizard*>(this);
        static_cast<IOTAMenuWizard*>(*obj)->AddRef();
        return S_OK;
    }
    if (iid == __uuidof(IOTAWizard)) {
        *obj = static_cast<IOTAWizard*>(this);
        static_cast<IOTAWizard*>(*obj)->AddRef();
        return S_OK;
    }
    return inherited::QueryInterface(iid, obj);
}
```

Your implementation of *IInterface* must follow the normal rules for Delphi interfaces, which are the same as the rules for COM interfaces. That is, *QueryInterface* performs type casts, and *_AddRef* and *_Release* manage reference counting. You might want to use a common base class to simplify writing wizard and notifier classes. For this purpose, the ToolsAPI unit defines a class, *TNotifierObject*, which implements *IOTANotifier* interface with empty method bodies.

You can write a class similar to *TNotifierObject* in C++.

```
class PACKAGE NotifierObject : public IOTANotifier {
    public:
        __fastcall NotifierObject() : ref_count(0) {}
        virtual __fastcall ~NotifierObject();
        void __fastcall AfterSave();
        void __fastcall BeforeSave();
        void __fastcall Destroyed();
        void __fastcall Modified();
    protected:
        // IInterface
        virtual HRESULT __stdcall QueryInterface(const GUID&, void**);
        virtual ULONG __stdcall AddRef();
        virtual ULONG __stdcall Release();
    private:
        long ref_count;
};
// implementation
ULONG __stdcall NotifierObject::AddRef()
{
    return InterlockedIncrement(&ref_count);
}
ULONG __stdcall NotifierObject::Release()
{
    ULONG result = InterlockedDecrement(&ref_count);
    if (ref_count == 0)
        delete this;
    return result;
}
HRESULT __stdcall NotifierObject::QueryInterface(const GUID& iid, void** obj)
{
    if (iid == __uuidof(IInterface)) {
        *obj = static_cast<IInterface*>(this);
        static_cast<IInterface*>(*obj)->AddRef();
        return S_OK;
    }
    if (iid == __uuidof(IOTANotifier)) {
        *obj = static_cast<IOTANotifier*>(this);
        static_cast<IOTANotifier*>(*obj)->AddRef();
        return S_OK;
    }
    return E_NOINTERFACE;
}
```

Although wizards inherit from *IOTANotifier*, and must therefore implement all of its functions, the IDE does not usually make use of those functions, so your implementations can be empty (as they are in *TNotifierObject*). Thus, when you write your wizard class, you need only declare and implement those interface methods introduced by the wizard interfaces, accepting the *TNotifierObject* implementation of *IOTANotifier*.

```
// C++ empty implementations
void __fastcall NotifierObject::AfterSave()  {}
void __fastcall NotifierObject::BeforeSave() {}
void __fastcall NotifierObject::Destroyed()  {}
void __fastcall NotifierObject::Modified()   {}
```

See Also

Installing the Wizard Package (see page 1288)

3.2.1.6.8 Installing the Wizard Package

As with any other design-time package, a wizard package must have a *Register* function. (See Registering components (see page 1352) for details about the *Register* function.) In the *Register* function, you can register any number of wizards by calling *RegisterPackageWizard*, and passing a wizard object as the sole argument, as shown below:

```
procedure Register;
begin
  RegisterPackageWizard(MyWizard.Create);
  RegisterPackageWizard(MyOtherWizard.Create);
end;
```

```
namespace Example {
    void __fastcall PACKAGE Register()
    {
        RegisterPackageWizard(new MyWizard());
        RegisterPackageWizard(new MyOtherWizard());
    }
}
```

You can also register property editors, components, and so on, as part of the same package.

Remember that a design-time package is part of the main RAD Studio application, which means any form names must be unique throughout the entire application and all other design-time packages. This is the main disadvantage to using packages: you never know what someone else might name their forms.

During development, install the wizard package the way you would any other design-time package: click the Install button in the package manager. The IDE will compile and link the package and attempt to load it. The IDE displays a dialog box telling you whether it successfully loaded the package.

Implementing the Wizard Interfaces (see page 1286)

3.2.1.6.9 Interface Version Numbers

If you look closely at the declarations of some of the interfaces, such as *IOTAMessageServices*, you will see that they inherit from other interfaces with similar names, such as *IOTAMessageServices50*, which inherits from *IOTAMessageServices40*. This use of version numbers helps insulate your code from changes between releases of Delphi.

The Tools API follows the basic principle of COM, namely, that an interface and its GUID never change. If a new release adds features to an interface, the Tools API declares a new interface that inherits from the old one. The GUID remains the same, attached to the old, unchanged interface. The new interface gets a brand new GUID. Old wizards that use the old GUIDs continue to work.

The Tools API also changes interface names to try to preserve source-code compatibility. To see how this works, it is important to distinguish between the two kinds of interfaces in the Tools API: Borland-implemented and user-implemented. If the IDE implements the interface, the name stays with the most recent version of the interface. The new functionality does not affect existing code. The old interfaces have the old version number appended.

For a user-implemented interface, however, new member functions in the base interface require new functions in your code. Therefore, the name tends to stick with the old interface, and the new interface has a version number tacked onto the end.

For example, consider the message services. Delphi 6 introduced a new feature: message groups. Therefore, the basic message services interface required new member functions. These functions were declared in a new interface class, which retained the name *IOTAMessageServices*. The old message services interface was renamed to *IOTAMessageServices50* (for version 5). The GUID of the old *IOTAMessageServices* is the same as the GUID of the new *IOTAMessageServices50* because the member functions are the same.

Consider *IOTAIDENotifier* as an example of a user-implemented interface. Delphi 5 added new overloaded functions: *AfterCompile* and *BeforeCompile*. Existing code that used *IOTAIDENotifier* did not need to change, but new code that required the new functionality had to be modified to override the new functions inherited from *IOTAIDENotifier50*. Version 6 did not add any more functions, so the current version to use is *IOTAIDENotifier50*.

The rule of thumb is to use the most-derived class when writing new code. Leave the source code alone if you are merely recompiling an existing wizard under a new release of Delphi.

Obtaining Tools API Services (see page 1293)

3.2.1.6.10 Notifying a Wizard of IDE Events

An important aspect of writing a well-behaved wizard is to have the wizard respond to IDE events. In particular, any wizard that keeps track of module interfaces must know when the user closes the module, so the wizard can release the interface. To do this, the wizard needs a notifier, which means you must write a notifier class.

All notifier classes implement one or more notifier interfaces. The notifier interfaces define callback methods; the wizard registers a notifier object with the Tools API, and the IDE calls back to the notifier when something important happens.

Every notifier interface inherits from *IOTANotifier*, although not all of its methods are used for a particular notifier. The following table lists all the notifier interfaces, and gives a brief description of each one.

Notifier interfaces

Interface	Description
IOTANotifier	Abstract base class for all notifiers
IOTABreakpointNotifier	Triggering or changing a breakpoint in the debugger
IOTADebuggerNotifier	Running a program in the debugger, or adding or deleting breakpoints
IOTAEditLineNotifier	Tracking movements of lines in the source editor
IOTAEditorNotifier	Modifying or saving a source file, or switching files in the editor
IOTAFormNotifier	Saving a form, or modifying the form or any components on the form (or data module)
IOTAIDENotifier	Loading projects, installing packages, and other global IDE events
IOTAMessageNotifier	Adding or removing tabs (message groups) in the message view
IOTAModuleNotifier	Changing, saving, or renaming a module
IOTAProcessModNotifier	Loading a process module in the debugger
IOTAProcessNotifier	Creating or destroying threads and processes in the debugger
IOTAThreadNotifier	Changing a thread's state in the debugger
IOTAToolsFilterNotifier	Invoking a tools filter

To see how to use notifiers, consider the example in Creating forms and projects (see page 1279). Using module creators, the example creates a wizard that adds a comment to each source file. The comment includes the unit's initial name, but the user almost always saves the file under a different name. In that case, it would be a courtesy to the user if the wizard updated the comment to match the file's true name.

To do this, you need a module notifier. The wizard saves the module interface that *CreateModule* returns, and uses it to register a module notifier. The module notifier receives notification when the user modifies the file or saves the file, but these events are not important for this wizard, so the *AfterSave* and related functions all have empty bodies. The important function is *ModuleRenamed*, which the IDE calls when the user saves the file under a new name. The declaration for the module notifier class is shown below:

```
TModuleIdentifier = class(TNotifierObject, IOTAModuleNotifier)
public
constructor Create(const Module: IOTAModule);
  destructor Destroy; override;
  function CheckOverwrite: Boolean;
  procedure ModuleRenamed(const NewName: string);
  procedure Destroyed;
private
  FModule: IOTAModule;
  FName: string;
  FIndex: Integer;
end;
class ModuleNotifier : public NotifierObject, public IOTAModuleNotifier
{
typedef NotifierObject inherited;
public:
__fastcall ModuleNotifier(const _di_IOTAModule module);
__fastcall ~ModuleNotifier();
// IOTAModuleNotifier
virtual bool __fastcall CheckOverwrite();
virtual void __fastcall ModuleRenamed(const AnsiString NewName);
// IOTANotifier
void __fastcall AfterSave();
void __fastcall BeforeSave();
void __fastcall Destroyed();
void __fastcall Modified();
protected:
// IInterface
virtual HRESULT __stdcall QueryInterface(const GUID&, void**);
virtual ULONG __stdcall AddRef();
virtual ULONG __stdcall Release();
private:
_di_IOTAModule module;
AnsiString name;        // Remember the module's old name.
int index;              // Notifier index.
};
```

One way to write a notifier is to have it register itself automatically in its constructor. The destructor unregisters the notifier. In the case of a module notifier, the IDE calls the *Destroyed* method when the user closes the file. In that case, the notifier must unregister itself and release its reference to the module interface. The IDE releases its reference to the notifier, which reduces its reference count to zero and frees the object. Therefore, you need to write the destructor defensively: the notifier might already be unregistered.

```
constructor TModuleNotifier.Create( const Module: IOTAModule);
begin
  FIndex := -1;
  FModule := Module;
  { Register this notifier. }
  FIndex := Module.AddNotifier(self);
  { Remember the module's old name. }
  FName := ChangeFileExt(ExtractFileName(Module.FileName), '');
end;
destructor TModuleNotifier.Destroy;
begin
  { Unregister the notifier if that hasn't happened already. }
  if Findex >= 0 then
    FModule.RemoveNotifier(FIndex);
end;
procedure TModuleNotifier.Destroyed;
begin
   { The module interface is being destroyed, so clean up the notifier. }
  if Findex >= 0 then
  begin
    { Unregister the notifier. }
    FModule.RemoveNotifier(FIndex);
    FIndex := -1;
```

```
  end;
  FModule := nil;
end;
__fastcall ModuleNotifier::ModuleNotifier(const _di_IOTAModule module)
: index(-1), module(module)
{
// Register this notifier.
index = module->AddNotifier(this);
// Remember the module's old name.
name = ChangeFileExt(ExtractFileName(module->FileName), "");
}
__fastcall ModuleNotifier::~ModuleNotifier()
{
// Unregister the notifier if that hasn't happened already.
if (index >= 0)
module->RemoveNotifier(index);
}
void __fastcall ModuleNotifier::Destroyed()
{
// The module interface is being destroyed, so clean up the notifier.
if (index >= 0)
{
// Unregister the notifier.
module->RemoveNotifier(index);
index = -1;
}
module = 0;
}
```

The IDE calls back to the notifier's *ModuleRenamed* function when the user renames the file. The function takes the new name as a parameter, which the wizard uses to update the comment in the file. To edit the source buffer, the wizard uses an edit position interface. The wizard finds the right position, double checks that it found the right text, and replaces that text with the new name.

```
procedure TModuleNotifier.ModuleRenamed(const NewName: string);
var
  ModuleName: string;
  I: Integer;
  Editor: IOTAEditor;
  Buffer: IOTAEditBuffer;
  Pos: IOTAEditPosition;
  Check: string;
begin
  { Get the module name from the new file name. }
  ModuleName := ChangeFileExt(ExtractFileName(NewName), '');
for I := 0 to FModule.GetModuleFileCount - 1 do
  begin
   { Update every source editor buffer. }
    Editor := FModule.GetModuleFileEditor(I);
    if Supports(Editor, IOTAEditBuffer, Buffer) then
    begin
      Pos := Buffer.GetEditPosition;
{ The module name is on line 2 of the comment.
        Skip leading white space and copy the old module name,
        to double check we have the right spot. }
      Pos.Move(2, 1);
      Pos.MoveCursor(mmSkipWhite or mmSkipRight);
Check := Pos.RipText('', rfIncludeNumericChars or rfIncludeAlphaChars);
if Check = FName then
      begin
        Pos.Delete(Length(Check));    // Delete the old name.
        Pos.InsertText(ModuleName);   // Insert the new name.
        FName := ModuleName;          // Remember the new name.
      end;
    end;
  end;
```

```
end;
void __fastcall ModuleNotifier::ModuleRenamed(const AnsiString NewName)
{
// Get the module name from the new file name.
AnsiString ModuleName = ChangeFileExt(ExtractFileName(NewName), "");
for (int i = 0; i < module->GetModuleFileCount(); ++i)
{
// Update every source editor buffer.
_di_IOTAEditor editor = module->GetModuleFileEditor(i);
_di_IOTAEditBuffer buffer;
if (editor->Supports(buffer))
{
_di_IOTAEditPosition pos = buffer->GetEditPosition();
// The module name is on line 2 of the comment.
// Skip leading white space and copy the old module name,
// to double check we have the right spot.
pos->Move(2, 1);
pos->MoveCursor(mmSkipWhite | mmSkipRight);
AnsiString check = pos->RipText("", rfIncludeNumericChars | rfIncludeAlphaChars);
if (check == name)
{
pos->Delete(check.Length());    // Delete the old name.
pos->InsertText(ModuleName);    // Insert the new name.
name = ModuleName;              // Remember the new name.
}
}
}
}
```

What if the user inserts additional comments above the module name? In that case, you need to use an edit line notifier to keep track of the line number where the module name sits. To do this, use the *IOTAEditLineNotifier* and *IOTAEditLineTracker* interfaces.

You need to be cautious when writing notifiers. You must make sure that no notifier outlives its wizard. For example, if the user were to use the wizard to create a new unit, then unload the wizard, there would still be a notifier attached to the unit. The results would be unpredictable, but most likely, the IDE would crash. Thus, the wizard needs to keep track of all of its notifiers, and must unregister every notifier before the wizard is destroyed. On the other hand, if the user closes the file first, the module notifier receives a *Destroyed* notification, which means the notifier must unregister itself and release all references to the module. The notifier must remove itself from the wizard's master notifier list, too.

Below is the final version of the wizard's *Execute* function. It creates the new module, uses the module interface and creates a module notifier, then saves the module notifier in an interface list (*TInterfaceList*).

```
procedure DocWizard.Execute;
var
  Svc: IOTAModuleServices;
  Module: IOTAModule;
  Notifier: IOTAModuleNotifier;
begin
  { Return the current project. }
  Supports(BorlandIDEServices, IOTAModuleServices, Svc);
  Module := Svc.CreateModule(TCreator.Create(creator_type));
  Notifier := TModuleNotifier.Create(Module);
list.Add(Notifier);
end
void __fastcall DocWizard::Execute()
{
_di_IOTAModuleServices svc;
  BorlandIDEServices->Supports(svc);
_di_IOTAModule module = svc->CreateModule(new Creator(creator_type));
_di_IOTAModuleNotifier notifier = new ModuleNotifier(module);
list->Add(notifier);
}
```

The wizard's destructor iterates over the interface list and unregisters every notifier in the list. Simply letting the interface list

release the interfaces it holds is not sufficient because the IDE also holds the same interfaces. You must tell the IDE to release the notifier interfaces in order to free the notifier objects. In this case, the destructor tricks the notifiers into thinking their modules have been destroyed. In a more complicated situation, you might find it best to write a separate Unregister function for the notifier class.

```
destructor DocWizard.Destroy; override;
var
  Notifier: IOTAModuleNotifier;
  I: Integer;
begin
  { Unregister all the notifiers in the list. }
for I := list.Count - 1 downto 0 do
  begin
    Supports(list.Items[I], IOTANotifier, Notifier);
    { Pretend the associated object has been destroyed.
      That convinces the notifier to clean itself up. }
    Notifier.Destroyed;
    list.Delete(I);
  end;
  list.Free;
  FItem.Free;
end;
__fastcall DocWizard::~DocWizard()
{
// Unregister all the notifiers in the list.
for (int i = list->Count; --i >= 0; )
{
_di_IOTANotifier notifier;
    list->Items[i]->Supports(notifier);
// Pretend the associated object has been destroyed.
// That convinces the notifier to clean itself up.
notifier->Destroyed();
list->Delete(i);
}
delete list;
delete item;
}
```

The rest of the wizard manages the mundane details of registering the wizard, installing menu items, and the like.

Using Module Interfaces (see page 1296)

3.2.1.6.11 Obtaining Tools API Services

To do anything useful, a wizard needs access to the IDE: its editors, windows, menus, and so on. This is the role of the service interfaces. The Tools API includes many services, such as action services to perform file actions, editor services to access the source code editor, debugger services to access the debugger, and so on. The following table summarizes all the service interfaces.

Tools API service interfaces

Interface	Description
INTAServices	Provides access to native IDE objects: main menu, action list, image list, and tool bars.
IOTAActionServices	Performs basic file actions: open, close, save, and reload a file.
IOTACodeCompletionServices	Provides access to code completion, allowing a wizard to install a custom code completion manager.

IOTADebuggerServices	Provides access to debugger.
IOTAEditorServices	Provides access to source code editor and its internal buffers.
IOTAKeyBindingServices	Permits a wizard to register custom keyboard bindings.
IOTAKeyboardServices	Provides access to keyboard macros and bindings.
IOTAKeyboardDiagnostics	Toggle debugging of keystrokes.
IOTAMessageServices	Provides access to message view.
IOTAModuleServices	Provides access to open files.
IOTAPackageServices	Queries the names of all installed packages and their components.
IOTAServices	Miscellaneous services.
IOTAToDoServices	Provides access to the To-Do list, allowing a wizard to install a custom To-Do manager.
IOTAToolsFilter	Registers tools filter notifiers.
IOTAWizardServices	Registers and unregisters wizards.

To use a service interface, cast the *BorlandIDEServices* variable to the desired service using the global Supports function, which is defined in the SysUtils unit. For example,

```
procedure set_keystroke_debugging(debugging: Boolean);
var
  diag: IOTAKeyboardDiagnostics
begin
  if Supports(BorlandIDEServices, IOTAKeyboardDiagnostics, diag) then
    diag.KeyTracing := debugging;
end;
void set_keystroke_debugging(bool debugging)
{
_di_IOTAKeyboardDiagnostics diag;
if (BorlandIDEServices->Supports(diag))
diag->KeyTracing = debugging;
}
```

If your wizard needs to use a specific service often, you can keep a pointer to the service as a data member of your wizard class.

The following topics discuss special considerations when working with the Tools API service interfaces:

- Using native IDE objects (see page 1297)
- Debugging a wizard (see page 1284)
- Interface version numbers (see page 1288)

Notifying a Wizard of IDE Events (see page 1289)

3.2.1.6.12 Overview of the Tools API

All of the Tools API declarations reside in a single unit, ToolsAPI. To use the Tools API, you typically use the designide package, which means you must build your Tools API add-in as a design-time package or as a DLL that uses runtime packages. For information about package and library issues, see Installing the wizard package (see page 1288).

The main interface for writing a Tools API extension is *IOTAWizard*, so most IDE add-ins are called wizards. C++Builder and Delphi wizards are, for the most part, interoperable. You can write and compile a wizard in Delphi, then use it in C++Builder, and

vice versa. Interoperability works best with the same version number, but it is also possible to write wizards so they can be used in future versions of both products.

To use the Tools API, you write wizard classes that implement one or more of the interfaces defined in the ToolsAPI unit.

A wizard makes use of services that the Tools API provides. Each service is an interface that presents a set of related functions. The implementation of the interface is hidden within the IDE. The Tools API publishes only the interface, which you can use to write your wizards without concerning yourself with the implementation of the interfaces. The various services offer access to the source editor, form designer, debugger, and so on. See Obtaining Tools API services (see page 1293) for information about using the interfaces that expose services to your wizard.

The service and other interfaces fall into two basic categories. You can tell them apart by the prefix used for the type name:

- The NTA (native tools API) grants direct access to actual IDE objects, such as the IDE's *TMainMenu* object. When using these interfaces, the wizard must use CodeGear packages, which also means the wizard is tied to a specific version of the IDE. The wizard can reside in a design-time package or in a DLL that uses runtime packages.
- The OTA (open tools API) does not require packages and accesses the IDE only through interfaces. In theory, you could write a wizard in any language that supports COM-style interfaces, provided you can also work with the Delphi calling conventions and Delphi types such as AnsiString. OTA interfaces do not grant full access to the IDE, but almost all the functionality of the Tools API is available through OTA interfaces. If a wizard uses only OTA interfaces, it is possible to write a DLL that is not dependent on a specific version of the IDE.

The Tools API has two kinds of interfaces: those that you, the programmer, must implement and those that the IDE implements. Most of the interfaces are in the latter category: the interfaces define the capability of the IDE but hide the actual implementation. The kinds of interfaces that you must implement fall into three categories: wizards, notifiers, and creators:

- As mentioned earlier in this topic, a wizard class implements the *IOTAWizard* interface and possibly derived interfaces.
- A notifier is another kind of interface in the Tools API. The IDE uses notifiers to call back to your wizard when something interesting happens. You write a class that implements the notifier interface, register the notifier with the Tools API, and the IDE calls back to your notifier object when the user opens a file, edits source code, modifies a form, starts a debugging session, and so on. Notifiers are covered in Notifying a wizard of IDE events (see page 1289) .
- A creator is another kind of interface that you must implement. The Tools API uses creators to create new units, projects, or other files, or to open existing files. See Creating forms and projects (see page 1279) for information about creator interfaces.

Other important interfaces are modules and editors. A module interface represents an open unit, which has one or more files. An editor interface represents an open file. Different kinds of editor interfaces give you access to different aspects of the IDE: the source editor for source files, the form designer for form files, and project resources for a resource file. See Working with files and editors (see page 1297) for information about module and editor interfaces.

3.2.1.6.13 Using Editor Interfaces

Every module has at least one editor interface. Some modules have several editors, such as a source (.pas) file and form description (.dfm) file. All editors implement the *IOTAEditor* interface; cast the editor to a specific type to learn what kind of editor it is. For example, to obtain the form editor interface for a unit, you can do the following:

```
{ Return the form editor for a module, or nil if the unit has no form. }
function GetFormEditor(Module: IOTAModule): IOTAFormEditor;
var
  I: Integer;
  Editor: IOTAEditor;
begin
  for I := 0 to Module.ModuleFileCount - 1 do
  begin
    Editor := Module.ModuleFileEditors[I];
    if Supports(Editor, IOTAFormEditor, Result) then
      Exit;
  end;
  Result := nil;
end;
```

```
// Return the form editor for a module, or 0 if the unit has no form.
_di_IOTAFormEditor __fastcall GetFormEditor(_di_IOTAModule module)
{
for (int i = 0; i < module->ModuleFileCount; ++i)
{
_di_IOTAEditor editor = module->ModuleFileEditors[i];
_di_IOTAFormEditor formEditor;
if (editor->Supports(formEditor))
return formEditor;
}
return 0;
}
```

The editor interfaces give you access to the editor's internal state. You can examine the source code or components that the user is editing, make changes to the source code, components, or properties, change the selection in the source and form editors, and carry out almost any editor action that the end user can perform.

Using a form editor interface, a wizard can access all the components on the form. Each component (including the root form or data module) has an associated *IOTAComponent* interface. A wizard can examine or change most of the component's properties. If you need complete control over the component, you can cast the *IOTAComponent* interface to *INTAComponent*. The native component interface enables your wizard to access the *TComponent* pointer directly. This is important if you need to read or modify a class-type property, such as *TFont*, which is possible only through NTA-style interfaces.

Using Module Interfaces (see page 1296)

3.2.1.6.14 Using Module Interfaces

To obtain a module interface, start with the module services (*IOTAModuleServices*). You can query the module services for all open modules, look up a module from a file name or form name, or open a file to obtain its module interface.

There are different kinds of modules for different kinds of files, such as projects, resources, and type libraries. Cast a module interface to a specific kind of module interface to learn whether the module is of that type. For example, one way to obtain the current project group interface is as follows:

```
{ Return the current project group, or nil if there is no project group. }
function CurrentProjectGroup: IOTAProjectGroup;
var
  I: Integer;
  Svc: IOTAModuleServices;
  Module: IOTAModule;
begin
  Supports(BorlandIDEServices, IOTAModuleServices, Svc);
  for I := 0 to Svc.ModuleCount - 1 do
  begin
    Module := Svc.Modules[I];
    if Supports(Module, IOTAProjectGroup, Result) then
      Exit;
  end;
  Result := nil;
end;
// Return the current project group, or 0 if there is no project group.
_di_IOTAProjectGroup __fastcall CurrentProjectGroup()
{
_di_IOTAModuleServices svc;
  BorlandIDEServices->Supports(svc);
  for (int i = 0; i < svc->ModuleCount; ++i)
{
_di_IOTAModule module = svc->Modules[i];
_di_IOTAProjectGroup group;
if (module->Supports(group))
return group;
```

```
}
return 0;
}
```

Using Editor Interfaces (see page 1295)

3.2.1.6.15 Using Native IDE Objects

Wizards have full access to the main menu, tool bars, action list, and image list of the IDE. (Note that the IDE's many context menus are not accessible through the Tools API.)

The starting point for working with native IDE objects is the *INTAServices* interface. Use this interface to add an image to the image list, an action to the action list, a menu item to the main menu, and a button to a tool bar. You can tie the action to the menu item and tool button. When the wizard is destroyed, it must clean up the objects it creates, but it must not delete the image it added to the image list. Deleting an image would scramble the indices for all images added after this wizard.

The wizard uses the actual *TMainMenu*, *TActionList*, *TImageList*, and *TToolBar* objects from the IDE, so you can write code the way you would any other application. It also means you have a lot of scope for crashing the IDE or otherwise disabling important features, such as deleting the File menu. Debugging a wizard (see page 1284) discusses steps you can take to debug your wizard if you find it has caused problems like these.

The following topics illustrate how to perform these tasks:

- Adding an image to the image list (see page 1279)
- Adding an action to the action list (see page 1278)
- Deleting toolbar buttons (see page 1284)

3.2.1.6.16 Working with Files and Editors

It is important to understand how the Tools API works with files. The main interface is *IOTAModule*. A module represents a set of logically related open files. For example, a single module represents a single unit. The module, in turn, has one or more editors, where each editor represents one file, such as the unit source (.pas) or form (.dfm or .xfm) file. The editor interfaces reflect the internal state of the IDE's editors, so a wizard can see the modified code and forms that the user sees, even if the user has not saved any changes.

The following topics provide information about the module and editor interfaces:

- Using module interfaces (see page 1296)
- Using editor interfaces (see page 1295)

3.2.1.6.17 Writing a Wizard Class

There are four kinds of wizards, where the wizard kind depends on the interfaces that the wizard class implements. The following table describes the four kinds of wizards.

The four kinds of wizards

Interface	Description
IOTAFormWizard	Typically creates a new unit, form, or other file
IOTAMenuWizard	Automatically added to Help menu
IOTAProjectWizard	Typically creates a new application or other project
IOTAWizard	Miscellaneous wizard that doesn't fit into other categories

The four kinds of wizards differ only in how the user invokes the wizard:

- A menu wizard is added to the IDE's Help menu. When the user picks the menu item, the IDE calls the wizard's *Execute* function. Plain wizards offer much more flexibility, so menu wizards are typically used only for prototypes and debugging.
- Form and project wizards are called repository wizards because they reside in the Object Repository. The user invokes these wizards from the New Items dialog box. The user can also see the wizards in the object repository (by choosing the **Tools** ▶ **Repository** menu item). The user can check the New Form check box for a form wizard, which tells the IDE to invoke the form wizard when the user chooses the **File** ▶ **New** ▶ **Form** menu item. The user can also check the Main Form check box. This tells the IDE to use the form wizard as the default form for a new application. The user can check the New Project check box for a project wizard. When the user chooses **File** ▶ **New** ▶ **Application**, the IDE invokes the selected project wizard.
- The fourth kind of wizard is for situations that don't fit into the other categories. A plain wizard does not do anything automatically or by itself. Instead, you must define how the wizard is invoked.

The Tools API does not enforce any restrictions on wizards, such as requiring a project wizard to create a project. You can just as easily write a project wizard to create a form and a form wizard to create a project (if that's something you really want to do).

The following topics provide details on how to implement and install a wizard:

- Implementing the wizard interfaces (see page 1286)
- Installing the wizard package (see page 1288)

3.2.1.7 Handling messages

Topics

Name	Description
Broadcasting a Message to All Controls in a Form (see page 1301)	When your component changes global settings that affect all of the controls in a form or other container, you may want to send a message to those controls so that they can update themselves appropriately. Not every control may need to respond to the notification, but by broadcasting the message, you can inform all controls that know how to respond and allow the other controls to ignore the message. To broadcast a message to all the controls in another control, use the Broadcast method. Before you broadcast a message, you fill out a message record (see page 1305) with the information you want... more (see page 1301)
Calling a Control's Message Handler Directly (see page 1302)	Sometimes there is only a single control that needs to respond to your message. If you know the control that should receive your message, the simplest and most straightforward way to send the message is to call the control's Perform method. There are two main reasons why you call a control's *Perform* method: • You want to trigger the same response that the control makes to a standard Windows (or other) message. For example, when a grid control receives a keystroke message, it creates an inline edit control and then sends the keystroke message on to the edit control. • You may... more (see page 1302)

Responding to System Events (see page 1302)	When the widget layer receives an event notification from the operating system, it generates a special event object (*QEvent* or one of its descendants) to represent the event. The event object contains read-only information about the event that occurred. The type of the event object indicates the type of event that occurred. The widget layer notifies your CLX component of system events using a special signal of type event. It passes the *QEvent* object to the signal handler for the event. The processing of the event signal is a bit more complicated than processing other signals because it goes... more (see page 1302)
Sending a Message That Does Not Execute Immediately (see page 1303)	There are times you may want to send a message but you do not know whether it is safe for the target of the message to execute right away. For example, if the code that sends a message is called from an event handler on the target control, you may want to make sure that the event handler has finished executing before the control executes your message. You can handle this situation as long as you do not need to know the message result. Use the Windows API call, *PostMessage*, to send a message to a control but allow... more (see page 1303)
Sending a Message Using the Windows Message Queue (see page 1303)	In a multithreaded application, you can't just call the *Perform* method because the target control is in a different thread than the one that is executing. However, by using the Windows message queue, you can safely communicate with other threads. Message handling always occurs in the main VCL thread, but you can send a message using the Windows message queue from any thread in the application. A call to *SendMessage* is synchronous. That is, *SendMessage* does not return until the target control has handled the message, even if it is in another thread. Use the Windows API call, *SendMessage*,... more (see page 1303)
Sending Messages (see page 1303)	Typically, an application sends message to send notifications of state changes or to broadcast information. Your component can broadcast messages to all the controls in a form, send messages to a particular control (or to the application itself), or even send messages to itself. There are several different ways to send a Windows message. Which method you use depends on why you are sending the message. The following topics describe the different ways to send Windows messages: • Broadcasting a message to all controls in a form. (see page 1301) • Calling a control's message handler directly. (see page 1302) • Sending a message using the Windows message queue. (see page 1303)... more (see page 1303)
Changing Message Handling (see page 1304)	Before changing the message handling of your components, make sure that is what you really want to do. The VCL translates most Windows messages into events that both the component writer and the component user can handle. Rather than changing the message-handling behavior, you should probably change the event-handling behavior. To change message handling in VCL components, you override the message-handling method. You can also prevent a component from handling a message under certain circumstances by trapping the message.
Creating New Message Handlers (see page 1304)	Because the VCL provides handlers for most common messages, the time you will most likely need to create new message handlers is when you define your own messages. Working with user-defined messages has three aspects: • Defining your own messages. (see page 1306) • Declaring a new message-handling method. (see page 1305) • Sending messages. (see page 1303)
Declaring a Message Identifier (see page 1304)	A message identifier is an integer-sized constant. Windows reserves the messages below 1,024 for its own use, so when you declare your own messages you should start above that level. The constant *WM_APP* represents the starting number for user-defined messages. When defining message identifiers, you should base them on *WM_APP*. Be aware that some standard Windows controls use messages in the user-defined range. These include list boxes, combo boxes, edit boxes, and command buttons. If you derive a component from one of these and want to define a new message for it, be sure to check the Messages... more (see page 1304)
Example: User-defined Messages (see page 1304)	The following code shows two user-defined messages.

Example: Message Structure (see page 1305)	For example, here is the message record for all mouse messages, TWMMouse, which uses a variant record to define two sets of names for the same parameters.
Declaring a Message-structure Type (see page 1305)	If you want to give useful names to the parameters of your message, you need to declare a message-record type for that message. The message-record is the type of the parameter passed to the message-handling method. If you do not use the message's parameters, or if you want to use the old-style parameter notation (wParam, lParam, and so on), you can use the default message-record, TMessage.
Declaring a New Message-handling Method (see page 1305)	There are two sets of circumstances that require you to declare new message-handling methods: • Your component needs to handle a Windows message that is not already handled by the standard components. • You have defined your own message for use by your components.
Example: Message Handler (see page 1306)	Here is the declaration of a message handler for a user-defined message called *CM_CHANGECOLOR*.
Defining Your Own Messages (see page 1306)	A number of the standard components define messages for internal use. The most common reasons for defining messages are broadcasting information not covered by standard messages and notification of state changes. You can define your own messages in the VCL. Defining a message is a two-step process. The steps are: 1. Declaring a message identifier. (see page 1304) 2. Declaring a message-record type. (see page 1305)
Dispatching Messages (see page 1306)	When an application creates a window, it registers a *window procedure* with the Windows kernel. The window procedure is the routine that handles messages for the window. Traditionally, the window procedure contains a huge **case** statement with entries for each message the window has to handle. Keep in mind that "window" in this sense means just about anything on the screen: each window, each control, and so on. Every time you create a new type of window, you have to create a complete window procedure. The VCL simplifies message dispatching in several ways: • Each component inherits a complete message-dispatching system.... more (see page 1306)
Example: Overriding a Message Handler (see page 1307)	For example, to override a component's handling of the *WM_PAINT* message, you redeclare the WMPaint method:
Overriding the Handler Method (see page 1307)	To change the way a component handles a particular message, you override the message-handling method for that message. If the component does not already handle the particular message, you need to declare a new message-handling method. To override a message-handling method, you declare a new method in your component with the same message index as the method it overrides. Do *not* use the **override** directive; you must use the **message** directive and a matching message index. Note that the name of the method and the type of the single **var** parameter do not have to match the overridden method. Only... more (see page 1307)
Handling Messages and System Notifications: Overview (see page 1308)	Components often need to respond to notifications from the underlying operating system. The operating system informs the application of occurrences such as what the user does with the mouse and keyboard. Some controls also generate notifications, such as the results from user actions such as selecting an item in a list box. The component library handles most of the common notifications already. It is possible, however, that you will need to write your own code for handling such notifications. For VCL applications, notifications arrive in the form of *messages*. These messages can come from any source, including Windows, VCL... more (see page 1308)
Trapping Messages (see page 1308)	Under some circumstances, you might want your components to ignore messages. That is, you want to keep the component from dispatching the message to its handler. To trap a message, you override the virtual method WndProc. For VCL components, the WndProc method screens messages before passing them to the Dispatch method, which in turn determines which method gets to handle the message. By overriding WndProc, your component gets a chance to filter out messages before dispatching them. An override of WndProc for a control derived from TWinControl looks like this:

The WndProc Method (see page 1308)	**Note:** This information is applicable when writing VCL components only. Here is part of the WndProc method for TControl, for example:
Understanding the message-handling system (see page 1309)	All VCL classes have a built-in mechanism for handling messages, called *message-handling methods* or *message handlers*. The basic idea of message handlers is that the class receives messages of some sort and dispatches them, calling one of a set of specified methods depending on the message received. If no specific method exists for a particular message, there is a default handler. The following diagram shows the message-dispatch system:  The Visual Component Library defines a message-dispatching system that translates all Windows messages (including user-defined messages) directed to a particular class into method calls. You should never need to alter this... more (see page 1309)
Using Message Parameters (see page 1309)	Once inside a message-handling method, your component has access to all the parameters of the message structure. Because the parameter passed to the message handler is a **var** parameter, the handler can change the values of the parameters if necessary. The only parameter that changes frequently is the Result field for the message: the value returned by the SendMessage call that sends the message. Because the type of the Message parameter in the message-handling method varies with the message being handled, you should refer to the documentation on Windows messages for the names and meanings of individual parameters. If for... more (see page 1309)
What's in a Windows Message? (see page 1309)	A Windows message is a data record that contains several fields. The most important of these is an integer-size value that identifies the message. Windows defines many messages, and the *Messages* unit declares identifiers for all of them. Other useful information in a message comes in two parameter fields and a result field. One parameter contains 16 bits, the other 32 bits. You often see Windows code that refers to those values as wParam and lParam, for *word parameter* and *long parameter*. Often, each parameter will contain more than one piece of information, and you see references to... more (see page 1309)

3.2.1.7.1 Broadcasting a Message to All Controls in a Form

When your component changes global settings that affect all of the controls in a form or other container, you may want to send a message to those controls so that they can update themselves appropriately. Not every control may need to respond to the notification, but by broadcasting the message, you can inform all controls that know how to respond and allow the other controls to ignore the message.

To broadcast a message to all the controls in another control, use the Broadcast method. Before you broadcast a message, you fill out a message record (see page 1305) with the information you want to convey.

```
var
Msg: TMessage;
begin
  Msg.Msg := MY_MYCUSTOMMESSAGE;
  Msg.WParam := 0;
  Msg.LParam := Longint(Self);
  Msg.Result := 0;
TMessage Msg;
Msg.Msg = MY_MYCUSTOMMESSAGE;
Msg.WParam = 0;
Msg.LParam = (int)(this);
Msg.Result = 0;
```

Then, pass this message record to the parent of all the controls you want to notify. This can be any control in the application. For example, it can be the parent of the control you are writing:

```
Parent.Broadcast(Msg);
Parent->Broadcast(Msg);
```

It can be the form that contains your control:

```
GetParentForm(self).Broadcast(Msg);
GetParentForm(this)->Broadcast(Msg);
```

It can be the active form:

```
Screen.ActiveForm.Broadcast(Msg);
Screen->ActiveForm->Broadcast(Msg);
```

It can even be all the forms in your application:

```
for I:= 0 to Screen.FormCount - 1 do
  Screen.Forms[I].Broadcast(Msg);
for (int i = 0; i < Screen->FormCount; i++)
  Screen->Forms[i]->Broadcast(Msg);
```

Sending a Message Using the Windows Message Queue (see page 1303)

3.2.1.7.2 Calling a Control's Message Handler Directly

Sometimes there is only a single control that needs to respond to your message. If you know the control that should receive your message, the simplest and most straightforward way to send the message is to call the control's Perform method.

There are two main reasons why you call a control's *Perform* method:

- You want to trigger the same response that the control makes to a standard Windows (or other) message. For example, when a grid control receives a keystroke message, it creates an inline edit control and then sends the keystroke message on to the edit control.
- You may know what control you want to notify, but not know what type of control it is. Because you don't know the type of the target control, you cannot use any of its specialized methods, but all controls have message-handling capabilities so you can always send a message. If the control has a message handler for the message you send, it will respond appropriately. Otherwise, it will ignore the message you send and return 0.

To call the *Perform* method, you do not need to create a message record. You need only pass the message identifier, WParam, and LParam as parameters. Perform returns the message result.

See Also

Sending a Message That Does Not Execute Immediately (see page 1303)

Broadcasting a Message to All Controls in a Form (see page 1301)

Sending a Message Using the Windows Message Queue (see page 1303)

3.2.1.7.3 Responding to System Events

When the widget layer receives an event notification from the operating system, it generates a special event object (*QEvent* or one of its descendants) to represent the event. The event object contains read-only information about the event that occurred. The type of the event object indicates the type of event that occurred.

The widget layer notifies your CLX component of system events using a special signal of type event. It passes the *QEvent* object to the signal handler for the event. The processing of the event signal is a bit more complicated than processing other signals because it goes first to the application object. This means an application has two opportunities to respond to a system event: once at the application level (*TApplication*) and once at the level of the individual component (your *TWidgetControl* or *THandleComponent* descendant.) All of these classes (*TApplication*, *TWidgetControl*, and *THandleComponent*) already assign a signal handler for the event signal from the widget layer. That is, all system events are automatically directed to the *EventFilter* method, which plays a role similar to the *WndProc* method on VCL controls.

EventFilter handles most of the commonly used system notifications, translating them into the events that are introduced by your component's base classes. Thus, for example, the *EventFilter* method of *TWidgetControl* responds to mouse events (*QMouseEvent*) by generating the *OnMouseDown*, *OnMouseMove*, and *OnMouseUp* events, to keyboard events (*QKeyEvent*)

by generating the *OnKeyDown*, *OnKeyPress*, *OnKeyString*, and *OnKeyUp* events, and so on.

The following topics describe how to customize the way your control works with system events:

- Commonly used events
- Overriding the EventFilter method
- Generating Qt events

3.2.1.7.4 Sending a Message That Does Not Execute Immediately

There are times you may want to send a message but you do not know whether it is safe for the target of the message to execute right away. For example, if the code that sends a message is called from an event handler on the target control, you may want to make sure that the event handler has finished executing before the control executes your message. You can handle this situation as long as you do not need to know the message result.

Use the Windows API call, *PostMessage*, to send a message to a control but allow the control to wait until it has finished any other messages before it handles yours. *PostMessage* takes exactly the same parameters as *SendMessage*.

For more information on the PostMessage function, see the Microsoft MSDN documentation.

See Also

Broadcasting a Message to All Controls in a Form (see page 1301)

Sending a Message Using the Windows Message Queue (see page 1303)

3.2.1.7.5 Sending a Message Using the Windows Message Queue

In a multithreaded application, you can't just call the *Perform* method because the target control is in a different thread than the one that is executing. However, by using the Windows message queue, you can safely communicate with other threads. Message handling always occurs in the main VCL thread, but you can send a message using the Windows message queue from any thread in the application. A call to *SendMessage* is synchronous. That is, *SendMessage* does not return until the target control has handled the message, even if it is in another thread.

Use the Windows API call, *SendMessage*, to send a message to a control using the Windows message queue. *SendMessage* takes the same parameters as the *Perform* method, except that you must identify the target control by passing its Window handle. Thus, instead of writing

```
MsgResult := TargetControl.Perform(MY_MYMESSAGE, 0, 0);
MsgResult = TargetControl->Perform(MY_MYMESSAGE, 0, 0);
```

you would write

```
MsgResult := SendMessage(TargetControl.Handle, MYMESSAGE, 0, 0);
MsgResult = SendMessage(TargetControl->Handle, MYMESSAGE, 0, 0);
```

For more information on the SendMessage function, see the Microsoft MSDN documentation. For more information on writing multiple threads that may be executing simultaneously, see Coordinating threads (see page 2227).

Sending a Message That Does Not Execute Immediately (see page 1303)

Broadcasting a Message to All Controls in a Form (see page 1301)

3.2.1.7.6 Sending Messages

Typically, an application sends message to send notifications of state changes or to broadcast information. Your component can

broadcast messages to all the controls in a form, send messages to a particular control (or to the application itself), or even send messages to itself.

There are several different ways to send a Windows message. Which method you use depends on why you are sending the message. The following topics describe the different ways to send Windows messages:

- Broadcasting a message to all controls in a form. (see page 1301)
- Calling a control's message handler directly. (see page 1302)
- Sending a message using the Windows message queue. (see page 1303)
- Sending a message that does not execute immediately. (see page 1303)

3.2.1.7.7 Changing Message Handling

Before changing the message handling of your components, make sure that is what you really want to do. The VCL translates most Windows messages into events that both the component writer and the component user can handle. Rather than changing the message-handling behavior, you should probably change the event-handling behavior.

To change message handling in VCL components, you override the message-handling method. You can also prevent a component from handling a message under certain circumstances by trapping the message.

3.2.1.7.8 Creating New Message Handlers

Because the VCL provides handlers for most common messages, the time you will most likely need to create new message handlers is when you define your own messages. Working with user-defined messages has three aspects:

- Defining your own messages. (see page 1306)
- Declaring a new message-handling method. (see page 1305)
- Sending messages. (see page 1303)

3.2.1.7.9 Declaring a Message Identifier

A message identifier is an integer-sized constant. Windows reserves the messages below 1,024 for its own use, so when you declare your own messages you should start above that level.

The constant *WM_APP* represents the starting number for user-defined messages. When defining message identifiers, you should base them on *WM_APP*.

Be aware that some standard Windows controls use messages in the user-defined range. These include list boxes, combo boxes, edit boxes, and command buttons. If you derive a component from one of these and want to define a new message for it, be sure to check the Messages unit to see which messages Windows already defines for that control.

3.2.1.7.10 Example: User-defined Messages

The following code shows two user-defined messages.

```
const
  MY_MYFIRSTMESSAGE = WM_APP + 400;
  MY_MYSECONDMESSAGE = WM_APP + 401;
#define MY_MYFIRSTMESSAGE  (WM_APP + 400)
#define MY_MYSECONDMESSAGE (WM_APP + 401)
```

3.2.1.7.11 Example: Message Structure

For example, here is the message record for all mouse messages, TWMMouse, which uses a variant record to define two sets of names for the same parameters.

```
type
  TWMMouse = record
    Msg: TMsgParam;        ( first is the message ID )
    Keys: Word;            ( this is the wParam )
    case Integer of        ( two ways to look at the lParam )
      0: {
         XPos: Integer;    ( either as x- and y-coordinates...)
         YPos: Integer);
      1: {
         Pos: TPoint;      ( ... or as a single point )
         Result: Longint); ( and finally, the result field )
end;
struct TWMKey
{
  Cardinal Msg;                    // first parameter is the message ID
  Word CharCode;                   // this is the first wParam
  Word Unused;
  Longint KeyData;                 // this is the lParam
  Longint Result;                  // this is the result data member
};
```

3.2.1.7.12 Declaring a Message-structure Type

If you want to give useful names to the parameters of your message, you need to declare a message-record type for that message. The message-record is the type of the parameter passed to the message-handling method. If you do not use the message's parameters, or if you want to use the old-style parameter notation (wParam, lParam, and so on), you can use the default message-record, TMessage.

To declare a message-record type, follow these conventions:

1. Name the record type after the message, preceded by a *T*.
2. Call the first field in the record `Msg`, of type TMsgParam.
3. Define the next two bytes to correspond to the Word parameter, and the next two bytes as unused. Or Define the next four bytes to correspond to the Longint parameter.
4. Add a final field called Result, of type Longint.

3.2.1.7.13 Declaring a New Message-handling Method

There are two sets of circumstances that require you to declare new message-handling methods:

- Your component needs to handle a Windows message that is not already handled by the standard components.
- You have defined your own message for use by your components.

To declare a message-handling method, do the following:

1. Declare the method in a **protected** part of the component's class declaration.
2. Make the method a procedure.
3. Name the method after the message it handles, but without any underline characters.
4. Pass a single **var** parameter called Message, of the type of the message record.
5. Within the message method implementation, write code for any handling specific to the component.

6. Call the inherited message handler.

3.2.1.7.14 Example: Message Handler

Here is the declaration of a message handler for a user-defined message called *CM_CHANGECOLOR*.

```
const
  CM_CHANGECOLOR = WM_APP + 400;
type
  TMyComponent = class(TControl)
  .
  .
  .
protected
  procedure CMChangeColor(var Message: TMessage); message CM_CHANGECOLOR;
end;
procedure TMyComponent.CMChangeColor(var Message: TMessage);
begin
  Color := Message.lParam;
  inherited;
end;
#define CM_CHANGECOLOR (WM_APP + 400)
class TMyControl : public TControl
{
protected:
    void __fastcall CMChangeColor(TMessage &Message);
BEGIN_MESSAGE_MAP
  MESSAGE_HANDLER(CM_CHANGECOLOR, TMessage, CMChangeColor)
END_MESSAGE_MAP(TControl)
};
void __fastcall TMyControl::CMChangeColor(TMessage &Message)
{
  Color = Message.LParam;                    // set color from long parameter
  TControl::CMChangeColor(Message);          // call the inherited message handler
}
```

3.2.1.7.15 Defining Your Own Messages

A number of the standard components define messages for internal use. The most common reasons for defining messages are broadcasting information not covered by standard messages and notification of state changes. You can define your own messages in the VCL.

Defining a message is a two-step process. The steps are:

1. Declaring a message identifier. (see page 1304)
2. Declaring a message-record type. (see page 1305)

3.2.1.7.16 Dispatching Messages

When an application creates a window, it registers a *window procedure* with the Windows kernel. The window procedure is the routine that handles messages for the window. Traditionally, the window procedure contains a huge **case** statement with entries for each message the window has to handle. Keep in mind that "window" in this sense means just about anything on the screen: each window, each control, and so on. Every time you create a new type of window, you have to create a complete window procedure.

The VCL simplifies message dispatching in several ways:

- Each component inherits a complete message-dispatching system.
- The dispatch system has default handling. You define handlers only for messages you need to respond to specially.

- You can modify small parts of the message handling and rely on inherited methods for most processing.

The greatest benefit of this message dispatch system is that you can safely send any message to any component at any time. If the component does not have a handler defined for the message, the default handling takes care of it, usually by ignoring the message.

Tracing the flow of messages

The VCL registers a method called MainWndProc as the window procedure for each type of component in an application. MainWndProc contains an exception-handling block, passing the message structure from Windows to a virtual method called WndProc and handling any exceptions by calling the application class's HandleException method.

MainWndProc is a nonvirtual method that contains no special handling for any particular messages. Customizations take place in WndProc, since each component type can override the method to suit its particular needs.

WndProc methods check for any special conditions that affect their processing so they can "trap" unwanted messages. For example, while being dragged, components ignore keyboard events, so the WndProc method of TWinControl passes along keyboard events only if the component is not being dragged. Ultimately, WndProc calls Dispatch, a nonvirtual method inherited from TObject, which determines which method to call to handle the message.

Dispatch uses the Msg field of the message structure to determine how to dispatch a particular message. If the component defines a handler for that particular message, Dispatch calls the method. If the component does not define a handler for that message, Dispatch calls DefaultHandler.

3.2.1.7.17 Example: Overriding a Message Handler

For example, to override a component's handling of the *WM_PAINT* message, you redeclare the WMPaint method:

```
type
  TMyComponent = class(...)
  .
  .
  .
  procedure WMPaint(var Message: TWMPaint); message WM_PAINT;
end;
```

```
class PACKAGE TMyComponent : public TComponent
{
protected:
    void __fastcall WMPaint(TWMPaint* Message);
BEGIN_MESSAGE_MAP
  MESSAGE_HANDLER(WM_PAINT, TWMPaint, WMPaint)
END_MESSAGE_MAP(TComponent)
};
```

3.2.1.7.18 Overriding the Handler Method

To change the way a component handles a particular message, you override the message-handling method for that message. If the component does not already handle the particular message, you need to declare a new message-handling method.

To override a message-handling method, you declare a new method in your component with the same message index as the method it overrides. Do *not* use the **override** directive; you must use the **message** directive and a matching message index.

Note that the name of the method and the type of the single **var** parameter do not have to match the overridden method. Only the message index is significant. For clarity, however, it is best to follow the convention of naming message-handling methods after the messages they handle.

```
BEGIN_MESSAGE_MAP
  MESSAGE_HANDLER(parameter1, parameter2, parameter3)
END_MESSAGE_MAP
```

3.2.1.7.19 Handling Messages and System Notifications: Overview

Components often need to respond to notifications from the underlying operating system. The operating system informs the application of occurrences such as what the user does with the mouse and keyboard. Some controls also generate notifications, such as the results from user actions such as selecting an item in a list box. The component library handles most of the common notifications already. It is possible, however, that you will need to write your own code for handling such notifications.

For VCL applications, notifications arrive in the form of *messages*. These messages can come from any source, including Windows, VCL components, and components you have defined. There are three aspects to working with messages:

- Understanding the message-handling system. (see page 1309)
- Changing message handling. (see page 1304)
- Creating new message handlers. (see page 1304)

3.2.1.7.20 Trapping Messages

Under some circumstances, you might want your components to ignore messages. That is, you want to keep the component from dispatching the message to its handler. To trap a message, you override the virtual method WndProc.

For VCL components, the WndProc method screens messages before passing them to the Dispatch method, which in turn determines which method gets to handle the message. By overriding WndProc, your component gets a chance to filter out messages before dispatching them. An override of WndProc for a control derived from TWinControl looks like this:

```
procedure TMyControl.WndProc(var Message: TMessage);
begin
  { tests to determine whether to continue processing }
  inherited WndProc(Message);
end;
void __fastcall TMyControl::WndProc(TMessage& Message)
{
   // tests to determine whether to continue processing
if(Message.Msg != WM_LBUTTONDOWN)

}
```

The TControl component defines entire ranges of mouse messages that it filters when a user is dragging and dropping controls. Overriding WndProc helps this in two ways:

- It can filter ranges of messages instead of having to specify handlers for each one.
- It can preclude dispatching the message at all, so the handlers are never called.

3.2.1.7.21 The WndProc Method

Note: This information is applicable when writing VCL components only.

Here is part of the WndProc method for TControl, for example:

```
procedure TControl.WndProc(var Message: TMessage);
begin
  .
  .
  .
  if (Message.Msg >= WM_MOUSEFIRST) and (Message.Msg <= WM_MOUSELAST) then
    if Dragging then                                    { handle dragging specially }
      DragMouseMsg(TWMMouse(Message))
    else
      .                                                 { handle others normally }
      .
```

```
      .
    end;
.                                                    { otherwise process normally }
.
.
end;
```

3.2.1.7.22 Understanding the message-handling system

All VCL classes have a built-in mechanism for handling messages, called *message-handling methods* or *message handlers*. The basic idea of message handlers is that the class receives messages of some sort and dispatches them, calling one of a set of specified methods depending on the message received. If no specific method exists for a particular message, there is a default handler.

The following diagram shows the message-dispatch system:

The Visual Component Library defines a message-dispatching system that translates all Windows messages (including user-defined messages) directed to a particular class into method calls. You should never need to alter this message-dispatch mechanism. All you will need to do is create message-handling methods. See the section Declaring a new message-handling method (see page 1305) for more on this subject.

3.2.1.7.23 Using Message Parameters

Once inside a message-handling method, your component has access to all the parameters of the message structure. Because the parameter passed to the message handler is a **var** parameter, the handler can change the values of the parameters if necessary. The only parameter that changes frequently is the Result field for the message: the value returned by the SendMessage call that sends the message.

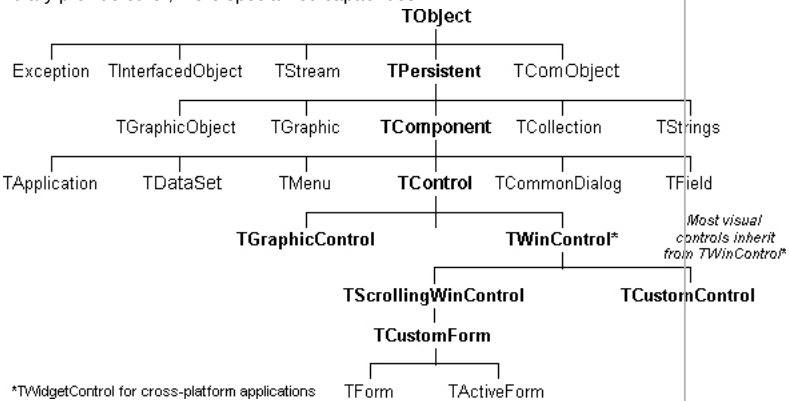
Because the type of the Message parameter in the message-handling method varies with the message being handled, you should refer to the documentation on Windows messages for the names and meanings of individual parameters. If for some reason you need to refer to the message parameters by their old-style names (WParam, LParam, and so on), you can typecast Message to the generic type TMessage, which uses those parameter names.

3.2.1.7.24 What's in a Windows Message?

A Windows message is a data record that contains several fields. The most important of these is an integer-size value that identifies the message. Windows defines many messages, and the *Messages* unit declares identifiers for all of them. Other useful information in a message comes in two parameter fields and a result field.

One parameter contains 16 bits, the other 32 bits. You often see Windows code that refers to those values as wParam and lParam, for *word parameter* and *long parameter*. Often, each parameter will contain more than one piece of information, and you see references to names such as lParamHi, which refers to the high-order word in the long parameter.

Originally, Windows programmers had to remember or look up in the Windows APIs what each parameter contained. Now Microsoft has named the parameters. This so-called *message cracking* makes it much simpler to understand what information accompanies each message. For example, the parameters to the *WM_KEYDOWN* message are now called nVirtKey and lKeyData, which gives much more specific information than wParam and lParam.



For each type of message, Delphi defines a record type that gives a mnemonic name to each parameter. For example, mouse messages pass the x- and y-coordinates of the mouse event in the long parameter, one in the high-order word, and the other in the low-order word. Using the mouse-message structure, you do not have to worry about which word is which, because you refer to the parameters by the names XPos and YPos instead of lParamLo and lParamHi.

```
void MyKeyDownHandler(  HWND hwnd, UINT nVirtKey, BOOL fDown, int CRepeat, UINT flags )
```

```
{
   .
   .
   .
}
LRESULT MyWndProc( HWND hwnd, UINT Message, WPARAM wParam, LPARAM lParam )
{
  switch(  Message )
  {
    HANDLE_MSG( hwnd, WM_KEYDOWN, MyKeyDownHandler );
     .
     .
     .
}
```

3.2.1.8 Introduction to component creation

Topics

Name	Description
Overview of Component Creation (see page 1313)	This set of topics provides an overview of component design and the process of writing components for Delphi applications. The material here assumes that you are familiar with Delphi and its standard components. The main topics discussed are • Class library (see page 1314) • Components and classes (see page 1315) • Creating components (see page 1315) • What goes into a component? (see page 1323) • Creating a new component (see page 1317) • Testing uninstalled components (see page 1324) • Testing installed components (see page 1324) For information on installing new components, see Installing component packages (see page 2217).
Class library (see page 1314)	Delphi's components reside in the Visual Component Library (VCL) . The following figure shows the relationship of selected classes that make up the VCL hierarchy. For a more detailed discussion of class hierarchies and the inheritance relationships among classes, see Object-oriented programming for component writers (see page 1369) The *TComponent* class is the shared ancestor of every component in the component library. *TComponent* provides the minimal properties and events necessary for a component to work in the IDE. The various branches of the library provide other, more specialized capabilities.  When you create a component, you add to the component library by deriving a... more (see page 1314)

Components and Classes (see page 1315)	Because components are classes, component writers work with objects at a different level from application developers. Creating new components requires that you derive new classes. Briefly, there are two main differences between creating components and using them in applications. When creating components, • You access parts of the class that are inaccessible to application programmers. • You add new parts (such as properties) to your components. Because of these differences, you need to be aware of more conventions and think about how application developers will use the components you write.
Creating Components (see page 1315)	A component can be almost any program element that you want to manipulate at design time. Creating a component means deriving a new class from an existing one. You can derive a new component in several ways: • Modifying existing controls (see page 1316) • Creating windowed controls (see page 1316) • Creating graphic controls (see page 1318) • Subclassing Windows controls (see page 1321) • Creating nonvisual components (see page 1318) The following table summarizes the different kinds of components and the classes you use as starting points for each. ***Component creation starting points***
Modifying Existing Controls (see page 1316)	The simplest way to create a component is to customize an existing one. You can derive a new component from any of the components provided in the component library. Some controls, such as list boxes and grids, come in several variations on a basic theme. In these cases, the component library includes an abstract class (with the word "custom" in its name, such as *TCustomGrid*) from which to derive customized versions. For example, you might want to create a special list box that does not have some of the properties of the standard *TListBox* class. You cannot remove (hide)... more (see page 1316)
Creating Original Controls (see page 1316)	Windowed controls in the component library are objects that appear at runtime and that the user can interact with. Each windowed control has a window handle, accessed through its *Handle* property, that lets the operating system identify and operate on the control. If using VCL controls, the handle allows the control to receive input focus and can be passed to Windows API functions. Each widget-based control has a handle, accessed through its *Handle* property, that identifies the underlying widget.--> All windowed controls descend from the *TWinControl*class. These include most standard windowed controls, such as pushbuttons, list boxes, and edit... more (see page 1316)
Creating a New Component (see page 1317)	This topic describes how to create and setup a component.
Creating a Unit File (see page 1317)	A unit is a separately compiled module of Delphi code. Delphi uses units for several purposes. Every form has its own unit, and most components (or groups of related components) have their own units as well. When you create a component, you either create a new unit for the component or add the new component to an existing unit.
Declaring A New Constructor (C++) (see page 1318)	Each new component must have a constructor that overrides the constructor of the class from which it was derived. When you write the constructor for your new component, it must always call the inherited constructor. Within the class declaration, declare a virtual constructor in the public section of the class. For example,

Deriving the Component (see page 1318)	Every component is a class derived from *TComponent*, from one of its more specialized descendants (such as *TControl* or *TGraphicControl*), or from an existing component class. The section Creating components (see page 1315) describes which class to derive different kinds of components from. Deriving classes is explained in more detail in The section Defining new classes. (see page 1370) To derive a component, add an object type declaration to the **interface** part of the unit that will contain the component. A simple component class is a nonvisual component descended directly from *TComponent*.
Creating Nonvisual Components (see page 1318)	Nonvisual components are used as interfaces for elements like databases (*TDataSet or TSQLConnection*) and system clocks (*TTimer*), and as placeholders for dialog boxes (*TCommonDialog* and its descendants). Most of the components you write are likely to be visual controls. Nonvisual components can be derived directly from *TComponent*, the abstract base class for all components.
Creating Graphic Controls (see page 1318)	If your control does not need to receive input focus, you can make it a graphic control. Graphic controls are similar to windowed controls, but have no window handles, and therefore consume fewer system resources. Components like *TLabel*, which never receive input focus, are graphic controls. Although these controls cannot receive focus, you can design them to react to mouse messages. You can create custom controls through the *TGraphicControl* component. *TGraphicControl* is an abstract class derived from *TControl*. Although you can derive controls directly from *TControl*, it is better to start from *TGraphicControl*, which provides a... more (see page 1318)
Encapsulating Graphics (see page 1319)	Delphi simplifies Windows graphics by encapsulating various graphics tools into a canvas. The canvas represents the drawing surface of a window or control and contains other classes, such as a pen, a brush, and a font. A canvas is like a Windows device context, but it takes care of all the bookkeeping for you. If you have written a graphical Windows application, you are familiar with the requirements imposed by Windows' graphics device interface (GDI). For example, GDI limits the number of device contexts available and requires that you restore graphic objects to their initial state before destroying them. With... more (see page 1319)
Setting Properties, Methods, and Events (see page 1319)	Aside from the visible image manipulated in the Form designer, the most obvious attributes of a component are its properties, events, and methods. Each of these has a section devoted to it in this file, but the discussion that follows explains some of the motivation for their use.
Registering the Component (see page 1320)	Registration is a simple process that tells the IDE which components to add to its component library, and on which pages of the Tool palette they should appear. For a more detailed discussion of the registration process, see Making components available at design time (see page 1352)
Removing Dependencies (see page 1321)	One quality that makes components usable is the absence of restrictions on what they can do at any point in their code. By their nature, components are incorporated into applications in varying combinations, orders, and contexts. You should design components that function in any situation, without preconditions. An example of removing dependencies is the *Handle* property of *TWinControl*. If you have written Windows applications before, you know that one of the most difficult and error-prone aspects of getting a program running is making sure that you do not try to access a windowed control until you have created it... more (see page 1321)
Registering Components (Introduction) (see page 1321)	Before you can install your components in the IDE, you have to register them. Registration tells Delphi where to place the component on the Tool palette. You can also customize the way Delphi stores your components in the form file. For information on registering a component, see Registering components. (see page 1352)
Subclassing Windows Controls (see page 1321)	In traditional Windows programming, you create custom controls by defining a new *window class* and registering it with Windows. The window class (which is similar to the *objects* or *classes* in object-oriented programming) contains information shared among instances of the same sort of control; you can base a new window class on an existing class, which is called *subclassing*. You then put your control in a dynamic-link library (DLL), much like the standard Windows controls, and provide an interface to it. You can create a component "wrapper" around any existing window class. So if you already have a library... more (see page 1321)

Creating a Component with the Component Wizard (see page 1321)	The Component wizard simplifies the initial stages of creating a component. When you use the Component wizard, you need to specify: • The class from which the component is derived. • The class name for the new component. • The Tool palette category where you want it to appear. • The name of the unit in which the component is created. • The search path where the unit is found. • The name of the package in which you want to place the component. The Component wizard performs the same tasks you would when creating a component manually: • Creating a unit. • Deriving the component. • Registering the... more (see page 1321)
What Goes into a Component? (see page 1323)	To make your components reliable parts of the Delphi environment, you need to follow certain conventions in their design. This section discusses the following topics: • Removing dependencies (see page 1321) • Setting properties (see page 1319) • Encapsulating graphics (see page 1319) • Registering components (see page 1321)
Making Source Files Available (see page 1323)	Component writers should make all source files used by a component should be located in the same directory. These files include source code files (.pas) and additional project files (.dfm/.xfm, .res, .rc, and .dcr). The process of adding a component results in the creation of a number of files. These files are automatically put in directories specified in the IDE environment options (use the menu command **Tools** ▶ **Options**, navigate to the **Environment Options** ▶ **Delphi Options** ▶ **Library** page). The .lib files are placed in the DCP output directory. If adding the component entails creating a new package (as opposed to... more (see page 1323)
Testing Installed Components (see page 1324)	You can test the design-time behavior of a component after you install it on the Tool palette. This is particularly useful for debugging newly created components, but the same technique works with any component, whether or not it is on the Tool palette. For information on testing components that have not yet been installed, see Testing uninstalled components (see page 1324). Testing your components after installing allows you to debug the component that only generates design-time exceptions when dropped on a form.
Testing Uninstalled Components (see page 1324)	You can test the runtime behavior of a component before you install it on the Tool palette. This is particularly useful for debugging newly created components, but the same technique works with any component, whether or not it is on the Tool palette. For information on testing already installed components, see Testing installed components (see page 1324). You test an uninstalled component by emulating the actions performed by Delphi when the component is selected from the palette and placed on a form.

3.2.1.8.1 Overview of Component Creation

This set of topics provides an overview of component design and the process of writing components for Delphi applications. The material here assumes that you are familiar with Delphi and its standard components.

The main topics discussed are

- Class library (see page 1314)
- Components and classes (see page 1315)

- Creating components (see page 1315)
- What goes into a component? (see page 1323)
- Creating a new component (see page 1317)
- Testing uninstalled components (see page 1324)
- Testing installed components (see page 1324)

For information on installing new components, see Installing component packages (see page 2217).

3.2.1.8.4 Creating Components

A component can be almost any program element that you want to manipulate at design time. Creating a component means deriving a new class from an existing one. You can derive a new component in several ways:

- Modifying existing controls (see page 1316)
- Creating windowed controls (see page 1316)
- Creating graphic controls (see page 1318)
- Subclassing Windows controls (see page 1321)
- Creating nonvisual components (see page 1318)

The following table summarizes the different kinds of components and the classes you use as starting points for each.

Component creation starting points

To do this	Start with this type
Modify an existing component	Any existing component, such as *TButton* or *TListBox*, or an abstract component type, such as *TCustomListBox*
Create a windowed control	*TWinControl*
Create a graphic control	*TGraphicControl*
Subclassing a control	Any Windows control
Create a nonvisual component	*TComponent*

You can also derive classes that are not components and cannot be manipulated on a form, such as *TRegIniFile* and *TFont*.

What Goes into a Component (see page 1323)

Creating a New Component (see page 1317)

Testing Uninstalled Components (see page 1324)

3.2.1.8.5 Modifying Existing Controls

The simplest way to create a component is to customize an existing one. You can derive a new component from any of the components provided in the component library.

Some controls, such as list boxes and grids, come in several variations on a basic theme. In these cases, the component library includes an abstract class (with the word "custom" in its name, such as *TCustomGrid*) from which to derive customized versions.

For example, you might want to create a special list box that does not have some of the properties of the standard *TListBox* class. You cannot remove (hide) a property inherited from an ancestor class, so you need to derive your component from something above *TListBox* in the hierarchy. Rather than force you to start from the abstract *TWinControl*class and reinvent all the list box functions, the component library provides *TCustomListBox*, which implements the properties of a list box but does not publish all of them. When you derive a component from an abstract class like *TCustomListBox*, you publish only the properties you want to make available in your component and leave the rest protected.

The section Creating properties (see page 1249) explains publishing inherited properties. The section Modifying an existing component (see page 1365) and the section Customizing a grid (see page 1264) show examples of modifying existing controls.

Generic Components (see page 1318)

Windowed Controls (see page 1316)

Graphical Controls (see page 1318)

Subclassed Controls (see page 1321)

3.2.1.8.6 Creating Original Controls

Windowed controls in the component library are objects that appear at runtime and that the user can interact with. Each windowed control has a window handle, accessed through its *Handle* property, that lets the operating system identify and operate on the control. If using VCL controls, the handle allows the control to receive input focus and can be passed to Windows API functions. Each widget-based control has a handle, accessed through its *Handle* property, that identifies the underlying widget.-->

All windowed controls descend from the *TWinControl*class. These include most standard windowed controls, such as pushbuttons, list boxes, and edit boxes. While you could derive an original control (one that's not related to any existing control) directly from *TWinControl*, Delphi provides the *TCustomControl* component for this purpose. *TCustomControl* is a specialized windowed control that makes it easier to draw complex visual images.

The section Customizing a grid (see page 1264) presents an example of creating a windowed control.

3.2.1.8.7 Creating a New Component

This topic describes how to create and setup a component.

To create a component, follow these steps:

1. Creating a unit file (see page 1317)
2. Deriving the component (see page 1318)
3. Registering the component (see page 1320)

Now you will have a minimally functional component ready to install on the Tool palette. After installing, you can add your new component to a form and test it at both design time and runtime. You can then add more features to the component, update the Tool palette, and continue testing.

There are several basic steps that you perform whenever you create a new component. These steps are described below; other examples in this document assume that you know how to perform them.

1. Create a unit for the new component.
2. Derive your component from an existing component type.
3. Add properties, methods, and events.
4. Register your component with the IDE.
5. Create a bitmap for the component.
6. Create a package (a special dynamic-link library) so that you can install your component in the IDE.
7. Create a Help file for your component and its properties, methods, and events.

   Note: Creating a Help file to instruct component users on how to use the component is optional.

   When you finish, the complete component includes the following files:

- A package (.BPL) or package collection (.DPC) file
- A compiled package (.DCP) file
- A compiled unit (.DCU) file
- A palette bitmap (.DCR) file
- A Help (.HLP) file

You can also create a bitmap to represent your new component. .

3.2.1.8.8 Creating a Unit File

A unit is a separately compiled module of Delphi code. Delphi uses units for several purposes. Every form has its own unit, and most components (or groups of related components) have their own units as well.

When you create a component, you either create a new unit for the component or add the new component to an existing unit.

To create a new unit for a component:

1. Choose either:

- **File ▶ New ▶ Unit**.
- **File ▶ New ▶ Other** to display the New Items dialog box, select **Delphi Projects ▶ Delphi Files ▶ Unit**, and choose OK. The IDE creates a new unit file and opens it in the Code editor.

2. Save the file with a meaningful name.
3. Derive the component class.

To open an existing unit:

1. Choose **File** ▸ **Open** and select the source code unit to which you want to add your component.

   Note: When adding a component to an existing unit, make sure that the unit contains only component code. For example, adding component code to a unit that contains a form causes errors in the Tool palette.

2. Derive the component class.

3.2.1.8.9 Declaring A New Constructor (C++)

Each new component must have a constructor that overrides the constructor of the class from which it was derived. When you write the constructor for your new component, it must always call the inherited constructor.

Within the class declaration, declare a virtual constructor in the public section of the class.

For example,

```
class PACKAGE TNewComponent : public TComponent
{
public:
  virtual __fastcall TNewComponent(TComponent* AOwner);
};
```

In the .CPP file, implement the constructor:

```
__fastcall TNewComponent::TNewComponent(TComponent* AOwner): TComponent(AOwner)
{
}
```

Within the constructor, you add the code you want to execute when the component is created.

3.2.1.8.10 Deriving the Component

Every component is a class derived from *TComponent*, from one of its more specialized descendants (such as *TControl* or *TGraphicControl*), or from an existing component class. The section Creating components (see page 1315) describes which class to derive different kinds of components from.

Deriving classes is explained in more detail in The section Defining new classes. (see page 1370)

To derive a component, add an object type declaration to the **interface** part of the unit that will contain the component.

A simple component class is a nonvisual component descended directly from *TComponent*.

3.2.1.8.11 Creating Nonvisual Components

Nonvisual components are used as interfaces for elements like databases (*TDataSet or TSQLConnection*) and system clocks (*TTimer*), and as placeholders for dialog boxes (*TCommonDialog* and its descendants). Most of the components you write are likely to be visual controls. Nonvisual components can be derived directly from *TComponent*, the abstract base class for all components.

3.2.1.8.12 Creating Graphic Controls

If your control does not need to receive input focus, you can make it a graphic control. Graphic controls are similar to windowed controls, but have no window handles, and therefore consume fewer system resources. Components like *TLabel*, which never receive input focus, are graphic controls. Although these controls cannot receive focus, you can design them to react to mouse

messages.

You can create custom controls through the *TGraphicControl* component. *TGraphicControl* is an abstract class derived from *TControl*. Although you can derive controls directly from *TControl*, it is better to start from *TGraphicControl*, which provides a canvas to paint on and on Windows, handles *WM_PAINT* messages; all you need to do is override the *Paint* method.

The section Creating a graphic control (see page 1220) presents an example of creating a graphic control.

3.2.1.8.13 Encapsulating Graphics

Delphi simplifies Windows graphics by encapsulating various graphics tools into a canvas. The canvas represents the drawing surface of a window or control and contains other classes, such as a pen, a brush, and a font. A canvas is like a Windows device context, but it takes care of all the bookkeeping for you.

If you have written a graphical Windows application, you are familiar with the requirements imposed by Windows' graphics device interface (GDI). For example, GDI limits the number of device contexts available and requires that you restore graphic objects to their initial state before destroying them.

With Delphi, you do not have to worry about these things. To draw on a form or other component, you access the component's *Canvas* property. If you want to customize a pen or brush, you set its color or style. When you finish, Delphi disposes of the resources. Delphi caches resources to avoid recreating them if your application frequently uses the same kinds of resource.

You still have full access to the Windows GDI, but you will often find that your code is simpler and runs faster if you use the canvas built into Delphi components.

How graphics images work in the component depends on the canvas of the object from which your component descends. Graphics features are detailed in the section Using graphics in components. (see page 1380)

3.2.1.8.14 Setting Properties, Methods, and Events

Aside from the visible image manipulated in the Form designer, the most obvious attributes of a component are its properties, events, and methods. Each of these has a section devoted to it in this file, but the discussion that follows explains some of the motivation for their use.

Properties

Properties give the application developer the illusion of setting or reading the value of a variable, while allowing the component writer to hide the underlying data structure or to implement special processing when the value is accessed.

There are several advantages to using properties:

- Properties are available at design time. The application developer can set or change initial values of properties without having to write code.
- Properties can check values or formats as the application developer assigns them. Validating input at design time prevents errors.
- The component can construct appropriate values on demand. Perhaps the most common type of error programmers make is to reference a variable that has not been initialized. By representing data with a property, you can ensure that a value is always available on demand.
- Properties allow you to hide data under a simple, consistent interface. You can alter the way information is structured in a property without making the change visible to application developers.

The section Overview of component creation (see page 1249) explains how to add properties to your components.

Methods

Class methods are procedures and functions that operate on a class rather than on specific instances of the class. For example, every component's constructor method (*Create*) is a class method. Component methods are procedures and functions that

operate on the component instances themselves. Application developers use methods to direct a component to perform a specific action or return a value not contained by any property.

Because they require execution of code, methods can be called only at runtime. Methods are useful for several reasons:

- Methods encapsulate the functionality of a component in the same object where the data resides.
- Methods can hide complicated procedures under a simple, consistent interface. An application developer can call a component's *AlignControls* method without knowing how the method works or how it differs from the *AlignControls* method in another component.
- Methods allow updating of several properties with a single call.

The section Creating methods (see page 1243) explains how to add methods to your components.

Events

An event is a special property that invokes code in response to input or other activity at runtime. Events give the application developer a way to attach specific blocks of code to specific runtime occurrences, such as mouse actions and keystrokes. The code that executes when an event occurs is called an *event handler*.

Events allow application developers to specify responses to different kinds of input without defining new components.

The section Creating events (see page 1233) explains how to implement standard events and how to define new ones.

3.2.1.8.15 Registering the Component

Registration is a simple process that tells the IDE which components to add to its component library, and on which pages of the Tool palette they should appear. For a more detailed discussion of the registration process, see Making components available at design time (see page 1352)

To register a component:

1. Add a procedure named *Register* to the **interface** part of the component's unit. *Register* takes no parameters, so the declaration is very simple:

```
procedure Register;
namespace Newcomp
{
  void __fastcall PACKAGE Register()
  {
  }
}
TComponentClass classes[1] = {__classid(TNewComponent)};
```

If you are adding a component to a unit that already contains components, it should already have a *Register* procedure declared, so you do not need to change the declaration.

Note: Although Delphi is a case insensitive language, the *Register* procedure is case sensitive and must be spelled with an uppercase R.

2. Write the *Register* procedure in the **implementation** part of the unit, calling *RegisterComponents* for each component you want to register. *RegisterComponents* is a procedure that takes two parameters: the name of a Tool palette category and a set of component types. If you are adding a component to an existing registration, you can either add the new component to the set in the existing statement, or add a new statement that calls *RegisterComponents*.

Declaring a New Constructor (see page 1318)

3.2.1.8.16 Removing Dependencies

One quality that makes components usable is the absence of restrictions on what they can do at any point in their code. By their nature, components are incorporated into applications in varying combinations, orders, and contexts. You should design components that function in any situation, without preconditions.

An example of removing dependencies is the *Handle* property of *TWinControl*. If you have written Windows applications before, you know that one of the most difficult and error-prone aspects of getting a program running is making sure that you do not try to access a windowed control until you have created it by calling the *CreateWindow* API function. Delphi windowed controls relieve users from this concern by ensuring that a valid window handle is always available when needed. By using a property to represent the window handle, the control can check whether the window has been created; if the handle is not valid, the control creates a window and returns the handle. Thus, whenever an application's code accesses the *Handle* property, it is assured of getting a valid handle.

By removing background tasks like creating the window, Delphi components allow developers to focus on what they really want to do. Before passing a window handle to an API function, you do not need to verify that the handle exists or to create the window. The application developer can assume that things will work, instead of constantly checking for things that might go wrong.

Although it can take time to create components that are free of dependencies, it is generally time well spent. It not only spares application developers from repetition and drudgery, but it reduces your documentation and support burdens.

3.2.1.8.17 Registering Components (Introduction)

Before you can install your components in the IDE, you have to register them. Registration tells Delphi where to place the component on the Tool palette. You can also customize the way Delphi stores your components in the form file. For information on registering a component, see Registering components. (see page 1352)

3.2.1.8.18 Subclassing Windows Controls

In traditional Windows programming, you create custom controls by defining a new *window class* and registering it with Windows. The window class (which is similar to the *objects* or *classes* in object-oriented programming) contains information shared among instances of the same sort of control; you can base a new window class on an existing class, which is called *subclassing*. You then put your control in a dynamic-link library (DLL), much like the standard Windows controls, and provide an interface to it.

You can create a component "wrapper" around any existing window class. So if you already have a library of custom controls that you want to use in Delphi applications, you can create Delphi components that behave like your controls, and derive new controls from them just as you would with any other component.

For examples of the techniques used in subclassing Windows controls, see the components in the StdCtls unit that represent standard Windows controls, such as *TEdit*.

3.2.1.8.19 Creating a Component with the Component Wizard

The Component wizard simplifies the initial stages of creating a component. When you use the Component wizard, you need to specify:

- The class from which the component is derived.
- The class name for the new component.
- The Tool palette category where you want it to appear.

- The name of the unit in which the component is created.
- The search path where the unit is found.
- The name of the package in which you want to place the component.

The Component wizard performs the same tasks you would when creating a component manually:

- Creating a unit.
- Deriving the component.
- Registering the component.

The Component wizard cannot add components to an existing unit. You must add components to existing units manually.

To add a new component with the Component Wizard

1. To start the Component wizard, choose one of these two methods:

- Choose **Component** ▸ **New VCL Component**.
- Choose **File** ▸ **New** ▸ **Other**, goto the **Delphi Projects** ▸ **Delphi Files** page and double-click Component.

2. Fill in the fields in the Component wizard:

- In the Ancestor Type field, specify the class from which you are deriving your new component.
- In the Class Name field, specify the name of your new component class.
- In the Palette Page field, specify the category on the Tool palette on which you want the new component to be installed.
- In the Unit file name field, specify the name of the unit you want the component class declared in. If the unit is not on the search path, edit the search path in the Search Path field as necessary.

3. After you fill in the fields in the Component wizard, Click Install. To place the component in a new or existing package, click **Component** ▸ **Install** and use the dialog box that appears to specify a package.
4. Click OK. The IDE creates a new unit.

   Warning: If you derive a component from a class whose name begins with "custom" (such as *TCustomControl*), do not try to place the new component on a form until you have overridden any abstract methods in the original component. Delphi cannot create instance objects of a class that has abstract properties or methods.

   To see the source code for your unit, click **View** ▸ **Units...** (If the Component wizard is already closed, open the unit file in the Code editor by selecting **File** ▸ **Open**.) Delphi creates a new unit containing the class declaration and the *Register* procedure, and adds a **uses** clause that includes all the standard Delphi units.

   The unit looks like this:

```
unit MyControl;
    interface
    uses
      Windows, Messages, SysUtils, Types, Classes, Controls;
    type
      TMyControl = class(TCustomControl)
      private
      { Private declarations }
      protected
      { Protected declarations }
      public
      { Public declarations }
      published
      { Published declarations }
    end;
    procedure Register;
    implementation
    procedure Register;
    begin
      RegisterComponents('Samples', [TMyControl]); //In CLX, use a different page than
'Samples'
    end;
```

```
    end.
//header file
#ifndef NewComponentH
#define NewComponentH
//---------------------------------------------------------------------------
#include <SysUtils.hpp>
#include <Controls.hpp>
#include <Classes.hpp>
#include <Forms.hpp>
//---------------------------------------------------------------------------
class PACKAGE TNewComponent : public TComponent
{
private:
protected:
public:
__fastcall TNewComponent(TComponent* Owner);
__published:
};
//---------------------------------------------------------------------------
#endif
//implementation file
#include <vcl.h>
#pragma hdrstop
#include "NewComponent.h"
#pragma package(smart_init);
//---------------------------------------------------------------------------
// ValidCtrCheck is used to assure that the components created do not have
// any pure virtual functions.
//
static inline void ValidCtrCheck(TNewComponent *)
{
new TNewComponent(NULL);
}
//---------------------------------------------------------------------------
__fastcall TNewComponent::TNewComponent(TComponent* Owner)
: TComponent(Owner)
{
}
//---------------------------------------------------------------------------
namespace Newcomponent
{
void __fastcall PACKAGE Register()
{
TComponentClass classes[1] = {__classid(TNewComponent)};
RegisterComponents("Samples", classes, 0); //In CLX use a different page than Samples
}
}
```

3.2.1.8.20 What Goes into a Component?

To make your components reliable parts of the Delphi environment, you need to follow certain conventions in their design. This section discusses the following topics:

- Removing dependencies (see page 1321)
- Setting properties (see page 1319)
- Encapsulating graphics (see page 1319)
- Registering components (see page 1321)

3.2.1.8.21 Making Source Files Available

Component writers should make all source files used by a component should be located in the same directory. These files

include source code files (.pas) and additional project files (.dfm/.xfm, .res, .rc, and .dcr).

The process of adding a component results in the creation of a number of files. These files are automatically put in directories specified in the IDE environment options (use the menu command **Tools ▸ Options**, navigate to the **Environment Options ▸ Delphi Options ▸ Library** page). The .lib files are placed in the DCP output directory. If adding the component entails creating a new package (as opposed to installing it into an existing package), the .bpl file is put in the BPL output directory.

3.2.1.8.22 Testing Installed Components

You can test the design-time behavior of a component after you install it on the Tool palette. This is particularly useful for debugging newly created components, but the same technique works with any component, whether or not it is on the Tool palette. For information on testing components that have not yet been installed, see Testing uninstalled components (see page 1324).

Testing your components after installing allows you to debug the component that only generates design-time exceptions when dropped on a form.

Test an installed component using a second running instance of the IDE:

1. Choose **Project ▸ Options ▸ Debugger** and set the Debug Source Path to point to the component's source file.
2. Then select **Tools ▸ Options**. On the **Debugger Options ▸ Borland Debuggers ▸ Language Exceptions** page, enable the exceptions you want to track.
3. Open the component source file and set breakpoints.
4. Select **Run ▸ Parameters** and set the Host Application field to the name and location of the Delphi executable file.
5. In the Run Parameters dialog, click the Load button to start a second instance of Delphi.
6. Then drop the components to be tested on the form, which should break on your breakpoints in the source.

3.2.1.8.23 Testing Uninstalled Components

You can test the runtime behavior of a component before you install it on the Tool palette. This is particularly useful for debugging newly created components, but the same technique works with any component, whether or not it is on the Tool palette. For information on testing already installed components, see Testing installed components (see page 1324).

You test an uninstalled component by emulating the actions performed by Delphi when the component is selected from the palette and placed on a form.

To test an uninstalled component,

1. Add the name of component's unit to the form unit's **uses** clause.
2. Add an object field to the form to represent the component. This is one of the main differences between the way you add components and the way Delphi does it. You add the object field to the public part at the bottom of the form's type declaration. Delphi would add it above, in the part of the type declaration that it manages. Never add fields to the Delphi-managed part of the form's type declaration. The items in that part of the type declaration correspond to the items stored in the form file. Adding the names of components that do not exist on the form can render your form file invalid.
3. Attach a handler to the form's *OnCreate* event.
4. Construct the component in the form's *OnCreate* handler. When you call the component's constructor, you must pass a parameter specifying the owner of the component (the component responsible for destroying the component when the time comes). You will nearly always pass *Self* as the owner. In a method, *Self* is a reference to the object that contains the method. In this case, in the form's *OnCreate* handler, *Self* refers to the form.
5. Assign the *Parent* property. Setting the *Parent* property is always the first thing to do after constructing a control. The parent is the component that contains the control visually; usually it is the form on which the control appears, but it might be a group box or panel. Normally, you'll set *Parent* to *Self*, that is, the form. Always set *Parent* before setting other properties of the

control.

Warning: If your component is not a control (that is, if *TControl* is not one of its ancestors), skip this step. If you accidentally set the form's *Parent* property (instead of the component's) to *Self*, you can cause an operating-system problem.

6. Set any other component properties as desired.

3.2.1.9 Making a control data aware

Topics

Name	Description
Adding the Data Link (see page 1327)	The connection between a control and a database is handled by a class called a *data link*. The data link class that connects a control with a single field in a database is *TFieldDataLink*. There are also data links for entire tables. A data-aware control *owns* its data link class. That is, the control has the responsibility for constructing and destroying the data link. For details on management of owned classes, see Creating a graphic control (see page 1220)
Adding the ReadOnly property (see page 1328)	By adding a *ReadOnly* property, you will provide a way to make the control read-only at design time. When that property is set to *True*, you can make all cells in the control unable to be selected.
Allowing Needed Updates (see page 1329)	The read-only calendar uses the *SelectCell* method for all kinds of changes, including setting the *Row* and *Col* properties. The *UpdateCalendar* method sets *Row* and *Col* every time the date changes, but because *SelectCell* disallows changes, the selection remains in place, even though the date changes. To get around this absolute prohibition on changes, you can add an internal Boolean flag to the calendar, and permit changes when that flag is set to *True*:
Changing the Default Value of FReadOnly (see page 1330)	Because this is a data editing control, the *ReadOnly* property should be set to *False* by default. To make the *ReadOnly* property *False*, change the value of *FReadOnly* in the constructor:
Creating a Data Browsing Control (see page 1330)	Creating a data-aware calendar control, whether it is a read-only control or one in which the user can change the underlying data in the dataset, involves the following steps: • Creating and registering the component (see page 1331). • Adding the data link (see page 1327). • Responding to data changes (see page 1334).
Creating a Data Editing Control (see page 1330)	When you create a data editing control, you create and register the component and add the data link just as you do for a data browsing control. You also respond to data changes in the underlying field in a similar manner, but you must handle a few more issues. For example, you probably want your control to respond to both key and mouse events. Your control must respond when the user changes the contents of the control. When the user exits the control, you want the changes made in the control to be reflected in the dataset. The data editing... more (see page 1330)

Creating and registering the data-aware component (see page 1331)	You create every component the same way: create a unit, derive a component class, register it, compile it, and install it on the Tool palette. This process is outlined in Creating a new component (see page 1317). For this example, follow the general procedure for creating a component, with these specifics: • Call the component's unit *DBCal*. • Derive a new component class called *TDBCalendar*, descended from the component *TSampleCalendar*. The section Customizing a grid (see page 1264) shows you how to create the *TSampleCalendar* component. • Register *TDBCalendar* on the Samples page of the Tool palette. The resulting unit descending from *TCustomGrid* in a... more (see page 1331)
Declaring the Access Properties for a Data-aware Control (see page 1331)	Every data-aware control has a *DataSource* property that specifies which data source class in the application provides the data to the control. In addition, a control that accesses a single field needs a *DataField* property to specify that field in the data source. Unlike the access properties for the owned classes in the example in Creating a graphic control (see page 1220) these access properties do not provide access to the owned classes themselves, but rather to corresponding properties in the owned class. That is, you will create properties that enable the control and its data link to share the same data source... more (see page 1331)
Declaring the Class Field (see page 1332)	A component needs a field for each of its owned classes, as explained in Declaring the class fields (see page 1222). In this case, the calendar needs a field of type *TFieldDataLink* for its data link. Declare a field for the data link in the calendar:
Handling Mouse-down and Key-down Messages (see page 1332)	When the user of the control begins interacting with it, the control receives either mouse-down messages (*WM_LBUTTONDOWN*, *WM_MBUTTONDOWN*, or *WM_RBUTTONDOWN*) or a key-down message (*WM_KEYDOWN*) from Windows. To enable a control to respond to these messages, you must write handlers that respond to these messages. • Responding to mouse-down messages (see page 1336). • Responding to key-down messages (see page 1335).
Initializing the Data Link (see page 1332)	A data-aware control needs access to its data link throughout its existence, so it must construct the data link object as part of its own constructor, and destroy the data link object before it is itself destroyed. Override the *Create* and *Destroy* methods of the calendar to construct and destroy the datalink object, respectively:
Making a Control Data Aware (see page 1333)	When working with database connections, it is often convenient to have controls that are *data aware*. That is, the application can establish a link between the control and some part of a database. Delphi includes data-aware labels, edit boxes, list boxes, combo boxes, lookup controls, and grids. You can also make your own controls data aware. For more information about using data-aware controls, see Using data controls (see page 1778) . There are several degrees of data awareness. The simplest is read-only data awareness, or *data browsing*, the ability to reflect the current state of a database. More complicated is editable... more (see page 1333)
Making the Control Read-only (see page 1333)	Because this data calendar will be read-only with respect to the data, it makes sense to make the control itself read-only, so users will not make changes within the control and expect them to be reflected in the database. Making the calendar read-only involves: • Adding the ReadOnly property. (see page 1328) • Allowing needed updates. (see page 1329) **Note:** Note that if you started with the *TCalendar* component from Delphi's Samples page instead of *TSampleCalendar*, it already has a *ReadOnly* property, so you can skip these steps.

Modifying the Change Method (see page 1334)	The *Change* method of the *TDBCalendar* is called whenever a new date value is set. *Change* calls the *OnChange* event handler, if one exists. The component user can write code in the *OnChange* event handler to respond to changes in the date. When the calendar date changes, the underlying dataset should be notified that a change has occurred. You can do that by overriding the *Change* method and adding one more line of code.
Responding to Data Changes (see page 1334)	Once a control has a data link and properties to specify the data source and data field, it needs to respond to changes in the data in that field, either because of a move to a different record or because of a change made to that field. Data link classes all have events named *OnDataChange*. When the data source indicates a change in its data, the data link object calls any event handler attached to its *OnDataChange* event. To update a control in response to data changes, attach a handler to the data link's *OnDataChange* event. In this case,... more (see page 1334)
Responding to Key-down Messages (see page 1335)	A *KeyDown* method is a protected method for a control's *OnKeyDown* event. The control itself calls *KeyDown* in response to a Windows key-down message. When overriding the inherited *KeyDown* method, you can include code that provides other responses in addition to calling the *OnKeyDown* event.
Responding to Mouse-down Messages (see page 1336)	A *MouseDown* method is a protected method for a control's *OnMouseDown* event. The control itself calls *MouseDown* in response to a Windows mouse-down message. When you override the inherited *MouseDown* method, you can include code that provides other responses in addition to calling the *OnMouseDown* event. To override *MouseDown*, add the *MouseDown* method to the *TDBCalendar* class:
Updating the Dataset (see page 1337)	So far, a change within the data-aware control has changed values in the field data link class. The final step in creating a data editing control is to update the dataset with the new value. This should happen after the person changing the value in the data-aware control exits the control by clicking outside the control or pressing the `Tab` key. **Note:** VCL applications define message control IDs for operations on controls. For example, the *CM_EXIT* message is sent to the control when the user exits the control. You can write message handlers that respond to the message. In this... more (see page 1337)
Updating the Field Data Link Class (see page 1338)	There are two types of data changes: • A change in a field value that must be reflected in the data-aware control. • A change in the data-aware control that must be reflected in the field value. The *TDBCalendar* component already has a *DataChange* method that handles a change in the field's value in the dataset by assigning that value to the *CalendarDate* property. The *DataChange* method is the handler for the *OnDataChange* event. So the calendar component can handle the first type of data change. Similarly, the field data link class also has an *OnUpdateData* event that occurs as the user... more (see page 1338)

3.2.1.9.1 Adding the Data Link

The connection between a control and a database is handled by a class called a *data link*. The data link class that connects a control with a single field in a database is *TFieldDataLink*. There are also data links for entire tables.

A data-aware control *owns* its data link class. That is, the control has the responsibility for constructing and destroying the data link. For details on management of owned classes, see Creating a graphic control (see page 1220)

Establishing a data link as an owned class requires these three steps:

1. Declaring the class field (see page 1332).
2. Declaring the access properties (see page 1331).

3. Initializing the data link (see page 1332).

3.2.1.9.2 Adding the ReadOnly property

By adding a *ReadOnly* property, you will provide a way to make the control read-only at design time. When that property is set to *True*, you can make all cells in the control unable to be selected.

To add the ReadOnly property, follow these steps:

1. Add the property declaration and a **private** field to hold the value:

```
type
  TDBCalendar = class(TSampleCalendar)
  private
    FReadOnly: Boolean;                                    { field for internal storage }
  public
    constructor Create(AOwner: TComponent); override;     { must override to set default }
  published
    property ReadOnly: Boolean read FReadOnly write FReadOnly default True;
  end;
.
.
.
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                    { always call the inherited constructor! }
  FReadOnly := True;                                          { set the default value }
end;
//header file
class PACKAGE TDBCalendar : public TSampleCalendar
{
private:
    bool FReadOnly;                                  // field for internal storage
protected:
public:
    virtual __fastcall TDBCalendar(TComponent* Owner);
__published:
    __property ReadOnly = {read=FReadOnly, write=FReadOnly, default=true};
};
//implementation file:
virtual __fastcall TDBCalendar::TDBCalendar(TComponent* Owner) :
  TSampleCalendar(Owner)
{
  FReadOnly = true;                                   // sets the default value
}
```

2. Override the *SelectCell* method to disallow selection if the control is read-only. Use of *SelectCell* is explained in Excluding blank cells (see page 1265).

```
function TDBCalendar.SelectCell(ACol, ARow: Longint): Boolean;
begin
  if FReadOnly then Result := False                          { cannot select if read only }
  else Result := inherited SelectCell(ACol, ARow);     { otherwise, use inherited method }
end;
bool __fastcall TDBCalendar::SelectCell(long ACol, long ARow)
{
  if (FReadOnly) return false;                           // can't select if read only
  return TSampleCalendar::SelectCell(ACol, ARow);     // otherwise, use inherited method
}
```

Remember to add the declaration of *SelectCell* to the type declaration of *TDBCalendar*, and append the **override** directive.

If you now add the calendar to a form, you will find that the component ignores clicks and keystrokes. It also fails to update the selection position when you change the date.

3.2.1.9.3 Allowing Needed Updates

The read-only calendar uses the *SelectCell* method for all kinds of changes, including setting the *Row* and *Col* properties. The *UpdateCalendar* method sets *Row* and *Col* every time the date changes, but because *SelectCell* disallows changes, the selection remains in place, even though the date changes.

To get around this absolute prohibition on changes, you can add an internal Boolean flag to the calendar, and permit changes when that flag is set to *True*:

```
type
  TDBCalendar = class(TSampleCalendar)
  private
    FUpdating: Boolean;                                    { private flag for internal use }
  protected
    function SelectCell(ACol, ARow: Longint): Boolean; override;
  public
    procedure UpdateCalendar; override;                { remember the override directive }
  end;
.
.
.
function TDBCalendar.SelectCell(ACol, ARow: Longint): Boolean;
begin
  if (not FUpdating) and FReadOnly then Result := False       { allow select if updating }
  else Result := inherited SelectCell(ACol, ARow);     { otherwise, use inherited method }
end;
procedure TDBCalendar.UpdateCalendar;
begin
  FUpdating := True;                                          { set flag to allow updates }
  try
    inherited UpdateCalendar;                                          { update as usual }
  finally
    FUpdating := False;                                       { always clear the flag }
  end;
end;
class PACKAGE TDBCalendar : public TSampleCalendar
{
private:
    .
    .
    .
    bool FUpdating;                                    // private flag for internal use
protected:
    virtual bool __fastcall SelectCell(long ACol, long ARow);
public:
    .
    .
    .
    virtual void __fastcall UpdateCalendar();
    .
    .
    .
};
bool __fastcall TDBCalendar::SelectCell(long ACol, long ARow)
{
    if (!FUpdating && FReadOnly) return false;          // can't select if read only
    return TSampleCalendar::SelectCell(ACol, ARow);     // otherwise, use inherited method
}
void __fastcall TDBCalendar::UpdateCalendar()
{
  FUpdating=true;                                       // set flag to allow updates
  try
  {
     TSampleCalendar::UpdateCalendar();              // update as usual
```

```
  }
  catch(...)
  {
    FUpdating = false;
    throw;
  }
  FUpdating = false;                                    // always clear the flag
}
```

The calendar still disallows user changes, but now correctly reflects changes made in the date by changing the date properties. Now that you have a true read-only calendar control, you are ready to add the data browsing ability.

3.2.1.9.4 Changing the Default Value of FReadOnly

Because this is a data editing control, the *ReadOnly* property should be set to *False* by default. To make the *ReadOnly* property *False*, change the value of *FReadOnly* in the constructor:

```
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  .
  .
  .
  FReadOnly := False;  { set the default value }
  .
  .
  .
end;
__fastcall TDBCalendar::TDBCalendar (TComponent* Owner) : TSampleCalendar(Owner)
{
  FReadOnly = false;             // set the default value
  .
  .
  .
}
```

3.2.1.9.5 Creating a Data Browsing Control

Creating a data-aware calendar control, whether it is a read-only control or one in which the user can change the underlying data in the dataset, involves the following steps:

- Creating and registering the component (see page 1331).
- Adding the data link (see page 1327).
- Responding to data changes (see page 1334).

3.2.1.9.6 Creating a Data Editing Control

When you create a data editing control, you create and register the component and add the data link just as you do for a data browsing control. You also respond to data changes in the underlying field in a similar manner, but you must handle a few more issues.

For example, you probably want your control to respond to both key and mouse events. Your control must respond when the user changes the contents of the control. When the user exits the control, you want the changes made in the control to be reflected in the dataset.

The data editing control described here is the same calendar control described in Creating a data browsing control (see page 1330). The control is modified so that it can edit as well as view the data in its linked field.

Modifying the existing control to make it a data editing control involves:

- Changing the default value of FReadOnly. (see page 1330)
- Handling mouse-down and key-down messages. (see page 1332)
- Updating the field data link class. (see page 1338)
- Modifying the Change method. (see page 1334)
- Updating the dataset. (see page 1337)

3.2.1.9.7 Creating and registering the data-aware component

You create every component the same way: create a unit, derive a component class, register it, compile it, and install it on the Tool palette. This process is outlined in Creating a new component (see page 1317).

For this example, follow the general procedure for creating a component, with these specifics:

- Call the component's unit *DBCal*.
- Derive a new component class called *TDBCalendar*, descended from the component *TSampleCalendar*. The section Customizing a grid (see page 1264) shows you how to create the *TSampleCalendar* component.
- Register *TDBCalendar* on the Samples page of the Tool palette.

The resulting unit descending from *TCustomGrid* in a VCL application should look like this:

```
unit CalSamp;
interface
uses
  Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs, Grids;
type
  TSampleCalendar = class(TCustomGrid)
  end;
procedure Register;
implementation
procedure Register;
begin
  RegisterComponents('Samples', [TSampleCalendar]);
end;
end.
```

If you install the calendar component now, you will find that it appears on the Samples page. The only properties available are the most basic control properties. The next step is to make some of the more specialized properties available to users of the calendar.

Note: While you can install the sample calendar component you have just compiled, do not try to place it on a form yet. The *TCustomGrid* component has an abstract *DrawCell* method that must be redeclared before instance objects can be created. Overriding the DrawCell method is described in Filling in the cells (see page 1265).

3.2.1.9.8 Declaring the Access Properties for a Data-aware Control

Every data-aware control has a *DataSource* property that specifies which data source class in the application provides the data to the control. In addition, a control that accesses a single field needs a *DataField* property to specify that field in the data source.

Unlike the access properties for the owned classes in the example in Creating a graphic control (see page 1220) these access properties do not provide access to the owned classes themselves, but rather to corresponding properties in the owned class. That is, you will create properties that enable the control and its data link to share the same data source and field.

Declare the *DataSource* and *DataField* properties and their implementation methods, then write the methods as "pass-through" methods to the corresponding properties of the data link class.

See Also

Initializing the Data Link (see page 1332)

3.2.1.9.9 Declaring the Class Field

A component needs a field for each of its owned classes, as explained in Declaring the class fields (see page 1222). In this case, the calendar needs a field of type *TFieldDataLink* for its data link.

Declare a field for the data link in the calendar:

```
type
  TDBCalendar = class(TSampleCalendar)
  private
    FDataLink: TFieldDataLink;
  .
  .
  .
  end;
```

```
class PACKAGE TDBCalendar : public TSampleCalendar
{
private:
    TFieldDataLink *FDataLink;
    .
    .
    .
};
#include <DB.hpp>
#include <DBTables.hpp>
```

Before you can compile the application, you need to add DB and DBCtrls to the unit's **uses** clause.

3.2.1.9.10 Handling Mouse-down and Key-down Messages

When the user of the control begins interacting with it, the control receives either mouse-down messages (*WM_LBUTTONDOWN*, *WM_MBUTTONDOWN*, or *WM_RBUTTONDOWN*) or a key-down message (*WM_KEYDOWN*) from Windows. To enable a control to respond to these messages, you must write handlers that respond to these messages.

- Responding to mouse-down messages (see page 1336).
- Responding to key-down messages (see page 1335).

3.2.1.9.11 Initializing the Data Link

A data-aware control needs access to its data link throughout its existence, so it must construct the data link object as part of its own constructor, and destroy the data link object before it is itself destroyed.

Override the *Create* and *Destroy* methods of the calendar to construct and destroy the datalink object, respectively:

```
type
  TDBCalendar = class(TSampleCalendar)
  public                                  { constructors and destructors are always public }
    constructor Create(AOwner: TComponent); override;
    destructor Destroy; override;
    .
    .
    .
  end;
.
.
.
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);                  { always call the inherited constructor first }
  FDataLink := TFieldDataLink.Create;                        { construct the datalink object }
```

```
  FDataLink.Control := self;                {let the datalink know about the calendar }
  FReadOnly := True;                                                { this is already here }
end;
destructor TDBCalendar.Destroy;
begin
  FDataLink.Free;                                    { always destroy owned objects first... }
  inherited Destroy;                                     { ...then call inherited destructor }
end;
class PACKAGE TDBCalendar : public TSampleCalendar
{
public:
    virtual __fastcall TDBCalendar(TComponent *Owner);
    __fastcall ~TDBCalendar();
};
__fastcall TDBCalendar::TDBCalendar(TComponent* Owner) : TSampleCalendar(Owner)
{
    FReadOnly = true;
    FDataLink = new TFieldDataLink();
    FDataLink->Control = this;
}
__fastcall TDBCalendar::~TDBCalendar()
{
    FDataLink->Control = NULL;
    FDataLink->OnUpdateData = NULL;
    delete FDataLink;
}
```

Now you have a complete data link, but you have not yet told the control what data it should read from the linked field. The next section (see page 1334) explains how to do that.

See Also

Declaring the Access Properties for a Data-aware Control (see page 1331)

3.2.1.9.12 Making a Control Data Aware

When working with database connections, it is often convenient to have controls that are *data aware*. That is, the application can establish a link between the control and some part of a database. Delphi includes data-aware labels, edit boxes, list boxes, combo boxes, lookup controls, and grids. You can also make your own controls data aware. For more information about using data-aware controls, see Using data controls (see page 1778) .

There are several degrees of data awareness. The simplest is read-only data awareness, or *data browsing*, the ability to reflect the current state of a database. More complicated is editable data awareness, or *data editing*, where the user can edit the values in the database by manipulating the control. Note also that the degree of involvement with the database can vary, from the simplest case, a link with a single field, to more complex cases, such as multiple-record controls.

This section first illustrates the simplest case, making a read-only control that links to a single field in a dataset. The specific control used will be the *TSampleCalendar* calendar created in Customizing a grid (see page 1264) You can also use the standard calendar control on the Samples page of the Tool palette, *TCalendar*.

The section then continues with an explanation of how to make the new data browsing control a data editing control.

3.2.1.9.13 Making the Control Read-only

Because this data calendar will be read-only with respect to the data, it makes sense to make the control itself read-only, so users will not make changes within the control and expect them to be reflected in the database.

Making the calendar read-only involves:

- Adding the ReadOnly property. (see page 1328)

- Allowing needed updates. (see page 1329)

  Note: Note that if you started with the *TCalendar* component from Delphi's Samples page instead of *TSampleCalendar*, it already has a *ReadOnly* property, so you can skip these steps.

3.2.1.9.14 Modifying the Change Method

The *Change* method of the *TDBCalendar* is called whenever a new date value is set. *Change* calls the *OnChange* event handler, if one exists. The component user can write code in the *OnChange* event handler to respond to changes in the date.

When the calendar date changes, the underlying dataset should be notified that a change has occurred. You can do that by overriding the *Change* method and adding one more line of code.

These are the steps to follow:

1. Add a new *Change* method to the *TDBCalendar* component:

```
type
  TDBCalendar = class(TSampleCalendar);
  private
    procedure Change; override;
   .
   .
   .
  end;
class PACKAGE TDBCalendar : public TSampleCalendar
{
protected:
    virtual void __fastcall Change();
     .
     .
     .
};
```

2. Write the *Change* method, calling the *Modified* method that informs the dataset the data has changed, then call the inherited *Change* method:

```
procedure TDBCalendar.Change;
begin
  FDataLink.Modified;                  { call the Modified method }
  inherited Change;                    { call the inherited Change method }
end;
void __fastcall TDBCalendar::Change()
{
  if (FDataLink != NULL)
    FDataLink->Modified();               // call the Modified method
  TSampleCalendar::Change();             // call the inherited Change method
}
```

3.2.1.9.15 Responding to Data Changes

Once a control has a data link and properties to specify the data source and data field, it needs to respond to changes in the data in that field, either because of a move to a different record or because of a change made to that field.

Data link classes all have events named *OnDataChange*. When the data source indicates a change in its data, the data link object calls any event handler attached to its *OnDataChange* event.

To update a control in response to data changes, attach a handler to the data link's *OnDataChange* event.

In this case, you will add a method to the calendar, then designate it as the handler for the data link's *OnDataChange*.

Declare and implement the *DataChange* method, then assign it to the data link's *OnDataChange* event in the constructor. In the destructor, detach the *OnDataChange* handler before destroying the object.

3.2.1.9.16 Responding to Key-down Messages

A *KeyDown* method is a protected method for a control's *OnKeyDown* event. The control itself calls *KeyDown* in response to a Windows key-down message. When overriding the inherited *KeyDown* method, you can include code that provides other responses in addition to calling the *OnKeyDown* event.

To override KeyDown, follow these steps:

1. Add a *KeyDown* method to the *TDBCalendar* class:

```
type
  TDBCalendar = class(TSampleCalendar);
    .
    .
    .
  protected
    procedure KeyDown(var Key: Word; Shift: TShiftState; X: Integer; Y: Integer);
      override;
    .
    .
    .
  end;
class PACKAGE TDBCalendar : public TSampleCalendar
{
    .
    .
    .
protected:
    virtual void __fastcall KeyDown(unsigned short &Key,  TShiftState Shift);
    .
    .
    .
};
```

2. Implement the *KeyDown* method:

```
procedure KeyDown(var Key: Word; Shift: TShiftState);
var
  MyKeyDown: TKeyEvent;
begin
  if not ReadOnly and (Key in [VK_UP, VK_DOWN, VK_LEFT, VK_RIGHT, VK_END,
    VK_HOME, VK_PRIOR, VK_NEXT]) and FDataLink.Edit then
    inherited KeyDown(Key, Shift)
  else
  begin
    MyKeyDown := OnKeyDown;
    if Assigned(MyKeyDown) then MyKeyDown(Self, Key, Shift);
  end;
end;
void __fastcall TDBCalendar::KeyDown(unsigned short &Key,  TShiftState Shift)
{
  TKeyEvent MyKeyDown;                                  // declare event type
  Set<unsigned short,0,8> keySet;
  keySet = keySet << VK_UP << VK_DOWN << VK_LEFT      // assign virtual keys to set
    << VK_RIGHT << VK_END << VK_HOME << VK_PRIOR << VK_NEXT;
  if (!FReadOnly &&                                  // if control is not read only...
      (keySet.Contains(Key)) &&                       // ...and key is in the set...
      FDataLink->Edit() )                             // ...and field is in edit mode
  {
    TCustomGrid::KeyDown(Key, Shift);           // call the inherited KeyDown method
  }
  else
  {
    MyKeyDown = OnKeyDown;                              // assign OnKeyDown event
    if (MyKeyDown != NULL) MyKeyDown(this,Key,Shift); // execute code in...
```

```
  }                                                    // ...OnKeyDown event handler
}
```

When *KeyDown* responds to a mouse-down message, the inherited *KeyDown* method is called only if the control's *ReadOnly* property is *False*, the key pressed is one of the cursor control keys, and the data link object is in edit mode, which means the field can be edited. If the field cannot be edited or some other key is pressed, the code the programmer put in the *OnKeyDown* event handler, if one exists, is executed.

3.2.1.9.17 Responding to Mouse-down Messages

A *MouseDown* method is a protected method for a control's *OnMouseDown* event. The control itself calls *MouseDown* in response to a Windows mouse-down message. When you override the inherited *MouseDown* method, you can include code that provides other responses in addition to calling the *OnMouseDown* event.

To override *MouseDown*, add the *MouseDown* method to the *TDBCalendar* class:

```
type
  TDBCalendar = class(TSampleCalendar);
    .
    .
    .
  protected
    procedure MouseDown(Button: TButton, Shift: TShiftState, X: Integer, Y: Integer);
      override;
    .
    .
    .
  end;
procedure TDBCalendar.MouseDown(Button: TButton; Shift: TShiftState; X, Y: Integer);
var
  MyMouseDown: TMouseEvent;
begin
  if not ReadOnly and FDataLink.Edit then
    inherited MouseDown(Button, Shift, X, Y)
  else
  begin
    MyMouseDown := OnMouseDown;
    if Assigned(MyMouseDown then MyMouseDown(Self, Button, Shift, X, Y);
  end;
end;
//header file
class PACKAGE TDBCalendar : public TSampleCalendar
{
.
.
.
protected:
    virtual void __fastcall MouseDown(TMouseButton Button,  TShiftState Shift, int X,
int Y);
    .
    .
    .
};
//implmentation file
void __fastcall TDBCalendar::MouseDown(TMouseButton Button,  TShiftState Shift, int  X,   int
Y)
{
  TMouseEvent MyMouseDown;                              // declare event type
  if (!FReadOnly && FDataLink->Edit())                  // if the field can be edited
    TSampleCalendar::MouseDown(Button, Shift, X, Y);   // call the inherited MouseDown
  else
  {
    MyMouseDown = OnMouseDown;                          // assign OnMouseDown event
    if (MyMouseDown != NULL) MyMouseDown(this, Button,  // execute code in the...
```

```
      Shift, X, Y);                                  // ...OnMouseDown event handler
  }
}
```

When *MouseDown* responds to a mouse-down message, the inherited *MouseDown* method is called only if the control's *ReadOnly* property is *False* and the data link object is in edit mode, which means the field can be edited. If the field cannot be edited, the code the programmer put in the *OnMouseDown* event handler, if one exists, is executed.

3.2.1.9.18 Updating the Dataset

So far, a change within the data-aware control has changed values in the field data link class. The final step in creating a data editing control is to update the dataset with the new value. This should happen after the person changing the value in the data-aware control exits the control by clicking outside the control or pressing the Tab key.

Note: VCL applications define message control IDs for operations on controls. For example, the *CM_EXIT* message is sent to the control when the user exits the control. You can write message handlers that respond to the message. In this case, when the user exits the control, the *CMExit* method, the message handler for *CM_EXIT*, responds by updating the record in the dataset with the changed values in the field data link class. For more information about message handlers, see Handling messages and system notifications. (see page 1308)

To update the dataset within a message handler, follow these steps:

1. Add the message handler to the *TDBCalendar* component:

```
type
  TDBCalendar = class(TSampleCalendar);
  private
    procedure CMExit(var Message: TWMNoParams); message CM_EXIT;
   .
   .
   .
  end;
class PACKAGE TDBCalendar : public TSampleCalendar
{
private:
    void __fastcall CMExit(TWMNoParams Message);
BEGIN_MESSAGE_MAP
  MESSAGE_HANDLER(CM_EXIT, TWMNoParams, CMExit)
END_MESSAGE_MAP
};
```

2. Implement the *CMExit* method so it looks like this:

```
procedure TDBCalendar.CMExit(var Message: TWMNoParams);
begin
  try
    FDataLink.UpdateRecord;                          { tell data link to update database }
  except
    on Exception do SetFocus;                       { if it failed, don't let focus leave }
 end;
  inherited;
end;
void __fastcall TDBCalendar::CMExit(TWMNoParams &Message)
{
  try
  {
    FDataLink.UpdateRecord();          // tell data link to update database
  }
  catch(...)
  {
    SetFocus();                        // if it failed, don't let focus leave
    throw;
  }
```

```
}
```

To update the dataset when the user exits the control, follow these steps:

1. Add an override for the *DoExit* method to the *TDBCalendar* component:

```
type
  TDBCalendar = class(TSampleCalendar);
  private
    procedure DoExit; override;
   .
   .
   .
  end;
class PACKAGE TDBCalendar : public TSampleCalendar
{
private:
    DYNAMIC void __fastcall DoExit(void);
   .
   .
   .
};
```

2. Implement the *DoExit* method so it looks like this:

```
procedure TDBCalendar.CMExit(var Message: TWMNoParams);
begin
  try
    FDataLink.UpdateRecord;                          { tell data link to update database }
  except
    on Exception do SetFocus;                       { if it failed, don't let focus leave }
 end;
  inherited;                           { let the inherited method generate an OnExit event }
end;
void __fastcall TDBCalendar::DoExit(void)
{
  try
  {
    FDataLink.UpdateRecord();          // tell data link to update database
  }
  catch(...)
  {
    SetFocus();                        // if it failed, don't let focus leave
    throw;
  }
  TCustomGrid::DoExit(); // let the inherited method generate an OnExit event
}
```

3.2.1.9.19 Updating the Field Data Link Class

There are two types of data changes:

- A change in a field value that must be reflected in the data-aware control.
- A change in the data-aware control that must be reflected in the field value.

The *TDBCalendar* component already has a *DataChange* method that handles a change in the field's value in the dataset by assigning that value to the *CalendarDate* property. The *DataChange* method is the handler for the *OnDataChange* event. So the calendar component can handle the first type of data change.

Similarly, the field data link class also has an *OnUpdateData* event that occurs as the user of the control modifies the contents of the data-aware control. The calendar control has a *UpdateData* method that becomes the event handler for the *OnUpdateData* event. *UpdateData* assigns the changed value in the data-aware control to the field data link.

To reflect a change made to the value in the calendar in the field value:

1. Add an *UpdateData* method to the private section of the calendar component:

```
type
  TDBCalendar = class(TSampleCalendar);
  private
    procedure UpdateData(Sender: TObject);
   .
   .
   .
  end;
class PACKAGE TDBCalendar : public TSampleCalendar
{
private:
    void __fastcall UpdateData(TObject *Sender);
};
```

2. Implement the *UpdateData* method:

```
procedure UpdateData(Sender: TObject);
begin
  FDataLink.Field.AsDateTime := CalendarDate;        { set field link to calendar date }
end;
void __fastcall TDBCalendar::UpdateData( TObject* Sender)
{
    FDataLink->Field->AsDateTime = CalendarDate;     // set field link to calendar date
}
```

3. Within the constructor for *TDBCalendar*, assign the *UpdateData* method to the *OnUpdateData* event:

```
constructor TDBCalendar.Create(AOwner: TComponent);
begin
  inherited Create(AOwner);
  FReadOnly := True;
  FDataLink := TFieldDataLink.Create;
  FDataLink.OnDataChange := DataChange;
  FDataLink.OnUpdateData := UpdateData;
end;
__fastcall TDBCalendar::TDBCalendar(TComponent* Owner)
  : TSampleCalendar(Owner)
{
  FDataLink = new TFieldDataLink();       // this was already here
  FDataLink->OnDataChange = DataChange;   // this was here too
  FDataLink->OnUpdateData = UpdateData;   // assign UpdateData to the OnUpdateData event
}
```

3.2.1.10 Making components available at design time

Topics

Name	Description
Adding Clipboard Formats (see page 1344)	By default, when a user chooses Copy while a component is selected in the IDE, the component is copied in Delphi's internal format. It can then be pasted into another form or data module. Your component can copy additional formats to the Clipboard by overriding the *Copy* method. For example, the following *Copy* method allows a *TImage* component to copy its picture to the Clipboard. This picture is ignored by the Delphi IDE, but can be pasted into other applications.
Adding Component Editors (see page 1344)	Component editors determine what happens when the component is double-clicked in the designer and add commands to the context menu that appears when the component is right-clicked. They can also copy your component to the Windows clipboard in custom formats. If you do not give your components a component editor, Delphi uses the default component editor. The default component editor is implemented by the class *TDefaultEditor*. *TDefaultEditor* does not add any new items to a component's context menu. When the component is double-clicked, *TDefaultEditor* searches the properties of the component and generates (or navigates to) the first event handler... more (see page 1344)

Adding Items to the Context Menu (see page 1345)	When the user right-clicks the component, the *GetVerbCount* and *GetVerb* methods of the component editor are called to build context menu. You can override these methods to add commands (verbs) to the context menu. Adding items to the context menu requires the steps: • Specifying menu items (see page 1355) • Implementing commands (see page 1349)
Adding Property Editors (see page 1345)	The Object Inspector provides default editing for all types of properties. You can, however, provide an alternate editor for specific properties by writing and registering property editors. You can register property editors that apply only to the properties in the components you write, but you can also create editors that apply to all properties of a certain type. At the simplest level, a property editor can operate in either or both of two ways: displaying and allowing the user to edit the current value as a text string, and displaying a dialog box that permits some other kind of editing.... more (see page 1345)
Changing the Double-click Behavior (see page 1345)	When the component is double-clicked, the *Edit* method of the component editor is called. By default, the *Edit* method executes the first command added to the context menu. Thus, in the previous example (see page 1349), double-clicking the component executes the *DoThis* command. While executing the first command is usually a good idea, you may want to change this default behavior. For example, you can provide an alternate behavior if • you are not adding any commands to the context menu. • you want to display a dialog that combines several commands when the component is double-clicked. Override the *Edit* method to specify a... more (see page 1345)
Compiling Components into Packages (see page 1346)	Once your components are registered, you must compile them as packages before they can be installed in the IDE. A package can contain one or several components as well as custom property editors. For more information about packages, see Working with packages and components (see page 2211) . To create and compile a package, see Creating and editing packages (see page 2213) . Put the source-code units for your custom components in the package's Contains list. If your components depend on other packages, include those packages in the Requires list. To install your components in the IDE, see Installing component packages (see page 2217).
Creating the Entries (see page 1346)	To make your component's Help integrate seamlessly with the Help for the rest of the components in the library, observe the following conventions: **Each component should have a Help topic:** The component topic should show which unit the component is declared in and briefly describe the component. The component topic should link to secondary windows that describe the component's position in the object hierarchy and list all of its properties, events, and methods. Application developers access this topic by selecting the component on a form and pressing `F1`. For an example of a component topic, place any component on... more (see page 1346)
Creating the Help File (see page 1347)	You can use any tool you want to create the source file for a Windows Help file (in .rtf format). Delphi includes the Microsoft Help Workshop, which compiles your Help files and provides an online Help authoring guide. You can find complete information about creating Help files in the online guide for Help Workshop. Composing Help files for components consists of the steps: • Creating the entries (see page 1346). • Making component Help context-sensitive (see page 1350).
Declaring the Register Procedure (see page 1347)	Registration involves writing a single procedure in the unit, which must have the name *Register*. The *Register* procedure must appear in the interface part of the unit, and (unlike the rest of Delphi) its name is case-sensitive. **Note:** Although Delphi is a case insensitive language, the Register procedure is case sensitive and must be spelled with an uppercase R. The following code shows the outline of a simple unit that creates and registers new components:

Deriving a Property-editor Class (see page 1348)	Both the component library define several kinds of property editors, all of which descend from *TPropertyEditor*. When you create a property editor, your property-editor class can either descend directly from *TPropertyEditor* or indirectly through one of the property-editor classes described in the table below. The classes in the DesignEditors unit can be used for VCL applications. **Note:** All that is absolutely necessary for a property editor is that it descend from *TBasePropertyEditor* and that it support the *IProperty* interface. *TPropertyEditor*, however, provides a default implementation of the *IProperty* interface. The list in the table below is not... more (see page 1348)
Editing the Property as a Whole (see page 1349)	You can optionally provide a dialog box in which the user can visually edit a property. The most common use of property editors is for properties that are themselves classes. An example is the *Font* property, for which the user can open a font dialog box to choose all the attributes of the font at once. To provide a whole-property editor dialog box, override the property-editor class's *Edit* method. *Edit* methods use the same Get and Set methods used in writing *GetValue* and *SetValue* methods. In fact, an *Edit* method calls both a Get method and a Set method. Because... more (see page 1349)
Implementing Commands (see page 1349)	When the command provided by *GetVerb* is selected in the designer, the *ExecuteVerb* method is called. For every command you provide in the *GetVerb* method, implement an action in the *ExecuteVerb* method. You can access the component that is being edited using the *Component* property of the editor. For example, the following *ExecuteVerb* method implements the commands for the *GetVerb* method in the previous (see page 1355) example.
Making Component Help Context-sensitive (see page 1350)	Each component, property, method, and event topic must have an A footnote. The A footnote is used to display the topic when the user selects a component and presses `F1`, or when a property or event is selected in the Object Inspector and the user presses `F1`. The A footnotes must follow certain naming conventions: If the Help topic is for a component, the A footnote consists of two entries separated by a semicolon using this syntax:
Making Components Available at Design Time: Overview (see page 1350)	Making your components available at design time requires several steps: • Registering components (see page 1352) • Providing Help for your component (see page 1351) • Adding property editors (see page 1345) • Adding component editors (see page 1344) • Compiling components into packages (see page 1346) Not all these steps apply to every component. For example, if you don't define any new properties or events, you don't need to provide Help for them. The only steps that are always necessary are registration and compilation. Once your components have been registered and compiled into packages, they can be distributed to other developers and installed in the IDE. For information on installing packages in the IDE, see Installing component packages (see page 2217).... more (see page 1350)
Property Categories (see page 1350)	In the IDE, the Object Inspector lets you selectively hide and display properties based on property categories. The properties of new custom components can be fit into this scheme by registering properties in categories. Do this at the same time you register the component by calling *RegisterPropertyInCategory* or *RegisterPropertiesInCategory*. Use *RegisterPropertyInCategory* to register a single property. Use *RegisterPropertiesInCategory* to register multiple properties in a single function call. These functions are defined in the unit DesignIntf. Note that it is not mandatory that you register properties or that you register all of the properties of a custom component... more (see page 1350)
Specifying Property Categories (see page 1351)	When you register properties in a category, you can use any string you want as the name of the category. If you use a string that has not been used before, the Object Inspector generates a new property category class with that name. You can also, however, register properties into one of the categories that are built-in. The built-in property categories are described in the following table: ***Property categories***

Providing Help for Your Component (see page 1351)	When you select a standard component on a form, or a property or event in the Object Inspector, you can press F1 to get Help on that item. You can provide developers with the same kind of documentation for your components if you create the appropriate Help files. You can provide a small Help file to describe your components, and your Help file becomes part of the user's overall Delphi Help system. See the section Creating the Help file (see page 1347) for information on how to compose the Help file for use with a component.
Registering Components (see page 1352)	Registration works on a compilation unit basis, so if you create several components in a single compilation unit, you can register them all at once. To register a component, add a *Register* procedure to the unit. Within the *Register* procedure, you register the components and determine where to install them on the Tool palette. **Note:** If you create your component by choosing Component->New Component in the IDE, the code required to register your component is added automatically. The steps for manually registering a component are: • Declaring the Register procedure (see page 1347) • Writing the Register procedure (see page 1357)
Registering Multiple Properties at Once (see page 1352)	Register multiple properties at one time and associate them with a property category using the *RegisterPropertiesInCategory* function. *RegisterPropertiesInCategory* comes in three overloaded variations, each providing a different set of criteria for identifying the property in the custom component to be associated with property categories. The first variation lets you identify properties based on property name or type. The list is passed as an array of constants. In the example below, any property that either has the name "Text" or belongs to a class of type *TEdit* is registered in the category 'Localizable.'
Registering One Property at a Time (see page 1353)	Register one property at a time and associate it with a property category using the *RegisterPropertyInCategory* function. *RegisterPropertyInCategory* comes in four overloaded variations, each providing a different set of criteria for identifying the property in the custom component to be associated with the property category. The first variation lets you identify the property by the property's name. The line below registers a property related to visual display of the component, identifying the property by its name, "AutoSize".
Registering the Component Editor (see page 1353)	Once the component editor is defined, it can be registered to work with a particular component class. A registered component editor is created for each component of that class when it is selected in the form designer. To create the association between a component editor and a component class, call *RegisterComponentEditor*. *RegisterComponentEditor* takes the name of the component class that uses the editor, and the name of the component editor class that you have defined. For example, the following statement registers a component editor class named *TMyEditor* to work with all components of type *TMyComponent*:
Registering the Property Editor (see page 1354)	Once you create a property editor, you need to register it with Delphi. Registering a property editor associates a type of property with a specific property editor. You can register the editor with all properties of a given type or just with a particular property of a particular type of component. To register a property editor, call the *RegisterPropertyEditor* procedure. *RegisterPropertyEditor* takes four parameters: • A type-information pointer for the type of property to edit—this is always a call to the built-in function *TypeInfo*, such as `TypeInfo(TMyComponent)__typeinfo(TMyComponent)`. • The type of the component to which this editor applies—if this... more (see page 1354)
Setting the Property Value (see page 1354)	The property editor's *SetValue* method takes a string typed by the user in the Object Inspector, converts it into the appropriate type, and sets the value of the property. If the string does not represent a proper value for the property, *SetValue* should throw an exception and not use the improper value. To read string values into properties, override the property editor's *SetValue* method. *SetValue* should convert the string and validate the value before calling one of the Set methods.

Specifying Editor Attributes (see page 1354)	The property editor must provide information that the Object Inspector can use to determine what tools to display. For example, the Object Inspector needs to know whether the property has subproperties or can display a list of possible values. To specify editor attributes, override the property editor's *GetAttributes* method. *GetAttributes* is a method that returns a set of values of type *TPropertyAttributes* that can include any or all of the following values: ***Property-editor attribute flags***
Specifying Menu Items (see page 1355)	Override the *GetVerbCount* method to return the number of commands you are adding to the context menu. Override the *GetVerb* method to return the strings that should be added for each of these commands. When overriding *GetVerb*, add an ampersand (&) to a string to cause the following character to appear underlined in the context menu and act as a shortcut key for selecting the menu item. Be sure to add an ellipsis (...) to the end of a command if it brings up a dialog. *GetVerb* has a single parameter that indicates the index of the command. The... more (see page 1355)
Specifying the Components (see page 1355)	Within the Register procedure, pass the component names in an open array, which you can construct inside the call to RegisterComponents.
Specifying the Palette Page (see page 1356)	The palette category name is a string. If the name you give for the palette category does not already exist, Delphi creates a new category with that name. Delphi stores the names of the standard categories in string-list resources so that international versions of the product can name the categories in their native languages. If you want to install a component on one of the standard categories, you should obtain the string for the category name by calling the *LoadStr* function, passing the constant representing the string resource for that category, such as *srSystem* for the System category.
Troubleshooting Custom Components (C++) (see page 1356)	A common problem when registering and installing custom components is that the component does not appear in the list of components after the package is successfully installed. The most common causes for components not appearing in the list or on the palette: • Missing **PACKAGE** modifier on the `Register` function • Missing **PACKAGE** modifier on the class • Missing `#pragma package(smart_init)` in the C++ source file • `Register` function is not found in a namespace with the same name as the source code module name. • `Register` is not being successfully exported. Use `tdump` on the `.BPL` to look for the exported function: `tdump -ebpl... more (see page 1356)`
Using the IsPropertyInCategory Function (see page 1356)	An application can query the existing registered properties to determine whether a given property is already registered in a specified category. This can be especially useful in situations like a localization utility that checks the categorization of properties preparatory to performing its localization operations. Two overloaded variations of the *IsPropertyInCategory* function are available, allowing for different criteria in determining whether a property is in a category. The first variation lets you base the comparison criteria on a combination of the class type of the owning component and the property's name. In the command line below, for *IsPropertyInCategory* to return *True... more (see page 1356)*
Using the RegisterComponents Function (see page 1357)	Within the *Register* procedure, call *RegisterComponents* to register the components in the classes array. *RegisterComponents* is a function that takes two parameters: the name of a Tool palette category and the array of component classes. Set the Page parameter to the name of the category on the Tool palette where the components should appear. If the named category already exists, the components are added to that category. If the named category does not exist, Delphi creates a new palette category with that name. Call RegisterComponents from the implementation of the Register procedure in one of the units that defines the... more (see page 1357)

Writing the Register Procedure (see page 1357)	Inside the *Register* procedure of a unit containing components, you must register each component you want to add to the Tool palette. If the unit contains several components, you can register them at the same time. To register a component, call the *RegisterComponents* procedure once for each category of the Tool palette to which you want to add components. *RegisterComponents* involves three important things: 1. Specifying the components. (see page 1355) 2. Specifying the palette page. (see page 1356) 3. Using the RegisterComponents function (see page 1357).

3.2.1.10.1 Adding Clipboard Formats

By default, when a user chooses Copy while a component is selected in the IDE, the component is copied in Delphi's internal format. It can then be pasted into another form or data module. Your component can copy additional formats to the Clipboard by overriding the *Copy* method.

For example, the following *Copy* method allows a *TImage* component to copy its picture to the Clipboard. This picture is ignored by the Delphi IDE, but can be pasted into other applications.

```
procedure TMyComponent.Copy;
var
  MyFormat : Word;
  AData,APalette : THandle;
begin
  TImage(Component).Picture.Bitmap.SaveToClipBoardFormat(MyFormat, AData, APalette);
  ClipBoard.SetAsHandle(MyFormat, AData);
end;
void __fastcall TMyComponentEditor::Copy(void)
{
WORD AFormat;
int AData;
HPALETTE APalette;
((TImage *)Component)->Picture->SaveToClipboardFormat(AFormat, AData, APalette);
TClipboard *pClip = Clipboard(); // don't clear the clipboard!
pClip->SetAsHandle(AFormat, AData);
}
```

3.2.1.10.2 Adding Component Editors

Component editors determine what happens when the component is double-clicked in the designer and add commands to the context menu that appears when the component is right-clicked. They can also copy your component to the Windows clipboard in custom formats.

If you do not give your components a component editor, Delphi uses the default component editor. The default component editor is implemented by the class *TDefaultEditor*. *TDefaultEditor* does not add any new items to a component's context menu. When the component is double-clicked, *TDefaultEditor* searches the properties of the component and generates (or navigates to) the first event handler it finds.

To add items to the context menu, change the behavior when the component is double-clicked, or add new clipboard formats, derive a new class from *TComponentEditor* and register its use with your component. In your overridden methods, you can use the *Component* property of *TComponentEditor* to access the component that is being edited.

Adding a custom component editor consists of the steps:

- Adding items to the context menu (see page 1345)
- Changing the double-click behavior (see page 1345)
- Adding clipboard formats (see page 1344)

- Registering the component editor (see page 1353)

3.2.1.10.3 Adding Items to the Context Menu

When the user right-clicks the component, the *GetVerbCount* and *GetVerb* methods of the component editor are called to build context menu. You can override these methods to add commands (verbs) to the context menu.

Adding items to the context menu requires the steps:

- Specifying menu items (see page 1355)
- Implementing commands (see page 1349)

3.2.1.10.4 Adding Property Editors

The Object Inspector provides default editing for all types of properties. You can, however, provide an alternate editor for specific properties by writing and registering property editors. You can register property editors that apply only to the properties in the components you write, but you can also create editors that apply to all properties of a certain type.

At the simplest level, a property editor can operate in either or both of two ways: displaying and allowing the user to edit the current value as a text string, and displaying a dialog box that permits some other kind of editing. Depending on the property being edited, you might find it useful to provide either or both kinds.

Writing a property editor requires these five steps:

1. Deriving a property-editor class (see page 1348).
2. Editing the property as text.
3. Editing the property as a whole (see page 1349).
4. Specifying editor attributes (see page 1354).
5. Registering the property editor (see page 1354).

3.2.1.10.5 Changing the Double-click Behavior

When the component is double-clicked, the *Edit* method of the component editor is called. By default, the *Edit* method executes the first command added to the context menu. Thus, in the previous example (see page 1349), double-clicking the component executes the *DoThis* command.

While executing the first command is usually a good idea, you may want to change this default behavior. For example, you can provide an alternate behavior if

- you are not adding any commands to the context menu.
- you want to display a dialog that combines several commands when the component is double-clicked.

Override the *Edit* method to specify a new behavior when the component is double-clicked. For example, the following *Edit* method brings up a font dialog when the user double-clicks the component:

```
procedure TMyEditor.Edit;
var
  FontDlg: TFontDialog;
begin
  FontDlg := TFontDialog.Create(Application);
  try
    if FontDlg.Execute then
      MyComponent.FFont.Assign(FontDlg.Font);
  finally
    FontDlg.Free
  end;
```

```
end;
void __fastcall TMyEditor::Edit(void)
{
TFontDialog *pFontDlg = new TFontDialog(NULL);
pFontDlg->Execute();
((TMyComponent *)Component)->Font = pFontDlg->Font;
delete pFontDlg;
}
```

Note: If you want a double-click on the component to display the Code editor for an event handler, use *TDefaultEditor* as a base class for your component editor instead of *TComponentEditor*. Then, instead of overriding the *Edit* method, override the protected *TDefaultEditor.EditProperty* method instead. *EditProperty* scans through the event handlers of the component, and brings up the first one it finds. You can change this to look a particular event instead. For example:

```
procedure TMyEditor.EditProperty(PropertyEditor: TPropertyEditor;
  Continue, FreeEditor: Boolean)
begin
  if (PropertyEditor.ClassName = 'TMethodProperty') and
    (PropertyEditor.GetName = 'OnSpecialEvent') then
    // DefaultEditor.EditProperty(PropertyEditor, Continue, FreeEditor);
end;
void __fastcall TMyEditor::EditProperty(TPropertyEditor* PropertyEditor,
bool &Continue, bool &FreeEditor)
{
if (PropertyEditor->ClassNameIs("TMethodProperty") &&
CompareText(PropertyEditor->GetName, "OnSpecialEvent") == 0)
{
TDefaultEditor::EditProperty(PropertyEditor, Continue, FreeEditor);
}
}
```

3.2.1.10.6 Compiling Components into Packages

Once your components are registered, you must compile them as packages before they can be installed in the IDE. A package can contain one or several components as well as custom property editors. For more information about packages, see Working with packages and components (see page 2211) .

To create and compile a package, see Creating and editing packages (see page 2213) . Put the source-code units for your custom components in the package's Contains list. If your components depend on other packages, include those packages in the Requires list.

To install your components in the IDE, see Installing component packages (see page 2217).

3.2.1.10.7 Creating the Entries

To make your component's Help integrate seamlessly with the Help for the rest of the components in the library, observe the following conventions:

Each component should have a Help topic:

The component topic should show which unit the component is declared in and briefly describe the component. The component topic should link to secondary windows that describe the component's position in the object hierarchy and list all of its properties, events, and methods. Application developers access this topic by selecting the component on a form and pressing F1. For an example of a component topic, place any component on a form and press F1.

The component topic must have a # footnote with a value unique to the topic. The # footnote uniquely identifies each topic by the Help system.

The component topic should have a K footnote for keyword searching in the Help system Index that includes the name of the

component class. For example, the keyword footnote for the *TMemo* component is "TMemo."

The component topic should also have a $ footnote that provides the title of the topic. The title appears in the Topics Found dialog box, the Bookmark dialog box, and the History window.

Each component should include the following secondary navigational topics:

- A hierarchy topic with links to every ancestor of the component in the component hierarchy.
- A list of all properties available in the component, with links to entries describing those properties.
- A list of all events available in the component, with links to entries describing those events.
- A list of methods available in the component, with links to entries describing those methods.

Links to object classes, properties, methods, or events in the Delphi Help system can be made using Alinks. When linking to an object class, the Alink uses the class name of the object, followed by an underscore and the string "object". For example, to link to the *TCustomPanel* object, use the following:

```
!AL(TCustomPanel_object,1)
```

When linking to a property, method, or event, precede the name of the property, method, or event by the name of the object that implements it and an underscore. For example, to link to the *Text* property which is implemented by *TControl*, use the following:

```
!AL(TControl_Text,1)
```

To see an example of the secondary navigation topics, display the Help for any component and click on the links labeled hierarchy, properties, methods, or events.

Each property, method, and event that is declared within the component should have a topic:

A property, event, or method topic should show the declaration of the item and describe its use. Application developers see these topics either by highlighting the item in the Object Inspector and pressing `F1` or by placing the cursor in the Code editor on the name of the item and pressing `F1`. To see an example of a property topic, select any item in the Object Inspector and press `F1`.

The property, event, and method topics should include a K footnote that lists the name of the property, method, or event, and its name in combination with the name of the component. Thus, the *Text* property of *TControl* has the following K footnote:

```
Text,TControl;TControl,Text;Text,
```

The property, method, and event topics should also include a $ footnote that indicates the title of the topic, such as TControl.Text.

All of these topics should have a topic ID that is unique to the topic, entered as a # footnote.

3.2.1.10.8 Creating the Help File

You can use any tool you want to create the source file for a Windows Help file (in .rtf format). Delphi includes the Microsoft Help Workshop, which compiles your Help files and provides an online Help authoring guide. You can find complete information about creating Help files in the online guide for Help Workshop.

Composing Help files for components consists of the steps:

- Creating the entries (see page 1346).
- Making component Help context-sensitive (see page 1350).

3.2.1.10.9 Declaring the Register Procedure

Registration involves writing a single procedure in the unit, which must have the name *Register*. The *Register* procedure must appear in the interface part of the unit, and (unlike the rest of Delphi) its name is case-sensitive.

Note: Although Delphi is a case insensitive language, the Register procedure is case sensitive and must be spelled with an

uppercase R.

The following code shows the outline of a simple unit that creates and registers new components:

```
unit MyBtns;
interface
type
  ...                                                { declare your component types here }
procedure Register;                                { this must appear in the interface section }
implementation
  ...                                                { component implementation goes here }
procedure Register;
begin
  ...                                                                { register the components }
end;
end.
namespace Newcomp
{
void __fastcall PACKAGE Register()
{
}
}
```

Within the *Register* procedure, call *RegisterComponents* for each component you want to add to the Tool palette. If the unit contains several components, you can register them all in one step.

3.2.1.10.10 Deriving a Property-editor Class

Both the component library define several kinds of property editors, all of which descend from *TPropertyEditor*. When you create a property editor, your property-editor class can either descend directly from *TPropertyEditor* or indirectly through one of the property-editor classes described in the table below. The classes in the DesignEditors unit can be used for VCL applications.

Note: All that is absolutely necessary for a property editor is that it descend from *TBasePropertyEditor* and that it support the *IProperty* interface. *TPropertyEditor*, however, provides a default implementation of the *IProperty* interface.

The list in the table below is not complete. The VCLEditors unit also defines some very specialized property editors used by unique properties such as the component name. The listed property editors are the ones that are the most useful for user-defined properties.

Predefined property-editor types

Type	Properties edited
TOrdinalProperty	All ordinal-property editors (those for integer, character, and enumerated properties) descend from *TOrdinalProperty*.
TIntegerProperty	All integer types, including predefined and user-defined subranges.
TCharProperty	*Char*-type and subranges of *Char*, such as 'A'..'Z'.
TEnumProperty	Any enumerated type.
TFloatProperty	All floating-point numbers.
TStringProperty	Strings.
TSetElementProperty	Individual elements in sets, shown as Boolean values
TSetProperty	All sets. Sets are not directly editable, but can expand into a list of set-element properties.
TClassProperty	Classes. Displays the name of the class and allows expansion of the class's properties.
TMethodProperty	Method pointers, most notably events.
TComponentProperty	Components in the same form. The user cannot edit the component's properties, but can point to a specific component of a compatible type.

TColorProperty	Component colors. Shows color constants if applicable, otherwise displays hexadecimal value. Drop down list contains the color constants. Double-click opens the color-selection dialog box.
TFontNameProperty	Font names. The drop down list displays all currently installed fonts.
TFontProperty	Fonts. Allows expansion of individual font properties as well as access to the font dialog box.

3.2.1.10.11 Editing the Property as a Whole

You can optionally provide a dialog box in which the user can visually edit a property. The most common use of property editors is for properties that are themselves classes. An example is the *Font* property, for which the user can open a font dialog box to choose all the attributes of the font at once.

To provide a whole-property editor dialog box, override the property-editor class's *Edit* method.

Edit methods use the same Get and Set methods used in writing *GetValue* and *SetValue* methods. In fact, an *Edit* method calls both a Get method and a Set method. Because the editor is type-specific, there is usually no need to convert the property values to strings. The editor generally deals with the value "as retrieved."

When the user clicks the '...' button next to the property or double-clicks the value column, the Object Inspector calls the property editor's *Edit* method.

Within your implementation of the Edit method, follow these steps:

1. Construct the editor you are using for the property.
2. Read the current value and assign it to the property using a Get method.
3. When the user selects a new value, assign that value to the property using a Set method.
4. Destroy the editor.

3.2.1.10.12 Implementing Commands

When the command provided by *GetVerb* is selected in the designer, the *ExecuteVerb* method is called. For every command you provide in the *GetVerb* method, implement an action in the *ExecuteVerb* method. You can access the component that is being edited using the *Component* property of the editor.

For example, the following *ExecuteVerb* method implements the commands for the *GetVerb* method in the previous (see page 1355) example.

```
procedure TMyEditor.ExecuteVerb(Index: Integer);
var
  MySpecialDialog: TMyDialog;
begin
  case Index of
    0: begin
         MyDialog := TMySpecialDialog.Create(Application);       { instantiate the editor }
         if MySpecialDialog.Execute then;                 { if the user OKs the dialog... }
           MyComponent.FThisProperty := MySpecialDialog.ReturnValue;   { ...use the value }
         MySpecialDialog.Free;                                    { destroy the editor }
       end;
    1: That;                                                 { call the That method }
  end;
end;
void __fastcall TMyEditor::ExecuteVerb(int Index)
{
switch (Index)
{
case 0:
TMyDialog *MySpecialDialog = new TMyDialog();
```

```
MySpecialDialog->Execute();
((TMyComponent *)Component)->ThisProperty = MySpecialDialog->ReturnValue;
delete MySpecialDialog;
break;
case 1:
That();  // call the "That" method
break;
}
}
```

3.2.1.10.13 Making Component Help Context-sensitive

Each component, property, method, and event topic must have an A footnote. The A footnote is used to display the topic when the user selects a component and presses F1, or when a property or event is selected in the Object Inspector and the user presses F1. The A footnotes must follow certain naming conventions:

If the Help topic is for a component, the A footnote consists of two entries separated by a semicolon using this syntax:

`ComponentClass_Object;ComponentClass`

where *ComponentClass* is the name of the component class.

If the Help topic is for a property or event, the A footnote consists of three entries separated by semicolons using this syntax:

`ComponentClass_Element;Element_Type;Element`

where *ComponentClass* is the name of the component class, *Element* is the name of the property, method, or event, and *Type* is the either Property, Method, or Event

For example, for a property named *BackgroundColor* of a component named *TMyGrid*, the A footnote is

`TMyGrid_BackgroundColor;BackgroundColor_Property;BackgroundColor`

3.2.1.10.14 Making Components Available at Design Time: Overview

Making your components available at design time requires several steps:

- Registering components (see page 1352)
- Providing Help for your component (see page 1351)
- Adding property editors (see page 1345)
- Adding component editors (see page 1344)
- Compiling components into packages (see page 1346)

Not all these steps apply to every component. For example, if you don't define any new properties or events, you don't need to provide Help for them. The only steps that are always necessary are registration and compilation.

Once your components have been registered and compiled into packages, they can be distributed to other developers and installed in the IDE. For information on installing packages in the IDE, see Installing component packages (see page 2217).

See Also

Extending the IDE (see page 1285)

3.2.1.10.15 Property Categories

In the IDE, the Object Inspector lets you selectively hide and display properties based on property categories. The properties of new custom components can be fit into this scheme by registering properties in categories. Do this at the same time you register the component by calling *RegisterPropertyInCategory* or *RegisterPropertiesInCategory*. Use *RegisterPropertyInCategory* to register a single property. Use *RegisterPropertiesInCategory* to register multiple properties in a single function call. These functions are defined in the unit DesignIntf.

Note that it is not mandatory that you register properties or that you register all of the properties of a custom component when some are registered. Any property not explicitly associated with a category is included in the *TMiscellaneousCategory* category. Such properties are displayed or hidden in the Object Inspector based on that default categorization.

In addition to these two functions for registering properties, there is an *IsPropertyInCategory* function. This function is useful for creating localization utilities, in which you must determine whether a property is registered in a given property category.

- Registering one property at a time (see page 1353)
- Registering multiple properties at once (see page 1352)
- Specifying property categories (see page 1351)
- Using the IsPropertyInCategory function (see page 1356)

3.2.1.10.16 Specifying Property Categories

When you register properties in a category, you can use any string you want as the name of the category. If you use a string that has not been used before, the Object Inspector generates a new property category class with that name. You can also, however, register properties into one of the categories that are built-in. The built-in property categories are described in the following table:

Property categories

Category	Purpose
Action	Properties related to runtime actions; the *Enabled* and *Hint* properties of *TEdit* are in this category.
Database	Properties related to database operations; the *DatabaseName* and *SQL* properties of *TQuery* are in this category.
Drag, Drop, and Docking	Properties related to drag-and-drop and docking operations; the *DragCursor* and *DragKind* properties of *TImage* are in this category.
Help and Hints	Properties related to using online Help or hints; the *HelpContext* and *Hint* properties of *TMemo* are in this category.
Layout	Properties related to the visual display of a control at design-time; the *Top* and *Left* properties of *TDBEdit* are in this category.
Legacy	Properties related to obsolete operations; the *Ctl3D* and *ParentCtl3D* properties of *TComboBox* are in this category.
Linkage	Properties related to associating or linking one component to another; the *DataSet* property of *TDataSource* is in this category.
Locale	Properties related to international locales; the *BiDiMode* and *ParentBiDiMode* properties of *TMainMenu* are in this category.
Localizable	Properties that may require modification in localized versions of an application. Many string properties (such as *Caption*) are in this category, as are properties that determine the size and position of controls.
Visual	Properties related to the visual display of a control at runtime; the *Align* and *Visible* properties of *TScrollBox* are in this category.
Input	Properties related to the input of data (need not be related to database operations); the *Enabled* and *ReadOnly* properties of *TEdit* are in this category.
Miscellaneous	Properties that do not fit a category or do not need to be categorized (and properties not explicitly registered to a specific category); the AllowAllUp and Name properties of TSpeedButton are in this category.

3.2.1.10.17 Providing Help for Your Component

When you select a standard component on a form, or a property or event in the Object Inspector, you can press F1 to get Help

on that item. You can provide developers with the same kind of documentation for your components if you create the appropriate Help files.

You can provide a small Help file to describe your components, and your Help file becomes part of the user's overall Delphi Help system.

See the section Creating the Help file (see page 1347) for information on how to compose the Help file for use with a component.

3.2.1.10.18 Registering Components

Registration works on a compilation unit basis, so if you create several components in a single compilation unit, you can register them all at once.

To register a component, add a *Register* procedure to the unit. Within the *Register* procedure, you register the components and determine where to install them on the Tool palette.

Note: If you create your component by choosing Component->New Component

in the IDE, the code required to register your component is added automatically. The steps for manually registering a component are:

- Declaring the Register procedure (see page 1347)
- Writing the Register procedure (see page 1357)

3.2.1.10.19 Registering Multiple Properties at Once

Register multiple properties at one time and associate them with a property category using the *RegisterPropertiesInCategory* function. *RegisterPropertiesInCategory* comes in three overloaded variations, each providing a different set of criteria for identifying the property in the custom component to be associated with property categories.

The first variation lets you identify properties based on property name or type. The list is passed as an array of constants. In the example below, any property that either has the name "Text" or belongs to a class of type *TEdit* is registered in the category 'Localizable.'

```
RegisterPropertiesInCategory('Localizable', ['Text', TEdit]);
RegisterPropertiesInCategory("Localizable", ARRAYOFCONST("Text", __typeinfo(TEdit)));
```

The second variation lets you limit the registered properties to those that belong to a specific component. The list of properties to register include only names, not types. For example, the following code registers a number of properties into the 'Help and Hints' category for all components:

```
RegisterPropertiesInCategory('Help and Hints', TComponent, ['HelpContext', 'Hint',
'ParentShowHint', 'ShowHint']);
RegisterPropertyInCategory("Help and Hints", __classid(TComponent),
ARRAYOFCONST("HelpContext", "Hint", "ParentShowHint"));
```

The third variation lets you limit the registered properties to those that have a specific type. As with the second variation, the list of properties to register can include only names:

```
RegisterPropertiesInCategory('Localizable', TypeInfo(String), ['Text', 'Caption']);
RegisterPropertiesInCategory("Localizable", __typeinfo(TStrings), ARRAYOFCONST("Lines",
"Commands"));
```

See the section Specifying property categories (see page 1351) for a list of the available property categories and a brief description of their uses.

3.2.1.10.20 Registering One Property at a Time

Register one property at a time and associate it with a property category using the *RegisterPropertyInCategory* function. *RegisterPropertyInCategory* comes in four overloaded variations, each providing a different set of criteria for identifying the property in the custom component to be associated with the property category.

The first variation lets you identify the property by the property's name. The line below registers a property related to visual display of the component, identifying the property by its name, "AutoSize".

```
RegisterPropertyInCategory('Visual', 'AutoSize');
RegisterPropertyInCategory("Visual", "AutoSize");
```

The second variation is much like the first, except that it limits the category to only those properties of the given name that appear on components of a given type. The example below registers (into the 'Help and Hints' category) a property named "HelpContext" of a component of the custom class *TMyButton*.

```
RegisterPropertyInCategory('Help and Hints', TMyButton, 'HelpContext');
RegisterPropertyInCategory("Help and Hints", __classid(TMyButton), "HelpContext");
```

The third variation identifies the property using its type rather than its name. The example below registers a property based on its type, Integer.

```
RegisterPropertyInCategory('Visual', TypeInfo(Integer));
RegisterPropertyInCategory("Visual", typeid(TArrangement));
```

The final variation uses both the property's type and its name to identify the property. The example below registers a property based on a combination of its type, *TBitmap*, and its name, "Pattern."

```
RegisterPropertyInCategory('Visual', TypeInfo(TBitmap), 'Pattern');
RegisterPropertyInCategory("Visual", typeid(TBitmap), "Pattern");
```

See the section Specifying property categories (see page 1351) for a list of the available property categories and a brief description of their uses.

3.2.1.10.21 Registering the Component Editor

Once the component editor is defined, it can be registered to work with a particular component class. A registered component editor is created for each component of that class when it is selected in the form designer.

To create the association between a component editor and a component class, call *RegisterComponentEditor*. *RegisterComponentEditor* takes the name of the component class that uses the editor, and the name of the component editor class that you have defined. For example, the following statement registers a component editor class named *TMyEditor* to work with all components of type *TMyComponent*:

```
RegisterComponentEditor(TMyComponent, TMyEditor);
RegisterComponentEditor(__classid( TMyComponent), __classid(TMyEditor));
```

Place the call to *RegisterComponentEditor* in the *Register* procedure where you register your component. For example, if a new component named *TMyComponent* and its component editor *TMyEditor* are both implemented in the same unit, the following code registers the component and its association with the component editor.

```
procedure Register;
begin
  RegisterComponents('Miscellaneous', [TMyComponent);
  RegisterComponentEditor(classes[0], TMyEditor);
end;
namespace Newcomp
{
  void __fastcall PACKAGE Register()
  {
```

```
    RegisterComponents("Miscellaneous", classes, 0);
    RegisterComponentEditor(classes[0], __classid(TMyEditor));
  }
}
```

3.2.1.10.22 Registering the Property Editor

Once you create a property editor, you need to register it with Delphi. Registering a property editor associates a type of property with a specific property editor. You can register the editor with all properties of a given type or just with a particular property of a particular type of component.

To register a property editor, call the *RegisterPropertyEditor* procedure.

RegisterPropertyEditor takes four parameters:

- A type-information pointer for the type of property to edit—this is always a call to the built-in function *TypeInfo*, such as `TypeInfo(TMyComponent)`__`typeinfo(TMyComponent)`.
- The type of the component to which this editor applies—if this parameter is **nil**, the editor applies to all properties of the given type.
- The name of the property—this parameter only has meaning if the previous parameter specifies a particular type of component. In that case, you can specify the name of a particular property in that component type to which this editor applies.
- The type of property editor to use for editing the specified property.

3.2.1.10.23 Setting the Property Value

The property editor's *SetValue* method takes a string typed by the user in the Object Inspector, converts it into the appropriate type, and sets the value of the property. If the string does not represent a proper value for the property, *SetValue* should throw an exception and not use the improper value.

To read string values into properties, override the property editor's *SetValue* method.

SetValue should convert the string and validate the value before calling one of the Set methods.

3.2.1.10.24 Specifying Editor Attributes

The property editor must provide information that the Object Inspector can use to determine what tools to display. For example, the Object Inspector needs to know whether the property has subproperties or can display a list of possible values.

To specify editor attributes, override the property editor's *GetAttributes* method.

GetAttributes is a method that returns a set of values of type *TPropertyAttributes* that can include any or all of the following values:

Property-editor attribute flags

Flag	Related method	Meaning if included
paValueList	GetValues	The editor can give a list of enumerated values.
paSubProperties	GetProperties	The property has subproperties that can display.
paDialog	Edit	The editor can display a dialog box for editing the entire property.
paMultiSelect	N/A	The property should display when the user selects more than one component.
paAutoUpdate	SetValue	Updates the component after every change instead of waiting for approval of the value.

paSortList	N/A	The Object Inspector should sort the value list.
paReadOnly	N/A	Users cannot modify the property value.
paRevertable	N/A	Enables the Revert to Inherited menu item on the Object Inspector's context menu. The menu item tells the property editor to discard the current property value and return to some previously established default or standard value.
paFullWidthName	N/A	The value does not need to be displayed. The Object Inspector uses its full width for the property name instead.
paVolatileSubProperties	GetProperties	The Object Inspector re-fetches the values of all subproperties any time the property value changes.
paReference	GetComponentValue	The value is a reference to something else. When used in conjunction with paSubProperties the referenced object should be displayed as sub properties to this property.

3.2.1.10.25 Specifying Menu Items

Override the *GetVerbCount* method to return the number of commands you are adding to the context menu. Override the *GetVerb* method to return the strings that should be added for each of these commands. When overriding *GetVerb*, add an ampersand (&) to a string to cause the following character to appear underlined in the context menu and act as a shortcut key for selecting the menu item. Be sure to add an ellipsis (...) to the end of a command if it brings up a dialog. *GetVerb* has a single parameter that indicates the index of the command.

The following code overrides the *GetVerbCount* and *GetVerb* methods to add two commands to the context menu.

```
function TMyEditor.GetVerbCount: Integer;
begin
  Result := 2;
end;
function TMyEditor.GetVerb(Index: Integer): String;
begin
  case Index of
    0: Result := '&DoThis ...';
    1: Result := 'Do&That';
  end;
end;
int __fastcall TMyEditor::GetVerbCount(void)
{
return 2;
}
System::AnsiStringBase __fastcall TMyEditor::GetVerb(int Index)
{
switch (Index)
{
case 0: return "&DoThis ..."; break;
case 1: return "Do&That"; break;
}
}
```

Note: Be sure that your *GetVerb* method returns a value for every possible index indicated by *GetVerbCount*.

3.2.1.10.26 Specifying the Components

Within the Register procedure, pass the component names in an open array, which you can construct inside the call to RegisterComponents.

```
RegisterComponents('Miscellaneous', [TMyComponent]);
TMetaClass classes[1] = {__classid(TNewComponent)};
```

You could also register several components on the same page at once, or register components on different pages, as shown in the following code:

```
procedure Register;
begin
  RegisterComponents('Miscellaneous', [TFirst, TSecond]);            { two on this page... }
  RegisterComponents('Assorted', [TThird]);                         { ...one on another... }
  RegisterComponents(LoadStr(srStandard), [TFourth]);    { ...and one on the Standard page }
end;
TMetaClass classes[2] =
{__classid(TNewComponent), __classid(TAnotherComponent)};
//Another way to add a component to the array
TMetaClass classes[2];
classes[0] = __classid(TNewComponent);
classes[1] = __classid(TAnotherComponent);
```

3.2.1.10.27 Specifying the Palette Page

The palette category name is a string. If the name you give for the palette category does not already exist, Delphi creates a new category with that name. Delphi stores the names of the standard categories in string-list resources so that international versions of the product can name the categories in their native languages. If you want to install a component on one of the standard categories, you should obtain the string for the category name by calling the *LoadStr* function, passing the constant representing the string resource for that category, such as *srSystem* for the System category.

3.2.1.10.28 Troubleshooting Custom Components (C++)

A common problem when registering and installing custom components is that the component does not appear in the list of components after the package is successfully installed.

The most common causes for components not appearing in the list or on the palette:

- Missing **PACKAGE** modifier on the `Register` function
- Missing **PACKAGE** modifier on the class
- Missing `#pragma package(smart_init)` in the C++ source file
- `Register` function is not found in a namespace with the same name as the source code module name.
- `Register` is not being successfully exported. Use `tdump` on the `.BPL` to look for the exported function:

```
tdump -ebpl mypack.bpl mypack.dmp
```

In the exports section of the dump, you should see the `Register` function (within the namespace) being exported.

3.2.1.10.29 Using the IsPropertyInCategory Function

An application can query the existing registered properties to determine whether a given property is already registered in a specified category. This can be especially useful in situations like a localization utility that checks the categorization of properties preparatory to performing its localization operations. Two overloaded variations of the *IsPropertyInCategory* function are available, allowing for different criteria in determining whether a property is in a category.

The first variation lets you base the comparison criteria on a combination of the class type of the owning component and the property's name. In the command line below, for *IsPropertyInCategory* to return *True*, the property must belong to a *TCustomEdit* descendant, have the name "Text," and be in the property category 'Localizable'.

```
IsItThere := IsPropertyInCategory('Localizable', TCustomEdit, 'Text');
IsItThere = IsPropertyInCategory("Localizable", __classid(TCustomEdit), "Text");
```

The second variation lets you base the comparison criteria on a combination of the class name of the owning component and the property's name. In the command line below, for *IsPropertyInCategory* to return *True*, the property must be a *TCustomEdit*

descendant, have the name "Text", and be in the property category 'Localizable'.

```
IsItThere := IsPropertyInCategory('Localizable', 'TCustomEdit', 'Text');
IsItThere = IsPropertyInCategory("Localizable", "TCustomEdit", "Text");
```

3.2.1.10.30 Using the RegisterComponents Function

Within the *Register* procedure, call *RegisterComponents* to register the components in the classes array. *RegisterComponents* is a function that takes two parameters: the name of a Tool palette category and the array of component classes.

Set the Page parameter to the name of the category on the Tool palette where the components should appear. If the named category already exists, the components are added to that category. If the named category does not exist, Delphi creates a new palette category with that name.

Call RegisterComponents from the implementation of the Register procedure in one of the units that defines the custom components. The units that define the components must then be compiled into a package and the package must be installed before the custom components are added to the Tool palette.

```
procedure Register;
begin
  RegisterComponents('System', [TSystem1, TSystem2]);                    {add to system
category}
  RegisterComponents('MyCustomPage',[TCustom1, TCustom2]);                          { new
category}
end;
namespace Newcomp
{
void __fastcall PACKAGE Register()
{
TMetaClass* classes[1] = {__classid(TMyComponent)};
RegisterComponents("Miscellaneous", classes, 0);
}
}
namespace Mycomps
{
 void __fastcall PACKAGE Register()
{
// declares an array that holds two components
TMetaClass classes1[2] = {__classid(TFirst), __classid(TSecond)};
// adds a new palette page with the two components in the classes1 array
RegisterComponents("Miscellaneous", classes1, 1);
// declares a second array
TMetaClass classes2[1];
// assigns a component to be the first element in the array
classes2[0]  = __classid(TThird);
// adds the component in the classes2 array to the Samples page
RegisterComponents("Samples", classes2, 0);
}
}
```

3.2.1.10.31 Writing the Register Procedure

Inside the *Register* procedure of a unit containing components, you must register each component you want to add to the Tool palette. If the unit contains several components, you can register them at the same time.

To register a component, call the *RegisterComponents* procedure once for each category of the Tool palette to which you want to add components. *RegisterComponents* involves three important things:

1. Specifying the components. (see page 1355)
2. Specifying the palette page. (see page 1356)
3. Using the RegisterComponents function (see page 1357).

3.2.1.11 Making a dialog box a component

Topics

Name	Description
Adding Interface Properties (see page 1359)	Before proceeding, decide on the properties your wrapper needs to enable developers to use your dialog box as a component in their applications. Then, you can add declarations for those properties to the component's class declaration. Properties in wrapper components are somewhat simpler than the properties you would create if you were writing a regular component. Remember that in this case, you are just creating some persistent data that the wrapper can pass back and forth to the dialog box. By putting that data in the form of properties, you enable developers to set data at design time so that... more (see page 1359)
Adding the Execute Method (see page 1359)	The final part of the component interface is a way to open the dialog box and return a result when it closes. As with the common dialog box components, you use a boolean function called *Execute* that returns *True* if the user clicks OK, or *False* if the user cancels the dialog box. The declaration for the *Execute* method always looks like this:
Creating and Registering the Component (Dialog Box) (see page 1360)	Creation of every component begins the same way: create a unit, derive a component class, register it, compile it, and install it on the Tool palette. This process is outlined in Creating a new component. (see page 1317) For this example, follow the general procedure for creating a component, with these specifics: • Call the component's unit *AboutDlg*. • Derive a new component type called *TAboutBoxDlg*, descended from *TComponent*. • Register *TAboutBoxDlg* on the Samples page of the Tool palette. The resulting unit should look like this:
Creating the Component Interface (see page 1361)	These are the steps to create the component interface: 1. Including the form unit files (see page 1361). 2. Adding interface properties (see page 1359). 3. Adding the Execute method (see page 1359).
Defining the Component Interface (see page 1361)	Before you can create the component for your dialog box, you need to decide how you want developers to use it. You create an interface between your dialog box and applications that use it. For example, look at the properties for the common dialog box components. They enable the developer to set the initial state of the dialog box, such as the caption and initial control settings, then read back any needed information after the dialog box closes. There is no direct interaction with the individual controls in the dialog box, just with the properties in the wrapper component. The... more (see page 1361)
Including the Form Unit (see page 1361)	For your wrapper component to initialize and display the wrapped dialog box, you must add the form's unit to the **uses** clause of the wrapper component's unit. Append *About* to the **uses** clause of the *AboutDlg* unit. The **uses** clause now looks like this:

Making a Dialog Box a Component: Overview (see page 1362)	You will find it convenient to make a frequently used dialog box into a component that you add to the Tool palette. Your dialog box components will work just like the components that represent the standard common dialog boxes. The goal is to create a simple component that a user can add to a project and set properties for at design time. Making a dialog box a component requires these steps: 1. Defining the component interface (see page 1361) 2. Creating and registering the component (see page 1360) 3. Creating the component interface (see page 1361) 4. Testing the component (see page 1362) The Delphi "wrapper" component associated with the dialog box creates and executes the... more (see page 1362)
Testing the Component (see page 1362)	Once you have installed the dialog box component, you can use it as you would any of the common dialog boxes, by placing one on a form and executing it. A quick way to test the About box is to add a command button to a form and execute the dialog box when the user clicks the button.

3.2.1.11.1 Adding Interface Properties

Before proceeding, decide on the properties your wrapper needs to enable developers to use your dialog box as a component in their applications. Then, you can add declarations for those properties to the component's class declaration.

Properties in wrapper components are somewhat simpler than the properties you would create if you were writing a regular component. Remember that in this case, you are just creating some persistent data that the wrapper can pass back and forth to the dialog box. By putting that data in the form of properties, you enable developers to set data at design time so that the wrapper can pass it to the dialog box at runtime.

Declaring an interface property requires two additions to the component's class declaration:

- A private class field, which is a variable the wrapper uses to store the value of the property
- The published property declaration itself, which specifies the name of the property and tells it which field to use for storage

Interface properties of this sort do not need access methods. They use direct access to their stored data. By convention, the class field that stores the property's value has the same name as the property, but with the letter *F* in front. The field and the property *must* be of the same type.

3.2.1.11.2 Adding the Execute Method

The final part of the component interface is a way to open the dialog box and return a result when it closes. As with the common dialog box components, you use a boolean function called *Execute* that returns *True* if the user clicks OK, or *False* if the user cancels the dialog box.

The declaration for the *Execute* method always looks like this:

```
type
  TMyWrapper = class(TComponent)
  public
    function Execute: Boolean;
  end;
class PACKAGE TMyWrapper : public TComponent
{
  .
  .
  .
public:
    bool __fastcall Execute();
  .
```

```
  .
  .
};
```

The minimum implementation for *Execute* needs to construct the dialog box form, show it as a modal dialog box, and return either *True* or *False*, depending on the return value from *ShowModal*.

3.2.1.11.3 Creating and Registering the Component (Dialog Box)

Creation of every component begins the same way: create a unit, derive a component class, register it, compile it, and install it on the Tool palette. This process is outlined in Creating a new component. (see page 1317)

For this example, follow the general procedure for creating a component, with these specifics:

- Call the component's unit *AboutDlg*.
- Derive a new component type called *TAboutBoxDlg*, descended from *TComponent*.
- Register *TAboutBoxDlg* on the Samples page of the Tool palette.

The resulting unit should look like this:

```
unit AboutDlg;
interface
uses
  SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls, Forms;
type
  TAboutBoxDlg = class(TComponent)
  end;
procedure Register;
implementation
procedure Register;
begin
  RegisterComponents('Samples', [TAboutBoxDlg]);
end;
end.
#include <vcl\vcl.h>
#pragma hdrstop
#include "AboutDlg.h"
//---------------------------------------------------------------------------
#pragma package(smart_init);
//---------------------------------------------------------------------------
static inline TAboutBoxDlg *ValidCtrCheck()
{
  return new TAboutBoxDlg(NULL);
}
//---------------------------------------------------------------------------
namespace AboutDlg {
{
  void __fastcall PACKAGE Register()
  {
    TComponentClass classes[1] = {__classid(TAboutBoxDlg)};
    RegisterComponents("Samples", classes, 0);
  }
}
#ifndef AboutDlgH
#define AboutDlgH
//---------------------------------------------------------------------------
#include <vcl\sysutils.hpp>
#include <vcl\controls.hpp>
#include <vcl\classes.hpp>
#include <vcl\forms.hpp>
//---------------------------------------------------------------------------
class PACKAGE TAboutBoxDlg : public TComponent
{
private:
```

```
protected:
public:
__published:
};
//---------------------------------------------------------------------------
#endif
```

The new component now has only the capabilities built into *TComponent*. It is the simplest nonvisual component. In the next section (see page 1361), you will create the interface between the component and the dialog box.

3.2.1.11.4 Creating the Component Interface

These are the steps to create the component interface:

1. Including the form unit files (see page 1361).
2. Adding interface properties (see page 1359).
3. Adding the Execute method (see page 1359).

3.2.1.11.5 Defining the Component Interface

Before you can create the component for your dialog box, you need to decide how you want developers to use it. You create an interface between your dialog box and applications that use it.

For example, look at the properties for the common dialog box components. They enable the developer to set the initial state of the dialog box, such as the caption and initial control settings, then read back any needed information after the dialog box closes. There is no direct interaction with the individual controls in the dialog box, just with the properties in the wrapper component.

The interface must therefore contain enough information that the dialog box form can appear in the way the developer specifies and return any information the application needs. You can think of the properties in the wrapper component as being persistent data for a transient dialog box.

In the case of the About box, you do not need to return any information, so the wrapper's properties only have to contain the information needed to display the About box properly. Because there are four separate fields in the About box that the application might affect, you will provide four string-type properties to provide for them.

3.2.1.11.6 Including the Form Unit

For your wrapper component to initialize and display the wrapped dialog box, you must add the form's unit to the **uses** clause of the wrapper component's unit.

Append *About* to the **uses** clause of the *AboutDlg* unit.

The **uses** clause now looks like this:

```
uses
  Windows, SysUtils, Messages, WinTypes, WinProcs, Messages, Classes, Graphics, Controls,
Forms,
  About;
// for C++
#include "About.h"
#pragma link "About.obj"
```

The form unit always declares an instance of the form class. In the case of the About box, the form class is *TAboutBox*, and the *About* unit includes the following declaration:

```
var
  AboutBox: TAboutBox;
extern TAboutBox *AboutBox;
```

So by adding *About* to the **uses** clause, you make *AboutBox* available to the wrapper component.

3.2.1.11.7 Making a Dialog Box a Component: Overview

You will find it convenient to make a frequently used dialog box into a component that you add to the Tool palette. Your dialog box components will work just like the components that represent the standard common dialog boxes. The goal is to create a simple component that a user can add to a project and set properties for at design time.

Making a dialog box a component requires these steps:

1. Defining the component interface (see page 1361)
2. Creating and registering the component (see page 1360)
3. Creating the component interface (see page 1361)
4. Testing the component (see page 1362)

The Delphi "wrapper" component associated with the dialog box creates and executes the dialog box at runtime, passing along the data the user specified. The dialog-box component is therefore both reusable and customizable.

In this section, you will see how to create a wrapper component around the generic About Box form provided in the Delphi Object Repository.

Note: Copy the files ABOUT.PAS and ABOUT.DFM into your working directory.

There are not many special considerations for designing a dialog box that will be wrapped into a component. Nearly any form can operate as a dialog box in this context.

3.2.1.11.8 Testing the Component

Once you have installed the dialog box component, you can use it as you would any of the common dialog boxes, by placing one on a form and executing it. A quick way to test the About box is to add a command button to a form and execute the dialog box when the user clicks the button.

For example, if you created an About dialog box, made it a component, and added it to the Tool palette, you can test it with the following steps:

1. Create a new project.
2. Place an About box component on the main form.
3. Place a command button on the form.
4. Double-click the command button to create an empty click-event handler.
5. In the click-event handler, type the following line of code:

```
AboutBoxDlg1.Execute;
AboutBoxDlg1->Execute();
```

6. Run the application.

When the main form appears, click the command button. The About box appears with the default project icon and the name Project1. Choose OK to close the dialog box.

You can further test the component by setting the various properties of the About box component and again running the application.

3.2.1.12 Modifying an existing component

Topics

Name	Description
Creating and Registering the Modified Component (see page 1363)	You create every component the same way: you create a unit, derive a component class, register it, and install it on the Tool palette. This process is outlined in Creating a new component. (see page 1317) For this example, follow the general procedure for creating a component, with these specifics: • Call the component's unit *Memos*. • Derive a new component type called *TWrapMemo*, descended from *TMemo*. • Register *TWrapMemo* on the Samples page of the Tool palette. • The resulting unit should look like this:
Modifying an Existing Component: Overview (see page 1365)	The easiest way to create a component is to derive it from a component that does nearly everything you want, then make whatever changes you need. What follows is a simple example that modifies the standard memo component to create a memo that does not wrap words by default. The value of the memo component's *WordWrap* property is initialized to *True*. If you frequently use non-wrapping memos, you can create a new memo component that does not wrap words by default. **Note:** To modify published properties or save specific event handlers for an existing component, it is often easier... more (see page 1365)
Modifying the Component Object (see page 1365)	Once you have created a new component class, you can modify it in almost any way. In this case, you will change only the initial value of one property in the memo component. This involves two small changes to the component class: • Overriding the constructor. • Specifying the new default property value. The constructor actually sets the value of the property. The default tells Delphi what values to store in the form (.dfm for VCL applications) file. Delphi stores only values that differ from the default, so it is important to perform both steps.
Overriding the Constructor (see page 1365)	When a component is placed on a form at design time, or when an application constructs a component at runtime, the component's constructor sets the property values. When a component is loaded from a form file, the application sets any properties changed at design time. **Note:** When you override a constructor, the new constructor must call the inherited constructor before doing anything else. For more information, see Overriding methods (see page 1374). For this example, your new component needs to override the constructor inherited from *TMemo* to set the *WordWrap* property to *False*. To achieve this, add the constructor override to... more (see page 1365)
Specifying the New Default Property Value (see page 1366)	When Delphi stores a description of a form in a form file, it stores the values only of properties that differ from their defaults. Storing only the differing values keeps the form files small and makes loading the form faster. If you create a property or change the default value, it is a good idea to update the property declaration to include the new default. Form files, loading, and default values are explained in more detail in Making components available at design time (see page 1350). To change the default value of a property, redeclare the property name, followed by the directive... more (see page 1366)

3.2.1.12.1 Creating and Registering the Modified Component

You create every component the same way: you create a unit, derive a component class, register it, and install it on the Tool palette. This process is outlined in Creating a new component. (see page 1317)

For this example, follow the general procedure for creating a component, with these specifics:

- Call the component's unit *Memos*.
- Derive a new component type called *TWrapMemo*, descended from *TMemo*.
- Register *TWrapMemo* on the Samples page of the Tool palette.
- The resulting unit should look like this:

```
unit Memos;
interface
uses
 SysUtils, WinTypes, WinProcs, Messages, Classes, Graphics, Controls,
 Forms, StdCtrls;
type
 TWrapMemo = class(TMemo)
 end;
procedure Register;
implementation
procedure Register;
begin
 RegisterComponents('Samples', [TWrapMemo]);
end;
end.
#include <vcl.h>
#pragma hdrstop
#include "Yelmemo.h"
//---------------------------------------------------------------------------
#pragma package(smart_init);
//---------------------------------------------------------------------------
// ValidCtrCheck is used to assure that the components created do not have
// any pure virtual functions.
//
static inline void ValidCtrCheck(TYellowMemo *)
{
  new TYellowMemo(NULL);
}
//---------------------------------------------------------------------------
__fastcall TYellowMemo::TYellowMemo(TComponent* Owner)
: TMemo(Owner)
{
}
//---------------------------------------------------------------------------
namespace Yelmemo
{
  void __fastcall PACKAGE Register()
  {
    TComponentClass classes[1] = {__classid(TYellowMemo)};
    RegisterComponents("Samples", classes, 0); //"Common Controls" in CLX applications
  }
}
#ifndef YelMemoH
#define YelmemoH
//---------------------------------------------------------------------------
#include <sysutils.hpp>
#include <controls.hpp>
#include <classes.hpp>
#include <forms.hpp>
#include <StdCtrls.hpp>
//---------------------------------------------------------------------------
class PACKAGE TYellowMemo : public TMemo
{
private:
protected:
public:
__published:
};
```

```
//---------------------------------------------------------------------------
#endif
```

If you compile and install the new component now, it behaves exactly like its ancestor, *TMemo*. In the next section, you will make a simple change to your component.

3.2.1.12.2 Modifying an Existing Component: Overview

The easiest way to create a component is to derive it from a component that does nearly everything you want, then make whatever changes you need. What follows is a simple example that modifies the standard memo component to create a memo that does not wrap words by default.

The value of the memo component's *WordWrap* property is initialized to *True*. If you frequently use non-wrapping memos, you can create a new memo component that does not wrap words by default.

Note: To modify published properties or save specific event handlers for an existing component, it is often easier to use a *component template* rather than create a new class.

Modifying an existing component takes only two steps:

- Creating and registering the component (see page 1363).
- Modifying the component class (see page 1365).

3.2.1.12.3 Modifying the Component Object

Once you have created a new component class, you can modify it in almost any way. In this case, you will change only the initial value of one property in the memo component. This involves two small changes to the component class:

- Overriding the constructor.
- Specifying the new default property value.

The constructor actually sets the value of the property. The default tells Delphi what values to store in the form (.dfm for VCL applications) file. Delphi stores only values that differ from the default, so it is important to perform both steps.

3.2.1.12.4 Overriding the Constructor

When a component is placed on a form at design time, or when an application constructs a component at runtime, the component's constructor sets the property values. When a component is loaded from a form file, the application sets any properties changed at design time.

Note: When you override a constructor, the new constructor must call the inherited constructor before doing anything else. For more information, see Overriding methods (see page 1374).

For this example, your new component needs to override the constructor inherited from *TMemo* to set the *WordWrap* property to *False*. To achieve this, add the constructor override to the forward declaration, then write the new constructor in the **implementation** part of the unit:

```
type
  TWrapMemo = class(TMemo)
  public                                              { constructors are always public }
    constructor Create(AOwner: TComponent); override; { this syntax is always the same }
  end;
.
.
.
constructor TWrapMemo.Create(AOwner: TComponent);     { this goes after implementation }
begin
  inherited Create(AOwner);                           { ALWAYS do this first! }
```

```
  WordWrap := False;                                    { set the new desired value }
end;
class PACKAGE TYellowMemo : public TMemo
{
public:
    virtual __fastcall TYellowMemo(TComponent* Owner); // the constructor declaration
__published:
    __property Color;
};
__fastcall TYellowMemo::TYellowMemo(TComponent* Owner)
  : TMemo(Owner)                                     // the constructor implementation
first...                                                    // ...calls the constructor for TMemo
{
  Color = clYellow;                                 // colors the component yellow
}
```

Now you can install the new component on the Tool palette and add it to a form. Note that the *WordWrap* property is now initialized to *False*.

If you change an initial property value, you should also designate that value as the default. If you fail to match the value set by the constructor to the specified default value, Delphi cannot store and restore the proper value.

3.2.1.12.5 Specifying the New Default Property Value

When Delphi stores a description of a form in a form file, it stores the values only of properties that differ from their defaults. Storing only the differing values keeps the form files small and makes loading the form faster. If you create a property or change the default value, it is a good idea to update the property declaration to include the new default. Form files, loading, and default values are explained in more detail in Making components available at design time (see page 1350).

To change the default value of a property, redeclare the property name, followed by the directive **default** and the new default value. You don't need to redeclare the entire property, just the name and the default value.

For the word-wrapping memo component, you redeclare the *WordWrap* property in the **published** part of the object declaration, with a default value of *False*:

```
type
  TWrapMemo = class(TMemo)
  .
  .
  .
  published
    property WordWrap default False;
  end;
//header file
class PACKAGE TYellowMemo : public TMemo
{
public:
    virtual __fastcall TYellowMemo(TComponent* Owner);
__published:
    __property Color = {default=clYellow};
};
//implmentation file
__fastcall TYellowMemo::TYellowMemo(TComponent* AOwner) : TMemo(AOwner)
{
  Color = clYellow;
  WordWrap = false;
}
//header file with WordWrap as default value of false:
class PACKAGE TYellowMemo : public TMemo
{
public:
    virtual __fastcall TYellowMemo(TComponent* Owner);
__published:
```

```
    __property Color = {default=clYellow};
    __property WordWrap = {default=false};
};
```

Specifying the default property value does not affect the workings of the component. You must still initialize the value in the component's constructor. Redeclaring the default ensures that Delphi knows when to write *WordWrap* to the form file.

3.2.1.13 Object-oriented programming for component writers

Topics

Name	Description
Object-oriented Programming for Component Writers: Overview (see page 1369)	If you have written applications with Delphi, you know that a class contains both data and code, and that you can manipulate classes at design time and at runtime. In that sense, you've become a component user. When you create new components, you deal with classes in ways that application developers never need to. You also try to hide the inner workings of the component from the developers who will use it. By choosing appropriate ancestors for your components, designing interfaces that expose only the properties and methods that developers need, and following the other guidelines in the following topics,... more (see page 1369)
Defining New Classes (see page 1370)	The difference between component writers and application developers is that component writers create new classes while application developers manipulate instances of classes. A class is essentially a type. As a programmer, you are always working with types and instances, even if you do not use that terminology. For example, you create variables of a type, such as *Integer*. Classes are usually more complex than simple data types, but they work the same way: By assigning different values to instances of the same type, you can perform different tasks. For example, it is quite common to create a form... more (see page 1370)
Deriving New Classes (see page 1370)	There are two reasons to derive a new class: • To change class defaults to avoid repetition (see page 1371) • To add new capabilities to a class (see page 1370) In either case, the goal is to create reusable objects. If you design components with reuse in mind, you can save work later on. Give your classes usable default values, but allow them to be customized.
Abstract Class Members (see page 1370)	When a method is declared as **abstract** in an ancestor class, you should surface it (by redeclaring and implementing it) in any descendant component before you use the new component in applications. On the Win32 platform, Delphi can create instances of a class that contains abstract members. This is not recommended, however. For more information about surfacing inherited parts of classes, see Creating properties (see page 1249) and Creating methods. (see page 1243)
Adding New Capabilities to a Class (see page 1370)	A common reason for creating new components is to add capabilities not found in existing components. When you do this, you derive the new component from either an existing component or an abstract base class, such as *TComponent* or *TControl*. Derive your new component from the class that contains the closest subset of the features you want. You can add capabilities to a class, but you cannot take them away; so if an existing component class contains properties that you do *not* want to include in yours, you should derive from that component's ancestor. For example, if you want... more (see page 1370)
Ancestors, Descendants, and Class Hierarchies (see page 1371)	Application developers take for granted that every control has properties named *Top* and *Left* that determine its position on the form. To them, it may not matter that all controls inherit these properties from a common ancestor, *TControl*. When you create a component, however, you must know which class to derive it from so that it inherits the appropriate features. And you must know everything that your control inherits, so you can take advantage of inherited features without recreating them. The class from which you derive a component is called its *immediate ancestor*. Each component inherits from its... more (see page 1371)

Changing Class Defaults to Avoid Repetition (see page 1371)	Most programmers try to avoid repetition. Thus, if you find yourself rewriting the same lines of code over and over, you place the code in a subroutine or function, or build a library of routines that you can use in many programs. The same reasoning holds for components. If you find yourself changing the same properties or making the same method calls, you can create a new component that does these things by default. For example, suppose that each time you create an application, you add a dialog box to perform a particular operation. Although it is not difficult to... more (see page 1371)
Controlling Access (see page 1371)	There are five levels of *access control* - also called *visibility* - on properties, methods, and fields. Visibility determines which code can access which parts of the class. By specifying visibility, you define the *interface* to your components. The table below shows the levels of visibility, from most restrictive to most accessible: ***Levels of visibility within an object***
Declaring a New Component Class (see page 1372)	In addition to standard components, Delphi provides many abstract classes designed as bases for deriving new components. The Creating components (see page 1315) topic shows the classes you can start from when you create your own components. To declare a new component class, add a class declaration to the component's unit file.
Defining the Design-time Interface (see page 1372)	Declaring part of a class as **published** makes that part public and also generates runtime type information. Among other things, runtime type information allows the Object Inspector to access properties and events. Because they show up in the Object Inspector, the published parts of a class define that class's *design-time interface*. The design-time interface should include any aspects of the class that an application developer might want to customize at design time, but must exclude any properties that depend on specific information about the runtime environment. Read-only properties cannot be part of the design-time interface because the application developer... more (see page 1372)
Defining the Component Writer's Interface (see page 1373)	Declaring part of a class as **protected** makes that part visible only to the class itself and its descendants (and to other classes that share their unit files). You can use **protected** declarations to define a *component writer's interface* to the class. Application units do not have access to the protected parts, but derived classes do. This means that component writers can change the way a class works without making the details visible to application developers. **Note:** A common mistake is trying to access protected methods from an event handler. Event handlers are typically methods of the form, not the... more (see page 1373)
Defining the Runtime Interface (see page 1373)	Declaring part of a class as **public** makes that part visible to any code that has access to the class as a whole. Public parts are available at runtime to all code, so the public parts of a class define its *runtime interface*. The runtime interface is useful for items that are not meaningful or appropriate at design time, such as properties that depend on runtime input or which are read-only. Methods that you intend for application developers to call must also be public.
Dispatching Methods (see page 1373)	*Dispatch* refers to the way a program determines where a method should be invoked when it encounters a method call. The code that calls a method looks like any other procedure or function call. But classes have different ways of dispatching methods. The three types of method dispatch are • Static • Virtual • Dynamic
Dynamic Methods (see page 1373)	Dynamic methods are virtual methods with a slightly different dispatch mechanism. Because dynamic methods don't have entries in the object's virtual method table, they can reduce the amount of memory that objects consume. However, dispatching dynamic methods is somewhat slower than dispatching regular virtual methods. If a method is called frequently, or if its execution is time-critical, you should probably declare it as virtual rather than dynamic. Objects must store the addresses of their dynamic methods. But instead of receiving entries in the virtual method table, dynamic methods are listed separately. The dynamic method list contains entries only for methods... more (see page 1373)
Hiding Implementation Details (see page 1374)	Declaring part of a class as **private** makes that part invisible to code outside the class's unit file. Within the unit that contains the declaration, code can access the part as if it were public.

Virtual Methods (see page 1374)	Virtual methods employ a more complicated, and more flexible, dispatch mechanism than static methods. A virtual method can be redefined in descendant classes, but still be called in the ancestor class. The address of a virtual method isn't determined at compile time; instead, the object where the method is defined looks up the address at runtime. To make a method virtual, add the directive **virtual** after the method declaration. The **virtual** directive creates an entry in the object's *virtual method table*, or VMT, which holds the addresses of all the virtual methods in an object type. When you derive... more (see page 1374)
Classes and Pointers (see page 1374)	Every class (and therefore every component) is really a pointer. The compiler automatically dereferences class pointers for you, so most of the time you do not need to think about this. The status of classes as pointers becomes important when you pass a class as a parameter. In general, you should pass classes by value rather than by reference. The reason is that classes are already pointers, which are references; passing a class by reference amounts to passing a reference to a reference.
Overriding Methods (see page 1374)	*Overriding* a method means extending or refining it, rather than replacing it. A descendant class can override any of its inherited virtual methods. To override a method in a descendant class, add the directive **override** to the end of the method declaration. Overriding a method causes a compilation error if • The method does not exist in the ancestor class. • The ancestor's method of that name is static. • The declarations are not otherwise identical (number and type of arguments parameters differ).
Regular Methods (C++) (see page 1375)	Class methods are regular (or nonvirtual) unless you specifically declare them as virtual, or unless they override a **virtual** method in a base class. The compiler can determine the exact address of a regular class member at compile time. This is known as compile-time binding. A base class regular method is inherited by derived classes. In the following example, an object of type `Derived` can call the method `Regular()` as it were its own method. Declaring a method in a derived class with the same name and parameters as a regular method in the class's ancestor replaces the ancestor's... more (see page 1375)
Static Methods (see page 1375)	All methods are static unless you specify otherwise when you declare them. Static methods work like regular procedures or functions. The compiler determines the exact address of the method and links the method at compile time. The primary advantage of static methods is that dispatching them is very quick. Because the compiler can determine the exact address of the method, it links the method directly. Virtual and dynamic methods, by contrast, use indirect means to look up the address of their methods at runtime, which takes somewhat longer. A static method does not change when inherited by a descendant class.... more (see page 1375)

3.2.1.13.1 Object-oriented Programming for Component Writers: Overview

If you have written applications with Delphi, you know that a class contains both data and code, and that you can manipulate classes at design time and at runtime. In that sense, you've become a component user.

When you create new components, you deal with classes in ways that application developers never need to. You also try to hide the inner workings of the component from the developers who will use it. By choosing appropriate ancestors for your components, designing interfaces that expose only the properties and methods that developers need, and following the other guidelines in the following topics, you can create versatile, reusable components.

Before you start creating components, you should be familiar with these topics, which are related to object-oriented programming (OOP):

- Defining new classes (see page 1370)
- Ancestors (see page 1371)
- Controlling access (see page 1371)
- Dispatching methods (see page 1373)

- Abstract class members (see page 1370)
- Classes and pointers (see page 1374)

3.2.1.13.2 Defining New Classes

The difference between component writers and application developers is that component writers create new classes while application developers manipulate instances of classes.

A class is essentially a type. As a programmer, you are always working with types and instances, even if you do not use that terminology. For example, you create variables of a type, such as *Integer*. Classes are usually more complex than simple data types, but they work the same way: By assigning different values to instances of the same type, you can perform different tasks.

For example, it is quite common to create a form containing two buttons, one labeled OK and one labeled Cancel. Each is an instance of the class *TButton*, but by assigning different values to their *Caption* properties and different handlers to their *OnClick* events, you make the two instances behave differently.

Deriving New Types (see page 1370)

Declaring a New Component Type (see page 1372)

3.2.1.13.3 Deriving New Classes

There are two reasons to derive a new class:

- To change class defaults to avoid repetition (see page 1371)
- To add new capabilities to a class (see page 1370)

In either case, the goal is to create reusable objects. If you design components with reuse in mind, you can save work later on. Give your classes usable default values, but allow them to be customized.

3.2.1.13.4 Abstract Class Members

When a method is declared as **abstract** in an ancestor class, you should surface it (by redeclaring and implementing it) in any descendant component before you use the new component in applications. On the Win32 platform, Delphi can create instances of a class that contains abstract members. This is not recommended, however. For more information about surfacing inherited parts of classes, see Creating properties (see page 1249) and Creating methods. (see page 1243)

3.2.1.13.5 Adding New Capabilities to a Class

A common reason for creating new components is to add capabilities not found in existing components. When you do this, you derive the new component from either an existing component or an abstract base class, such as *TComponent* or *TControl*.

Derive your new component from the class that contains the closest subset of the features you want. You can add capabilities to a class, but you cannot take them away; so if an existing component class contains properties that you do *not* want to include in yours, you should derive from that component's ancestor.

For example, if you want to add features to a list box, you could derive your component from *TListBox*. However, if you want to add new features but exclude some capabilities of the standard list box, you need to derive your component from *TCustomListBox*, the ancestor of *TListBox*. Then you can recreate (or make visible) only the list-box capabilities you want, and add your new features.

Customizing a grid (see page 1264) shows an example of customizing an abstract component class.

3.2.1.13.6 Ancestors, Descendants, and Class Hierarchies

Application developers take for granted that every control has properties named *Top* and *Left* that determine its position on the form. To them, it may not matter that all controls inherit these properties from a common ancestor, *TControl*. When you create a component, however, you must know which class to derive it from so that it inherits the appropriate features. And you must know everything that your control inherits, so you can take advantage of inherited features without recreating them.

The class from which you derive a component is called its *immediate ancestor*. Each component inherits from its immediate ancestor, and from the immediate ancestor of its immediate ancestor, and so forth. All of the classes from which a component inherits are called its *ancestors*; the component is a *descendant* of its ancestors.

Together, all the ancestor-descendant relationships in an application constitute a hierarchy of classes. Each generation in the hierarchy contains more than its ancestors, since a class inherits everything from its ancestors, then adds new properties and methods or redefines existing ones.

If you do not specify an immediate ancestor, Delphi derives your component from the default ancestor, *TObject*. *TObject* is the ultimate ancestor of all classes in the object hierarchy.

The general rule for choosing which object to derive from is simple: Pick the object that contains as much as possible of what you want to include in your new object, but which does not include anything you do not want in the new object. You can always add things to your objects, but you cannot take things out.

3.2.1.13.7 Changing Class Defaults to Avoid Repetition

Most programmers try to avoid repetition. Thus, if you find yourself rewriting the same lines of code over and over, you place the code in a subroutine or function, or build a library of routines that you can use in many programs. The same reasoning holds for components. If you find yourself changing the same properties or making the same method calls, you can create a new component that does these things by default.

For example, suppose that each time you create an application, you add a dialog box to perform a particular operation. Although it is not difficult to recreate the dialog each time, it is also not necessary. You can design the dialog once, set its properties, and install a wrapper component associated with it onto the Tool palette. By making the dialog into a reusable component, you not only eliminate a repetitive task, but you encourage standardization and reduce the likelihood of errors each time the dialog is recreated.

Modifying an existing component (see page 1365) shows an example of changing a component's default properties.

Note: If you want to modify only the published properties of an existing component, or to save specific event handlers for a component or group of components, you may be able to accomplish this more easily by creating a *component template*.

3.2.1.13.8 Controlling Access

There are five levels of *access control* - also called *visibility* - on properties, methods, and fields. Visibility determines which code can access which parts of the class. By specifying visibility, you define the *interface* to your components.

The table below shows the levels of visibility, from most restrictive to most accessible:

Levels of visibility within an object

Visibility	Meaning	Used for
private	Accessible only to code in the unit where the class is defined.	Hiding implementation details. (see page 1374)

protected	Accessible to code in the unit(s) where the class and its descendants are defined.	Defining the component writer's interface. (see page 1373)
public	Accessible to all code.	Defining the runtime interface. (see page 1373)
automated	Accessible to all code. Automation type information is generated.	OLE automation only.
published	Accessible to all code and accessible from the Object Inspector. Saved in a form file.	Defining the design-time interface. (see page 1372)

Declare members as **private** if you want them to be available only within the class where they are defined; declare them as **protected** if you want them to be available only within that class and its descendants. Remember, though, that if a member is available anywhere within a unit file, it is available *everywhere* in that file. Thus, if you define two classes in the same unit, the classes will be able to access each other's private methods. And if you derive a class in a different unit from its ancestor, all the classes in the new unit will be able to access the ancestor's protected methods.

Hiding Implementation Details (see page 1374)

Defining the Component Writer's Interface (see page 1373)

Defining the Runtime Interface (see page 1373)

Defining the Design-time Interface (see page 1372)

3.2.1.13.9 Declaring a New Component Class

In addition to standard components, Delphi provides many abstract classes designed as bases for deriving new components. The Creating components (see page 1315) topic shows the classes you can start from when you create your own components.

To declare a new component class, add a class declaration to the component's unit file.

See Also

Deriving New Types (see page 1370)

3.2.1.13.10 Defining the Design-time Interface

Declaring part of a class as **published** makes that part public and also generates runtime type information. Among other things, runtime type information allows the Object Inspector to access properties and events.

Because they show up in the Object Inspector, the published parts of a class define that class's *design-time interface*. The design-time interface should include any aspects of the class that an application developer might want to customize at design time, but must exclude any properties that depend on specific information about the runtime environment.

Read-only properties cannot be part of the design-time interface because the application developer cannot assign values to them directly. Read-only properties should therefore be public, rather than published.

See Also

Hiding Implementation Details (see page 1374)

Defining the Component Writer's Interface (see page 1373)

Defining the Runtime Interface (see page 1373)

3.2.1.13.11 Defining the Component Writer's Interface

Declaring part of a class as **protected** makes that part visible only to the class itself and its descendants (and to other classes that share their unit files).

You can use **protected** declarations to define a *component writer's interface* to the class. Application units do not have access to the protected parts, but derived classes do. This means that component writers can change the way a class works without making the details visible to application developers.

Note: A common mistake is trying to access protected methods from an event handler. Event handlers are typically methods of the form, not the component that receives the event. As a result, they do not have access to the component's protected methods (unless the component is declared in the same unit as the form).

See Also

Hiding Implementation Details (see page 1374)

Defining the Runtime Interface (see page 1373)

Defining the Design-time Interface (see page 1372)

3.2.1.13.12 Defining the Runtime Interface

Declaring part of a class as **public** makes that part visible to any code that has access to the class as a whole.

Public parts are available at runtime to all code, so the public parts of a class define its *runtime interface*. The runtime interface is useful for items that are not meaningful or appropriate at design time, such as properties that depend on runtime input or which are read-only. Methods that you intend for application developers to call must also be public.

Defining the Design-time Interface (see page 1372)

3.2.1.13.13 Dispatching Methods

Dispatch refers to the way a program determines where a method should be invoked when it encounters a method call. The code that calls a method looks like any other procedure or function call. But classes have different ways of dispatching methods.

The three types of method dispatch are

- Static
- Virtual
- Dynamic

3.2.1.13.14 Dynamic Methods

Dynamic methods are virtual methods with a slightly different dispatch mechanism. Because dynamic methods don't have entries in the object's virtual method table, they can reduce the amount of memory that objects consume. However, dispatching dynamic methods is somewhat slower than dispatching regular virtual methods. If a method is called frequently, or if its execution is time-critical, you should probably declare it as virtual rather than dynamic.

Objects must store the addresses of their dynamic methods. But instead of receiving entries in the virtual method table, dynamic

methods are listed separately. The dynamic method list contains entries only for methods introduced or overridden by a particular class. (The virtual method table, in contrast, includes all of the object's virtual methods, both inherited and introduced.) Inherited dynamic methods are dispatched by searching each ancestor's dynamic method list, working backwards through the inheritance tree.

To make a method dynamic, add the directive **dynamic** after the method declaration.

3.2.1.13.15 Hiding Implementation Details

Declaring part of a class as **private** makes that part invisible to code outside the class's unit file. Within the unit that contains the declaration, code can access the part as if it were public.

See Also

Defining the Component Writer's Interface (see page 1373)

Defining the Runtime Interface (see page 1373)

Defining the Design-time Interface (see page 1372)

3.2.1.13.16 Virtual Methods

Virtual methods employ a more complicated, and more flexible, dispatch mechanism than static methods. A virtual method can be redefined in descendant classes, but still be called in the ancestor class. The address of a virtual method isn't determined at compile time; instead, the object where the method is defined looks up the address at runtime.

To make a method virtual, add the directive **virtual** after the method declaration. The **virtual** directive creates an entry in the object's *virtual method table*, or VMT, which holds the addresses of all the virtual methods in an object type.

When you derive a new class from an existing one, the new class gets its own VMT, which includes all the entries from the ancestor's VMT plus any additional virtual methods declared in the new class.

See Also

Regular Methods (see page 1375)

Overriding Methods (see page 1374)

3.2.1.13.17 Classes and Pointers

Every class (and therefore every component) is really a pointer. The compiler automatically dereferences class pointers for you, so most of the time you do not need to think about this. The status of classes as pointers becomes important when you pass a class as a parameter. In general, you should pass classes by value rather than by reference. The reason is that classes are already pointers, which are references; passing a class by reference amounts to passing a reference to a reference.

3.2.1.13.18 Overriding Methods

Overriding a method means extending or refining it, rather than replacing it. A descendant class can override any of its inherited virtual methods.

To override a method in a descendant class, add the directive **override** to the end of the method declaration.

Overriding a method causes a compilation error if

- The method does not exist in the ancestor class.
- The ancestor's method of that name is static.

- The declarations are not otherwise identical (number and type of arguments parameters differ).

See Also

Making Methods Virtual (see page 1245)

3.2.1.13.19 Regular Methods (C++)

Class methods are regular (or nonvirtual) unless you specifically declare them as virtual, or unless they override a **virtual** method in a base class. The compiler can determine the exact address of a regular class member at compile time. This is known as compile-time binding.

A base class regular method is inherited by derived classes. In the following example, an object of type `Derived` can call the method `Regular()` as it were its own method. Declaring a method in a derived class with the same name and parameters as a regular method in the class's ancestor replaces the ancestor's method. In the following example, when `d->AnotherRegular()` is called, it is being dispatched to the `Derived` class replacement for `AnotherRegular()`.

```
class Base
{
public:
    void Regular();
    void AnotherRegular();
    virtual void Virtual();
};
class Derived : public Base
{
public:
    void AnotherRegular();          // replaces Base::AnotherRegular()
    void Virtual();                 // overrides Base::Virtual()
};
void FunctionOne()
{
  Derived *d;
  d = new Derived;
  d->Regular();                   // Calling Regular() as it were a member of Derived
                                  // The same as calling d->Base::Regular()
  d->AnotherRegular();            // Calling the redefined AnotherRegular(), ...
                                  // ... the replacement for Base::AnotherRegular()
  delete d;
}
void FunctionTwo(Base *b)
{
  b->Virtual();
  b->AnotherRegular();
}
```

3.2.1.13.20 Static Methods

All methods are static unless you specify otherwise when you declare them. Static methods work like regular procedures or functions. The compiler determines the exact address of the method and links the method at compile time.

The primary advantage of static methods is that dispatching them is very quick. Because the compiler can determine the exact address of the method, it links the method directly. Virtual and dynamic methods, by contrast, use indirect means to look up the address of their methods at runtime, which takes somewhat longer.

A static method does not change when inherited by a descendant class. If you declare a class that includes a static method, then derive a new class from it, the derived class shares exactly the same method at the same address. This means that you cannot override static methods; a static method always does exactly the same thing no matter what class it is called in. If you declare a method in a derived class with the same name as a static method in the ancestor class, the new method simply replaces the inherited one in the derived class.

3.2.1.14 Using graphics in components

Topics

Name	Description
Creating and Managing Off-screen Bitmaps (see page 1378)	When creating complex graphic images, you should avoid drawing them directly on a canvas that appears onscreen. Instead of drawing on the canvas for a form or control, you can construct a bitmap object, draw on its canvas, and then copy its completed image to the onscreen canvas. The most common use of an off-screen bitmap is in the *Paint* method of a graphic control. As with any temporary object, the bitmap should be protected with a **try**..**finally** block:
Loading and Storing Graphics (see page 1378)	All pictures and graphics in Delphi can load their images from files and store them back again (or into different files). You can load or store the image of a picture at any time. To load an image into a picture from a file, call the picture's *LoadFromFile* method. To save an image from a picture into a file, call the picture's *SaveToFile* method. *LoadFromFile* and *SaveToFile* each take the name of a file as the only parameter. *LoadFromFile* uses the extension of the file name to determine what kind of graphic object it will create and load. *SaveToFile* saves... more (see page 1378)
Handling Palettes (see page 1378)	For VCL components, when running on a palette-based device (typically, a 256-color video mode), Delphi controls automatically support palette realization. That is, if you have a control that has a palette, you can use two methods inherited from *TControl* to control how Windows accommodates that palette. Palette support for controls has these two aspects: • Specifying a palette for a control (see page 1380) • Responding to palette changes (see page 1380) Most controls have no need for a palette, but controls that contain "rich color" graphic images (such as the image control) might need to interact with Windows and the screen device driver to ensure the proper... more (see page 1378)
Off-screen Bitmaps (see page 1379)	When drawing complex graphic images, a common technique in graphics programming is to create an off-screen bitmap, draw the image on the bitmap, and then copy the complete image from the bitmap to the final destination onscreen. Using an off-screen image reduces flicker caused by repeated drawing directly to the screen. The bitmap class in Delphi, which represents bitmapped images in resources and files, can also work as an off-screen image. There are two main aspects to working with off-screen bitmaps: • Creating and managing off-screen bitmaps. (see page 1378) • Copying bitmapped images.
Overview of Graphics (see page 1379)	Delphi encapsulates the Windows GDI at several levels. The most important to you as a component writer is the way components display their images on the screen. When calling GDI functions directly, you need to have a handle to a device context, into which you have selected various drawing tools such as pens, brushes, and fonts. After rendering your graphic images, you must restore the device context to its original state before disposing of it. Instead of forcing you to deal with graphics at a detailed level, Delphi provides a simple yet complete interface: your component's *Canvas* property. The canvas... more (see page 1379)

Using a Picture, Graphic, or Canvas (see page 1379)	There are three kinds of classes in Delphi that deal with graphics: • A *canvas* represents a bitmapped drawing surface on a form, graphic control, printer, or bitmap. A canvas is always a property of something else, never a stand-alone class. • A *graphic* represents a graphic image of the sort usually found in a file or resource, such as a bitmap, icon, or metafile. Delphi defines classes *TBitmap*, *TIcon*, and *TMetafile*, all descended from a generic *TGraphic*. You can also define your own graphic classes. By defining a minimal standard interface for all graphics, *TGraphic* provides a... more (see page 1379)
Responding to Changes (see page 1380)	All graphic objects, including canvases and their owned objects (pens, brushes, and fonts) have events built into them for responding to changes in the object. By using these events, you can make your components (or the applications that use them) respond to changes by redrawing their images. Responding to changes in graphic objects is particularly important if you publish them as part of the design-time interface of your components. The only way to ensure that the design-time appearance of the component matches the properties set in the Object Inspector is to respond to changes in the objects. To respond to... more (see page 1380)
Responding to Palette Changes (see page 1380)	If your VCL control specifies a palette by overriding *GetPalette*, Delphi automatically takes care of responding to palette messages from Windows. The method that handles the palette messages is *PaletteChanged*. The primary role of *PaletteChanged* is to determine whether to realize the control's palette in the foreground or the background. Windows handles this realization of palettes by making the topmost window have a foreground palette, with other windows resolved in background palettes. Delphi goes one step further, in that it also realizes palettes for controls within a window in tab order. The only time you might need to... more (see page 1380)
Specifying a Palette for a Control (see page 1380)	To specify a palette for a control, override the control's *GetPalette* method to return the handle of the palette. Specifying the palette for a control does these things for your application: • It tells the application that your control's palette needs to be realized. • It designates the palette to use for realization.
Using Graphics in Components: Overview (see page 1380)	Windows provides a powerful graphics device interface (GDI) for drawing device-independent graphics. The GDI, however, imposes extra requirements on the programmer, such as managing graphic resources. Delphi takes care of all the GDI drudgery, allowing you to focus on productive work instead of searching for lost handles or unreleased resources. As with any part of the Windows API, you can call GDI functions directly from your Delphi application. But you will probably find that using Delphi's encapsulation of the graphic functions is faster and easier. The topics in this section include: • Overview of graphics (see page 1379) • Using the canvas (see page 1381) • Working with pictures (see page 1381)... more (see page 1380)
Using the Canvas (see page 1381)	The canvas class encapsulates graphics controls at several levels, including high-level functions for drawing individual lines, shapes, and text; intermediate properties for manipulating the drawing capabilities of the canvas; and in the component library, provides low-level access to the Windows GDI. The following table summarizes the capabilities of the canvas. ***Canvas capability summary***

Working with Pictures (see page 1381)	Most of the graphics work you do in Delphi is limited to drawing directly on the canvases of components and forms. Delphi also provides for handling stand-alone graphic images, such as bitmaps, metafiles, and icons, including automatic management of palettes. There are three important aspects to working with pictures in Delphi: • Using a picture (see page 1379) • Loading and storing graphics (see page 1378) • Handling palettes (see page 1378)

3.2.1.14.1 Creating and Managing Off-screen Bitmaps

When creating complex graphic images, you should avoid drawing them directly on a canvas that appears onscreen. Instead of drawing on the canvas for a form or control, you can construct a bitmap object, draw on its canvas, and then copy its completed image to the onscreen canvas.

The most common use of an off-screen bitmap is in the *Paint* method of a graphic control. As with any temporary object, the bitmap should be protected with a **try**..**finally** block:

```
type
  TFancyControl = class(TGraphicControl)
  protected
    procedure Paint; override;                              { override the Paint method }
  end;
procedure TFancyControl.Paint;
var
  Bitmap: TBitmap;                          { temporary variable for the off-screen bitmap }
begin
  Bitmap := TBitmap.Create;                                { construct the bitmap object }
  try
    { draw on the bitmap }
    { copy the result into the control's canvas }
  finally
    Bitmap.Free;                                            { destroy the bitmap object }
  end;
end;
```

3.2.1.14.2 Loading and Storing Graphics

All pictures and graphics in Delphi can load their images from files and store them back again (or into different files). You can load or store the image of a picture at any time.

To load an image into a picture from a file, call the picture's *LoadFromFile* method. To save an image from a picture into a file, call the picture's *SaveToFile* method.

LoadFromFile and *SaveToFile* each take the name of a file as the only parameter. *LoadFromFile* uses the extension of the file name to determine what kind of graphic object it will create and load. *SaveToFile* saves whatever type of file is appropriate for the type of graphic object being saved.

3.2.1.14.3 Handling Palettes

For VCL components, when running on a palette-based device (typically, a 256-color video mode), Delphi controls automatically support palette realization. That is, if you have a control that has a palette, you can use two methods inherited from *TControl* to control how Windows accommodates that palette.

Palette support for controls has these two aspects:

- Specifying a palette for a control (see page 1380)

- Responding to palette changes (see page 1380)

Most controls have no need for a palette, but controls that contain "rich color" graphic images (such as the image control) might need to interact with Windows and the screen device driver to ensure the proper appearance of the control. Windows refers to this process as *realizing* palettes.

Realizing palettes is the process of ensuring that the foremost window uses its full palette, and that windows in the background use as much of their palettes as possible, then map any other colors to the closest available colors in the "real" palette. As windows move in front of one another, Windows continually realizes the palettes.

Note: Delphi itself provides no specific support for creating or maintaining palettes, other than in bitmaps. If you have a palette handle, however, Delphi controls can manage it for you.

3.2.1.14.4 Off-screen Bitmaps

When drawing complex graphic images, a common technique in graphics programming is to create an off-screen bitmap, draw the image on the bitmap, and then copy the complete image from the bitmap to the final destination onscreen. Using an off-screen image reduces flicker caused by repeated drawing directly to the screen.

The bitmap class in Delphi, which represents bitmapped images in resources and files, can also work as an off-screen image.

There are two main aspects to working with off-screen bitmaps:

- Creating and managing off-screen bitmaps. (see page 1378)
- Copying bitmapped images.

3.2.1.14.5 Overview of Graphics

Delphi encapsulates the Windows GDI at several levels. The most important to you as a component writer is the way components display their images on the screen. When calling GDI functions directly, you need to have a handle to a device context, into which you have selected various drawing tools such as pens, brushes, and fonts. After rendering your graphic images, you must restore the device context to its original state before disposing of it.

Instead of forcing you to deal with graphics at a detailed level, Delphi provides a simple yet complete interface: your component's *Canvas* property. The canvas ensures that it has a valid device context, and releases the context when you are not using it. Similarly, the canvas has its own properties representing the current pen, brush, and font.

The canvas manages all these resources for you, so you need not concern yourself with creating, selecting, and releasing things like pen handles. You just tell the canvas what kind of pen it should use, and it takes care of the rest.

One of the benefits of letting Delphi manage graphic resources is that it can cache resources for later use, which can speed up repetitive operations. For example, if you have a program that repeatedly creates, uses, and disposes of a particular kind of pen tool, you need to repeat those steps each time you use it. Because Delphi caches graphic resources, chances are good that a tool you use repeatedly is still in the cache, so instead of having to recreate a tool, Delphi uses an existing one.

An example of this is an application that has dozens of forms open, with hundreds of controls. Each of these controls might have one or more *TFont* properties. Though this could result in hundreds or thousands of instances of *TFont* objects, most applications wind up using only two or three font handles, thanks to a font cache.

3.2.1.14.6 Using a Picture, Graphic, or Canvas

There are three kinds of classes in Delphi that deal with graphics:

- A *canvas* represents a bitmapped drawing surface on a form, graphic control, printer, or bitmap. A canvas is always a property of something else, never a stand-alone class.
- A *graphic* represents a graphic image of the sort usually found in a file or resource, such as a bitmap, icon, or metafile. Delphi defines classes *TBitmap*, *TIcon*, and *TMetafile*, all descended from a generic *TGraphic*. You can also define your own graphic

classes. By defining a minimal standard interface for all graphics, *TGraphic* provides a simple mechanism for applications to use different kinds of graphics easily.

- A *picture* is a container for a graphic, meaning it could contain any of the graphic classes. That is, an item of type *TPicture* can contain a bitmap, an icon, a metafile, or a user-defined graphic type, and an application can access them all in the same way through the picture class. For example, the image control has a property called *Picture*, of type *TPicture*, enabling the control to display images from many kinds of graphics.

Keep in mind that a picture class always has a graphic, and a graphic might have a canvas. (The only standard graphic that has a canvas is *TBitmap*.) Normally, when dealing with a picture, you work only with the parts of the graphic class exposed through *TPicture*. If you need access to the specifics of the graphic class itself, you can refer to the picture's *Graphic* property.

3.2.1.14.7 Responding to Changes

All graphic objects, including canvases and their owned objects (pens, brushes, and fonts) have events built into them for responding to changes in the object. By using these events, you can make your components (or the applications that use them) respond to changes by redrawing their images.

Responding to changes in graphic objects is particularly important if you publish them as part of the design-time interface of your components. The only way to ensure that the design-time appearance of the component matches the properties set in the Object Inspector is to respond to changes in the objects.

To respond to changes in a graphic object, assign a method to the class's *OnChange* event.

3.2.1.14.8 Responding to Palette Changes

If your VCL control specifies a palette by overriding *GetPalette*, Delphi automatically takes care of responding to palette messages from Windows. The method that handles the palette messages is *PaletteChanged*.

The primary role of *PaletteChanged* is to determine whether to realize the control's palette in the foreground or the background. Windows handles this realization of palettes by making the topmost window have a foreground palette, with other windows resolved in background palettes. Delphi goes one step further, in that it also realizes palettes for controls within a window in tab order. The only time you might need to override this default behavior is if you want a control that is not first in tab order to have the foreground palette.

3.2.1.14.9 Specifying a Palette for a Control

To specify a palette for a control, override the control's *GetPalette* method to return the handle of the palette.

Specifying the palette for a control does these things for your application:

- It tells the application that your control's palette needs to be realized.
- It designates the palette to use for realization.

3.2.1.14.10 Using Graphics in Components: Overview

Windows provides a powerful graphics device interface (GDI) for drawing device-independent graphics. The GDI, however, imposes extra requirements on the programmer, such as managing graphic resources. Delphi takes care of all the GDI drudgery, allowing you to focus on productive work instead of searching for lost handles or unreleased resources.

As with any part of the Windows API, you can call GDI functions directly from your Delphi application. But you will probably find that using Delphi's encapsulation of the graphic functions is faster and easier.

The topics in this section include:

- Overview of graphics (see page 1379)

- Using the canvas (see page 1381)
- Working with pictures (see page 1381)
- Off-screen bitmaps (see page 1379)
- Responding to changes (see page 1380)

3.2.1.14.11 Using the Canvas

The canvas class encapsulates graphics controls at several levels, including high-level functions for drawing individual lines, shapes, and text; intermediate properties for manipulating the drawing capabilities of the canvas; and in the component library, provides low-level access to the Windows GDI.

The following table summarizes the capabilities of the canvas.

Canvas capability summary

Level	Operation	Tools
High	Drawing lines and shapes	Methods such as *MoveTo*, *LineTo*, *Rectangle*, and *Ellipse*
	Displaying and measuring text	*TextOut*, *TextHeight*, *TextWidth*, and *TextRect* methods
	Filling areas	*FillRect* and *FloodFill* methods
Intermediate	Customizing text and graphics	*Pen*, *Brush*, and *Font* properties
	Manipulating pixels	*Pixels* property.
	Copying and merging images	*Draw, StretchDraw, BrushCopy,* and *CopyRect* methods; *CopyMode* property
Low	Calling Windows GDI functions	*Handle* property

3.2.1.14.12 Working with Pictures

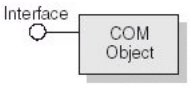
Most of the graphics work you do in Delphi is limited to drawing directly on the canvases of components and forms. Delphi also provides for handling stand-alone graphic images, such as bitmaps, metafiles, and icons, including automatic management of palettes.

There are three important aspects to working with pictures in Delphi:

- Using a picture (see page 1379)
- Loading and storing graphics (see page 1378)
- Handling palettes (see page 1378)

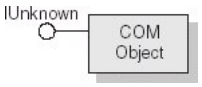
3.2.2 Developing COM-based Applications

Contains the Developer's Guide topics for creating COM-based applications in Delphi.

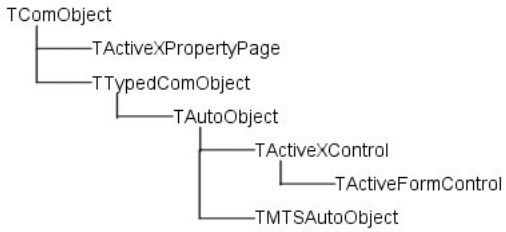


Topics

Name	Description
COM basics (see page 1382)	
Creating an Active Server Page (see page 1400)	
Using ActiveX controls (see page 1406)	
Creating COM clients (see page 1418)	



Creating simple COM servers (see page 1427)	
Working with type libraries (see page 1441)	



3.2.2.1 COM basics

Topics

Name	Description
Overview of COM Technologies (see page 1385)	Delphi provides wizards and classes to make it easy to implement applications based on the Component Object Model (COM) from Microsoft. With these wizards, you can create COM-based classes and components to use within applications or you can create fully functional COM clients or servers that implement COM objects, Automation servers (including Active Server Objects), ActiveX controls, or ActiveForms. COM is a language-independent software component model that enables interaction between software components and applications running on a Windows platform. The key aspect of COM is that it enables communication between components, between applications, and between clients and servers through clearly... more (see page 1385)
Parts of a COM Application (see page 1386)	When implementing a COM application, you supply the following:
COM Interfaces (see page 1386)	COM clients communicate with objects through COM interfaces. Interfaces are groups of logically or semantically related routines which provide communication between a provider of a service (server object) and its clients. The standard way to depict a COM interface is as follows:  For example, every COM object must implement the basic interface, IUnknown (see page 1387). Through a routine called *QueryInterface* in *IUnknown*, clients can request other interfaces implemented by the server. Objects can have multiple interfaces, where each interface implements a feature. An interface provides a way to convey to the client what service it provides, without... more (see page 1386)
The Fundamental COM Interface, IUnknown (see page 1387)	All COM objects must support the fundamental interface, called *IUnknown, a typedefto the base interface type IInterface. IUnknown contains the following routines:*
COM Interface Pointers (see page 1387)	An interface pointer is a pointer to an object instance that points, in turn, to the implementation of each method in the interface. The implementation is accessed through an array of pointers to these methods, which is called a **vtable**. Vtables are similar to the mechanism used to support virtual functions in Delphi. Because of this similarity, the compiler can resolve calls to methods on the interface the same way it resolves calls to methods on Delphi classes. The vtable is shared among all instances of an object class, so for each object instance, the object code allocates a... more (see page 1387)
COM Servers (see page 1388)	A COM server is an application or a library that provides services to a client application or library. A COM server consists of one or more COM objects, where a COM object is a set of properties and methods. Clients do not know *how* a COM object performs its service; the object's implementation remains encapsulated. An object makes its services available through its interfaces (see page 1386). In addition, clients do not need to know *where* a COM object resides. COM provides transparent access regardless of the object's location. (see page 1389) When a client requests a service from a COM object, the client passes... more (see page 1388)
CoClasses and Class Factories (see page 1388)	A COM object is an instance of a **CoClass**, which is a class that implements one or more COM interfaces. The COM object provides the services as defined by its interfaces. CoClasses are instantiated by a special type of object called a *class factory*. Whenever an object's services are requested by a client, a class factory creates an object instance for that particular client. Typically, if another client requests the object's services, the class factory creates another object instance to service the second client. (Clients can also bind to running COM objects that register themselves to support it.)... more (see page 1388)

In-process, Out-of-process, and Remote Servers (see page 1389)	With COM, a client does not need to know where an object resides, it simply makes a call to an object's interface. COM performs the necessary steps to make the call. These steps differ depending on whether the object resides in the same process as the client, in a different process on the client machine, or in a different machine across the network. The different types of servers are known as:
The Marshaling Mechanism (see page 1390)	Marshaling is the mechanism that allows a client to make interface function calls to remote objects in another process or on a different machine. Marshaling • Takes an interface pointer in the server's process and makes a proxy pointer available to code in the client process. • Transfers the arguments of an interface call as passed from the client and places the arguments into the remote object's process space. For any interface call, the client pushes arguments onto a stack and makes a function call through the interface pointer. If the call to the object is not in-process, the call gets passed... more (see page 1390)
Aggregation (COM) (see page 1391)	Sometimes, a server object makes use of another COM object to perform some of its functions. For example, an inventory management object might make use of a separate invoicing object to handle customer invoices. If the inventory management object wants to present the invoice interface to clients, however, there is a problem: Although a client that has the inventory interface can call *QueryInterface* to obtain the invoice interface, when the invoice object was created it did not know about the inventory management object and can't return an inventory interface in response to a call to *QueryInterface*. A client that... more (see page 1391)
COM Clients (see page 1391)	Clients can always query the interfaces of a COM object to determine what it is capable of providing. All COM objects allow clients to request known interfaces. In addition, if the server supports the *IDispatch* interface, clients can query the server for information about what methods the interface supports. Server objects have no expectations about the client using its objects. Similarly, clients don't need to know how (or even where) an object provides the services; they simply rely on server objects to provide the services they advertise through their interfaces. There are two types of COM clients, controllers and containers.... more (see page 1391)
COM Extensions (see page 1392)	COM was originally designed to provide core communication functionality and to enable the broadening of this functionality through extensions. COM itself has extended its core functionality by defining specialized sets of interfaces for specific purposes. The following lists some of the services COM extensions currently provide.
Automation Servers (see page 1393)	Automation refers to the ability of an application to control the objects in another application programmatically, like a macro that can manipulate more than one application at the same time. The server object being manipulated is called the Automation object, and the client of the Automation object is referred to as an Automation controller. Automation can be used on in-process, local, and remote servers. Automation is characterized by two key points: • The Automation object defines a set of properties and commands, and describes their capabilities through type descriptions. In order to do this, it must have a way to provide... more (see page 1393)
Active Server Pages (see page 1393)	The Active Server Page (ASP) technology lets you write simple scripts, called Active Server Pages, that can be launched by clients via a Web server. Unlike ActiveX controls, which run on the client, Active Server Pages run on the server, and return a resulting HTML page to clients. Active Server Pages are written in Jscript or VB script. The script runs every time the server loads the Web page. That script can then launch an embedded Automation server (or Enterprise Java Bean). For example, you can write an Automation server, such as one to create a bitmap or connect... more (see page 1393)

ActiveX Controls (see page 1394)	ActiveX is a technology that allows COM components, especially controls, to be more compact and efficient. This is especially necessary for controls that are intended for Intranet applications that need to be downloaded by a client before they are used. ActiveX controls are visual controls that run only as in-process servers, and can be plugged into an ActiveX control container application. They are not complete applications in themselves, but can be thought of as prefabricated OLE controls that are reusable in various applications. ActiveX controls have a visible user interface, and rely on predefined interfaces to negotiate I/O and display... more (see page 1394)
Active Documents (see page 1394)	Active Documents (previously referred to as OLE documents) are a set of COM services that support linking and embedding, drag-and-drop, and visual editing. Active Documents can seamlessly incorporate data or objects of different formats, such as sound clips, spreadsheets, text, and bitmaps. Unlike ActiveX controls, Active Documents are not limited to in-process servers; they can be used in cross-process applications. Unlike Automation objects, which are almost never visual, Active Document objects can be visually active in another application. Thus, Active Document objects are associated with two types of data: presentation data, used for visually displaying the object on a display... more (see page 1394)
Type Libraries (see page 1395)	Type libraries provide a way to get more type information about an object than can be determined from an object's interface. The type information contained in type libraries provides needed information about objects and their interfaces, such as what interfaces exist on what objects (given the CLSID), what member functions exist on each interface, and what arguments those functions require. You can obtain type information either by querying a running instance of an object or by loading and reading type libraries. With this information, you can implement a client which uses a desired object, knowing specifically what member functions you... more (see page 1395)
Implementing COM Objects with Wizards (see page 1397)	Delphi makes it easier to write COM server applications by providing wizards that handle many of the details involved. Delphi provides separate wizards to create the following: • A simple COM object • An Automation object • A COM+ Event Object • A Type library • An ActiveX library The wizards handle many of the tasks involved in creating each type of COM object. They provide the required COM interfaces for each type of object. With a simple COM object, the wizard implements the one required COM interface, *IUnknown*, which provides an interface pointer to the object.  The COM object... more (see page 1397)

Code Generated by Wizards (see page 1398)	Delphi's wizards generate classes that are derived from the Delphi ActiveX framework (DAX). Despite its name, the Delphi ActiveX framework supports all types of COM objects, not just ActiveX controls. The classes in this framework provide the underlying implementation of the standard COM interfaces for the objects you create using a wizard. The following figure illustrates the objects in the Delphi ActiveX framework:  Each wizard generates an implementation unit that implements your COM server object. The COM server object (the implementation object) descends from one of the classes in DAX: ***DAX Base classes for generated implementation classes... more (see page 1398)***
COM+ Event And Event Subscriber Objects (see page 1399)	The COM+ Events system introduces a middle layer of software that decouples applications that generate events (called publishers) from applications that respond to events (called subscribers). Instead of being tightly bound to each other, publishers and subscribers can be developed, deployed and activated independently of each other. In the COM+ Events model, an event interface is first created using the COM+ Event Object wizard. The event interface has no implementation; it simply defines the event methods that publishers will generate, and that subscribers will respond to. The COM+ event object is then installed into a COM+ Application, in the COM+... more (see page 1399)

3.2.2.1.1 Overview of COM Technologies

Delphi provides wizards and classes to make it easy to implement applications based on the Component Object Model (COM) from Microsoft. With these wizards, you can create COM-based classes and components to use within applications or you can create fully functional COM clients or servers that implement COM objects, Automation servers (including Active Server Objects), ActiveX controls, or ActiveForms.

COM is a language-independent software component model that enables interaction between software components and applications running on a Windows platform. The key aspect of COM is that it enables communication between components, between applications, and between clients and servers through clearly defined interfaces. Interfaces provide a way for clients to ask a COM component which features it supports at runtime. To provide additional features for your component, you simply add an additional interface for those features.

Applications can access the interfaces of COM components that exist on the same computer as the application or that exist on another computer on the network using a mechanism called Distributed COM (DCOM). For more information on clients, servers, and interfaces see Parts of a COM Application (see page 1386).

COM as a specification and implementation

COM is both a specification and an implementation. The COM specification defines how objects are created and how they communicate with each other. According to this specification, COM objects can be written in different languages, run in different process spaces and on different platforms. As long as the objects adhere to the written specification, they can communicate. This allows you to integrate legacy code as a component with new components implemented in object-oriented languages.

The COM implementation is built into the Win32 subsystem, which provides a number of core services that support the written specification. The COM library contains a set of standard interfaces that define the core functionality of a COM object, and a small set of API functions designed for the purpose of creating and managing COM objects.

When you use Delphi wizards and VCL objects in your application, you are using Delphi's implementation of the COM specification. In addition, Delphi provides some wrappers for COM services for those features that it does not implement directly. You can find these wrappers defined in the `ComObj` unit and the API definitions in the `AxCtrls` unit.

Note: Delphi's interfaces and language follow the COM specification. Delphi implements objects conforming to the COM spec using a set of classes called the Delphi ActiveX framework (DAX). These classes are found in the `AxCtrls`, `OleCtrls`, and `OleServer` units. In addition, the Delphi interface to the COM API is in ActiveX.pas

and `ComSvcs.pas`.

COM extensions

As COM has evolved, it has been extended beyond the basic COM services. COM serves as the basis for other technologies such as Automation, ActiveX controls, and Active Directories. For details on COM extensions, see COM Extensions (see page 1392).

Delphi provides wizards to easily implement applications that incorporate the above technologies in the Delphi environment. For details, see Implementing COM Objects with Wizards (see page 1397).

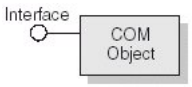
Creating Simple COM Servers: Overview (see page 1430)

Creating Active Server Pages: Overview (see page 1400)



3.2.2.1.2 Parts of a COM Application

When implementing a COM application, you supply the following:

COM interface (see page 1386)	The way in which an object exposes its services externally to clients. A COM object provides an interface for each set of related methods and properties. Note that COM properties are not identical to properties on VCL objects. COM properties always use read and write access methods.
COM server (see page 1388)	A module, either an EXE, DLL, or OCX, that contains the code for a COM object. Object implementations reside in servers. A COM object implements one or more interfaces.
COM client (see page 1391)	The code that calls the interfaces to get the requested services from the server. Clients know what they want to get from the server (through the interface); clients do not know the internals of how the server provides the services. Delphi eases the process in creating a client by letting you install COM servers (such as a Word document or PowerPoint slide) as components on the **Tool Palette**. This allows you to connect to the server and hook its events through the **Object Inspector**.

3.2.2.1.3 COM Interfaces

COM clients communicate with objects through COM interfaces. Interfaces are groups of logically or semantically related routines which provide communication between a provider of a service (server object) and its clients. The standard way to depict a COM interface is as follows:

For example, every COM object must implement the basic interface, IUnknown (see page 1387). Through a routine called *QueryInterface* in *IUnknown*, clients can request other interfaces implemented by the server.

Objects can have multiple interfaces, where each interface implements a feature. An interface provides a way to convey to the client what service it provides, without providing implementation details of how or where the object provides this service.

Key aspects of COM interfaces are as follows:

- Once published, interfaces are immutable; that is, they do not change. You can rely on an interface to provide a specific set of functions. Additional functionality is provided by additional interfaces.

- By convention, COM interface identifiers begin with a capital I and a symbolic name that defines the interface, such as *IMalloc* or *IPersist*.
- Interfaces are guaranteed to have a unique identification, called a **Globally Unique Identifier (GUID)**, which is a 128-bit randomly generated number. Interface GUIDs are called **Interface Identifiers (IIDs)**. This eliminates naming conflicts between different versions of a product or different products.
- Interfaces are language independent. You can use any language to implement a COM interface as long as the language supports a structure of pointers, and can call a function through a pointer either explicitly or implicitly.
- Interfaces are not objects themselves; they provide a way to access an object. Therefore, clients do not access data directly; clients access data through an interface pointer (see page 1387). Windows 2000 adds an additional layer of indirection known as an interceptor through which it provides COM+ features such as just-in-time activation and object pooling.
- Interfaces are always inherited from the fundamental interface, IUnknown. (see page 1387)
- Interfaces can be redirected by COM through proxies to enable interface method calls to call between threads, processes, and networked machines, all without the client or server objects ever being aware of the redirection. For more information, see In-process (see page 1389).

See Also

The Fundamental COM Interface (see page 1387)

COM Interface Pointers (see page 1387)

3.2.2.1.4 The Fundamental COM Interface, IUnknown

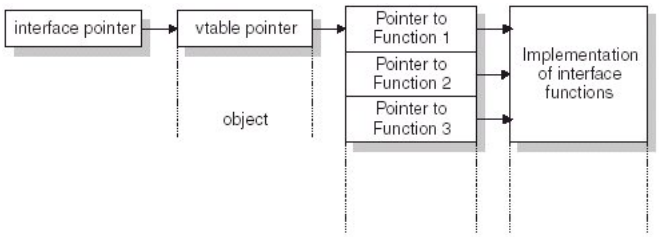
All COM objects must support the fundamental interface, called *IUnknown, a typedefto the base interface type IInterface. IUnknown contains the following routines:*

QueryInterface	Provides pointers to other interfaces that the object supports.
AddRef and Release	Simple reference counting methods that keep track of the object's lifetime so that an object can delete itself when the client no longer needs its service.

Clients obtain pointers to other interfaces through the *IUnknown* method, *QueryInterface*. *QueryInterface* knows about every interface in the server object and can give a client a pointer to the requested interface. When receiving a pointer to an interface, the client is assured that it can call any method of the interface.

Objects track their own lifetime through the *IUnknown* methods, *AddRef* and *Release*, which are simple reference counting methods. As long as an object's reference count is nonzero, the object remains in memory. Once the reference count reaches zero, the interface implementation can safely dispose of the underlying object(s).

See Also



COM Interfaces (see page 1386)

COM Interface Pointers (see page 1387)

3.2.2.1.5 COM Interface Pointers

An interface pointer is a pointer to an object instance that points, in turn, to the implementation of each method in the interface. The implementation is accessed through an array of pointers to these methods, which is called a **vtable**. Vtables are similar to the mechanism used to support virtual functions in Delphi. Because of this similarity, the compiler can resolve calls to methods on the interface the same way it resolves calls to methods on Delphi classes.

The vtable is shared among all instances of an object class, so for each object instance, the object code allocates a second structure that contains its private data. The client's interface pointer, then, is a pointer *to the pointer* to the vtable, as shown in the following diagram.

In Windows 2000 and subsequent versions of Windows, when an object is running under COM+, an added level of indirection is provided between the interface pointer and the vtable pointer. The interface pointer available to the client points at an interceptor, which in turn points at the vtable. This allows COM+ to provide such services as just-in-time activation, whereby the server can be deactivated and reactivated dynamically in a way that is opaque to the client. To achieve this, COM+ guarantees that the interceptor behaves as if it were an ordinary vtable pointer.

The Fundamental COM Interface (see page 1387)

COM Interfaces (see page 1386)

3.2.2.1.6 COM Servers

A COM server is an application or a library that provides services to a client application or library. A COM server consists of one or more COM objects, where a COM object is a set of properties and methods.

Clients do not know *how* a COM object performs its service; the object's implementation remains encapsulated. An object makes its services available through its interfaces (see page 1386).

In addition, clients do not need to know *where* a COM object resides. COM provides transparent access regardless of the object's location. (see page 1389)

When a client requests a service from a COM object, the client passes a class identifier (CLSID) to COM. A CLSID is simply a GUID that identifies a COM object. COM uses this CLSID, which is registered in the system registry, to locate the appropriate server implementation. Once the server is located, COM brings the code into memory, and has the server instantiate an object instance for the client. This process is handled indirectly, through a special object called a class factory (based on interfaces) that creates instances of objects on demand.

As a minimum, a COM server must perform the following:

- Register entries in the system registry that associate the server module with the class identifier (CLSID).
- Implement a class factory object (see page 1388), which manufactures another object of a particular CLSID.
- Expose the class factory to COM.
- Provide an unloading mechanism through which a server that is not servicing clients can be removed from memory.

Note: Delphi wizards automate the creation of COM objects and servers (see page 1397).

See Also

COM Interfaces (see page 1386)

CoClasses and Class Factories (see page 1388)

In-process (see page 1389)

3.2.2.1.7 CoClasses and Class Factories

A COM object is an instance of a **CoClass**, which is a class that implements one or more COM interfaces. The COM object

provides the services as defined by its interfaces.

CoClasses are instantiated by a special type of object called a *class factory*. Whenever an object's services are requested by a client, a class factory creates an object instance for that particular client. Typically, if another client requests the object's services, the class factory creates another object instance to service the second client. (Clients can also bind to running COM objects that register themselves to support it.)

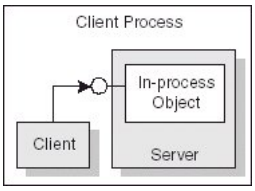
A CoClass must have a class factory and a class identifier (CLSID) so that it can be instantiated externally, that is, from another module. Using these unique identifiers for CoClasses means that they can be updated whenever new interfaces are implemented in their class. A new interface can modify or add methods without affecting older versions, which is a common problem when using DLLs.

Delphi wizards take care of assigning class identifiers and of implementing and instantiating class factories.

See Also

COM Servers (see page 1388)

In-process (see page 1389)

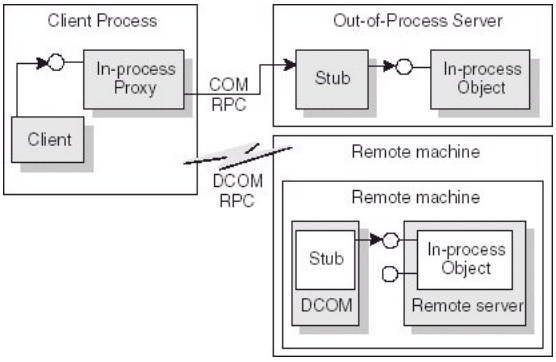


Aggregation (see page 1391)

3.2.2.1.8 In-process, Out-of-process, and Remote Servers

With COM, a client does not need to know where an object resides, it simply makes a call to an object's interface. COM performs the necessary steps to make the call. These steps differ depending on whether the object resides in the same process as the client, in a different process on the client machine, or in a different machine across the network. The different types of servers are known as:

In-process server	A library (DLL) running in the *same process space* as the client, for example, an ActiveX control embedded in a Web page viewed under Internet Explorer or Netscape. Here, the ActiveX control is downloaded to the client machine and invoked within the same process as the Web browser. The client communicates with the in-process server using direct calls to the COM interface.
Out-of-process server (or local server)	Another application (EXE) running in a *different process space* but on the *same machine* as the client. For example, an Excel spreadsheet embedded in a Word document are two separate applications running on the same machine. The local server uses COM to communicate with the client.
Remote server	A DLL or another application running on a *different machine* from that of the client. For example, a Delphi database application is connected to an application server on another machine in the network. The remote server uses distributed COM (DCOM) to access interfaces and communicate with the application server.



As shown in the following figure, for in-process servers, pointers to the object interfaces are in the same process space as the client, so COM makes direct calls into the object implementation.

Note: This is not always true under COM+. When a client makes a call to an object in a different context, COM+ intercepts the call so that it behaves like a call to an out-of-process server (see below), even if the server is in-process.

As shown in the following figure, when the process is either in a different process or in a different machine altogether, COM uses a proxy to initiate remote procedure calls. The **proxy** resides in the same process as the client, so from the client's

perspective, all interface calls look alike. The proxy intercepts the client's call and forwards it to where the real object is running. The mechanism that enables the client to access objects in a different process space, or even different machine, as if they were in their own process, is called marshaling (see page 1390).

The difference between out-of-process and remote servers is the type of interprocess communication used. The proxy uses COM to communicate with an out-of-process server, it uses distributed COM (DCOM) to communicate with a remote machine. DCOM transparently transfers a local object request to the remote object running on a different machine.

Note: For remote procedure calls, DCOM uses the RPC protocol provided by Open Group's Distributed Computing Environment (DCE). For distributed security, DCOM uses the NT LAN Manager (NTLM) security protocol. For directory services, DCOM uses the Domain Name System (DNS).

CoClasses and Class Factories (see page 1388)

COM Servers (see page 1388)

The Marshaling Mechanism (see page 1390)

Aggregation (see page 1391)

3.2.2.1.9 The Marshaling Mechanism

Marshaling is the mechanism that allows a client to make interface function calls to remote objects in another process or on a different machine. Marshaling

- Takes an interface pointer in the server's process and makes a proxy pointer available to code in the client process.
- Transfers the arguments of an interface call as passed from the client and places the arguments into the remote object's process space.

For any interface call, the client pushes arguments onto a stack and makes a function call through the interface pointer. If the call to the object is not in-process, the call gets passed to the proxy. The proxy packs the arguments into a marshaling packet and transmits the structure to the remote object. The object's stub unpacks the packet, pushes the arguments onto the stack, and calls the object's implementation. In essence, the object recreates the client's call in its own address space.

The type of marshaling that occurs depends on what interface the COM object implements. Objects can use a standard marshaling mechanism provided by the *IDispatch* interface. This is a generic marshaling mechanism that enables communication through a system-standard remote procedure call (RPC). For details on the *IDispatch* interface, see Automation Interfaces (see page 1438). Even if the object does not implement *IDispatch*, if it limits itself to automation-compatible types and has a registered type library, COM automatically provides marshaling support.

Applications that do not limit themselves to automation-compatible types or register a type library must provide their own marshaling. Marshaling is provided either through an implementation of the *IMarshal* interface, or by using a separately generated proxy/stub DLL. Delphi does not support the automatic generation of proxy/stub DLLs.

In-process (see page 1389)

Automation (see page 1393)

Aggregation (see page 1391)

3.2.2.1.10 Aggregation (COM)

Sometimes, a server object makes use of another COM object to perform some of its functions. For example, an inventory management object might make use of a separate invoicing object to handle customer invoices. If the inventory management object wants to present the invoice interface to clients, however, there is a problem: Although a client that has the inventory interface can call *QueryInterface* to obtain the invoice interface, when the invoice object was created it did not know about the inventory management object and can't return an inventory interface in response to a call to *QueryInterface*. A client that has the invoice interface can't get back to the inventory interface.

To avoid this problem, some COM objects support **aggregation**. When the inventory management object creates an instance of the invoice object, it passes it a copy of its own *IUnknown* interface. The invoice object can then use that *IUnknown* interface to handle any *QueryInterface* calls that request an interface, such as the inventory interface, that it does not support. When this happens, the two objects together are called an aggregate. The invoice object is called the inner, or contained object of the aggregate, and the inventory object is called the outer object.

Note: In order to act as the outer object of an aggregate, a COM object must create the inner object using the Windows API *CoCreateInstance* or *CoCreateInstanceEx*, passing its *IUnknown* pointer as a parameter that the inner object can use for *QueryInterface* calls.

In order to create an object that can act as the inner object of an aggregate, it must descend from TContainedObject. When the object is created, the *IUnknown* interface of the outer object is passed to the constructor so that it can be used by the *QueryInterface* method on calls that the inner object can't handle.

Automation (see page 1393)

The Marshaling Mechanism (see page 1390)

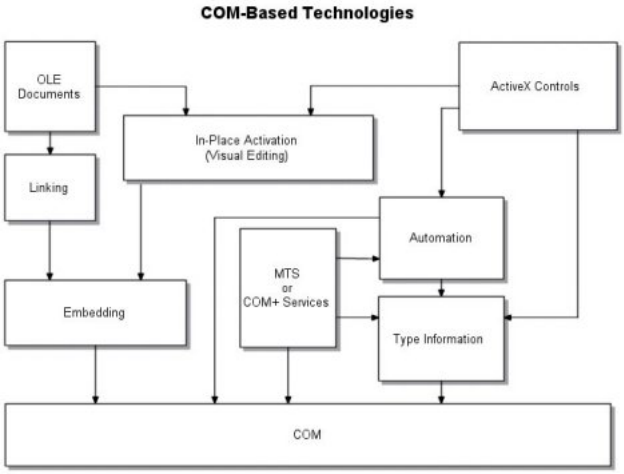
3.2.2.1.11 COM Clients

Clients can always query the interfaces of a COM object to determine what it is capable of providing. All COM objects allow clients to request known interfaces. In addition, if the server supports the *IDispatch* interface, clients can query the server for information about what methods the interface supports. Server objects have no expectations about the client using its objects. Similarly, clients don't need to know how (or even where) an object provides the services; they simply rely on server objects to provide the services they advertise through their interfaces.

There are two types of COM clients, controllers and containers. Controllers launch the server and interact with it through its interface. They request services from the COM object or drive it as a separate process. Containers host visual controls or objects that appear in the container's user interface. They use predefined interfaces to negotiate display issues with server objects. It is impossible to have a container relationship over DCOM; for example, visual controls that appear in the container's user interface must be located locally. This is because the controls are expected to paint themselves, which requires that they have access to local GDI resources.

Delphi makes it easier for you to develop COM clients by letting you import a type library or ActiveX control into a component wrapper so that server objects look like other VCL components. For details on this process, see Creating COM clients (see

page 1419)



3.2.2.1.12 COM Extensions

COM was originally designed to provide core communication functionality and to enable the broadening of this functionality through extensions. COM itself has extended its core functionality by defining specialized sets of interfaces for specific purposes.

The following lists some of the services COM extensions currently provide.

Automation servers (see page 1393)	Automation refers to the ability of an application to control the objects in another application programmatically. Automation servers are the objects that can be controlled by other executables at runtime.
ActiveX controls (see page 1394)	ActiveX controls are specialized in-process servers, typically intended for embedding in a client application. The controls offer both design and runtime behaviors as well as events.
Active Server Pages (see page 1393)	Active Server Pages are scripts that generate HTML pages. The scripting language includes constructs for creating and running Automation objects. That is, the Active Server Page acts as an Automation controller.
Active Documents (see page 1394)	Objects that support linking and embedding, drag-and-drop, visual editing, and in-place activation. Word documents and Excel spreadsheets are examples of Active Documents.
COM+ Event and event subscription objects	Objects that support the loosely coupled COM+ Events model. Unlike the tightly coupled model used by ActiveX controls, the COM+ Events model allows you to develop event publishers independently of event subscribers.
Type libraries (see page 1395)	A collection of static data structures, often saved as a resource, that provides detailed type information about an object and its interfaces. Clients of Automation servers, ActiveX controls, and transactional objects expect type information to be available.

The following diagram illustrates the relationship of the COM extensions and how they are built upon COM:

COM objects can be visual or non-visual. Some must run in the same process space as their clients; others can run in different processes or remote machines, as long as the objects provide marshaling support. The following table summarizes the types of COM objects that you can create, whether they are visual, process spaces they can run in, how they provide marshaling (see page 1390), and whether they require a type library.

COM object requirements

Object	Visual Object?	Process space	Communication	Type library
Active Document	Usually	In-process, or out-of-process	OLE Verbs	No
Automation Server	Occasionally	In-process, out-of-process, or remote	Automatically marshaled using the *IDispatch* interface (for out-of process and remote servers)	Required for automatic marshaling
ActiveX Control	Usually	In-process	Automatically marshaled using the *IDispatch* interface	Required
COM+	Occasionally	In-process for MTS,any for COM+	Automatically marshaled via a type library	Required
In-process custom interface object	Optionally	In-process	No marshaling required for in-process servers	Recommended
Other custom interface object	Optionally	In-process,out-of-process, or remote	Automatically marshaled via a type library; otherwise, manually marshaled using custom interfaces	Recommended

3.2.2.1.13 Automation Servers

Automation refers to the ability of an application to control the objects in another application programmatically, like a macro that can manipulate more than one application at the same time. The server object being manipulated is called the Automation object, and the client of the Automation object is referred to as an Automation controller.

Automation can be used on in-process, local, and remote servers.

Automation is characterized by two key points:

- The Automation object defines a set of properties and commands, and describes their capabilities through type descriptions. In order to do this, it must have a way to provide information about its interfaces, the interface methods, and those methods' arguments. Typically, this information is available in a type library (see page 1395). The Automation server can also generate type information dynamically when queried via its *IDispatch* interface (see following).
- Automation objects make their methods accessible so that other applications can use them. For this, they implement the *IDispatch* interface. Through this interface an object can expose all of its methods and properties. Through the primary method of this interface, the object's methods can be invoked, once having been identified through type information.

Developers often use Automation to create and use non-visual OLE objects that run in any process space because the Automation *IDispatch* interface automates the marshaling process. Automation does, however, restrict the types that you can use.

For a list of types that are valid for type libraries in general, and Automation interfaces in particular, see Valid types (see page 1454).

Creating Simple COM Servers: Overview (see page 1430)

Working with Type Libraries: Overview (see page 1445)

Creating Active Server Pages (see page 1400)

3.2.2.1.14 Active Server Pages

The Active Server Page (ASP) technology lets you write simple scripts, called Active Server Pages, that can be launched by clients via a Web server. Unlike ActiveX controls, which run on the client, Active Server Pages run on the server, and return a

resulting HTML page to clients.

Active Server Pages are written in Jscript or VB script. The script runs every time the server loads the Web page. That script can then launch an embedded Automation server (or Enterprise Java Bean). For example, you can write an Automation server, such as one to create a bitmap or connect to a database, and this server accesses data that gets updated every time a client loads the Web page.

Active Server Pages rely on the Microsoft Internet Information Server (IIS) environment to serve your Web pages.

Delphi wizards let you Create Active Server Pages (see page 1400), which is an Automation object specifically designed to work with an Active Server Page.

See Also

Creating Active Server Pages (see page 1400)

Working with Type Libraries: Overview (see page 1445)

3.2.2.1.15 ActiveX Controls

ActiveX is a technology that allows COM components, especially controls, to be more compact and efficient. This is especially necessary for controls that are intended for Intranet applications that need to be downloaded by a client before they are used.

ActiveX controls are visual controls that run only as in-process servers, and can be plugged into an ActiveX control container application. They are not complete applications in themselves, but can be thought of as prefabricated OLE controls that are reusable in various applications. ActiveX controls have a visible user interface, and rely on predefined interfaces to negotiate I/O and display issues with their host containers.

ActiveX controls make use of Automation to expose their properties, methods, and events. Features of ActiveX controls include the ability to fire events, bind to data sources, and support licensing.

One use of ActiveX controls is on a Web site as interactive objects in a Web page. As such, ActiveX is a standard that targets interactive content for the World Wide Web, including the use of ActiveX Documents used for viewing non-HTML documents through a Web browser. For more information about ActiveX technology, see the Microsoft ActiveX Web site.

See Also

Using ActiveX Controls (see page 1406)

3.2.2.1.16 Active Documents

Active Documents (previously referred to as OLE documents) are a set of COM services that support linking and embedding, drag-and-drop, and visual editing. Active Documents can seamlessly incorporate data or objects of different formats, such as sound clips, spreadsheets, text, and bitmaps.

Unlike ActiveX controls, Active Documents are not limited to in-process servers; they can be used in cross-process applications.

Unlike Automation objects, which are almost never visual, Active Document objects can be visually active in another application. Thus, Active Document objects are associated with two types of data: presentation data, used for visually displaying the object on a display or output device, and native data, used to edit an object.

Active Document objects can be document containers or document servers. While Delphi does not provide an automatic wizard for creating Active Documents, you can use the VCL class, TOleContainer, to support linking and embedding of existing Active Documents.

You can also use *TOleContainer* as a basis for an Active Document container. To create objects for Active Document servers, use the COM object wizard and add the appropriate interfaces, depending on the services the object needs to support. For more information about creating and using Active Document servers, see the Microsoft ActiveX Web site.

Note: While the specification for Active Documents has built-in support for marshaling in cross-process applications, Active Documents do not run on remote servers because they use types that are specific to a system on a given machine such as window handles, menu handles, and so on.

3.2.2.1.17 Type Libraries

Type libraries provide a way to get more type information about an object than can be determined from an object's interface. The type information contained in type libraries provides needed information about objects and their interfaces, such as what interfaces exist on what objects (given the CLSID), what member functions exist on each interface, and what arguments those functions require.

You can obtain type information either by querying a running instance of an object or by loading and reading type libraries. With this information, you can implement a client which uses a desired object, knowing specifically what member functions you need, and what to pass those member functions.

Clients of Automation servers, ActiveX controls, and transactional objects expect type information to be available. All of Delphi's wizards generate a type library automatically, although the COM object wizard makes this optional. You can view or edit this type information by using the Type Library Editor (see page 1445). The Type Library Editor displays the type information by way of an intermediate text-based format (the RIDL file (see page 1468)) and generates the corresponding .tlb file when you build or save your project. You can also use the GenTLB.exe (see page 1468) utility to create a .tlb file from a RIDL file.

The content of type libraries

Type libraries contain *type information*, which indicates which interfaces exist in which COM objects, and the types and numbers of arguments to the interface methods. These descriptions include the unique identifiers for the CoClasses (CLSIDs) and the interfaces (IIDs), so that they can be properly accessed, as well as the dispatch identifiers (dispIDs) for Automation interface methods and properties.

Type libraries can also contain the following information:

- Descriptions of custom type information associated with custom interfaces
- Routines that are exported by the Automation or ActiveX server, but that are not interface methods
- Information about enumeration, record (structures), unions, alias, and module data types
- References to type descriptions from other type libraries

Creating type libraries

With traditional development tools, you create type libraries by writing scripts in the Interface Definition Language (IDL) or the Object Description Language (ODL), then running that script through a compiler. However, Delphi automatically generates a type library when you create a COM object (including ActiveX controls, Automation objects, remote data modules, and so on) using any of the wizards on either the ActiveX or Multitier page of the new items dialog. You can also create a type library by choosing **File** ▸ **New** ▸ **Other**, selecting the ActiveX folder under Delphi Projects or C++Builder Projects, and in the right pane choosing Type Library.

You can view and edit the type library using Delphi's **Type Library Editor**. Delphi automatically updates the corresponding .tlb file (binary type library file) when the type library is saved. For any changes to Interfaces and CoClasses that were created using a wizard, the Type Library editor also updates your implementation files.

When to use type libraries

It is important to create a type library for each set of objects that is exposed to external users, for example,

- ActiveX controls require a type library, which must be included as a resource in the DLL that contains the ActiveX controls.
- Exposed objects that support vtable binding of custom interfaces must be described in a type library because vtable references are bound at compile time. Clients import information about the interfaces from the type library and use that information to compile. For more information about vtable and compile time binding, see Automation interfaces (see page

1438).

- Applications that implement Automation servers should provide a type library so that clients can early bind to it.
- Objects instantiated from classes that support the *IProvideClassInfo* interface, such as all descendants of the VCL *TTypedComObject* class, must have a type library.
- Type libraries are not required, but are useful for identifying the objects used with OLE drag-and-drop.

When defining interfaces for internal use only (within an application) you do not need to create a type library. .

Accessing type libraries

The binary type library is normally a part of a resource file (.res) or a stand-alone file with a .tlb file-name extension. When included in a resource file, the type library can be bound into a server (.dll, .ocx, or .exe).

Once a type library has been created, object browsers, compilers, and similar tools can access type libraries through special type interfaces:

Special Type Interfaces

Interface	Description
ITypeLib	Provides methods for accessing a library of type descriptions.
ITypeLib2	Augments *ITypeLib* to include support for documentation strings, custom data, and statistics about the type library.
ITypeInfo	Provides descriptions of individual objects contained in a type library. For example, a browser uses this interface to extract information about objects from the type library.
ITypeInfo2	Augments *ITypeInfo* to access additional type library information, including methods for accessing custom data elements.
ITypeComp	Provides a fast way to access information that compilers need when binding to an interface.

Delphi can import and use type libraries from other applications by choosing Component|Import Component. Most of the VCL classes used for COM applications support the essential interfaces that are used to store and retrieve type information from type libraries and from running instances of an object. The VCL class *TTypedComObject* supports interfaces that provide type information, and is used as a foundation for the ActiveX object framework.

Benefits of using type libraries

Even if your application does not require a type library, you can consider the following benefits of using one:

- Type checking can be performed at compile time.
- You can use early binding with Automation, and controllers that do not support vtables or dual interfaces can encode dispIDs at compile time, improving runtime performance.
- Type browsers can scan the library, so clients can see the characteristics of your objects.
- The *RegisterTypeLib* function can be used to register your exposed objects in the registration database.
- The *UnRegisterTypeLib* function can be used to completely uninstall an application's type library from the system registry.
- Local server access is improved because Automation uses information from the type library to package the parameters that are passed to an object in another process.
- GenTLB.exe is a utility provided by CodeGear that generates a .tlb file from a RIDL file (an intermediate text-based file used by the Type Library Editor).

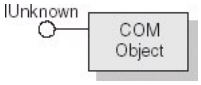
Using type library tools

The tools for working with type libraries are listed below.

- The TLIBIMP (Type Library Import) tool, which takes existing type libraries and creates Delphi Interface files (_TLB.pas files), is incorporated into the Type Library editor. TLIBIMP provides additional configuration options not available inside the Type Library editor.

- TRegSvr is a tool for registering and unregistering servers and type libraries, which comes with Delphi. The source to TRegSvr is available as an example in the Demos directory.
- The Microsoft IDL compiler (MIDL) compiles IDL scripts to create a type library.
- RegSvr32.exe is a standard Windows utility for registering and unregistering servers and type libraries.
- OLEView is a type library browser tool, found on Microsoft's Web site.

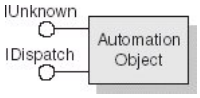
See Also



Working with Type Libraries (see page 1445)

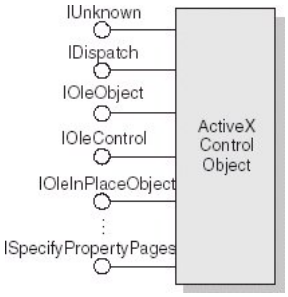
3.2.2.1.18 Implementing COM Objects with Wizards

Delphi makes it easier to write COM server applications by providing wizards that handle many of the details involved. Delphi provides separate wizards to create the following:



- A simple COM object
- An Automation object
- A COM+ Event Object
- A Type library
- An ActiveX library

The wizards handle many of the tasks involved in creating each type of COM object. They provide the required COM interfaces for each type of object. With a simple COM object, the wizard implements the one required COM interface, *IUnknown*, which provides an interface pointer to the object.

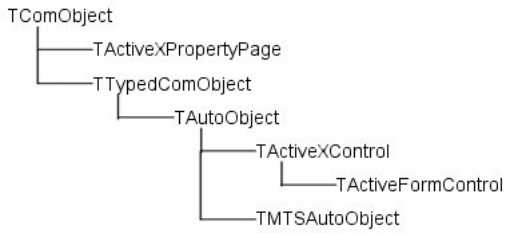


The COM object wizard also provides an implementation for *IDispatch* if you specify that you are creating an object that supports an *IDispatch* descendant.

For Automation and Active Server objects, the wizard implements *IUnknown* and *IDispatch*, which provides automatic marshaling.

For ActiveX control objects and ActiveX forms, the wizard implements all the required ActiveX control interfaces, from *IUnknown*, *IDispatch*, *IOleObject*, *IOleControl*, and so on. For a complete list of interfaces, see the reference page for TActiveXControl object.

The following table lists the various wizards and the interfaces they implement:



Delphi wizards for implementing COM, Automation, and ActiveX objects

Wizard	Implemented interfaces	What the wizard does
COM server (see page 1430)	*IUnknown* (and *IDispatch* if you select a default interface that descends from *IDispatch*)	Exports routines that handle server registration, class registration, loading and unloading the server, and object instantiation. Creates and manages class factories for objects implemented on the server. Provides registry entries for the object that specify the selected threading model. Declares the methods that implement a selected interface, providing skeletal implementations for you to complete. Provides a type library, if requested. Allows you to select an arbitrary interface that is registered in the type library and implement it. If you do this, you must use a type library.
Automation server (see page 1432)	*IUnknown*, *IDispatch*	Performs the tasks of a COM server wizard (described above), plus: Implements the interface that you specify, either dual or dispatch. Provides server-side support for generating events, if requested. Provides a type library automatically.
COM+ Event object	None, by default	Creates a COM+ event object that you can define using the Type Library editor. Unlike the other object wizards, the COM+ Event object wizard does not create an implementation unit because event objects have no implementation (it is provided by event subscriber objects).
Type Library (see page 1445)	None, by default	Creates a new type library and associates it with the active project.
ActiveX library	None, by default	Creates a new ActiveX or Com server DLL and exposes the necessary export functions.

You can add additional COM objects or reimplement an existing implementation. To add a new object, it is easiest to use the wizard a second time. This is because the wizard sets up an association between the type library and an implementation class, so that changes you make in the type library editor are automatically applied to your implementation object.

3.2.2.1.19 Code Generated by Wizards

Delphi's wizards generate classes that are derived from the Delphi ActiveX framework (DAX). Despite its name, the Delphi ActiveX framework supports all types of COM objects, not just ActiveX controls. The classes in this framework provide the underlying implementation of the standard COM interfaces for the objects you create using a wizard. The following figure illustrates the objects in the Delphi ActiveX framework:

Each wizard generates an implementation unit that implements your COM server object. The COM server object (the implementation object) descends from one of the classes in DAX:

DAX Base classes for generated implementation classes

Wizard	Base class from DAX	Inherited support
COM server (see page 1430)	TTypedComObject	Support for *IUnknown* and *ISupportErrorInfo* interfaces. Support for aggregation, OLE exception handling, and safecall calling convention on dual interfaces. Support for reading type library information.
Automation server (see page 1432) or Creating Active Server Pages (see page 1400)	TAutoObject	Everything provided by *TTypedComObject*, plus: Support for the IDispatch interface. Auto-marshaling support.

Corresponding to the classes in DAX is a hierarchy of class factory objects that handle the creation of these COM objects. The wizard adds code to the initialization section of your implementation unit that instantiates the appropriate class factory for your implementation class.

The wizards also generate a type library and its associated unit, which has a name of the form `Project1_TLB`. The `Project1_TLB` unit includes the definitions your application needs to use the type definitions and interfaces defined in the type library. For more information on the contents of this file, see Code generated when you import type library information (see page 1421).

You can modify the interface generated by the wizard using the type library editor. When you do this, the implementation class is automatically updated to reflect those changes. You need only fill in the bodies of the generated methods to complete the implementation.

3.2.2.1.20 COM+ Event And Event Subscriber Objects

The COM+ Events system introduces a middle layer of software that decouples applications that generate events (called publishers) from applications that respond to events (called subscribers). Instead of being tightly bound to each other, publishers and subscribers can be developed, deployed and activated independently of each other.

In the COM+ Events model, an event interface is first created using the COM+ Event Object wizard. The event interface has no implementation; it simply defines the event methods that publishers will generate, and that subscribers will respond to. The COM+ event object is then installed into a COM+ Application, in the COM+ Catalog. This can be done programatically using the TComAdminCatalog object, or by a system administrator using the Component Services tool.

Event subscribers are responsible for providing an implementation for the event interface. You can create event subscriber components using the COM+ Event Subscription wizard. Using the wizard, you can select the event object you want to implement, and the IDE will stub out each method of the interface. You can also select a type library if the event object has not yet been installed in the COM+ Catalog.

Finally, once the subscriber component has been implemented, it too must be installed in the COM+ Catalog. Again, this can be done with a TComAdminCatalog object, or by using the Component Services administrative tool.

When a publisher wishes to generate an event, it simply creates an instance of the event object (not the subscriber component), and calls the appropriate methods on the event interface. COM+ then steps in and notifies all applications that have subscribed to that event object, calling them synchronously, one at a time. This way, publishers need not know anything about those applications that are subscribing to the event. Subscribers don't need anything more than an implementation of the event interface, and to select those publishers they wish to subscribe to. COM+ handles the rest.

For more information regarding the COM+ Events system, see Generating events under COM+.

3.2.2.2 Creating an Active Server Page

Topics

Name	Description
Creating Active Server Pages: Overview (see page 1400)	If you are using the Microsoft Internet Information Server (IIS) environment to serve your Web pages, you can use Active Server Pages (ASP) to create dynamic Web-based client/server applications. Active Server Pages let you write a script that gets called every time the server loads the Web page. This script can, in turn, call on Automation objects (see page 1430) to obtain information that it includes in a generated HTML page. For example, you can write a Delphi Automation server, such as one to create a bitmap or connect to a database, and use this control to access data that gets updated every... more (see page 1400)
Creating an Active Server Object (see page 1401)	An Active Server Object is an Automation object that has access to information about the entire ASP application and the HTTP messages it uses to communicate with browsers. It descends from TASPObject or TASPMTSObject (which is in turn a descendant of TAutoObject), and supports Automation protocols, exposing itself for other applications (or the script in the Active Server page) to use. You create an Active Server Object using the Active Server Object wizard. Your Active Server Object project can be either an executable (exe) or library (dll), depending on your needs. However, you should be aware of the drawbacks of (see page 1405)... more (see page 1401)
Using the ASP Intrinsics (see page 1402)	The ASP intrinsics are a set of COM objects supplied by ASP to the objects running in an Active Server Page. They let your Active Server Object access information that reflects the messages passing between your application and the Web browser, as well as a place to store information that is shared among Active Server Objects that belong to the same ASP application. To make these objects easy to access, the base class for your Active Server Object surfaces them as properties. For a complete understanding of these objects, see the Microsoft documentation. However, the following topics provide a brief... more (see page 1402)
Creating ASPs for In-process or Out-of-process Servers (see page 1405)	You can use **Server.CreateObject** in an ASP page to launch either an in-process or out-of-process (see page 1389) server, depending on your requirements. However, launching in-process servers is more common. Unlike most in-process servers, an Active Server Object in an in-process server does not run in the client's process space. Instead, it runs in the IIS process space. This means that the client does not need to download your application (as, for example, it does when you use ActiveX objects). In-process component DLLs are faster and more secure than out-of-process servers, so they are better suited for server-side use. Because out-of-process servers are... more (see page 1405)
Registering an Active Server Object (see page 1405)	You can register the Active Server Page as an in-process or an out-of-process server (see page 1405). However, in-process servers are more common. **Note:** When you want to remove the Active Server Page object from your system, you should first unregister it, removing its entries from the Windows registry.
Testing and Debugging the Active Server Page Application (see page 1406)	Debugging any in-process server such as an Active Server Object is much like debugging a DLL. You choose a host application that loads the DLL, and debug as usual.

3.2.2.2.1 Creating Active Server Pages: Overview

If you are using the Microsoft Internet Information Server (IIS) environment to serve your Web pages, you can use Active Server Pages (ASP) to create dynamic Web-based client/server applications. Active Server Pages let you write a script that gets called every time the server loads the Web page. This script can, in turn, call on Automation objects (see page 1430) to obtain information that it includes in a generated HTML page. For example, you can write a Delphi Automation server, such as one to create a bitmap or connect to a database, and use this control to access data that gets updated every time the server loads the Web page.

On the client side, the ASP acts like a standard HTML document and can be viewed by users on any platform using any Web Browser.

ASP applications are analogous to applications you write using Delphi's Web broker technology. For more information about the Web broker technology, see Creating Internet server applications (see page 2251). ASP differs, however, in the way it separates the UI design from the implementation of business rules or complex application logic.

- The UI design is managed by the Active Server Page. This is essentially an HTML document, but it can include embedded script that calls on Active Server objects to supply it with content that reflects your business rules or application logic.
- The application logic is encapsulated by Active Server objects that expose simple methods to the Active Server Page, supplying it with the content it needs.

Note: Although ASP provides the advantage of separating UI design from application logic, its performance is limited in scale. For Web sites that respond to extremely large numbers of clients, an approach based on the Web broker technology is recommended instead.

The script in your Active Server Pages and the Automation objects you embed in an active server page can make use of the ASP intrinsics (see page 1402) (built-in objects that provide information about the current application, HTTP messages from the browser, and so on).

The following topics show how to create an Active Server Object using the Delphi Active Server Object wizard. This special Automation control can then be called by an Active Server Page and supply it with content.

Here are the steps for creating an Active Server Object:

- Create an Active Server Object (see page 1401) for the application.
- Define the Active Server Object's interface. (see page 1435)
- Register (see page 1405) the Active Server Object.
- Test and debug (see page 1406) the application.

Overview of COM Technologies (see page 1385)

Creating Simple COM Servers: Overview (see page 1430)

3.2.2.2.2 Creating an Active Server Object

An Active Server Object is an Automation object that has access to information about the entire ASP application and the HTTP messages it uses to communicate with browsers. It descends from TASPObject or TASPMTSObject (which is in turn a descendant of TAutoObject), and supports Automation protocols, exposing itself for other applications (or the script in the Active Server page) to use. You create an Active Server Object using the Active Server Object wizard.

Your Active Server Object project can be either an executable (exe) or library (dll), depending on your needs. However, you should be aware of the drawbacks of using an out-of-process server (see page 1405).

To display the Active Server Object wizard:

1. Choose **File** ▸ **New** ▸ **Other**.
2. Select the folder labeled ActiveX under Delphi Projects.
3. Double-click the Active Server Object icon. In the wizard, give your new Active Server Object a name, and specify the instancing (see page 1433) and threading (see page 1433) models you want to support. These details influence the way your object can be called. You must write the implementation so that it adheres to the model (for example, avoiding thread conflicts). The thing that makes an Active Server Object unique is its ability to access information about the ASP application and the HTTP messages that pass between the Active Server page and client Web browsers. This information is accessed using the ASP intrinsics (see page 1402). In the wizard, you can specify how your object accesses these by setting the Active Server Type:

- If you are working with IIS 3 or IIS 4, you use Page Level Event Methods. Under this model, your object implements the methods, OnStartPage and OnEndPage, which are called when the Active Server page loads and unloads. When your object is loaded, it automatically obtains an *IScripti*ngContext interface, which it uses to access the ASP intrinsics. These interfaces are, in turn, surfaced as properties inherited from the base class (*TASPObject*).

- If you are working with IIS5 or later, you use the Object Context type. Under this model, your object fetches an IObjectContext interface, which it uses to access the ASP intrinsics. Again, these interfaces are surfaced as properties in the inherited base class (TASPMTSObject). One advantage of this latter approach is that your object has access to all of the other services available through *IObjectContext*. To access the *IObjectContext* interface, simply call *GetObjectContext* (defined in the mtx unit) as follows: `ObjectContext := GetObjectContext;` For more information about the services available through *IObjectContext*, see Creating MTS or COM+ objects

You can tell the wizard to generate a simple ASP page to host your new Active Server Object. The generated page provides a minimal script (written in VBScript) that creates your Active Server Object based on its ProgID, and indicates where you can call its methods. This script calls **Server.CreateObject** to launch your Active Server Object.

Note: Although the generated test script uses VBScript, Active Server Pages also can be written using Jscript.

When you exit the wizard, a new unit is added to the current project that contains the definition for the Active Server Object. In addition, the wizard adds a type library project and opens the Type Library editor. Now you can expose the properties and methods of the interface through the type library as described in Defining a COM object's interface (see page 1435) As you write the implementation of your object's properties and methods, you can take advantage of the ASP intrinsics (see page 1402) to obtain information about the ASP application and the HTTP messages it uses to communicate with browsers.

The Active Server Object, like any other Automation object, implements a dual interface (see page 1438), which supports both early (compile-time) binding through the VTable and late (runtime) binding through the IDispatch interface.

3.2.2.2.3 Using the ASP Intrinsics

The ASP intrinsics are a set of COM objects supplied by ASP to the objects running in an Active Server Page. They let your Active Server Object access information that reflects the messages passing between your application and the Web browser, as well as a place to store information that is shared among Active Server Objects that belong to the same ASP application.

To make these objects easy to access, the base class for your Active Server Object surfaces them as properties. For a complete understanding of these objects, see the Microsoft documentation. However, the following topics provide a brief overview.

Application

The Application object is accessed through an *IApplicat*ionObject interface. It represents the entire ASP application, which is defined as the set of all .asp files in a virtual directory and its subdirectories. The Application object can be shared by multiple clients, so it includes locking support that you should use to prevent thread conflicts.

IApplicationObject includes the following:

IApplicationObject interface members

Property, Method, or Event	Meaning
Contents property	Lists all the objects that were added to the application using script commands. This interface has two methods, *Remove* and *RemoveAll*, that you can use to delete one or all objects from the list.
StaticObjects property	Lists all the objects that were added to the application with the <OBJECT> tag.
Lock method	Prevents other clients from locking the Application object until you call Unlock. All clients should call Lock before accessing shared memory (such as the properties).

Unlock method	Releases the lock that was set using the Lock method.
Application_OnEnd event	Occurs when the application quits, after the Session_OnEnd event. The only intrinsics available are Application and Server. The event handler must be written in VBScript or JScript.
Application_OnStart event	Occurs before the new session is created (before Session_OnStart). The only intrinsics available are Application and Server. The event handler must be written in VBScript or JScript.

Request

The Request object is accessed through an *IReque*st interface. It provides information about the HTTP request message that caused the Active Server Page to be opened.

IRequest includes the following:

IRequest interface members

Property, Method, or Event	Meaning
ClientCertificate property	Indicates the values of all fields in the client certificate that is sent with the HTTP message.
Cookies property	Indicates the values of all Cookie headers on the HTTP message.
Form property	Indicates the values of form elements in the HTTP body. These can be accessed by name.
QueryString property	Indicates the values of all variables in the query string from the HTTP header.
ServerVariables property	Indicates the values of various environment variables. These variables represent most of the common HTTP header variables.
TotalBytes property	Indicates the number of bytes in the request body. This is an upper limit on the number of bytes returned by the BinaryRead method.
BinaryRead method	Retrieves the content of a Post message. Call the method, specifying the maximum number of bytes to read. The resulting content is returns as a Variant array of bytes. After calling BinaryRead, you can't use the Form property.

Response

The Request object is accessed through an *IRe*sponse interface. It lets you specify information about the HTTP response message that is returned to the client browser.

IResponse includes the following:

IResponse interface members

Property, Method, or Event	Meaning
Cookies property	Determines the values of all Cookie headers on the HTTP message.
Buffer property	Indicates whether page output is buffered When page output is buffered, the server does not send a response to the client until all of the server scripts on the current page are processed.
CacheControl property	Determines whether proxy servers can cache the output in the response.
Charset property	Adds the name of the character set to the content type header.
ContentType property	Specifies the HTTP content type of the response message's body.
Expires property	Specifies how long the response can be cached by a browser before it expires.
ExpiresAbsolute property	Specifies the date and time when the response expires.
IsClientConnected property	Indicates whether the client has disconnected from the server.

Pics property	Set the value for the pics-label field of the response header.
Status property	Indicates the status of the response. This is the value of an HTTP status header.
AddHeader method	Adds an HTTP header with a specified name and value.
AppendToLog method	Adds a string to the end of the Web server log entry for this request.
BinaryWrite method	Writes raw (uninterpreted) information to the body of the response message.
Clear method	Erases any buffered HTML output.
End method	Stops processing the .asp file and returns the current result.
Flush method	Sends any buffered output immediately.
Redirect method	Sends a redirect response message, redirecting the client browser to a different URL.
Write method	Writes a variable to the current HTTP output as a string.

Session

The Session object is accessed through the *ISessionObject* interface. It allows you to store variables that persist for the duration of a client's interaction with the ASP application. That is, these variables are not freed when the client moves from page to page within the ASP application, but only when the client exits the application altogether.

ISessionObject includes the following:

ISessionObject interface members

Property, Method, or Event	Meaning
Contents property	Lists all the objects that were added to the session using the <OBJECT> tag. You can access any variable in the list by name, or call the Contents object's *Remove* or *RemoveAll* method to delete values.
StaticObjects property	Lists all the objects that were added to the session with the <OBJECT> tag.
CodePage property	Specifies the code page to use for symbol mapping. Different locales may use different code pages.
LCID property	Specifies the locale identifier to use for interpreting string content.
SessionID property	Indicates the session identifier for the current client.
TimeOut property	Specifies the time, in minutes, that the session persists without a request (or refresh) from the client until the application terminates.
Abandon method	Destroys the session and releases its resources.
Session_OnEnd event	Occurs when the session is abandoned or times out. The only intrinsics available are Application, Server, and Session. The event handler must be written in VBScript or JScript.
Session_OnStart event	Occurs when the server creates a new session is created (after Application_OnStart but before running the script on the Active Server Page). All intrinsics are available. The event handler must be written in VBScript or JScript.

Server

The Server object is accessed through an *IServer* interface. It provides various utilities for writing your ASP application.

IServer includes the following:

IServer interface members

Property, Method, or Event	Meaning
ScriptTimeOut property	Same as the TimeOut property on the Session object.
CreateObject method	Instantiates a specified Active Server Object.
Execute method	Executes the script in a specified .asp file.
GetLastError method	Returns an ASPError object that describes the error condition.
HTMLEncode method	Encodes a string for use in an HTML header, replacing reserved characters by the appropriate symbolic constants.
MapPath method	Maps a specified virtual path (an absolute path on the current server or a path relative to the current page) into a physical path.
Transfer method	Sends all of the current state information to another Active Server Page for processing.
URLEncode method	Applies URL encoding rules, including escape characters, to a specified string

Creating ASPs for In-process or Out-of-process Servers (see page 1405)

Defining a COM Object's Interface (see page 1435)

3.2.2.2.4 Creating ASPs for In-process or Out-of-process Servers

You can use **Server.CreateObject** in an ASP page to launch either an in-process or out-of-process (see page 1389) server, depending on your requirements. However, launching in-process servers is more common.

Unlike most in-process servers, an Active Server Object in an in-process server does not run in the client's process space. Instead, it runs in the IIS process space. This means that the client does not need to download your application (as, for example, it does when you use ActiveX objects). In-process component DLLs are faster and more secure than out-of-process servers, so they are better suited for server-side use.

Because out-of-process servers are less secure, it is common for IIS to be configured to *not* allow out-of-process executables. In this case, creating an out-of-process server for your Active Server Object would result in an error similar to the following:

```
Server object error 'ASP 0196'
Cannot launch out of process component
/path/outofprocess_exe.asp, line 11
```

Also, out-of-process components often create individual server processes for each object instance, so they are slower than CGI applications. They do not scale as well as component DLLs.

If performance and scalability are priorities for your site, in-process servers are highly recommended. However, Intranet sites that receive moderate to low traffic may use an out-of-process component without adversely affecting the site's overall performance.

See Also

Implementing COM objects with Wizards (see page 1397)

Creating Simple COM Servers: Overview (see page 1430)

3.2.2.2.5 Registering an Active Server Object

You can register the Active Server Page as an in-process or an out-of-process server (see page 1405). However, in-process servers are more common.

Note: When you want to remove the Active Server Page object from your system, you should first unregister it, removing its entries from the Windows registry.

Registering an in-process server

To register an in-process server (DLL or OCX), choose **Run ▶ Register ActiveX Server**.

To unregister an in-process server, choose **Run ▶ Unregister ActiveX Server**.

Registering an out-of-process server

To register an out-of-process server, run the server with the /regserver command-line option. You can also register the server by running it.

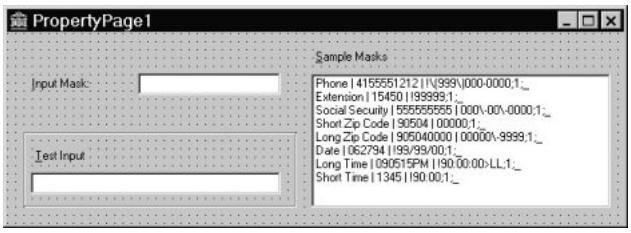
To unregister an out-of-process server, run the server with the /unregserver command-line option.

3.2.2.2.6 Testing and Debugging the Active Server Page Application

Debugging any in-process server such as an Active Server Object is much like debugging a DLL. You choose a host application that loads the DLL, and debug as usual.

To test and debug an Active Server Object,

1. Turn on debugging information using the Compiler tab on the **Project ▶ Options** dialog box, if necessary. Also, turn on Integrated Debugging in the **Tools ▶ Options ▶ Debugger Options** dialog.
2. Choose **Run ▶ Parameters**, type the name of your Web Server in the Host Application box, and choose OK.
3. Choose **Run ▶ Run**.
4. Set breakpoints in the Active Server Object implementation.
5. Use the Web browser to interact with the Active Server Page.



The debugger pauses when the breakpoints are reached.

3.2.2.3 Using ActiveX controls

Topics

Name	Description
Elements of an ActiveX Control (see page 1408)	An ActiveX control involves many elements which each perform a specific function. The elements include a VCL control, a corresponding COM object wrapper that exposes properties, methods, and events, and one or more associated type libraries.
Designing an ActiveX Control (see page 1409)	When designing an ActiveX control, you start by creating a custom VCL control. This forms the basis of your ActiveX control. For information on creating custom controls, see Creating custom components (see page 1313). When designing the VCL control, keep in mind that it will be embedded in another application; this control is not an application in itself. For this reason, you probably do not want to use elaborate dialog boxes or other major user-interface components. Your goal is typically to make a simple control that works inside of, and follows the rules of the main application. In addition, you should make... more (see page 1409)
Generating an ActiveX Control Based On a VCL Form (see page 1410)	Unlike other ActiveX controls, Active Forms are not first designed and then wrapped by an ActiveX wrapper class. Instead, the ActiveForm wizard generates a blank form that you design later when the wizard leaves you in the Form Designer. When an ActiveForm is deployed on the Web, Delphi creates an HTML page to contain the reference to the ActiveForm and specify its location on the page. The ActiveForm can then displayed and run from a Web browser. Inside the browser, the form behaves just like a stand-alone Delphi form. The form can contain any VCL components or ActiveX controls,... more (see page 1410)

Licensing ActiveX Controls (see page 1410)	Licensing an ActiveX control consists of providing a license key at design-time and supporting the creation of licenses dynamically for controls created at runtime. To provide design-time licenses, a key is created for the control , which is stored in a file with the same name as the project with the LIC extension. This `.LIC` file is added to the project. The user of the control must have a copy of the `.LIC` file to open the control in a development environment. Each control in the project that has Make Control Licensed checked has a separate key entry in... more (see page 1410)
Customizing the ActiveX Control's Interface (see page 1411)	You can add, edit, and remove the properties, methods, and events in an ActiveX control by editing the type library. You can use the Type Library editor as described in Using the Type Library Editor (see page 1453). Remember that when you add events, they should be added to the Events interface, not the ActiveX control's default interface. **Note:** You can add unpublished properties to your ActiveX control's interface. Such properties can be set at runtime and will appear in a development environment, but changes made to them will not persist. That is, when the user of the control changes the value... more (see page 1411)
Adding Additional Properties, Methods, and Events (see page 1412)	You can add additional properties, methods, and events to the control using the type library editor. The declaration is automatically added to the control's implementation unit, type library (TLB) file, and type library unit. The specifics of what Delphi supplies depends on whether you have added a property or method (see page 1412) or whether you have added an event (see page 1413).
How Delphi Adds Properties (see page 1412)	The ActiveX wrapper class implements properties in its interface using read and write access methods. That is, the wrapper class has COM properties, which appear on an interface as getter and/or setter methods. Unlike VCL properties, you do not see a "property" declaration on the interface for COM properties. Rather, you see methods that are flagged as property access methods. When you add a property to the ActiveX control's default interface, the wrapper class definition (which appears in the _TLB unit that is updated by the Type Library editor) gains one or two new methods (a getter and/or setter) that... more (see page 1412)
How Delphi Adds Events (see page 1413)	The ActiveX control can fire events to its container in the same way that an automation object fires events to clients. This mechanism is described in Managing events in your Automation object (see page 1437). If the VCL control you are using as the basis of your ActiveX control has any published events, the wizards automatically add the necessary support for managing a list of client event sinks to your ActiveX wrapper class and define the outgoing dispinterface that clients must implement to respond to events. You add events to this outgoing dispinterface. To add an event in the type library editor,... more (see page 1413)
Enabling Simple Data Binding with the Type Library (see page 1414)	With simple data binding, you can bind a property of your ActiveX control to a field in a database. To do this, the ActiveX control must communicate with its host application about what value represents field data and when it changes. You enable this communication by setting the property's binding flags using the Type Library editor. By marking a property bindable, when a user modifies the property (such as a field in a database), the control notifies its container (the client host application) that the value has changed and requests that the database record be updated. The container interacts with... more (see page 1414)
Creating a Property Page for an ActiveX Control (see page 1415)	A property page is a dialog box similar to the Delphi **Object Inspector** in which users can change the properties of an ActiveX control. A property page dialog allows you to group many properties for a control together to be edited at once. Or, you can provide a dialog box for more complex properties. Typically, users access the property page by right-clicking the ActiveX control and choosing Properties.
Creating a New Property Page (see page 1416)	You use the Property Page wizard to create a new property page.

Adding Controls to a Property Page (see page 1416)	You must add a control to the property page for each property of the ActiveX control that you want the user to access. For example, the following illustration shows a property page for setting the MaskEdit property of an ActiveX control.  The list box allows the user to select from a list of sample masks. The edit controls allow the user to test the mask before applying it to the ActiveX control. You add controls to the property page the same as you would to a form.
Associating Property Page Controls with ActiveX Control Properties (see page 1416)	After adding the controls you need to the property page, you must associate each control with its corresponding property. You make this association by adding code to the property page's UpdatePropertyPage (see page 1416) and UpdateObject (see page 1417) methods.
Updating the Property Page (see page 1416)	Add code to the *UpdatePropertyPage* method to update the control on the property page when the properties of the ActiveX control change. You must add code to the *UpdatePropertyPage* method to update the property page with the current values of the ActiveX control's properties. You can access the ActiveX control using the property page's OleObject property, which is an *OleVariant* that contains the ActiveX control's interface. For example, the following code updates the property page's edit control (InputMask) with the current value of the ActiveX control's *EditMask* property:
Updating the Object (see page 1417)	Add code to the *UpdateObject* method to update the property when the user changes the controls on the property page. You must add code to the *UpdateObject* method in order to set the properties of the ActiveX control to their new values. You use the OleObject property to access the ActiveX control. For example, the following code sets the *EditMask* property of the ActiveX control using the value in the property page's edit box control (InputMask):
Connecting a Property Page to an ActiveX Control (see page 1417)	Describes the steps in connecting an ActiveX control to a property page. **To connect a property page to an ActiveX control:** 1. Add DefinePropertyPage with the GUID constant of the property page as the parameter to the DefinePropertyPages method implementation in the control's implementation for the unit. For example, `procedure TButtonX.DefinePropertyPages(DefinePropertyPage: TDefinePropertyPage); begin DefinePropertyPage(Class_PropertyPage1); >end; BEGIN_PROPERTY_MAP(TActiveFormXImpl) // Define property pages here. Property pages are defined using // the PROP_PAGE macro with the class id of the page. For example, // PROP_PAGE(CLSID_ActiveFormXPage) PROP_PAGE(CLSID_PropertyPage1) END_PROPERTY_MAP()` The GUID constant, Class_PropertyPage1, of the property page can be found in the property pages unit. The GUID... more (see page 1417)

3.2.2.3.1 Elements of an ActiveX Control

An ActiveX control involves many elements which each perform a specific function. The elements include a VCL control, a corresponding COM object wrapper that exposes properties, methods, and events, and one or more associated type libraries.

VCL control

The underlying implementation of an ActiveX control in Delphi is a VCL control. When you create an ActiveX control, you must first design or choose the VCL control from which you will make your ActiveX control.

The underlying VCL control must be a descendant of *TWinControl*, because it must have a window that can be parented by the host application. When you create an Active form, this object is a descendant of TActiveForm.

Note: The ActiveX control wizard lists the available *TWinControl* descendants from which you can choose to make an ActiveX control. This list does not include all *TWinControl* descendants, however. Some controls, such as *THeaderControl*, are registered as incompatible with ActiveX (using the RegisterNonActiveXprocedure procedure) and do not appear in the list.

ActiveX wrapper

The actual COM object is an ActiveX wrapper object for the VCL control. For Active forms, this class is always TActiveFormControl. For other ActiveX controls, it has a name of the form *TVCLClass*X, where *TVCLClass* is the name of the VCL control class. Thus, for example, the ActiveX wrapper for *TButton* would be named *TButtonX*.

The wrapper class is a descendant of TActiveXControl, which provides support for the ActiveX interfaces. The ActiveX wrapper inherits this support, which allows it to forward Windows messages to the VCL control and parent its window in the host application.

The ActiveX wrapper exposes the VCL control's properties and methods to clients via its default interface. You must implement the wrapper class' properties and methods, delegating method calls to the underlying VCL control. You must also provide the wrapper class with methods that fire the VCL control's events on clients and assign these methods as event handlers on the VCL control.

Type library

You must generate a type library for your ActiveX control that contains the type definitions for the wrapper class, its default interface, and any type definitions that these require. This type information provides a way for your control to advertise its services to host applications. You can view and edit this information using the Type Library editor. Although this information is stored in a separate, binary type library file (.TLB extension), you may also compile it into the ActiveX control DLL as a resource.

Property page

You can optionally give your ActiveX control a property page. The property page allows the user of a host (client) application to view and edit your control's properties. You can group several properties on a page, or use a page to provide a dialog-like interface for a property. For information on how to create property pages, see Creating a property page for an ActiveX control (see page 1415).

3.2.2.3.2 Designing an ActiveX Control

When designing an ActiveX control, you start by creating a custom VCL control. This forms the basis of your ActiveX control. For information on creating custom controls, see Creating custom components (see page 1313).

When designing the VCL control, keep in mind that it will be embedded in another application; this control is not an application in itself. For this reason, you probably do not want to use elaborate dialog boxes or other major user-interface components. Your goal is typically to make a simple control that works inside of, and follows the rules of the main application.

In addition, you should make sure that the types for all properties and methods you want your object to expose to clients are Automation-compatible (see page 1454), because the ActiveX control's interface must support *IDispatch*. The wizards do not add any methods to the wrapper class's interface that have parameters that are not Automation-compatible.

The wizards implement all the necessary ActiveX interfaces required using the COM wrapper class. They also surface all Automation-compatible properties, methods, and events through the wrapper class's default interface. Once a wizard has generated the COM wrapper class and its interface, you can use the Type Library editor (see page 1446) to modify the default interface or augment the wrapper class by implementing additional interfaces.

See Also

Overview of Component Creation (see page 1313)

Elements of an ActiveX Control (see page 1408)

3.2.2.3.3 Generating an ActiveX Control Based On a VCL Form

Unlike other ActiveX controls, Active Forms are not first designed and then wrapped by an ActiveX wrapper class. Instead, the ActiveForm wizard generates a blank form that you design later when the wizard leaves you in the Form Designer.

When an ActiveForm is deployed on the Web, Delphi creates an HTML page to contain the reference to the ActiveForm and specify its location on the page. The ActiveForm can then displayed and run from a Web browser. Inside the browser, the form behaves just like a stand-alone Delphi form. The form can contain any VCL components or ActiveX controls, including custom-built VCL controls.

To start the ActiveForm wizard,

1. Choose **File** ▸ **New** ▸ **Other** to open the New Items dialog box.
2. Select the tab labeled ActiveX.
3. Double-click the ActiveForm icon.

On the Active Form wizard, you can't specify the name of the VCL class to wrap. This is because Active forms are always based on TActiveForm.

You can change the default names for the CoClass, implementation unit, and ActiveX library project. Similarly, this wizard lets you indicate whether you want your Active Form to require a license, whether it should include version information, and whether you want an About box form.

When you exit the wizard, it generates the following:

- An ActiveX Library project file, which contains the code required to start an ActiveX control. You usually don't change this file.
- A type library, which defines and CoClass for your control, the interface it exposes to clients, and any type definitions that these require. For more information about the type library, see Working with type libraries (see page 1445).
- A form that descends from TActiveForm. This form appears in the form designer, where you can use it to visually design the Active Form that appears to clients. Its implementation appears in the generated implementation unit. In the initialization section of the implementation unit, a class factory is created, setting up TActiveFormControl as the ActiveX wrapper for this form.
- An About box form and unit if you requested them.
- A .LIC file if you enabled licensing.

At this point, you can add controls and design the form as you like.

After you have designed and compiled the ActiveForm project into an ActiveX library (which has the OCX extension), you can deploy the project to your Web server and Delphi creates a test HTML page with a reference to the ActiveForm.

Elements of an ActiveX Control (see page 1408)

Implementing COM objects with Wizards (see page 1397)

Code Generated by Wizards (see page 1398)

3.2.2.3.4 Licensing ActiveX Controls

Licensing an ActiveX control consists of providing a license key at design-time and supporting the creation of licenses dynamically for controls created at runtime.

To provide design-time licenses, a key is created for the control , which is stored in a file with the same name as the project with the LIC extension. This `.LIC` file is added to the project. The user of the control must have a copy of the `.LIC` file to open the control in a development environment. Each control in the project that has Make Control Licensed checked has a separate key entry in the `.LIC` file.

To support runtime licenses, the wrapper class implements two methods, *GetLicenseString* and *GetLicenseFilename*. These return the license string for the control and the name of the `.LIC` file, respectively. When a host application tries to create the ActiveX control, the class factory for the control calls these methods and compares the string returned by *GetLicenseString* with the string stored in the `.LIC` file.

Runtime licenses for the Internet Explorer require an extra level of indirection because users can view HTML source code for any Web page, and because an ActiveX control is copied to the user's computer before it is displayed. To create runtime licenses for controls used in Internet Explorer, you must first generate a license package file (LPK file) and embed this file in the HTML page that contains the control. The LPK file is essentially an array of ActiveX control CLSIDs and license keys.

Note: To generate the LPK file, use the utility, LPK_TOOL.EXE, which you can download from the Microsoft Web site (www.microsoft.com).

To embed the LPK file in a Web page, use the HTML objects, <OBJECT> and <PARAM> as follows:

```
<OBJECT CLASSID="clsid:6980CB99-f75D-84cf-B254-55CA55A69452">
<PARAM NAME="LPKPath" VALUE="ctrllic.lpk">
</OBJECT>
```

The CLSID identifies the object as a license package and PARAM specifies the relative location of the license package file with respect to the HTML page.

When Internet Explorer tries to display the Web page containing the control, it parses the LPK file, extracts the license key, and if the license key matches the control's license (returned by *GetLicenseString*), it renders the control on the page. If more than one LPK is included in a Web page, Internet Explorer ignores all but the first.

For more information, look for Licensing ActiveX Controls on the Microsoft Web site.

3.2.2.3.5 Customizing the ActiveX Control's Interface

You can add, edit, and remove the properties, methods, and events in an ActiveX control by editing the type library. You can use the Type Library editor as described in Using the Type Library Editor (see page 1453). Remember that when you add events, they should be added to the Events interface, not the ActiveX control's default interface.

Note: You can add unpublished properties to your ActiveX control's interface. Such properties can be set at runtime and will appear in a development environment, but changes made to them will not persist. That is, when the user of the control changes the value of a property at design time, the changes are not reflected when the control is run. If the source is a VCL object and the property is not already published, you can make properties persistent by creating a descendant of the VCL object and publishing the property in the descendant.

You may also choose not to expose all of the VCL control's properties, methods, and events to host applications. You can use the Type Library editor to remove these from the interfaces that the wizard generated. When you remove properties and methods from an interface using the Type Library editor, the Type Library editor does not remove them from the corresponding implementation class. Edit the ActiveX wrapper class in the implementation unit to remove these after you have changed the interface in the Type Library editor.

Warning: Any changes you make to the type library will be lost if you regenerate the ActiveX control from the original VCL control or form.

Tip: It is a good idea to check the methods that the wizard adds to your ActiveX wrapper class. Not only does this give you a chance to note where the wizard omitted any data-aware properties or methods that were not Automation-compatible, it also lets you detect methods for which the wizard could not generate an implementation. Such methods appear with a comment in the

implementation that indicates the problem.

See Also

Generating an ActiveX Control Based On a VCL Form (see page 1410)

3.2.2.3.6 Adding Additional Properties, Methods, and Events

You can add additional properties, methods, and events to the control using the type library editor. The declaration is automatically added to the control's implementation unit, type library (TLB) file, and type library unit. The specifics of what Delphi supplies depends on whether you have added a property or method (see page 1412) or whether you have added an event (see page 1413).

See Also

Customizing the ActiveX Control's Interface (see page 1411)

3.2.2.3.7 How Delphi Adds Properties

The ActiveX wrapper class implements properties in its interface using read and write access methods. That is, the wrapper class has COM properties, which appear on an interface as getter and/or setter methods. Unlike VCL properties, you do not see a "property" declaration on the interface for COM properties. Rather, you see methods that are flagged as property access methods. When you add a property to the ActiveX control's default interface, the wrapper class definition (which appears in the _TLB unit that is updated by the Type Library editor) gains one or two new methods (a getter and/or setter) that you must implement, just as when you add a method to the interface, the wrapper class gains a corresponding method for you to implement. Thus, adding properties to the wrapper class's interface is essentially the same as adding methods: the wrapper class definition gains new skeletal method implementations for you to complete.

Note: For details on what appears in the generated _TLB unit, see Code generated when you import type library information (see page 1421).

For example, consider a *Caption* property, of type TCaption in the underlying VCL object. To Add this property to the object's interface, you enter the following when you add a property to the interface via the type library editor:

```
property Caption: TCaption read Get_Caption write Set_Caption;
```

Delphi adds the following declarations to the wrapper class:

```
function Get_Caption: WideString; safecall;
procedure Set_Caption(const Value: WideString); safecall;
STDMETHOD(get_Caption(BSTR* Value));
STDMETHOD(set_Caption(BSTR Value));
```

In addition, it adds skeletal method implementations for you to complete:

```
function TButtonX.Get_Caption: WideString;
begin
end;
procedure TButtonX.Set_Caption(Value: WideString);
begin
end;
STDMETHODIMP TButtonXImpl::get_Caption(BSTR* Value)
{
  try
  {
  }
  catch(Exception &e)
  {
    return Error(e.Message.c_str(), IID_IButtonX);
  }
  return S_OK;
```

```
};
STDMETHODIMP TButtonXImpl::set_Caption(BSTR Value)
{
  try
  {
  }
  catch(Exception &e)
  {
    return Error(e.Message.c_str(), IID_IButtonX);
  }
  return S_OK;
};
```

Typically, you can implement these methods by simply delegating to the associated VCL control, which can be accessed using the *FDelphiControl* member of the wrapper class:

```
function TButtonX.Get_Caption: WideString;
begin
   Result := WideString(FDelphiControl.Caption);
end;

procedure TButtonX.Set_Caption(const Value: WideString);
begin
   FDelphiControl.Caption := TCaption(Value);
end;
STDMETHODIMP TButtonXImpl::get_Caption(BSTR* Value)
{
try
{
*Value = WideString(m_VclCtl->Caption).Copy();
}
catch(Exception &e)
{
return Error(e.Message.c_str(), IID_IButtonX);
}
return S_OK;
};
STDMETHODIMP TButtonXImpl::set_Caption(BSTR Value)
{
  try
  {
    m_VclCtl->Caption = AnsiString(Value);
  }
  catch(Exception &e)
  {
    return Error(e.Message.c_str(), IID_IButtonX);
  }
  return S_OK;
};
```

In some cases, you may need to add code to convert the COM data types to native Delphi types. The preceding example manages this with typecasting.

Note: Because the Automation interface methods are declared**safecall, you do not have to implement COM exception code for these methods—the Delphi compiler handles this for you by generating code around the body of safecall methods to catch Delphi exceptions and to convert them into COM error info structures and return codes.**

Code Generated When You Import Type Library Information (see page 1421)

3.2.2.3.8 How Delphi Adds Events

The ActiveX control can fire events to its container in the same way that an automation object fires events to clients. This

mechanism is described in Managing events in your Automation object (see page 1437).

If the VCL control you are using as the basis of your ActiveX control has any published events, the wizards automatically add the necessary support for managing a list of client event sinks to your ActiveX wrapper class and define the outgoing dispinterface that clients must implement to respond to events.

You add events to this outgoing dispinterface. To add an event in the type library editor, select the event interface and click on the method icon. Then manually add the list of parameters you want include using the parameter page.

Next, you must declare a method in your wrapper class that is of the same type as the event handler for the event in the underlying VCL control. This is not generated automatically, because Delphi does not know which event handler you are using:

```
procedure KeyPressEvent(Sender: TObject; var Key: Char);
```

Implement this method to use the host application's event sink, which is stored in the wrapper class's *FEvents* member:

```
procedure TButtonX.KeyPressEvent(Sender: TObject; var Key: Char);
var
  TempKey: Smallint;
begin
    TempKey := Smallint(Key); {cast to an OleAutomation compatible type }
    if FEvents <> nil then
      FEvents.OnKeyPress(TempKey)
    Key := Char(TempKey);
  end;
void __fastcall TButtonXImpl::KeyPressEvent(TObject *Sender, char &Key)
{
short TempKey;
TempKey = (short)Key;
Fire_OnKeyPress(&TempKey);
Key = (short)TempKey;
};
```

Note: When firing events in an ActiveX control, you do not need to iterate through a list of event sinks because the control only has a single host application. This is simpler than the process for most Automation servers.

Finally, you must assign this event handler to the underlying VCL control, so that it is called when the event occurs. You make this assignment in the *InitializeControl* method:

```
procedure TButtonX.InitializeControl;
begin
  FDelphiControl := Control as TButton;
  FDelphiControl.OnClick := ClickEvent;
  FDelphiControl.OnKeyPress := KeyPressEvent;
end;
void InitializeControl()
{
  m_VclCtl->OnClick = ClickEvent;
  m_VclCtl->OnKeyPress = KeyPressEvent;
}
```

3.2.2.3.9 Enabling Simple Data Binding with the Type Library

With simple data binding, you can bind a property of your ActiveX control to a field in a database. To do this, the ActiveX control must communicate with its host application about what value represents field data and when it changes. You enable this communication by setting the property's binding flags using the Type Library editor.

By marking a property bindable, when a user modifies the property (such as a field in a database), the control notifies its container (the client host application) that the value has changed and requests that the database record be updated. The

container interacts with the database and then notifies the control whether it succeeded or failed to update the record.

Note: The container application that hosts your ActiveX control is responsible for connecting the data-aware properties you enable in the type library to the database.

Use the type library to enable simple data binding,

1. On the toolbar, click the property that you want to bind.
2. Choose the flags page.
3. Select the following binding attributes:

Binding attribute	Description
Bindable	Indicates that the property supports data binding. If marked bindable, the property notifies its container when the property value has changed.
Request Edit	Indicates that the property supports the OnRequestEdit notification. This allows the control to ask the container if its value can be edited by the user.
Display Bindable	Indicates that the container can show users that this property is bindable.
Default Bindable	Indicates the single, bindable property that best represents the object. Properties that have the default bind attribute must also have the bindable attribute. Cannot be specified on more than one property in a dispinterface.
Immediate Bindable	Allows individual bindable properties on a form to specify this behavior. When this bit is set, all changes will be notified. The bindable and request edit attribute bits need to be set for this new bit to have an effect.

4. Click the Refresh button on the toolbar to update the type library. To test a data-binding control, you must register it first. For example, to convert a *TEdit* control into a data-bound ActiveX control, create the ActiveX control from a *TEdit* and then change the Text property flags to Bindable, Display Bindable, Default Bindable, and Immediate Bindable. After the control is registered and imported, it can be used to display data.

Working with Type Libraries: Overview (see page 1445)

3.2.2.3.10 Creating a Property Page for an ActiveX Control

A property page is a dialog box similar to the Delphi **Object Inspector** in which users can change the properties of an ActiveX control. A property page dialog allows you to group many properties for a control together to be edited at once. Or, you can provide a dialog box for more complex properties.

Typically, users access the property page by right-clicking the ActiveX control and choosing Properties.

The process of creating a property page is similar to creating a form, you

1. Create a new property page (see page 1416).
2. Add controls to the property page (see page 1416).
3. Associate the controls the property page with the properties of an ActiveX control (see page 1416).
4. Connect the property page to the ActiveX control (see page 1417).

   Note: When adding properties to an ActiveX control or ActiveForm, you must publish the properties that you want to persist. If they are not published in the underlying VCL control, you must make a custom descendant of the VCL control that redeclares the properties as published and then create an ActiveX control from the descendant class.

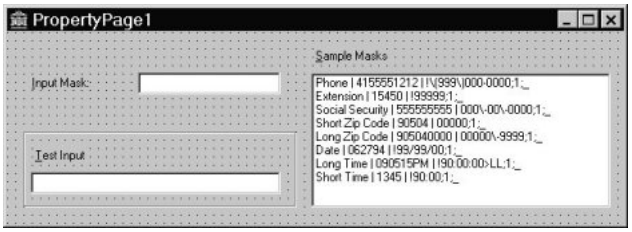
3.2.2.3.11 Creating a New Property Page

You use the Property Page wizard to create a new property page.

To create a new property page,

1. Choose **File** ▶ **New** ▶ **Other**.
2. Select the ActiveX folder under Delphi Projects .
3. Double-click the Property Page icon in the right pane.

The wizard creates a new form and implementation unit for the property page. The form is a descendant of TPropertyPage, which lets you associate the form with the ActiveX control whose properties it edits.



See Also

Creating a Property Page for an ActiveX Control (see page 1415)

3.2.2.3.12 Adding Controls to a Property Page

You must add a control to the property page for each property of the ActiveX control that you want the user to access.

For example, the following illustration shows a property page for setting the MaskEdit property of an ActiveX control.

The list box allows the user to select from a list of sample masks. The edit controls allow the user to test the mask before applying it to the ActiveX control. You add controls to the property page the same as you would to a form.

See Also

Creating a Property Page for an ActiveX Control (see page 1415)

3.2.2.3.13 Associating Property Page Controls with ActiveX Control Properties

After adding the controls you need to the property page, you must associate each control with its corresponding property. You make this association by adding code to the property page's UpdatePropertyPage (see page 1416) and UpdateObject (see page 1417) methods.

See Also

Creating a Property Page for an ActiveX Control (see page 1415)

3.2.2.3.14 Updating the Property Page

Add code to the *UpdatePropertyPage* method to update the control on the property page when the properties of the ActiveX control change. You must add code to the *UpdatePropertyPage* method to update the property page with the current values of the ActiveX control's properties.

You can access the ActiveX control using the property page's OleObject property, which is an *OleVariant* that contains the ActiveX control's interface.

For example, the following code updates the property page's edit control (InputMask) with the current value of the ActiveX control's *EditMask* property:

```
procedure TPropertyPage1.UpdatePropertyPage;
begin
   { Update your controls from OleObject }
   InputMask.Text := OleObject.EditMask;
end;
```

For example, the following code updates the property page's edit control (InputMask) with tthe current value of the ActiveX control's EditMask property:

```
void __fastcall TPropertyPage1::UpdatePropertyPage(void)
{
InputMask->Text = OleObject.OlePropertyGet("EditMask");
}
```

Note: It is also possible to write a property page that represents more than one ActiveX control. In this case, you don't use the *OleObject* property. Instead, you must iterate through a list of interfaces that is maintained by the *OleObjects* property.

See Also

Creating a Property Page for an ActiveX Control (see page 1415)

3.2.2.3.15 Updating the Object

Add code to the *UpdateObject* method to update the property when the user changes the controls on the property page. You must add code to the *UpdateObject* method in order to set the properties of the ActiveX control to their new values.

You use the OleObject property to access the ActiveX control.

For example, the following code sets the *EditMask* property of the ActiveX control using the value in the property page's edit box control (InputMask):

```
procedure TPropertyPage1.UpdateObject;
begin
   {Update OleObject from your control }
   OleObject.EditMask := InputMask.Text;
end;
void __fastcall TPropertyPage1::UpdateObject(void)
{
  // Update OleObject from your control
  OleObject.OlePropertySet<WideString>("EditMask", WideString(InputMast->Text).Copy());
}
```

Creating a Property Page for an ActiveX Control (see page 1415)

3.2.2.3.16 Connecting a Property Page to an ActiveX Control

Describes the steps in connecting an ActiveX control to a property page.

To connect a property page to an ActiveX control:

1. Add DefinePropertyPage with the GUID constant of the property page as the parameter to the DefinePropertyPages method implementation in the control's implementation for the unit. For example, `procedure TButtonX.DefinePropertyPages(DefinePropertyPage: TDefinePropertyPage); begin DefinePropertyPage(Class_PropertyPage1); >end; BEGIN_PROPERTY_MAP(TActiveFormXImpl) // Define property pages here. Property pages are defined using // the PROP_PAGE macro with the class id of the page. For example, // PROP_PAGE(CLSID_ActiveFormXPage) PROP_PAGE(CLSID_PropertyPage1) END_PROPERTY_MAP()` The GUID constant, Class_PropertyPage1, of the property page can be found in the property pages unit. The GUID is defined in the property page's implementation unit .

2. Add the property page unit to the **uses** clause of the controls implementation unit.

Creating a Property Page for an ActiveX Control (see page 1415)

3.2.2.4 Creating COM clients

Topics

Name	Description
Creating COM Clients (see page 1419)	COM clients are applications that make use of a COM object implemented by another application or library. The most common types are applications that control an Automation server (see page 1430) (Automation controllers) and applications that host an ActiveX control (ActiveX containers). At first glance these two types of COM client are very different: The typical Automation controller launches an external server EXE and issues commands to make that server perform tasks on its behalf. The Automation server is usually nonvisual and out-of-process. The typical ActiveX client, on the other hand, hosts a visual control, using it much the same way you use... more (see page 1419)
Importing Type Library Information (see page 1420)	To make information about the COM server available to your client application, you must import the information about the server that is stored in the server's type library (see page 1395). Your application can then use the resulting generated classes to control the server object. There are two ways to import type library information: • You can use the **Import Component dialog** to import all available information about the server types, objects, and interfaces. This is the most general method, because it lets you import information from any type library and can optionally generate component wrappers for all creatable CoClasses in the type... more (see page 1420)
Code Generated When You Import Type Library Information (see page 1421)	Once you import a type library, you can view the generated *TypeLibName*_TLB unit. At the top, you will find the following: First, constant declarations giving symbolic names to the GUIDS of the type library and its interfaces and CoClasses. The names for these constants are generated as follows: • the GUID for the type library has the form LBID_*TypeLibName*, where *TypeLibName* is the name of the type library. • The GUID for an interface has the form IID_*InterfaceName*, where *InterfaceName* is the name of the interface. • The GUID for a dispinterface has the form DIID_*InterfaceName*,... more (see page 1421)
Controlling an Imported Object (see page 1422)	After importing type library information (see page 1420), you are ready to start programming with the imported objects. How you proceed depends in part on the objects, and in part on whether you have chosen to create component wrappers. There are two basic approaches: • Using component wrappers (see page 1422). • Writing client code based on type library definitions (see page 1423).

Using Component Wrappers (see page 1422)	If you generated a component wrapper for your server object, writing your COM client application is not very different from writing any other application that contains VCL components. The server object's properties, methods, and events are already encapsulated in the VCL component. You need only assign event handlers, set property values, and call methods. To use the properties, methods, and events of the server object, see the documentation for your server. The component wrapper automatically provides a dual interface (see page 1438) where possible. Delphi determines the VTable layout from information in the type library. In addition, your new component inherits certain important... more (see page 1422)
Writing Client Code Based On Type Library Definitions (see page 1423)	Although you must use a component wrapper for hosting an ActiveX control, you can write an Automation controller using only the definitions from the type library that appear in the *TypeLibName*_TLB unit. This process is a bit more involved that letting a component do the work, especially if you need to respond to events. The following topics describe how to implement the various actions your Automation controller needs to perform: • Connect to the server (see page 1424). • Control the Automation server using a dual interface (see page 1424). • Control the Automation server using a dispinterface (see page 1424). • Respond to events generated by the Automation (see page 1425)... more (see page 1423)
Connecting to a Server (see page 1424)	Before you can drive an Automation server from your controller application, you must obtain a reference to an interface it supports. Typically, you connect to a server through its main interface. If the main interface is a dual interface (see page 1438), you can use the creator objects in the *TypeLibName*_TLB.pas file. The creator classes have the same name as the CoClass, with the prefix "Co" added. You can connect to a server on the same machine by calling the *Create* method, or a server on a remote machine using the *CreateRemote* method. Because *Create* and *CreateRemote* are class methods, you... more (see page 1424)
Controlling an Automation Server Using a Dual Interface (see page 1424)	After using the automatically generated creator class to connect to the server (see page 1424), you call methods of the interface. For example,
Controlling an Automation Server Using a Dispatch Interface (see page 1424)	Typically, you use the dual interface (see page 1424) to control the Automation server. However, you may find a need to control an Automation server with a dispatch interface (see page 1438) because no dual interface is available.
Handling Events in an Automation Controller (see page 1425)	When you generate a Component wrapper for an object whose type library you import, you can respond to events simply using the events that are added to the generated component. If you do not use a Component wrapper, however, (or if the server uses COM+ events), you must write the event sink code yourself.
Creating Clients for Servers That Do Not Have a Type Library (see page 1426)	Some older COM technologies, such as object linking and embedding (OLE), do not provide type information in a type library. Instead, they rely on a standard set of predefined interfaces. To write clients that host such objects, you can use the TOleContainer component. This component appears on the System category of the **Tool Palette.** *TOleContainer* acts as a host site for an Ole2 object. It implements the *IOleClientSite* interface and, optionally, *IOleDocumentSite*. Communication is handled using OLE verbs.

3.2.2.4.1 Creating COM Clients

COM clients are applications that make use of a COM object implemented by another application or library. The most common types are applications that control an Automation server (see page 1430) (Automation controllers) and applications that host an ActiveX control (ActiveX containers).

At first glance these two types of COM client are very different: The typical Automation controller launches an external server EXE and issues commands to make that server perform tasks on its behalf. The Automation server is usually nonvisual and out-of-process. The typical ActiveX client, on the other hand, hosts a visual control, using it much the same way you use any control on the Component palette. ActiveX servers are always in-process servers.

However, the task of writing these two types of COM client is remarkably similar: The client application obtains an interface for the server object and uses its properties and methods. RAD Studio makes this particularly easy by letting you wrap the server CoClass in a component on the client, which you can even install on the Component palette.

When writing a COM client, you must understand the interface that the server exposes to clients, just as you must understand the properties and methods of a component from the Component palette to use it in your application. This interface (or set of interfaces) is determined by the server application, and typically published in a type library (see page 1445). For specific information on a particular server application's published interfaces, you should consult that application's documentation.

Even if you do not choose to wrap a server object in a component wrapper and install it on the Component palette, you must make its interface definition available to your application. To do this, you can import the server's type information (see page 1420).

Once you have imported the type information, you can write code to control the imported object (see page 1422).

Note: You can also query the type information directly using COM APIs, but RAD Studio provides no special support for this.

Some older COM technologies, such as object linking and embedding (OLE), do not provide type information in a type library. Instead, they rely on a standard set of predefined interfaces. These are discussed in Creating Clients for Servers That Do Not Have a Type Library (see page 1426).

See Also

Creating Active Server Pages (see page 1400)

Working with Type Libraries: Overview (see page 1445)

Overview of COM Technologies (see page 1385)

3.2.2.4.2 Importing Type Library Information

To make information about the COM server available to your client application, you must import the information about the server that is stored in the server's type library (see page 1395). Your application can then use the resulting generated classes to control the server object.

There are two ways to import type library information:

- You can use the **Import Component dialog** to import all available information about the server types, objects, and interfaces. This is the most general method, because it lets you import information from any type library and can optionally generate component wrappers for all creatable CoClasses in the type library that are not flagged as Hidden, Restricted, or PreDeclID.
- You can also use the **Import Component dialog** if you are importing from the type library of an ActiveX control. This imports the same type information, but only creates component wrappers for CoClasses that represent ActiveX controls.
- You can use the command line utility tlibimp.exe which provides additional configuration options not available from within the IDE.
- A type library generated using a wizard is automatically imported using the same mechanism as the import type library menu item.

Regardless of which method you choose to import type library information, the resulting dialog creates a unit with the name *TypeLibName*_TLB, where *TypeLibName* is the name of the type library. This file contains declarations for the classes, types, and interfaces defined in the type library. By including it in your project, those definitions are available to your application so that you can create objects and call their interfaces. This file may be recreated by the IDE from time to time; as a result, making manual changes to the file is not recommended.

In addition to adding type definitions to the *TypeLibName*_TLB unit, the dialog can also create VCL class wrappers for any CoClasses defined in the type library. When you use the Import Type Library dialog, these wrappers are optional. When you use the Import ActiveX dialog, they are always generated for all CoClasses that represent controls.

The generated class wrappers represent the CoClasses to your application, and expose the properties and methods of its interfaces. If a CoClass supports the interfaces for generating events (*IConnectionPointContainer* and *IConnectionPoint*), the VCL class wrapper creates an event sink so that you can assign event handlers for the events as simply as you can for any

other component. If you tell the dialog to install the generated VCL classes on the **Tool Palette**, you can use the **Object Inspector** to assign property values and event handlers.

Note: The Import Component dialog

does not create class wrappers for COM+ event objects. To write a client that responds to events generated by a COM+ event object, you must create the event sink programmatically. This process is described in Handling COM+ events (see page 1425). For more details about the code generated when you import a type library, see Code generated when you import type library information (see page 1421).

See Also

Working with Type Libraries (see page 1445)

Controlling an Imported Object (see page 1422)

3.2.2.4.3 Code Generated When You Import Type Library Information

Once you import a type library, you can view the generated *TypeLibName*_TLB unit. At the top, you will find the following:

First, constant declarations giving symbolic names to the GUIDS of the type library and its interfaces and CoClasses. The names for these constants are generated as follows:

- the GUID for the type library has the form LBID_*TypeLibName*, where *TypeLibName* is the name of the type library.
- The GUID for an interface has the form IID_*InterfaceName*, where *InterfaceName* is the name of the interface.
- The GUID for a dispinterface has the form DIID_*InterfaceName*, where *InterfaceName* is the name of the dispinterface.
- The GUID for a CoClass has the form CLASS_*ClassName*, where *ClassName* is the name of the CoClass.
- The compiler directive VARPROPSETTER will be on. This allows the use of the keyword var in the parameter list of property setter methods. This disables a compiler optimization that would cause parameters to be passed by value instead of by reference. The VARPROPSETTER directive must be on, when creating TLB units for components written in a language other than Delphi.

Second, declarations for the CoClasses in the type library. These map each CoClass to its default interface.

Third, declarations for the interfaces and dispinterfaces in the type library.

Fourth, declarations for a creator class for each CoClass whose default interface supports VTable binding. The creator class has two class methods, *Create* and *CreateRemote*, that can be used to instantiate the CoClass locally (*Create*) or remotely (*CreateRemote*).These methods return the default interface for the CoClass.

These declarations provide you with what you need to create instances of the CoClass and access its interface. All you need do is add the generated *TypeLibName*_TLB.pas file to the uses clause of the unit where you wish to bind to a CoClass and call its interfaces.

Note: This portion of the *TypeLibName*_TLB unit is also generated when you use the Type Library editor or the command-line utility TLIBIMP.

If you want to use an ActiveX control, you also need the generated VCL wrapper in addition to the declarations described above. The VCL wrapper handles window management issues for the control. You may also have generated a VCL wrapper for other CoClasses in the Import Type Library dialog. These VCL wrappers simplify the task of creating server objects and calling their methods. They are especially recommended if you want your client application to respond to events.

The declarations for generated VCL wrappers appear at the bottom of the interface section. Component wrappers for ActiveX controls are descendants of TOleControl. Component wrappers for Automation objects descend from TOleServer. The generated component wrapper adds the properties, events, and methods exposed by the CoClass's interface. You can use this component like any other VCL component.

Warning: You should not edit the generated *TypeLibName*_TLB unit. It is regenerated each time the type library is refreshed, so any changes will be overwritten.

Note: For the most up-to-date information about the generated code, refer to the comments in the automatically-generated *TypeLibName*_TLB unit.

3.2.2.4.4 Controlling an Imported Object

After importing type library information (see page 1420), you are ready to start programming with the imported objects. How you proceed depends in part on the objects, and in part on whether you have chosen to create component wrappers. There are two basic approaches:

- Using component wrappers (see page 1422).
- Writing client code based on type library definitions (see page 1423).

See Also

Importing Type Library Information (see page 1420)

3.2.2.4.5 Using Component Wrappers

If you generated a component wrapper for your server object, writing your COM client application is not very different from writing any other application that contains VCL components. The server object's properties, methods, and events are already encapsulated in the VCL component. You need only assign event handlers, set property values, and call methods.

To use the properties, methods, and events of the server object, see the documentation for your server. The component wrapper automatically provides a dual interface (see page 1438) where possible. Delphi determines the VTable layout from information in the type library.

In addition, your new component inherits certain important properties and methods from its base class.

ActiveX wrappers

You should always use a component wrapper when hosting ActiveX controls, because the component wrapper integrates the control's window into the VCL framework.

The properties and methods an ActiveX control inherits from TOleControl allow you to access the underlying interface or obtain information about the control. Most applications, however, do not need to use these. Instead, you use the imported control the same way you would use any other VCL control.

Typically, ActiveX controls provide a property page that lets you set their properties. Property pages are similar to the component editors some components display when you double-click on them in the form designer. To display an ActiveX control's property page, right click and choose Properties.

The way you use most imported ActiveX controls is determined by the server application. However, ActiveX controls use a standard set of notifications when they represent the data from a database field. See TOleControl for information on how to host such ActiveX controls.

Automation object wrappers

The wrappers for Automation objects let you control how you want to form the connection to your server object:

First, the ConnectKind property indicates whether the server is local or remote and whether you want to connect to a server that is already running or if a new instance should be launched. When connecting to a remote server, you must specify the machine name using the RemoteMachineName property.

Second, once you have specified the *ConnectKind*, there are three ways you can connect your component to the server:

- you can explicitly connect to the server by calling the component's Connect method.
- You can tell the component to connect automatically when your application starts up by setting the AutoConnect property to *true*.
- You do not need to explicitly connect to the server. The component automatically forms a connection when you use one of the server's properties or methods using the component.

Calling methods or accessing properties is the same as using any other component:

```
TServerComponent1.DoSomething;
TServerComponent1->DoSomething();
```

Handling events is easy, because you can use the **Object Inspector** to write event handlers. Note, however, that the event handler on your component may have slightly different parameters than those defined for the event in the type library. Specifically, pointer types (var parameters and interface pointers) are changed to Variants. You must explicitly cast var parameters to the underlying type before assigning a value. Interface pointers can be cast to the appropriate interface type using the **as** operator.

For example, the following code shows an event handler for the ExcelApplication event, OnNewWorkBook. The event handler has a parameter that provides the interface of another CoClass (ExcelWorkbook). However, the interface is not passed as an ExcelWorkbook interface pointer, but rather as an OleVariant.

```
procedure TForm1.XLappNewWorkbook(Sender: TObject; var Wb:OleVariant);
begin
  { Note how the OleVariant for the interface must be cast to the correct type }
  ExcelWorkbook1.ConnectTo((iUnknown(wb) as ExcelWorkbook));
end;
void _fastcall TForm1::XLappNewWorkbook(TObject *Sender, ExcelWorkbookPtr Wb)
{
ExcelWorkbook1->ConnectTo(Wb);
}
```

In this example, the event handler assigns the workbook to an ExcelWorkbook component (ExcelWorkbook1). This demonstrates how to connect a component wrapper to an existing interface by using the *ConnectTo* method. The *ConnectTo* method is added to the generated code for the component wrapper.

Servers that have an application object expose a Quit method on that object to let clients terminate the connection. Quit typically exposes functionality that is equivalent to using the File menu to quit the application. Code to call the Quit method is generated in your component's Disconnect method. If it is possible to call the Quit method with no parameters, the component wrapper also has an *AutoQuit* property. *AutoQuit* causes your controller to call Quit when the component is freed. If you want to disconnect at some other time, or if the Quit method requires parameters, you must call it explicitly. Quit appears as a public method on the generated component.

Creating Clients for Servers That Do Not Have a Type Library (see page 1426)

3.2.2.4.6 Writing Client Code Based On Type Library Definitions

Although you must use a component wrapper for hosting an ActiveX control, you can write an Automation controller using only the definitions from the type library that appear in the *TypeLibName*_TLB unit. This process is a bit more involved that letting a component do the work, especially if you need to respond to events.

The following topics describe how to implement the various actions your Automation controller needs to perform:

- Connect to the server (see page 1424).
- Control the Automation server using a dual interface (see page 1424).
- Control the Automation server using a dispinterface (see page 1424).
- Respond to events generated by the Automation server (see page 1425).

See Also

Using Component Wrappers (see page 1422)

Creating Clients for Servers That Do Not Have a Type Library (see page 1426)

3.2.2.4.7 Connecting to a Server

Before you can drive an Automation server from your controller application, you must obtain a reference to an interface it supports. Typically, you connect to a server through its main interface.

If the main interface is a dual interface (see page 1438), you can use the creator objects in the *TypeLibName*_TLB.pas file. The creator classes have the same name as the CoClass, with the prefix "Co" added. You can connect to a server on the same machine by calling the *Create* method, or a server on a remote machine using the *CreateRemote* method. Because *Create* and *CreateRemote* are class methods, you do not need an instance of the creator class to call them.

```
MyInterface := CoServerClassName.Create;
MyInterface := CoServerClassName.CreateRemote('Machine1');
pInterface = CoServerClassName.Create();
pInterface = CoServerClassName.CreateRemote("Machine1");
```

Create and *CreateRemote* return the default interface for the CoClass.

If the default interface is a dispatch interface, then there is no Creator class generated for the CoClass. Instead, you can call the global CreateOleObject function, passing in the GUID for the CoClass (there is a constant for this GUID defined at the top of the _TLB unit). *CreateOleObject* returns an IDispatch pointer for the default interface.

Controlling an Automation Server Using a Dispatch Interface (see page 1424)

Controlling an Automation Server Using a Dual Interface (see page 1424)

Handling Events in an Automation Controller (see page 1425)

3.2.2.4.8 Controlling an Automation Server Using a Dual Interface

After using the automatically generated creator class to connect to the server (see page 1424), you call methods of the interface. For example,

```
var
  MyInterface : _Application;
begin
  MyInterface := CoWordApplication.Create;
  MyInterface.DoSomething;
TComApplication AppPtr = CoWordApplication_.Create();
AppPtr->DoSomething;
```

The interface and creator class are defined in the *TypeLibName*_TLB unit that is generated automatically when you import a type library.

See Also

Controlling an Automation Server Using a Dispatch Interface (see page 1424)

3.2.2.4.9 Controlling an Automation Server Using a Dispatch Interface

Typically, you use the dual interface (see page 1424) to control the Automation server. However, you may find a need to control an Automation server with a dispatch interface (see page 1438) because no dual interface is available.

To call the methods of a dispatch interface,

1. Connect to the server (see page 1424), using the global CreateOleObject function.
2. Use the **as** operator to cast the *IDispatch* interface returned by *CreateOleObject* to the dispinterface for the CoClass. This dispinterface type is declared in the *TypeLibName*_TLB unit.

3. Control the Automation server by calling methods of the dispinterface. Another way to use dispatch interfaces is to assign them to a *Variant*. By assigning the interface returned by *CreateOleObject* to a *Variant*, you can take advantage of the *Variant* type's built-in support for interfaces. Simply call the methods of the interface, and the *Variant* automatically handles all *IDispatch* calls, fetching the dispatch ID and invoking the appropriate method. The Variant type includes built-in support for calling dispatch interfaces, through its **var.**

```
  V: Variant;
begin
V:= CreateOleObject("TheServerObject");
V.MethodName; { calls the specified method }
...
```

An advantage of using *Variants* is that you do not need to import the type library, because *Variants* use only the standard *IDispatch* methods to call the server. The trade-off is that *Variants* are slower, because they use dynamic binding at runtime.

See Also

Controlling an Automation Server Using a Dual Interface (see page 1424)

3.2.2.4.10 Handling Events in an Automation Controller

When you generate a Component wrapper for an object whose type library you import, you can respond to events simply using the events that are added to the generated component. If you do not use a Component wrapper, however, (or if the server uses COM+ events), you must write the event sink code yourself.

Handling Automation events programmatically

Before you can handle events, you must define an event sink. This is a class that implements the event dispatch interface that is defined in the server's type library.

To write the event sink, create an object that implements the event dispatch interface:

```
TServerEventsSink = class(TObject, _TheServerEvents)
...{ declare the methods of _TheServerEvents here }
end;
class MyEventSinkClass: TEventDispatcher<MyEventSinkClass, DIID_TheServerEvents>
{
...// declare the methods of DIID_TheServerEvents here
}
```

Once you have an instance of your event sink, you must inform the server object of its existence so that the server can call it. To do this, you call the global InterfaceConnect procedure, passing it

- The interface to the server that generates events.
- The GUID for the event interface that your event sink handles.
- An IUnknown interface for your event sink.
- A variable that receives a Longint that represents the connection between the server and your event sink.

```
{MyInterface is the server interface you got when you connected to the server }
InterfaceConnect(MyInterface, DIID_TheServerEvents,
                 MyEventSinkObject as IUnknown, cookievar);
pInterface = CoServerClassName.CreateRemote("Machine1");
MyEventSinkClass ES;
ES.ConnectEvents(pInterface);
```

After calling *InterfaceConnect*, your event sink is connected and receives calls from the server when events occur.

You must terminate the connection before you free your event sink. To do this, call the global InterfaceDisconnect procedure, passing it all the same parameters except for the interface to your event sink (and the final parameter is ingoing rather than outgoing):

```
InterfaceDisconnect(MyInterface, DIID_TheServerEvents, cookievar);
ES.DisconnectEvents(pInterface);
```

Note: You must be certain that the server has released its connection to your event sink before you free it. Because you don't know how the server responds to the disconnect notification initiated by *InterfaceDisconnect*, this may lead to a race condition if you free your event sink immediately after the call. The easiest way to guard against problems is to have your event sink maintain its own reference count that is not decremented until the server releases the event sink's interface.

Handling COM+ events

Under COM+, servers use a special helper object to generate events rather than a set of special interfaces (*IConnectionPointContainer* and *IConnectionPoint*). Because of this, you can't use an event sink that descends from *TEventDispatcher. TEventDispatcher* is designed to work with those interfaces, not COM+ event objects.

Instead of defining an event sink, your client application defines a subscriber object. Subscriber objects, like event sinks, provide the implementation of the event interface. They differ from event sinks in that they subscribe to a particular event object rather than connecting to a server's connection point.

To define a subscriber object, use the COM Object wizard (see page 1431), selecting the event object's interface as the one you want to implement. The wizard generates an implementation unit with skeletal methods that you can fill in to create your event handlers.

Note: You may need to add the event object's interface to the registry using the wizard if it does not appear in the list of interfaces you can implement.

Once you create the subscriber object, you must subscribe to the event object's interface or to individual methods (events) on that interface. There are three types of subscriptions from which you can choose:

- **Transient subscriptions.** Like traditional event sinks, transient subscriptions are tied to the lifetime of an object instance. When the subscriber object is freed, the subscription ends and COM+ no longer forwards events to it.
- **Persistent subscriptions**. These are tied to the object class rather than a specific object instance. When the event occurs, COM locates or launches an instance of the subscriber object and calls its event handler. In-process objects (DLLs) use this type of subscription.
- **Per-user subscriptions**. These subscriptions provide a more secure version of transient subscriptions. Both the subscriber object and the server object that fires events must be running under the same user account on the same machine.

  Note: Objects that subscribe to COM+ events must be installed in a COM+ application.

3.2.2.4.11 Creating Clients for Servers That Do Not Have a Type Library

Some older COM technologies, such as object linking and embedding (OLE), do not provide type information in a type library. Instead, they rely on a standard set of predefined interfaces. To write clients that host such objects, you can use the TOleContainer component. This component appears on the System category of the **Tool Palette.**

TOleContainer acts as a host site for an Ole2 object. It implements the *IOleClientSite* interface and, optionally, *IOleDocumentSite*. Communication is handled using OLE verbs.

To use TOleContainer

1. Place a *TOleContainer* component on your form.
2. Set the *AllowActiveDoc* property to *true* if you want to host an Active document.
3. Set the *AllowInPlace* property to indicate whether the hosted object should appear in the *TOleContainer*, or in a separate window.
4. Write event handlers to respond when the object is activated, deactivated, moved, or resized.

5. To bind the *TOleContainer* object at design time, right click and choose Insert Object. In the Insert Object dialog, choose a server object to host.
6. To bind the *TOleContainer* object at runtime, you have several methods to choose from, depending on how you want to identify the server object. These include CreateObject, which takes a program id, CreateObjectFromFile, which takes the name of a file to which the object has been saved, CreateObjectFromInfo, which takes a record containing information on how to create the object, or CreateLinkToFile, which takes the name of a file to which the object was saved and links to it rather than embeds it.
7. Once the object is bound, you can access its interface using the OleObjectInterface property. However, because communication with Ole2 objects was based on OLE verbs, you will most likely want to send commands to the server using the DoVerb method.
8. When you want to release the server object, call the DestroyObject method.

Writing Client Code Based On Type Library Definitions (see page 1423)

3.2.2.5 Creating simple COM servers

Topics

Name	Description
Creating Simple COM Servers: Overview (see page 1430)	Delphi provides wizards to help you create various COM objects. The simplest COM objects are servers that expose properties and methods (and possibly events) through a default interface that clients can call. Two wizards, in particular, ease the process of creating simple COM objects: • The COM Object wizard (see page 1431) builds a lightweight COM object whose default interface descends from IUnknown (see page 1387) or that implements an interface already registered on your system. This wizard provides the most flexibility in the types of COM objects you can create. • The Automation Object wizard (see page 1432) creates a simple Automation object whose default interface descends from IDispatch (see page 1438).... more (see page 1430)
Designing a COM Object (see page 1430)	When designing the COM object, you need to decide what COM interfaces you want to implement. You can write a COM object to implement an interface that has already been defined, or you can define a new interface for your object to implement. In addition, you can have your object support more than one interface. For information about standard COM interfaces that you might want to support, see the MSDN documentation. • To create a COM object that implements an existing interface, use the COM Object wizard (see page 1431). • To create a COM object that implements a new interface that you define,... more (see page 1430)

Using the COM Object Wizard (see page 1431)	The COM object wizard performs the following tasks: • Creates a new unit. • Defines a new class that descends from TCOMObject and sets up the class factory constructor. For more information on the base class, see Code generated by wizards (see page 1398). • Adds a type library to your project and adds your object and its interface to the type library. • Opens the type library in the Type Library Editor Before you create a COM object, create or open the project for the application containing functionality that you want to implement. The project can be either an application or ActiveX library, depending on... more (see page 1431)
Using the Automation Object Wizard (see page 1432)	The Automation object wizard performs the following tasks: • Creates a new unit. • Defines a new class that descends from TAutoObject and sets up the class factory constructor. For more information on the base class, see Code generated by wizards (see page 1398). • Adds a type library to your project and adds your object and its interface to the type library. Before you create an Automation object, create or open the project for an application containing functionality that you want to expose. The project can be either an application or ActiveX library, depending on your needs.
COM Object Instancing Types (see page 1433)	Many of the COM wizards require you to specify an instancing mode for the object. Instancing determines how many instances of your object clients can create in a single executable. If you specify a Single Instance model, for example, then once a client has instantiated your object, COM removes the application from view so that other clients must launch their own instances of the application. Because this affects the visibility of your application as a whole, the instancing mode must be consistent across all objects in your application that can be instantiated by clients. That is, you should not create... more (see page 1433)
Choosing a Threading Model (see page 1433)	When creating an object using a wizard, you select a threading model that your object agrees to support. By adding thread support to your COM object, you can improve its performance, because multiple clients can access your application at the same time. The following table lists the different threading models you can specify. ***Threading models for COM objects***
Defining a COM Object's Interface (see page 1435)	When you use a wizard to create a COM object, the wizard automatically generates a type library (unless you specify otherwise in the COM object wizard). The type library provides a way for host applications to find out what the object can do. It also lets you define your object's interface using the Type Library editor (see page 1446). The interfaces you define in the Type Library editor define what properties, methods, and events your object exposes to clients. **Note:** If you selected an existing interface in the COM object wizard, you do not need to add properties and methods. The definition... more (see page 1435)
Managing Events in Your Automation Object (see page 1437)	The Automation wizard automatically generates event code if you check the option, Generate Support Code in the Automation Object wizard dialog box. For a server to support traditional COM events, it must provide the definition of an outgoing interface which is implemented by a client. This outgoing interface includes all the event handlers the client must implement to respond to server events. When a client has implemented the outgoing event interface, it registers its interest in receiving event notification by querying the server's *IConnectionPointContainer* interface. The *IConnectionPointContainer* interface returns the server's *IConnectionPoint* interface, which the client then uses to pass... more (see page 1437)

Automation Interfaces (see page 1438)	The **Automation Object** wizard implements a dual interface (see page 1438) by default, which means that the Automation object supports both • Late binding at runtime, which is through the *IDispatch* interface. This is implemented as a dispatch interface, or dispinterface (see page 1438). • Early binding at compile-time, which is accomplished through directly calling one of the member functions in the object's virtual function table (VTable). This is referred to as a custom interface (see page 1439). **Note:** Any interfaces generated by the COM Object wizard that do not descend from *IDispatch* only support VTable calls.
Dual Interfaces (see page 1438)	A dual interface is a custom interface and a dispinterface at the same time. It is implemented as a COM VTable interface that derives from *IDispatch. For* those controllers that can access the object only at runtime, the dispinterface is available. For objects that can take advantage of compile-time binding, the more efficient VTable interface is used. Dual interfaces offer the following combined advantages of VTable interfaces and dispinterfaces: • For VTable interfaces, the compiler performs type checking and provides more informative error messages. • For Automation controllers that cannot obtain type information, the dispinterface provides runtime access to the object. • For... more (see page 1438)
Dispatch Interfaces (see page 1438)	*Automation controllers are clients that use the COM IDispatch interface to access the COM server objects. The controller must first create the object, then query the object's IUnknown interface for a pointer to its IDispatch interface. IDispatch keeps track of methods and properties internally by a dispatch identifier (dispID), which is a unique identification number for an interface member. Through IDispatch, a controller retrieves the object's type information for the dispatch interface and then maps interface member names to specific dispIDs. These dispIDs are available at runtime, and controllers get them by calling the IDispatch method,GetIDsOfNames.* *Once... more (see page 1438)*
Custom Interfaces (see page 1439)	Custom interfaces are user-defined interfaces that allow clients to invoke interface methods based on their order in the VTable and knowledge of the argument types. The VTable lists the addresses of all the properties and methods that are members of the object, including the member functions of the interfaces that it supports. If the object does not support *IDispatch*, the entries for the members of the object's custom interfaces immediately follow the members of *IUnknown*. If the object has a type library, you can access the custom interface through its VTable layout, which you can get using the... more (see page 1439)
Marshaling Data (see page 1439)	For out-of-process and remote servers, you must consider how COM marshals data outside the current process. You can provide marshaling: • Automatically, using the *IDispatch* interface. • Automatically, by creating a type library with your server and marking the interface with the OLE Automation flag. COM knows how to marshal all the **Automation-compatible** types in the type library and can set up the proxies and stubs for you. Some type restrictions apply to enable automatic marshaling. • Manually by implementing all the methods of the *IMarshal* interface. This is called **custom marshaling**. **Note:** The first method (using *IDispatch*) is only available... more (see page 1439)

Registering a COM Object (see page 1440)	You can register your server object as an in-process or an out-of-process server. For more information on the server types, see In-process (see page 1389). **Note:** Before you remove a COM object from your system, you should unregister it.
Testing and Debugging the Application (see page 1440)	Once you have created a COM server application, you will want to test it before you deploy it.

3.2.2.5.1 Creating Simple COM Servers: Overview

Delphi provides wizards to help you create various COM objects. The simplest COM objects are servers that expose properties and methods (and possibly events) through a default interface that clients can call.

Two wizards, in particular, ease the process of creating simple COM objects:

- The COM Object wizard (see page 1431) builds a lightweight COM object whose default interface descends from IUnknown (see page 1387) or that implements an interface already registered on your system. This wizard provides the most flexibility in the types of COM objects you can create.
- The Automation Object wizard (see page 1432) creates a simple Automation object whose default interface descends from IDispatch (see page 1438). *IDispatch* introduces a standard marshaling mechanism and support for late binding of interface calls.

  Note: COM defines many standard interfaces and mechanisms for handling specific situations. The Delphi wizards automate the most common tasks. However, some tasks, such as custom marshaling, are not supported by any Delphi wizards. For information on that and other technologies not explicitly supported by Delphi, refer to the Microsoft Developer's Network (MSDN) documentation. The Microsoft Web site also provides current information on COM support.

Overview of creating a COM object

Whether you use the **Automation Object wizard** to create a new Automation server or the COM object wizard to create some other type of COM object, the process you follow is the same.

It involves these steps:

1. Design (see page 1430) the COM object.
2. Use the COM Object wizard (see page 1431) or the Automation Object wizard (see page 1432) to create the server object.
3. Define the interface (see page 1435) that the object exposes to clients.
4. Register the COM object (see page 1440).
5. Test and debug (see page 1440) the application.

See Also

Overview of COM Technologies (see page 1385)

Creating Active Server Pages (see page 1400)

3.2.2.5.2 Designing a COM Object

When designing the COM object, you need to decide what COM interfaces you want to implement. You can write a COM object to implement an interface that has already been defined, or you can define a new interface for your object to implement. In addition, you can have your object support more than one interface. For information about standard COM interfaces that you might want to support, see the MSDN documentation.

- To create a COM object that implements an existing interface, use the COM Object wizard (see page 1431).
- To create a COM object that implements a new interface that you define, use either the COM Object wizard (see page 1431) or the Automation Object wizard (see page 1432). The COM object wizard can generate a new default interface that descends from IUnknown (see page 1387), and the Automation object gives your object a default interface that descends from IDispatch (see page 1438). No matter which wizard you use, you can always use the Type Library editor later to

change the parent interface of the default interface that the wizard generates.

In addition to deciding what interfaces to support, you must decide whether the COM object is an in-process server (see page 1389). For in-process servers and for out-of-process and remote servers that use a type library, COM marshals the data for you. Otherwise, you must consider how to marshal the data to out-of-process servers.

3.2.2.5.3 Using the COM Object Wizard

The COM object wizard performs the following tasks:

- Creates a new unit.
- Defines a new class that descends from TCOMObject and sets up the class factory constructor. For more information on the base class, see Code generated by wizards (see page 1398).
- Adds a type library to your project and adds your object and its interface to the type library.
- Opens the type library in the Type Library Editor

Before you create a COM object, create or open the project for the application containing functionality that you want to implement. The project can be either an application or ActiveX library, depending on your needs.

To bring up the COM object wizard

1. Choose **File** ▶ **New** ▶ **Other** to open the New Items dialog box.
2. Select the folder labeled **ActiveX** under **Delphi Projects**
3. Double-click the COM object icon in the right pane.

In the wizard, you must specify the following:

- **CoClass name:** This is the name of the object as it appears to clients. The class created to implement your object has this name with a 'T' prepended. If you do not choose to implement an existing interface, the wizard gives your CoClass a default interface that has this name with an 'I' prepended.
- Instancing (see page 1433): Unless you are creating an in-process server, you need to indicate how COM launches the application that houses your COM object. If your application implements more than one COM object, you should specify the same instancing for all of them.
- Threading Model (see page 1433): Typically, client requests to your object enter on different threads of execution. You can specify how COM serializes these threads when it calls your object. Your choice of threading model determines how the object is registered. You are responsible for providing any threading support implied by the model you choose. For information on how to provide thread support to your application, see Writing multi-threaded applications
- **Interface:** The wizard gives your object a default interface that descends from IUnknown (see page 1387). By default, the wizard gives your interface the same name as the CoClass, preceded by “I” to indicate interface. After exiting the wizard, you can then use the Type Library editor to add properties and methods to this interface. However, you can also select a pre-defined interface for your object to implement. Click the **[...]** button in the COM object wizard to bring up the Interface Selection wizard, where you can select any dual or custom interface (see page 1438) defined in a type library registered on your system. The interface you select becomes the default interface for your new CoClass. The wizard adds all the methods on this interface to the generated implementation class, so that you only need to fill in the bodies of the methods in the implementation unit. Note that if you select an existing interface, the interface is not added to your project's type library. This means that when deploying your object, you must also deploy the type library that defines the interface.
- Include Type Library (see page 1395): You can choose whether you want to include a type library for your object. This is recommended for two reasons: it lets you use the Type Library editor to define interfaces, thereby updating much of the implementation, and it gives clients an easy way to obtain information about your object and its interfaces. If you are implementing an existing interface, Delphi requires your project to use a type library. This is the only way to provide access to the original interface declaration.
- Mark interface Oleautomation (see page 1439): If you have opted to create a type library and are willing to confine yourself to Automation-compatible types, you can let COM handle the marshaling for you when you are not generating an in-process server. By marking your object's interface as OleAutomation in the type library, you enable COM to set up the proxies and stubs for you and handles passing parameters across process boundaries. You can only specify whether your interface is Automation-compatible if you are generating a new interface. If you select an existing interface, its attributes are already

specified in its type library. If your object's interface is not marked as OleAutomation, you must either create an in-process server or write your own marshaling code.

You can optionally add a description of your COM object. This description appears in the type library for your object if you create one.

See Also

Implementing COM objects with Wizards (see page 1397)

Designing a COM Object (see page 1430)

Defining a COM Object's Interface (see page 1435)

Registering a COM Object (see page 1440)

3.2.2.5.4 Using the Automation Object Wizard

The Automation object wizard performs the following tasks:

- Creates a new unit.
- Defines a new class that descends from TAutoObject and sets up the class factory constructor. For more information on the base class, see Code generated by wizards (see page 1398).
- Adds a type library to your project and adds your object and its interface to the type library.

Before you create an Automation object, create or open the project for an application containing functionality that you want to expose. The project can be either an application or ActiveX library, depending on your needs.

To display the Automation wizard:

1. Choose **File** ▶ **New** ▶ **Other** to open the New Items dialog box.
2. Select the folder labeled **ActiveX** under **Delphi Projects**.
3. Double-click the **Automation Object** icon in the right pane.
4. In the wizard dialog, specify the following:

- **CoClass name:** This is the name of the object as it appears to clients. Your object's default interface is created with a name based on this CoClass name with an 'I' prepended, and the class created to implement your object has this name with a 'T' prepended.
- Instancing (see page 1433): Unless you are creating an in-process server, you need to indicate how COM launches the application that houses your COM object. If your application implements more than one COM object, you should specify the same instancing for all of them.
- Threading Model (see page 1433): Typically, client requests to your object enter on different threads of execution. You can specify how COM serializes these threads when it calls your object. Your choice of threading model determines how the object is registered. You are responsible for providing any threading support implied by the model you choose. For information on how to provide thread support to your application, see Writing multi-threaded applications.
- Generate Event support code (see page 1437): You must indicate whether you want your object to generate events to which clients can respond. The wizard can provide support for the interfaces required to generate events and the dispatching of calls to client event handlers.

The Automation object implements a dual interface (see page 1438), which supports both early (compile-time) binding through the VTable and late (runtime) binding through the IDispatch interface.

Defining a COM Object's Interface (see page 1435)

Registering a COM Object (see page 1440)

Using the COM Object Wizard (see page 1431)

3.2.2.5.5 COM Object Instancing Types

Many of the COM wizards require you to specify an instancing mode for the object. Instancing determines how many instances of your object clients can create in a single executable. If you specify a Single Instance model, for example, then once a client has instantiated your object, COM removes the application from view so that other clients must launch their own instances of the application. Because this affects the visibility of your application as a whole, the instancing mode must be consistent across all objects in your application that can be instantiated by clients. That is, you should not create one object in your application that uses Single Instance mode and another in the same application that uses Multiple Instance mode.

Note: Instancing is ignored when your COM object is used only as an in-process server.

When the wizard creates a new COM object, it can have any of the following instancing types:

Instancing	Meaning
Internal	The object can only be created internally. An external application cannot create an instance of the object directly, although your application can create the object and pass an interface for it to clients.
Single Instance	Allows clients to create only a single instance of the object for each executable (application), so creating multiple instances results in launching multiple instances of the application. Each client has its own dedicated instance of the server application.
Multiple Instances	Specifies that multiple clients can create instances of the object in the same process space.

3.2.2.5.6 Choosing a Threading Model

When creating an object using a wizard, you select a threading model that your object agrees to support. By adding thread support to your COM object, you can improve its performance, because multiple clients can access your application at the same time.

The following table lists the different threading models you can specify.

Threading models for COM objects

Threading model	Description	Implementation pros and cons
Single	The server provides no thread support. COM serializes client requests so that the application receives one request at a time.	Clients are handled one at a time so no threading support is needed. No performance benefit.
Apartment (or Single-threaded apartment)	COM ensures that only one client thread can call the object at a time. All client calls use the thread in which the object was created.	Objects can safely access their own instance data, but global data must be protected using critical sections or some other form of serialization. The thread's local variables are reliable across multiple calls. Some performance benefits.
Free (also called multi-threaded apartment)	Objects can receive calls on any number of threads at any time.	Objects must protect all instance and global data using critical sections or some other form of serialization. Thread local variables are not reliable across multiple calls.

Both	This is the same as the Free-threaded model except that outgoing calls (for example, callbacks) are guaranteed to execute in the same thread.	Maximum performance and flexibility. Does not require the application to provide thread support for parameters supplied to outgoing calls.
Neutral	Multiple clients can call the object on different threads at the same time, but COM ensures that no two calls conflict.	You must guard against thread conflicts involving global data and any instance data that is accessed by multiple methods. This model should not be used with objects that have a user interface (visual controls). This model is only available under COM+. Under COM, it is mapped to the Apartment model.

Note: Local variables (except those in callbacks) are always safe, regardless of the threading model. This is because local variables are stored on the stack and each thread has its own stack. Local variables may not be safe in callbacks when using free-threading.

The threading model you choose in the wizard determines how the object is registered in the system Registry. You must make sure that your object implementation adheres to the threading model you have chosen. For general information on writing thread-safe code, see Writing multi-threaded applications.

For in-process servers, setting the threading model in the wizard sets the threading model key in the CLSID registry entry.

Out-of-process servers are registered as EXE, and Delphi initializes COM for the highest threading model required. For example, if an EXE includes a free-threaded object, it is initialized for free threading, which means that it can provide the expected support for any free-threaded or apartment-threaded objects contained in the EXE. To manually override threading behavior in EXEs, use the CoInitFlags variable.

Writing an object that supports the free threading model

Use the free threading (or both) model rather than apartment threading whenever the object needs to be accessed from more than one thread. A common example is a client application connected to an object on a remote machine. When the remote client calls a method on that object, the server receives the call on a thread from the thread pool on the server machine. This receiving thread makes the call locally to the actual object; and, because the object supports the free threading model, the thread can make a direct call into the object.

If the object supported the apartment threading model instead, the call would have to be transferred to the thread on which the object was created, and the result would have to be transferred back into the receiving thread before returning to the client. This approach requires extra marshaling.

To support free threading, you must consider how instance data can be accessed for *each* method. If the method is writing to instance data, you must use critical sections or some other form of serialization, to protect the instance data. Likely, the overhead of serializing critical calls is less than executing COM's marshaling code.

Note that if the instance data is read-only, serialization is not needed.

Free-threaded in-process servers can improve performance by acting as the outer object in an aggregation (see page 1391) with the free-threaded marshaler. The free-threaded marshaler provides a shortcut for COM's standard thread handling when a free-threaded DLL is called by a host (client) that is not free-threaded.

To aggregate with the free threaded marshaler, you must

- Call *CoCreateFreeThreadedMarshaler*, passing your object's *IUnknown* interface for the resulting free-threaded marshaler to use: `CoCreateFreeThreadedMarshaler(self as IUnknown, FMarshaler);` `CoCreateFreeThreadedMarshaler(static_cast<IUnknown *>(this), &FMarshaler);`. This line assigns the interface for the free-threaded marshaler to a class member, *FMarshaler*.
- Using the **Type Library Editor**, add the *IMarshal* interface to the set of interfaces your CoClass implements.
- In your object's *QueryInterface* method, delegate calls for IDD_IMarshal to the free-threaded marshaler (stored as *FMarshaler* above).

Warning: The free-threaded marshaler violates the normal rules of COM marshaling to provide additional efficiency. It should be used with care. In particular, it should only be aggregated with free-threaded objects in an in-process server, and should only be instantiated by the object that uses it (not another thread).

Writing an object that supports the apartment threading model

To implement the (single-threaded) apartment threading model, you must follow a few rules:

- The first thread in the application that gets created is COM's main thread. This is typically the thread on which WinMain was called. This must also be the last thread to uninitialize COM.
- Each thread in the apartment threading model must have a message loop, and the message queue must be checked frequently.
- When a thread gets a pointer to a COM interface, that pointer may only be used in that thread.

The single-threaded apartment model is the middle ground between providing no threading support and full, multi-threading support of the free threading model. A server committing to the apartment model promises that the server has serialized access to all of its global data (such as its object count). This is because different objects may try to access the global data from different threads. However, the object's instance data is safe because the methods are always called on the same thread.

Typically, controls for use in Web browsers use the apartment threading model because browser applications always initialize their threads as apartment.

Writing an object that supports the neutral threading model

Under COM+, you can use another threading model that is in between free threading and apartment threading: the neutral model. Like the free-threading model, this model allows multiple threads to access your object at the same time. There is no extra marshaling to transfer to the thread on which the object was created. However, your object is guaranteed to receive no conflicting calls.

Writing an object that uses the neutral threading model follows much the same rules as writing an apartment-threaded object, except that you do need to guard instance data against thread conflicts if it can be accessed by different methods in the object's interface. Any instance data that is only accessed by a single interface method is automatically thread-safe.

3.2.2.5.7 Defining a COM Object's Interface

When you use a wizard to create a COM object, the wizard automatically generates a type library (unless you specify otherwise in the COM object wizard). The type library provides a way for host applications to find out what the object can do. It also lets you define your object's interface using the Type Library editor (see page 1446). The interfaces you define in the Type Library editor define what properties, methods, and events your object exposes to clients.

Note: If you selected an existing interface in the COM object wizard, you do not need to add properties and methods. The definition of the interface is imported from the type library in which it was defined. Instead, simply locate the methods of the imported interface in the implementation unit and fill in their bodies.

Adding a property to the object's interface

When you add a property (see page 1462) to your object's interface using the **Type Library Editor**, it automatically adds a method to read the property's value and/or a method to set the property's value. The **Type Library Editor**, in turn, adds these methods to your implementation class, and in your implementation unit creates empty method implementations for you to complete.

To add a property to your object's interface

1. In the **Type Library Editor**, select the default interface for the object. The default interface should be the name of the object preceded by the letter "I." To determine the default, in the **Type Library Editor**, click the CoClass and then select the **Implements** tab, and check the list of implemented interfaces for the one marked, "Default."
2. To expose a read/write property, click the **New Property** button on the toolbar; otherwise, click the arrow next to the **New Property** button on the toolbar, and then click the type of property to expose.

3. In the **Attributes** pane, specify the name and type of the property.
4. On the **Type Library Editor** toolbar, click the **Refresh Implementation** button. A definition and skeletal implementations for the property access methods are inserted into the object's implementation unit.
5. In the implementation unit, locate the access methods for the property. These have names of the form `Get_PropertyName` and `Set_PropertyName`. Add code that gets or sets the property value of your object. This code may simply call an existing function inside the application, access a data member that you add to the object definition, or otherwise implement the property.

Adding a method to the object's interface

When you add a method (see page 1462) to your object's interface using the **Type Library Editor**, the **Type Library Editor** can, in turn, add the methods to your implementation class, and in your implementation unit create empty implementation for you to complete.

To expose a method via your object's interface

1. In the **Type Library Editor**, select the default interface for the object. The default interface should be the name of the object preceded by the letter "I". To determine the default, in the **Type Library Editor**, click the CoClass and select the **Implements** tab, and check the list of implemented interfaces for the one marked, "Default."
2. Click the **New Method** button.
3. In the **Attributes** pane, specify the name of the method.
4. In the **Parameters** pane, specify the method's return type and add the appropriate parameters.
5. On the **Type Library Editor** toolbar, click the **Refresh Implementation** button. A definition and skeletal implementation for the method is inserted into the object's implementation unit.
6. In the implementation unit, locate the newly inserted method implementation. The method is completely empty. Fill in the body to perform whatever task the method represents.

Exposing events to clients

There are two types of events that a COM object can generate: traditional events and COM+ events.

- COM+ events require that you create a separate event object using the event object wizard and add code to call that event object from your server object.
- You can use the wizard to handle much of the work in generating traditional events. This process is described below.

  Note: The COM object wizard does not generate event support code. If you want your object to generate traditional events, you should use the Automation object wizard

  .

In order for an object to generate events, you need to do the following:

1. In the **Automation Object wizard**, check the box, **Generate event support code**. The wizard creates an object that includes an Events interface as well as the default interface. This Events interface has a name of the form `I`*`CoClassname`*`Events`. It is an outgoing (source) interface, which means that it is not an interface your object implements, but rather is an interface that clients must implement and which your object calls. (You can see this by selecting your CoClass, going to the **Implements** page, and noting that the **Source** column on the Events interface says true.) In addition to the Events interface, the wizard adds the *IConnectionPointContainer* interface to the declaration of your implementation class, and adds several class members for handling events. Of these new class members, the most important are *FConnectionPoint* and *FConnectionPoints*, which implement the *IConnectionPoint* and *IConnectionPointContainer* interfaces using built-in VCL classes. *FConnectionPoint* is maintained by another method that the wizard adds, *EventSinkChanged*.
2. In the **Type Library Editor**, select the outgoing Events interface for your object. (This is the one with a name of the form `I`*`CoClassName`*`Events`)
3. Click the **New Method** button from the **Type Library Editor** toolbar. Each method you add to the Events interface represents an event handler that the client must implement.
4. In the **Attributes** pane, specify the name of the event handler, such as `MyEvent`.

5. On the **Type Library Editor** toolbar, click the **Refresh Implementation** button. Your object implementation now has everything it needs to accept client event sinks and maintain a list of interfaces to call when the event occurs. To call these interfaces, you can create a method to generate each event on clients.
6. In the **Code Editor**, add a method to your object for firing each event. For example,

```
unit ev;
interface
uses
   ComObj, AxCtrls, ActiveX, Project1_TLB;
type
   TMyAutoObject = class (TAutoObject,IConnectionPointContainer, IMyAutoObject)
private
   .
   .
   .
public
   procedure Initialize; override;
   procedure Fire_MyEvent; { Add a method to fire the event}
```

7. Implement the method you added in the last step so that it iterates through all the event sinks maintained by your object's *FConnectionPoint* member:

```
procedure TMyAutoObject.Fire_MyEvent;
var
  I: Integer;
  EventSinkList: TList;
  EventSink: IMyAutoObjectEvents;
begin
  if FConnectionPoint <> nil then
  begin
    EventSinkList :=FConnectionPoint.SinkList; {get the list of client sinks }
    for I := 0 to EventSinkList.Count - 1 do
    begin
      EventSink := IUnknown(FEvents[I]) as IMyAutoObjectEvents;
      EventSink.MyEvent;
    end;
  end;
end;
```

8. Whenever you need to fire the event so that clients are informed of its occurrence, call the method that dispatches the event to all event sinks:

```
if EventOccurs then Fire_MyEvent; { Call method you created to fire events.}
if (EventOccurs) Fire_MyEvent; // Call method you created to fire events.
```

Working with Type Libraries: Overview (see page 1445)

3.2.2.5.8 Managing Events in Your Automation Object

The Automation wizard automatically generates event code if you check the option, Generate Support Code in the Automation Object wizard dialog box.

For a server to support traditional COM events, it must provide the definition of an outgoing interface which is implemented by a client. This outgoing interface includes all the event handlers the client must implement to respond to server events.

When a client has implemented the outgoing event interface, it registers its interest in receiving event notification by querying the server's *IConnectionPointContainer* interface. The *IConnectionPointContainer* interface returns the server's *IConnectionPoint* interface, which the client then uses to pass the server a pointer to its implementation of the event handlers (known as a sink).

The server maintains a list of all client sinks and calls methods on them when an event occurs.

When you select Generate Event Support Code, Delphi automatically generates the code necessary to support IConnectionPoint

and IConnectionPointContainer. This support, and the way you can use it to generate events is described in Exposing events to clients (see page 1435).

Using the Automation Object Wizard (see page 1432)

3.2.2.5.9 Automation Interfaces

The **Automation Object** wizard implements a dual interface (see page 1438) by default, which means that the Automation object supports both

- Late binding at runtime, which is through the *IDispatch* interface. This is implemented as a dispatch interface, or dispinterface (see page 1438).
- Early binding at compile-time, which is accomplished through directly calling one of the member functions in the object's virtual function table (VTable). This is referred to as a custom interface (see page 1439).

  Note: Any interfaces generated by the COM Object

  wizard that do not descend from *IDispatch* only support VTable calls.

3.2.2.5.10 Dual Interfaces

A dual interface is a custom interface and a dispinterface at the same time. It is implemented as a COM VTable interface that derives from *IDispatch. For* those controllers that can access the object only at runtime, the dispinterface is available. For objects that can take advantage of compile-time binding, the more efficient VTable interface is used.

Dual interfaces offer the following combined advantages of VTable interfaces and dispinterfaces:

- For VTable interfaces, the compiler performs type checking and provides more informative error messages.
- For Automation controllers that cannot obtain type information, the dispinterface provides runtime access to the object.
- For in-process servers, you have the benefit of fast access through VTable interfaces.
- For out-of-process servers, COM marshals data (see page 1439) for both VTable interfaces and dispinterfaces. COM provides a generic proxy/stub implementation that can marshal the interface based on the information contained in a type library.

The first three entries of the VTable for a dual interface refer to the *IUnknown* interface, the next four entries refer to the *IDispatch* interface, and the remaining entries are COM entries for direct access to members of the custom interface.

3.2.2.5.11 Dispatch Interfaces

Automation controllers are clients that use the COM IDispatch interface to access the COM server objects. The controller must first create the object, then query the object's IUnknown interface for a pointer to its IDispatch interface. IDispatch keeps track of methods and properties internally by a dispatch identifier (dispID), which is a unique identification number for an interface member. Through IDispatch, a controller retrieves the object's type information for the dispatch interface and then maps interface member names to specific dispIDs. These dispIDs are available at runtime, and controllers get them by calling the IDispatch method,GetIDsOfNames.

Once it has the dispID, the controller can then call the IDispatch method, Invoke, to execute the appropriate code (property or method), packaging the parameters for the property or method into one of the Invoke parameters. Invoke has a fixed compile-time signature that allows it to accept any number of arguments when calling an interface method.

The Automation object's implementation of Invoke must then unpackage the parameters, call the property or method, and be prepared to handle any errors that occur. When the property or method returns, the object passes its return value back to the controller.

This is called late binding because the controller binds to the property or method at runtime rather than at compile time.

3.2.2.5.12 Custom Interfaces

Custom interfaces are user-defined interfaces that allow clients to invoke interface methods based on their order in the VTable and knowledge of the argument types. The VTable lists the addresses of all the properties and methods that are members of the object, including the member functions of the interfaces that it supports. If the object does not support *IDispatch*, the entries for the members of the object's custom interfaces immediately follow the members of *IUnknown*.

If the object has a type library, you can access the custom interface through its VTable layout, which you can get using the **Type Library Editor**. If the object has a type library and also supports *IDispatch*, a client can also get the dispIDs of the *IDispatch* interface and bind directly to a VTable offset. Delphi's type library importer (TLIBIMP) retrieves dispIDs at import time, so clients that use dispinterfaces can avoid calls to *GetIDsOfNames; this* information is already in the _TLB unit. However, clients still need to call *Invoke*.

3.2.2.5.13 Marshaling Data

For out-of-process and remote servers, you must consider how COM marshals data outside the current process. You can provide marshaling:

- Automatically, using the *IDispatch* interface.
- Automatically, by creating a type library with your server and marking the interface with the OLE Automation flag. COM knows how to marshal all the **Automation-compatible** types in the type library and can set up the proxies and stubs for you. Some type restrictions apply to enable automatic marshaling.
- Manually by implementing all the methods of the *IMarshal* interface. This is called **custom marshaling**.

  Note: The first method (using *IDispatch*) is only available on Automation servers. The second method is automatically available on all objects that are created by wizards and which use a type library.

Automation compatible types

Function result and parameter types of the methods declared in dual and dispatch interfaces and interfaces that you mark as OLE Automation must be *Automation-compatible* types. The following types are OLE Automation-compatible:

First, the predefined valid types such as *Smallint*, *Integer*, *Single*, *Double*, *WideString*. For a complete list, see Valid types (see page 1454).

Second, enumeration types defined in a type library. OLE Automation-compatible enumeration types are stored as 32-bit values and are treated as values of type *Integer* for purposes of parameter passing.

Third, interface types defined in a type library that are OLE Automation safe, that is, derived from *IDispatch* and containing only OLE Automation compatible types.

Fourth, dispinterface types defined in a type library.

Fifth, any custom record type defined within the type library.

Sixth, *IFont*, *IStrings*, and *IPicture*. Helper objects must be instantiated to map

- an *IFont to* a *TFont*
- an *IStrings* to a *TStrings*
- an *IPicture* to a *TPicture*

The ActiveX control and ActiveForm wizards create these helper objects automatically when needed. To use the helper objects, call the global routines, GetOleFont, GetOleStrings, GetOlePicture, respectively.

Type restrictions for automatic marshaling

For an interface to support automatic marshaling (also called Automation marshaling or type library marshaling), the following restrictions apply. When you edit your object using the type library editor, the editor enforces these restrictions:

- String data types must be transferred as wide strings (BSTR). **PChar**, **UnicodeString** and **AnsiString** cannot be marshaled safely.
- All members of a dual interface must pass an HRESULT as the function's return value. If the method is declared using the safecall calling convention, this condition is imposed automatically, with the declared return type converted to an output parameter.
- Members of a dual interface that need to return other values should specify these parameters as **var** or **out**, indicating an output parameter that returns the value of the function.

  Note: One way to bypass the Automation types restrictions is to implement a separate *IDispatch* interface and a custom interface. By doing so, you can use the full range of possible argument types. This means that COM clients have the option of using the custom interface, which Automation controllers can still access. In this case, though, you must implement the marshaling code manually.

Custom marshaling

Typically, you use automatic marshaling in out-of-process and remote servers because it is easier—COM does the work for you. However, you may decide to provide custom marshaling if you think you can improve marshaling performance. When implementing your own custom marshaling, you must support the *IMarshal* interface. For more information, on this approach, see the Microsoft documentation.

Working with Type Libraries: Overview (see page 1445)

Automation Interfaces (see page 1438)

3.2.2.5.14 Registering a COM Object

You can register your server object as an in-process or an out-of-process server. For more information on the server types, see In-process (see page 1389).

Note: Before you remove a COM object from your system, you should unregister it.

Registering an in-process server

To register an in-process server (DLL or OCX), choose **Run** ▶ **Register ActiveX Server**.

To unregister an in-process server, choose **Run** ▶ **Unregister ActiveX Server**.

Registering an out-of-process server

To register an out-of-process server, run the server with the **/regserver** command-line option. You can set command-line options with the **Run** ▶ **Parameters** dialog box. You can also register the server by running it.

To unregister an out-of-process server, run the server with the **/unregserver** command-line option.

As an alternative, you can use the `tregsvr` command from the command line or run the `regsvr32` command from the operating system.

Note: If the COM server is intended for use under COM+, you should install it in a COM+ application rather than register it. (Installing the object in a COM+ application automatically takes care of registration.)

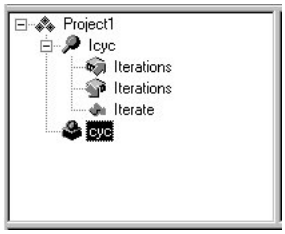
3.2.2.5.15 Testing and Debugging the Application

Once you have created a COM server application, you will want to test it before you deploy it.

To test and debug your COM server application,

1. Turn on debugging information using the **Compiler** page on the **Project ▸ Options** dialog box, if necessary. Also, turn on **Integrated Debugging** in the **Tools ▸ Options ▸ Debugger Options** dialog.
2. For an in-process server, choose **Run ▸ Parameters**, type the name of the Automation controller in the **Host Application** box, and choose OK.
3. Choose **Run ▸ Run**.
4. Set breakpoints in the Automation server.
5. Use the Automation controller to interact with the Automation server.

The Automation server pauses when the breakpoints are reached.



Note: As an alternate approach, if you are also writing the Automation controller, you can debug into an in-process server by enabling COM cross-process support. Use the CodeGear Debuggers

page of the **Tools ▸ Options ▸ Debugger Options** dialog to enable cross-process support.

3.2.2.6 Working with type libraries

Topics

Name	Description
Working with Type Libraries: Overview (see page 1445)	Type libraries are files that include information about data types, interfaces, member functions, and object classes exposed by a COM object. They provide a way to identify the types of objects and interfaces that are available on a server. For a detailed overview on why and when to use type libraries, see Type libraries (see page 1395). A type library can contain any and all of the following: • Information about custom data types such as aliases, enumerations, structures, and unions. • Descriptions of one or more COM elements, such as an interface, dispinterface, or CoClass. Each of these descriptions is commonly referred to... more (see page 1445)
Type Library Editor (see page 1446)	The **Type Library Editor** enables developers to examine and create type information for COM objects. Using the **Type Library Editor** can greatly simplify the task of developing COM objects by centralizing the tasks of defining interfaces, CoClasses, and types, obtaining GUIDs for new interfaces, associating interfaces with CoClasses, updating implementation units, and so on. The **Type Library Editor** outputs two types of file that represent the contents of the type library: ***Type Library editor files***
Parts of the Type Library Editor (see page 1446)	The main elements of the **Type Library Editor** are described in the following table: ***Type Library editor parts***
Toolbar (see page 1447)	The **Type Library Editor**'s toolbar, located at the top of the Type Library Editor, contains buttons that you click to add new objects into your type library. The first group of buttons let you add elements to the type library. When you click a toolbar button, the icon for that element appears in the object list pane. You can then customize its attributes in the right pane. Depending on the type of icon you select, different pages of information appear to the right. The following table lists the elements (see page 1451) you can add to your type library: ***Icons Representing... more (see page 1447)***

Object List Pane (see page 1448)	The **Object list** pane displays all the elements of the current type library in a tree view. The root of the tree represents the type library itself, and appears as the following icon: Descending from the type library node are the elements (see page 1451) in the type library:  When you select any of these elements (including the type library itself), the pages of type information (see page 1449) to the right change to reflect only the relevant information for that element. You can use these pages to edit the definition and properties of the selected element. You can manipulate the elements in the object... more (see page 1448)
Status Bar (see page 1449)	When editing or saving a type library, syntax, translation errors, and warnings are listed in the **Message** pane. For example, if you specify a type that the **Type Library Editor** does not support, you will get a syntax error. For a complete list of types supported by the **Type Library Editor**, see Valid types (see page 1454).
Pages of Type Information (see page 1449)	When you select an element (see page 1451) in the object list pane, pages of type information appear in the **Type Library Editor** that are valid for the selected element. Which pages appear depends on the element selected in the object list panel, as follows:
Type Library Elements (see page 1451)	The Type Library interface as represented in the Type Library Editor can seem overwhelmingly complicated at first. This is because it represents information about a great number of elements, each of which has its own characteristics. However, many of these characteristics are common to all elements. For example, every element (including the type library itself) has the following: • **Name**, which is used to describe the element and which is used when referring to the element in code. • **GUID** (globally unique identifier), which is a unique 128-bit value that COM uses to identify the element. This should always be supplied... more (see page 1451)
Using the Type Library Editor (see page 1453)	Using the type library editor, you can create new type libraries or edit existing ones. Typically, an application developer uses a wizard to create the objects that are exposed in the type library, letting Delphi generate the type library automatically. Then, the automatically-generated type library is opened in the Type Library editor so that the interfaces can be defined (or modified), type definitions added, and so on. However, even if you are not using a wizard to define the objects, you can use the Type Library editor to define a new type library. In this case, you must create any... more (see page 1453)
Valid Types (see page 1454)	In the Type Library editor, you use different type identifiers, depending on whether you are working in IDL or Delphi. Specify the language you want to use in the Environment options dialog. The following types are valid in a type library for COM development. The Automation compatible column specifies whether the type can be used by an interface that has its Automation or Dispinterface flag checked. These are the types that COM can marshal via the type library automatically.
SafeArrays (see page 1455)	COM requires that arrays be passed via a special data type known as a SafeArray. You can create and destroy SafeArrays by calling special COM functions to do so, and all elements within a SafeArray must be valid automation-compatible types (see page 1454). The Delphi compiler has built-in knowledge of COM SafeArrays and automatically calls the COM API to create, copy, and destroy SafeArrays. In the **Type Library Editor**, a *SafeArray* must specify the type of its elements. For example, the following line from the text page declares a method with a parameter that is a *SafeArray* with an element type... more (see page 1455)

Using Object Pascal or IDL Syntax (see page 1455)	The Code page of the Type Library editor displays your type information in RIDL format (Restricted Interface Definition Language). The format resembles Microsoft's IDL sytnax. However, RIDL supports only a subset of IDL. Like Delphi applications in general, identifiers in type libraries are case insensitive. Identifiers can be as many as 255 characters long, and for maximum portability should begin with a letter or an underscore (_).
Creating a New Type Library (see page 1460)	Use the **Type Library Wizard** to create a type library that is independent of a particular COM object. For example, you might want to define a type library that contains type definitions that you use in several other type libraries. You can then create a type library of basic definitions and add it to the `uses` page of other type libraries. You can also use the wizard to create a type library for an object that is not yet implemented. Once the type library contains the interface definition, you can use the COM object wizard (see page 1431) to generate a CoClass and... more (see page 1460)
Opening an Existing Type Library (see page 1460)	When you use the wizards to create an Automation object, COM object, transactional object, or a remote data module, a type library is automatically created with an implementation unit. Starting with the 2009 product, the wizards create type libraries in a text-based format (RIDL files). However, you can still open type libraries in `.tlb` format that are associated with previous versions or other products (servers) that are available on your system. The Type Library Explorer enables you to examine `.tlb` files.
Adding an Interface to the Type Library (see page 1461)	
Modifying an Interface Using the Type Library (see page 1461)	There are several ways to modify an interface or dispinterface once it is created. • You can change the interface's attributes using the page of type information that contains the information you want to change. Select the interface in the **Object List** pane and then use the controls on the appropriate page of type information. For example, you may want to change the parent interface using the attributes page, or use the flags page to change whether or not it is a dual interface. • You can edit the interface declaration directly by selecting the interface in the object list pane and... more (see page 1461)
Adding Properties and Methods to the Type Library (see page 1462)	
Adding a CoClass to the Type Library (see page 1463)	The easiest way to add a CoClass to your project is to choose **File** ▶ **New** ▶ **Other** from the main menu in the IDE and use the appropriate wizard (see page 1397) on the ActiveX page of the **New Items** dialog. The advantage to this approach is that, in addition to adding the CoClass and its interface to the type library, the wizard adds an implementation unit and updates the project file to include the new implementation unit in its uses clause. If you are not using a wizard, however, you can create a CoClass by clicking the CoClass icon on the toolbar and... more (see page 1463)
Adding an Interface to a CoClass (see page 1463)	CoClasses are defined by the interfaces they present to clients. While you can add any number of properties and methods to the implementation class of a CoClass, clients can only see those properties and methods that are exposed by interfaces associated with the CoClass. To associate an interface with a CoClass, right-click in the **Implements** page for the class and choose Insert Interface to display a list of interfaces from which you can choose. The list includes interfaces that are defined in the current type library and those defined in any type libraries that the current type library references. Choose... more (see page 1463)
Adding an Enumeration to the Type Library (see page 1464)	
Adding an Alias to the Type Library (see page 1464)	
Adding a Record or Union to the Type Library (see page 1464)	
Adding a Module to the Type Library (see page 1465)	

Saving and Registering Type Library Information (see page 1465)	After modifying your type library, you'll want to save and register the type library information. Saving the type library automatically updates: • Both the text-based type library file (`.ridl` extension) and the binary type library file (`.tlb` extension). • The *Project*_TLB unit that represents its contents • The implementation code for any CoClasses that were generated by a wizard. **Note:** The type library is stored as separate text (.RIDL) and binary (.TLB) files, but is also linked into the server (.EXE, DLL, or .OCX). The **Type Library Editor** gives you toolbar buttons for storing your type library information: • Refresh (see page 1467) updates... more (see page 1465)
Apply Updates Dialog (see page 1466)	The **Apply Updates** dialog appears when you refresh, register, or save the type library if you have selected **Display updates before refreshing** in the **Tools ▶ Options ▶ Type Library** page (which is not checked off by default). Without this option, the **Type Library Editor** automatically updates the sources of the associated object when you make changes in the editor. With this option, you have a chance to veto the proposed changes when you attempt to refresh, save, or register the type library. The **Apply Updates** dialog will warn you about potential errors, and will insert TODO comments in your source... more (see page 1466)
Saving a Type Library (see page 1466)	For 2009, RAD Studio stores type libraries as separate text-based files (RIDL, or Restricted Interface Definition Language); The RIDL file, which represents the TLB file in the Editor, is also linked into the server (.EXE, DLL, or .OCX). When you build your project, the RIDL file is saved on disk as both a `.tlb` file as well as a `.ridl` file. There are three ways to save a type library. • **File>Save Command:** To save the project and the type library, choose **File ▶ Save**. Saving a type library saves type information to a `.ridl` file. • **Save TLB Button in Type... more (see page 1466)**
Refreshing the Type Library (see page 1467)	To refresh the type library, choose the **Refresh Implementation** icon on the **Type Library Editor toolbar**. Refreshing the type library does the following: • Updates the xxxx_TLB units that contain a Delphi or C++ representation of the Type Library. • Notifies the IDE's module manager to update the implementation files that contain the implementation for the CoClasses, if the type library is associated with a CoClass that was generated by a wizard. On the **Tools ▶ Options ▶ Environment Options ▶ Delphi Options ▶ Type Library** or the **Tools ▶ Options ▶ Environment Options ▶ C++ Options ▶ Type Library** dialog box, you can designate specific instances when the... more (see page 1467)

Registering the Type Library (see page 1467)	To register the type library, click the **Register Type Library** button on the **Type Library Editor toolbar**. Typically, you do not need to explicitly register a type library because it is registered automatically when you register your COM server application (see Registering a COM object (see page 1440)). However, when you create a type library using the **Type Library wizard**, the type library is not associated with a server object. In this case, you can register the type library directly using the toolbar. Registering the type library adds an entry to the Windows registry for the type library.
Deploying Type Libraries (see page 1467)	By default, when you have a type library that was created as part of an Automation server project, the type library is automatically linked into the .DLL, .OCX, or EXE as a resource. You can, however, deploy your application with the type library as a separate .TLB, as Delphi maintains the type library, if you prefer. Historically, type libraries for Automation applications were stored as a separate file with the .TLB extension. Now, typical Automation applications compile the type libraries into the .OCX or .EXE file directly. The operating system expects the type library to be the first resource in... more (see page 1467)
GenTLB.exe (see page 1468)	A new type library generator (GenTLB.exe) has been added to RAD Studio. When you compile or build a project that contains a type library, the type library generator compiles the text-based RIDL file into the binary `.tlb` file. You can use GenTLB.exe in your custom builds. If you use MSBuild from the command line, then MSBuild automatically uses GenTLB.exe. **Examples** To create AppName.tlb from the contents of AppName.ridl:
RIDL File (see page 1468)	A new file type has been added to the COM architecture for 2009 – the RIDL file (Restricted Interface Definition Language). The RIDL file is the storage mechanism that the project uses to persist the type library data to disk. RAD Studio now uses the `.tlb` file as an intermediate file (like a `.res`, `.dcu`, `.obj`, and so forth). This means that you can rebuild the `.tlb` file from the command line (outside the IDE), that `.tlb` files can be edited with a text editor, and the history is stored by the IDE. The Type Library Editor... more (see page 1468)

3.2.2.6.1 Working with Type Libraries: Overview

Type libraries are files that include information about data types, interfaces, member functions, and object classes exposed by a COM object. They provide a way to identify the types of objects and interfaces that are available on a server. For a detailed overview on why and when to use type libraries, see Type libraries (see page 1395).

A type library can contain any and all of the following:

- Information about custom data types such as aliases, enumerations, structures, and unions.
- Descriptions of one or more COM elements, such as an interface, dispinterface, or CoClass. Each of these descriptions is commonly referred to as type information (see page 1449).
- Descriptions of constants and methods defined in external units.
- References to type descriptions from other type libraries.

By including a type library with your COM application or ActiveX library, you make information about the objects in your application available to other applications and programming tools through COM's type library tools and interfaces.

With traditional development tools, you create type libraries by writing scripts in the Interface Definition Language (IDL) or the Object Description Language (ODL), then run that script through a compiler. The Type Library editor automates some of this process, easing the burden of creating and modifying your own type libraries.

In addition, the Type Library Editor now uses an intermediate text file known as a RIDL file (see page 1468). The Code page of the Type Library Editor displays the RIDL code, and you use the Design page to view and change the type library fields (coClass, Methods, Properties, and so forth). When you save or build your project, the RIDL file is converted to a standard binary `.tlb` file. Both the RIDL file and the `.tlb` file are saved in your project.

When you create a COM server of any type (Automation object, remote data module, and so on) using Delphi wizards, the wizard automatically generates a type library for you (although in the case of the COM object wizard, this is optional). Most of the work you do in customizing the generated object starts with the type library, because that is where you define the properties and methods it exposes to clients: you change the interface of the CoClass generated by the wizard, using the

Type Library Editor. The Type Library editor automatically updates the implementation unit for your object, so that all you need do is fill in the bodies of the generated methods.

Overview of COM Technologies (see page 1385)

3.2.2.6.2 Type Library Editor

The **Type Library Editor** enables developers to examine and create type information for COM objects. Using the **Type Library Editor** can greatly simplify the task of developing COM objects by centralizing the tasks of defining interfaces, CoClasses, and types, obtaining GUIDs for new interfaces, associating interfaces with CoClasses, updating implementation units, and so on.

The **Type Library Editor** outputs two types of file that represent the contents of the type library:

Type Library editor files

File	Description
`.ridl` file	The text-based RIDL (Restricted Interface Definition Language) file, introduced for 2009.
`.tlb` file	The binary type library file. By default, you do not need to use this file, because the type library is automatically compiled into the application as a resource. However, you can use this file to explicitly compile the type library into another project or to deploy the type library separately from the .exe or .ocx. For more information, see Opening an existing type library (see page 1460) and Deploying type libraries (see page 1467).
_TLB unit	This unit reflects the contents of the type library for use by your application. It contains all the declarations your application needs to use the elements defined in the type library. Although you can open this file in the code editor, you should never edit it—it is maintained by the **Type Library Editor**, so any changes you make will be overwritten by the **Type Library Editor**. For more details on the contents of this file, see Code generated when you import type library information (see page 1421)

The following topics describe the **Type Library Editor** in greater detail:

- Parts of the Type Library editor (see page 1446)
- Using the Type Library editor (see page 1453)

Pages of Type Information (see page 1449)

3.2.2.6.3 Parts of the Type Library Editor

The main elements of the **Type Library Editor** are described in the following table:

Type Library editor parts

Part	Description
Toolbar (see page 1447)	Includes buttons to add new types, CoClasses, interfaces, and interface members to your type library. The toolbar also includes buttons for refreshing your implementation unit, registering the type library, and saving an IDL file with the information in your type library.
Object list pane (see page 1448)	Displays all the existing elements in the type library. When you click on an item in the object list pane, it displays pages valid for that object.
Status bar (see page 1449)	Displays syntax errors if you try to add invalid types to your type library.
Pages (see page 1449)	Display information about the selected object. Which pages appear here depends on the type of object selected.

Using the Type Library Editor (see page 1453)

Type Library Editor

3.2.2.6.4 Toolbar

The **Type Library Editor**'s toolbar, located at the top of the Type Library Editor, contains buttons that you click to add new objects into your type library.

The first group of buttons let you add elements to the type library. When you click a toolbar button, the icon for that element appears in the object list pane. You can then customize its attributes in the right pane. Depending on the type of icon you select, different pages of information appear to the right.

The following table lists the elements (see page 1451) you can add to your type library:

Icons Representing Type Library Elements

Icon	Meaning
	An interface description.
	A dispinterface description.
	A CoClass.
	An enumeration.
	An alias.
	A record.
	A union.
	A module.

When you select one of the elements listed above in the object list pane, the second group of buttons displays members that are valid for that element. For example, when you select Interface, the Method and Property icons in the second box become enabled because you can add methods and properties to your interface definition. When you select Enum, the second group of buttons changes to display the Const member, which is the only valid member for Enum type information.

The following table lists the members that can be added to elements in the object list pane:

Icons Representing Members of a Type Library

Icon	Meaning
	A method of the interface, dispinterface, or an entry point in a module.

	A property on an interface or dispinterface.
	A write-only property. (available from the drop-down list on the property button)
	A read-write property. (available from the drop-down list on the property button)
	A read-only property. (available from the drop-down list on the property button)
	A field in a record or union.
	A constant in an enum or a module.

The third group of buttons let you refresh, register, or save a type library as a TLB file, as described in Saving and registering type library information (see page 1465).

Icons Representing Actions You can Perform

Icon	Meaning
	Refresh implementation.
	Register Type Library.
	Save as TLB File.

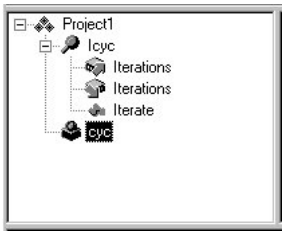
Object List Pane (see page 1448)

Status Bar (see page 1449)



Pages of Type Information (see page 1449)

Elements of Type Libraries (see page 1451)

3.2.2.6.5 Object List Pane

The **Object list** pane displays all the elements of the current type library in a tree view. The root of the tree represents the type library itself, and appears as the following icon:

Descending from the type library node are the elements (see page 1451) in the type library:

When you select any of these elements (including the type library itself), the pages of type information (see page 1449) to the right change to reflect only the relevant information for that element. You can use these pages to edit the definition and properties of the selected element.

You can manipulate the elements in the object list pane by right clicking to get the object list pane context menu. This menu includes commands that let you use the Windows clipboard to move or copy existing elements as well as commands to add new elements or customize the appearance of the **Type Library Editor**.

Toolbar (see page 1447)

Status Bar (see page 1449)

3.2.2.6.6 Status Bar

When editing or saving a type library, syntax, translation errors, and warnings are listed in the **Message** pane.

For example, if you specify a type that the **Type Library Editor** does not support, you will get a syntax error. For a complete list of types supported by the **Type Library Editor**, see Valid types (see page 1454).

See Also

Object List Pane (see page 1448)

Toolbar (see page 1447)

Pages of Type Information (see page 1449)

3.2.2.6.7 Pages of Type Information

When you select an element (see page 1451) in the object list pane, pages of type information appear in the **Type Library Editor** that are valid for the selected element. Which pages appear depends on the element selected in the object list panel, as follows:

Type Info element	Page of type information	Contents of page
Type library	Attributes	Name, version, and GUID for the type library, as well as information linking the type library to help.
	Uses	List of other type libraries that contain definitions on which this one depends.
	Flags	Flags that determine how other applications can use the type library.
	Text	All definitions and declarations defining the type library itself (see discussion below).
Interface	Attributes	Name, version, and GUID for the interface, the name of the interface from which it descends, and information linking the interface to help.
	Flags	Flags that indicate whether the interface is hidden, dual, Automation-compatible, and/or extensible.
	Text	The definitions and declarations for the Interface (see discussion below).
Dispinterface	Attributes	Name, version, and GUID for the interface, and information linking it to help.
	Flags	Flags that indicate whether the Dispinterface is hidden, dual, and/or extensible.
	Text	The definitions and declarations for the Dispinterface. (see discussion below).
CoClass	Attributes	Name, version, and GUID for the CoClass, and information linking it to help.
	Implements	A List of interfaces that the CoClass implements, as well as their attributes.
	COM+	The attributes of transactional objects, such as the transaction model, call synchronization, just-in-time activation, object pooling, and so on. Also includes the attributes of COM+ event objects.
	Flags	Flags that indicate various attributes of the CoClass, including how clients can create and use instances, whether it is visible to users in a browser, whether it is an ActiveX control, and whether it can be aggregated (act as part of a composite).

	Text	The definitions and declarations for the CoClass (see discussion below).
Enumeration	Attributes	Name, version, and GUID for the enumeration, and information linking it to help.
	Text	The definitions and declarations for the enumerated type (see discussion below).
Alias	Attributes	Name, version, and GUID for the enumeration, the type the alias represents, and information linking it to help.
	Text	The definitions and declarations for the alias (see discussion below).
Record	Attributes	Name, version, and GUID for the record, and information linking it to help.
	Text	The definitions and declarations for the record (see discussion below).
Union	Attributes	Name, version, and GUID for the union, and information linking it to help.
	Text	The definitions and declarations for the union (see discussion below).
Module	Attributes	Name, version, GUID, and associated DLL for the module, and information linking it to help.
	Text	The definitions and declarations for the module (see discussion below).
Method	Attributes	Name, dispatch ID or DLL entry point, and information linking it to help.
	Parameters	Method return type, and a list of all parameters with their types and any modifiers.
	Flags	Flags to indicate how clients can view and use the method, whether this is a default method for the interface, and whether it is replaceable.
	Text	The definitions and declarations for the method (see discussion below).
Property	Attributes	Name, dispatch ID, type of property access method (getter vs. setter), and information linking it to help.
	Parameters	Property access method return type, and a list of all parameters with their types and any modifiers.
	Flags	Flags to indicate how clients can view and use the property, whether this is a default for the interface, whether the property is replaceable, bindable, and so on.
	Text	The definitions and declarations for the property access method (see discussion below).
Const	Attributes	Name, value, type (for module consts), and information linking it to help.
	Flags	Flags to indicate how clients can view and use the constant, whether this represents a default value, whether the constant is bindable, and so on.
	Text	The definitions and declarations for the constant (see discussion below).
Field	Attributes	Name, type, and information linking it to help.
	Flags	Flags to indicate how clients can view and use the field, whether this represents a default value, whether the field is bindable, and so on.
	Text	The definitions and declarations for the field (see discussion below).

You can use each of the pages of type information to view or edit the values it displays. Most of the pages organize the information into a set of controls so that you can type in values or select them from a list without requiring that you know the syntax of the corresponding declarations. This can prevent many small mistakes such as typographic errors when specifying values from a limited set. However, you may find it faster to type in the declarations directly. To do this, use the Text page.

All type library elements have a text page that displays the syntax for the element. This syntax appears in an IDL subset of Microsoft Interface Definition Language, or Delphi. See Using Delphi or IDL syntax (see page 1455) for details. Any changes you make in other pages of the element are reflected on the text page. If you add code directly in the text page, changes are reflected in the other pages of the Type Library editor.

The **Type Library Editor** generates syntax errors if you add identifiers that are currently not supported by the editor; the editor currently supports only those identifiers that relate to type library support (not RPC support or constructs used by the Microsoft

IDL compiler for C++ code generation or marshaling support).

Object List Pane (see page 1448)

Toolbar (see page 1447)

Status Bar (see page 1449)

Type Library Elements (see page 1451)

3.2.2.6.8 Type Library Elements

The Type Library interface as represented in the Type Library Editor can seem overwhelmingly complicated at first. This is because it represents information about a great number of elements, each of which has its own characteristics. However, many of these characteristics are common to all elements. For example, every element (including the type library itself) has the following:

- **Name**, which is used to describe the element and which is used when referring to the element in code.
- **GUID** (globally unique identifier), which is a unique 128-bit value that COM uses to identify the element. This should always be supplied for the type library itself and for CoClasses and interfaces. It is optional otherwise.
- **Version number**, which distinguishes between multiple versions of the element. This is always optional, but should be provided for CoClasses and interfaces, because some tools can't use them without a version number.
- **Help properties** that link the element to a Help topic. These include a Help String, and Help Context or Help String Context value. The Help Context is used for a traditional Windows Help system where the type library has a stand-alone Help file. The Help String Context is used when help is supplied by a separate DLL instead. The Help Context or Help String Context refers to a Help file or DLL that is specified on the type library's **Attributes** page. This is always optional.

Interfaces

An interface describes the methods (and any properties expressed as `get` and `set` functions) for an object that must be accessed through a virtual function table (vtable). If an interface is flagged as dual, it will inherit from *IDispatch*, and your object can provide both early-bound, vtable access, and runtime binding through OLE automation. By default, the type library flags all interfaces you add as dual.

Interfaces can be assigned members: methods and properties. These appear in the object list pane as children of the interface node. Properties for interfaces are represented by the `get` and `set` methods used to read and write the property's underlying data. They are represented in the tree view using special icons that indicate their purpose.

Special Icons for 'get' and 'set' Methods

	A write (set, put) by value property function.
	A read (get) | write (set, put) | write by reference property function.
	A read (get) property function.

Note: Write by Reference: When a property is specified as Write By Reference, it is passed as a pointer rather than by value. Some applications, such as Visual Basic, use Write By Reference, if it is present, to optimize performance. To pass the property only by reference rather than by value, use the property type *By Reference Only*. To pass the property by reference as well as by value, select Read->Write->Write By Ref

. To invoke this menu, go to the toolbar and select the down-arrow next to the property icon. After you add the properties or methods using the toolbar button or the object list pane context menu, you describe their syntax and attributes by selecting the property or method and using the pages of type information.

The Attributes page lets you give the property or method a name and dispatch ID (so that it can be called using IDispatch). For properties, you also assign a type. The function signature is created using the Parameters page, where you can add, remove,

and rearrange parameters, set their type and any modifiers, and specify function return types.

Note: Members of interfaces that need to raise exceptions should return an HRESULT and specify a return value parameter (PARAM_RETVAL) for the actual return value. Declare these methods using the **safecall** calling convention.

Note that when you assign properties and methods to an interface, they are implicitly assigned to its associated CoClass. This is why the Type Library editor does not let you add properties and methods directly to a CoClass.

Dispinterfaces

Interfaces are more commonly used than dispinterfaces to describe the properties and methods of an object. Dispinterfaces are only accessible through dynamic binding, while interfaces can have static binding through a vtable.

You can add methods and properties to dispinterfaces in the same way you add them to interfaces. However, when you create a property for a dispinterface, you can't specify a function kind or parameter types.

CoClasses

A CoClass describes a unique COM object that implements one or more interfaces. When defining a CoClass, you must specify which implemented interface is the default for the object, and optionally, which dispinterface is the default source for events. Note that you do not add properties or methods to a CoClass in the Type Library editor. Properties and methods are exposed to clients by interfaces, which are associated with the CoClass using the Implements page.

Type definitions

Enumerations, aliases, records, and unions all declare types that can then be used elsewhere in the type library.

Enums consist of a list of constants, each of which must be numeric. Numeric input is usually an integer in decimal or hexadecimal format. The base value is zero by default. You can add constants to your enumeration by selecting the enumeration in the object list pane and clicking the Const button on the toolbar or selecting **New ▶ Const** command from the object list pane context menu.

Note: It is strongly recommended that you provide help strings for your enumerations to make their meaning clearer. The following is a sample entry of an enumeration type for a mouse button and includes a help string for each enumeration element.

```
mbLeft = 0 [helpstring 'mbLeft'];
mbRight = 1 [helpstring 'mbRight'];
mbMiddle = 3 [helpstring 'mbMiddle'];
typedef enum TxMouseButton
{
[helpstring("mbLeft")]
mbLeft = 0,
[helpstring("mbRight)]
mbRight = 1.
[helpstring("mbMiddle)]
mbMiddle = 2
} TxMouseButton;
```

An alias creates an alias (type definition) for a type. You can use the alias to define types that you want to use in other type info such as records or unions. Associate the alias with the underlying type definition by setting the Type attribute on the Attributes page.

A record consists of a list of structure members or fields. A union is a record with only a variant part. Like a record, a union consists of a list of structure members or fields. However, unlike the members of records, each member of a union occupies the same physical address, so that only one logical value can be stored.

Add the fields to a record or union by selecting it in the object list pane and clicking the field button in the toolbar or right clicking and choosing field from the object list pane context menu. Each field has a name and a type, which you assign by selecting the field and assigning values using the Attributes page. Records and unions can be defined with an optional tag.

Members can be of any built-in type, or you can specify a type using alias before you define the record.

Modules

A module defines a group of functions, typically a set of DLL entry points. You define a module by

- Specifying a DLL that it represents on the attributes page.
- Adding methods and constants using the toolbar or the object list pane context menu. For each method or constant, you must then define its attributes by selecting the it in the object list pane and setting the values on the Attributes page.

For module methods, you must assign a name and DLL entry point using the attributes page. Declare the function's parameters and return type using the parameters page.

For module constants, use the Attributes page to specify a name, type, and value.

Note: The Type Library Editor

does not generate any declarations or implementation related to a module. The specified DLL must be created as a separate project.

Type Library Editor

Type Library Explorer (Read-Only)

3.2.2.6.9 Using the Type Library Editor

Using the type library editor, you can create new type libraries or edit existing ones. Typically, an application developer uses a wizard to create the objects that are exposed in the type library, letting Delphi generate the type library automatically. Then, the automatically-generated type library is opened in the Type Library editor so that the interfaces can be defined (or modified), type definitions added, and so on.

However, even if you are not using a wizard to define the objects, you can use the Type Library editor to define a new type library. In this case, you must create any implementation classes yourself, because the Type Library editor does not generate code for CoClasses that were not associated with a type library by a wizard.

The editor supports a subset of valid types (see page 1454) in a type library

The following topics describe how to:

- Create a new type library (see page 1460)
- Open an existing type library (see page 1460)
- Add an interface to the type library (see page 1461)
- Modify an interface (see page 1461)
- Add properties and methods to the type library (see page 1462)
- Add a CoClass to the type library (see page 1463)
- Add an interface to a CoClass (see page 1463)
- Add an enumeration to the type library (see page 1464)
- Add an alias to the type library (see page 1464)
- Add a record or union to the type library (see page 1464)
- Add a module to the type library (see page 1465)
- Save and register type library information (see page 1465)

See Also

Type Libraries (see page 1395)

Parts of the Type Library Editor (see page 1446)

3.2.2.6.10 Valid Types

In the Type Library editor, you use different type identifiers, depending on whether you are working in IDL or Delphi. Specify the language you want to use in the Environment options dialog.

The following types are valid in a type library for COM development. The Automation compatible column specifies whether the type can be used by an interface that has its Automation or Dispinterface flag checked. These are the types that COM can marshal via the type library automatically.

Delphi type	IDL type	variant type	Automation compatible	Description
Smallint	short	VT_I2	Yes	2-byte signed integer
Integer	long	VT_I4	Yes	4-byte signed integer
Single	single	VT_R4	Yes	4-byte real
Double	double	VT_R8	Yes	8-byte real
Currency	CURRENCY	VT_CY	Yes	currency
TDateTime	DATE	VT_DATE	Yes	date
WideString	BSTR	VT_BSTR	Yes	binary string
IDispatch	IDispatch	VT_DISPATCH	Yes	pointer to IDispatch interface
SCODE	SCODE	VT_ERROR	Yes	Ole Error Code
WordBool	VARIANT_BOOL	VT_BOOL	Yes	True = -1, False = 0
OleVariant	VARIANT	VT_VARIANT	Yes	Ole Variant
IUnknown	IUnknown	VT_UNKNOWN	Yes	pointer to IUnknown interface
Shortint	byte	VT_I1	No	1 byte signed integer
Byte	unsigned char	VT_UI1	Yes	1 byte unsigned integer
Word	unsigned short	VT_UI2	Yes*	2 byte unsigned integer
LongWord	unsigned long	VT_UI4	Yes*	4 byte unsigned integer
Int64	__int64	VT_I8	No	8 byte signed integer
Largeuint	uint64	VT_UI8	No	8 byte unsigned integer
SYSINT	int	VT_INT	Yes*	system dependent integer (Win32=Integer)
SYSUINT	unsigned int	VT_UINT	Yes*	system dependent unsigned integer
HResult	HRESULT	VT_HRESULT	No	32 bit error code
Pointer		VT_PTR -> VT_VOID	No	untyped pointer
SafeArray	SAFEARRAY	VT_SAFEARRAY	No	OLE Safe Array
PAnsiChar	LPSTR	VT_LPSTR	No	pointer to Char
PChar	LPWSTR	VT_LPWSTR	No	pointer to WideChar
PWideChar	LPWSTR	VT_LPWSTR	No	pointer to WideChar

- Word, LongWord, SYSINT, and SYSUINT may be Automation-compatible with some applications.

See safe arrays (see page 1455) for more information about the SAFEARRAY Variant type.

Note: The Byte (VT_UI1) is Automation-compatible, but is not allowed in a Variant or OleVariant since many Automation servers do not handle this value correctly.

Besides these IDL types, any interfaces and types defined in the library or defined in referenced libraries can be used in a type library definition.

The Type Library editor stores type information in the generated type library (.TLB) file in binary form.

If a parameter type is specified as a Pointer type, the Type Library editor usually translates that type into a variable parameter. When the type library is saved, the variable parameter's associated ElemDesc's IDL flags are marked IDL_FIN or IDL_FOUT.

Often, ElemDesc IDL flags are not marked by IDL_FIN or IDL_FOUT when the type is preceded with a Pointer. Or, in the case of dispinterfaces, IDL flags are not typically used. In these cases, you may see a comment next to the variable identifier such as {IDL_None} or {IDL_In}. These comments are used when saving a type library to correctly mark the IDL flags.

3.2.2.6.11 SafeArrays

COM requires that arrays be passed via a special data type known as a SafeArray. You can create and destroy SafeArrays by calling special COM functions to do so, and all elements within a SafeArray must be valid automation-compatible types (see page 1454). The Delphi compiler has built-in knowledge of COM SafeArrays and automatically calls the COM API to create, copy, and destroy SafeArrays.

In the **Type Library Editor**, a *SafeArray* must specify the type of its elements. For example, the following line from the text page declares a method with a parameter that is a *SafeArray* with an element type of Integer:

```
procedure HighLightLines(Lines: SafeArray of Integer);
HRESULT _stdcall HighlightLines(SAFEARRAY(long) Lines);
```

Note: Although you must specify the element type when declaring a *SafeArray* type in the Type Library Editor

, the declaration in the generated _TLB unit does not indicate the element type.

See Also

Valid Types (see page 1454)

3.2.2.6.12 Using Object Pascal or IDL Syntax

The Code page of the Type Library editor displays your type information in RIDL format (Restricted Interface Definition Language). The format resembles Microsoft's IDL sytnax. However, RIDL supports only a subset of IDL. Like Delphi applications in general, identifiers in type libraries are case insensitive. Identifiers can be as many as 255 characters long, and for maximum portability should begin with a letter or an underscore (_).

Attribute specifications

Types declared in a RIDL file may contain attributes. Attribute specifications appear enclosed in square brackets and separated by commas. Each attribute specification consists of an attribute name followed (if appropriate) by a value.

The following table lists the attribute names and their corresponding values.

Attribute syntax

Attribute name	Example	Applies to
aggregatable	[aggregatable]	typeinfo
appobject	[appobject]	CoClass typeinfo
bindable	[bindable]	members except CoClass members

control	[control]	type library, typeinfo
custom	[custom '{7B5687A1-F4E9-11D1-92A8-00C04F8C8FC4}' 0]	anything
default	[default]	CoClass members
defaultbind	[defaultbind]	members except CoClass members
defaultcollection	[defaultcollection]	members except CoClass members
dispid	[dispid]	members except CoClass members
displaybind	[displaybind]	members except CoClass members
dllname	[dllname 'Helper.dll']	module typeinfo
dual	[dual]	interface typeinfo
helpfile	[helpfile 'c:\help\myhelp.hlp']	type library
helpstringdll	[helpstringdll 'c:\help\myhelp.dll']	type library
helpcontext	[helpcontext 2005]	anything except CoClass members and parameters
helpstring	[helpstring 'payroll interface']	anything except CoClass members and parameters
helpstringcontext	[helpstringcontext $17]	anything except CoClass members and parameters
hidden	[hidden]	anything except parameters
lcid	[lcid $324]	type library
licensed	[licensed]	type library, CoClass typeinfo
nonbrowsable	[nonbrowsable]	members except CoClass members
nonextensible	[nonextensible]	interface typeinfo
oleautomation	[oleautomation]	interface typeinfo
predeclid	[predeclid]	typeinfo
propget	[propget]	members except CoClass members
propput	[propput]	members except CoClass members
propputref	[propputref]	members except CoClass members
public	[public]	alias typeinfo
readonly	[readonly]	members except CoClass members
replaceable	[replaceable]	anything except CoClass members and parameters
requestedit	[requestedit]	members except CoClass members
restricted	[restricted]	anything except parameters
source	[source]	all members
uidefault	[uidefault]	members except CoClass members
usesgetlasterror	[usesgetlasterror]	members except CoClass members
uuid	[uuid '{7B5687A1-F4E9-11D1-92A8-00C04F8C8FC4}']	type library, typeinfo (required)

vararg	[vararg]	members except CoClass members
version	[version 1.1]	type library, typeinfo

Interface syntax

The Delphi syntax for declaring interface type information has the form

```
interfacename = interface[(baseinterface)] [attributes]
functionlist
[propertymethodlist]
end;
```

For example, the following text declares an interface with two methods and one property:

```
Interface1 = interface (IDispatch)
  [uuid '{7B5687A1-F4E9-11D1-92A8-00C04F8C8FC4}', version 1.0]
  function Calculate(optional seed:Integer=0): Integer;
  procedure Reset;
  procedure PutRange(Range: Integer) [propput, dispid $00000005]; stdcall;
  function GetRange: Integer;[propget, dispid $00000005]; stdcall;
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{5FD36EEF-70E5-11D1-AA62-00C04FB16F42}',version 1.0]
interface Interface1 :IDispatch
{
  long Calculate([in, optional, defaultvalue(0)] long seed);
  void Reset(void);
  [propput, id(0x00000005)] void _stdcall PutRange([in] long Value);
  [propput, id(0x00000005)] void _stdcall getRange([out, retval] long *Value);
};
```

Dispatch interface syntax

The Delphi syntax for declaring dispinterface type information has the form

```
dispinterfacename = dispinterface [attributes]
functionlist
[propertylist]
end;
```

For example, the following text declares a dispinterface with the same methods and property as the previous interface:

```
MyDispObj = dispinterface
[uuid '{5FD36EEF-70E5-11D1-AA62-00C04FB16F42}',
  version 1.0,
  helpstring 'dispatch interface for MyObj'
  function Calculate(seed:Integer): Integer [dispid 1];
  procedure Reset [dispid 2];
  property Range: Integer [dispid 3];
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{5FD36EEF-70E5-11D1-AA62-00C04FB16F42}',
  version 1.0,
  helpstring "dispatch interface for MyObj"
dispinterface Interface1
{
  methods:
    [id(1)] int Calculate([in] int seed);
    [id(2)] void Reset(void);
  properties:
    [id(3)] int Value;
};
```

CoClass syntax

The Delphi syntax for declaring CoClass type information has the form

```
classname = coclass(interfacename[interfaceattributes], ...); [attributes];
```

For example, the following text declares a coclass for the interface *IMyInt* and dispinterface *DmyInt*:

```
myapp = coclass(IMyInt [source], DMyInt);
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
  version 1.0,
  helpstring 'A class',
  appobject]
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
  version 1.0,
  helpstring "A class",
  appobject]
coclass myapp
{
  methods:
  [source] interface IMyInt);
  dispinterface DMyInt;
};
```

Enum syntax

The Delphi syntax for declaring Enum type information has the form

```
enumname = ([attributes] enumlist);
```

For example, the following text declares an enumerated type with three values:

```
location = ([uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
         helpstring 'location of booth']
  Inside = 1 [helpstring 'Inside the pavillion'];
  Outside = 2 [helpstring 'Outside the pavillion'];
  Offsite = 3 [helpstring 'Not near the pavillion'];);
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
        helpstring "location of booth"]
typedef enum
{
  [helpstring "Inside the pavillion"] Inside = 1,
  [helpstring "Outside the pavillion"] Outside = 2,
  [helpstring "Not near the pavillion"] Offsite = 3
} location;
```

Alias syntax

The Delphi syntax for declaring Alias type information has the form

```
aliasname = basetype[attributes];
```

For example, the following text declares DWORD as an alias for integer:

```
DWORD = Integer [uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}'];
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}'] typedef long DWORD;
```

Record syntax

The Delphi syntax for declaring Record type information has the form

```
recordname = record [attributes] fieldlist end;
```

For example, the following text declares a record:

```
Tasks = record [uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
                helpstring 'Task description']
  ID: Integer;
  StartDate: TDate;
  EndDate: TDate;
  Ownername: WideString;
  Subtasks: safearray of Integer;
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
        helpstring "Task description"]
typedef struct
{
  long ID;
  DATE StartDate;
  DATE EndDate;
  BSTR Ownername;
  SAFEARRAY (int) Subtasks;
} Tasks;
```

Union syntax

The Delphi syntax for declaring Union type information has the form

```
unionname = record [attributes]
case Integer of
  0: field1;
  1: field2;
  ...
end;
```

For example, the following text declares a union:

```
MyUnion = record [uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
                  helpstring "item description"]
case Integer of
  0: (Name: WideString);
  1: (ID: Integer);
  3: (Value: Double);
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
        helpstring "item description"]
typedef union
{
  BSTR Name;
  long ID;
  double Value;
  } MyUnion;
```

Module syntax

The Delphi syntax for declaring Module type information has the form

```
modulename = module constants entrypoints end;
```

For example, the following text declares the type information for a module:

```
MyModule = module [uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
                   dllname 'circle.dll']
  PI: Double = 3.14159;
  function area(radius: Double): Double [ entry 1 ]; stdcall;
  function circumference(radius: Double): Double [ entry 2 ]; stdcall;
end;
```

The corresponding syntax in Microsoft IDL is

```
[uuid '{2MD36ABF-90E3-11D1-AA75-02C04FB73F42}',
        dllname("circle.dll")]
module MyModule
{
  double PI = 3.14159;
  [entry(1)] double _stdcall area([in] double radius);
  [entry(2)] double _stdcall circumference([in] double radius);
};
```

Valid Types (see page 1454)

3.2.2.6.13 Creating a New Type Library

Use the **Type Library Wizard** to create a type library that is independent of a particular COM object. For example, you might want to define a type library that contains type definitions that you use in several other type libraries. You can then create a type library of basic definitions and add it to the `uses` page of other type libraries.

You can also use the wizard to create a type library for an object that is not yet implemented. Once the type library contains the interface definition, you can use the COM object wizard (see page 1431) to generate a CoClass and implementation.

To create a new type library

1. If you have a project open, click **File** ▸ **Close All**.
2. Choose **File** ▸ **New** ▸ **Other** to open the New Items dialog box.
3. Choose the **ActiveX** folder under either **Delphi Projects** or **C++Builder Projects**.
4. Select the **Type Library** icon in the right pane.
5. Choose **OK**. The wizard creates an empty RIDL file and opens it in the Design page of the Type Library Editor(in the Code Editor window).
6. Enter a name for the type library in the **Name**field.
7. Continue by adding elements to your type library by using the toolbar (see page 1447) buttons.

See Also

Opening an Existing Type Library (see page 1460)

Using the Type Library Editor (see page 1453)

Working with Type Libraries (see page 1441)

RIDL File (see page 1468)

3.2.2.6.14 Opening an Existing Type Library

When you use the wizards to create an Automation object, COM object, transactional object, or a remote data module, a type library is automatically created with an implementation unit. Starting with the 2009 product, the wizards create type libraries in a text-based format (RIDL files). However, you can still open type libraries in `.tlb` format that are associated with previous versions or other products (servers) that are available on your system. The Type Library Explorer enables you to examine `.tlb` files.

To open a legacy type library (.tlb file)

1. Choose **File** ▸ **Open**.

2. In the Open dialog box, set the File Type to type library.
3. Navigate to the desired `.tlb` file and choose Open.

The Type Library Explorer opens in the Code Editor. You can view the type library but you cannot edit it in the Explorer.

To open a type library created with a COM wizard in the 2009 product

1. In the Project Manager, locate the `.ridl` file associated with your project.
2. Double-click the `.ridl` file.

The Type Library Editor opens in the Code Editor window.

Alternatively, you can choose **View** ▶ **Type Library**. On the Design page of the Type Library Editor, you can add interfaces, CoClasses, and other elements of the type library such as enumerations, properties, and methods.

Note: Changes you make to any type library information with the Type Library Editor

can be automatically reflected in the associated implementation class. If you want to review the changes before they are added, be sure that the Apply Updates (see page 1466) dialog is checked on. It is on by default and can be changed in the setting "Display updates before refreshing" on the **Tools** ▶ **Options** ▶ **Delphi Options** ▶ **Type Library** page.

Tip: When writing client applications, you typically do not need to open the type library. You only need the *Project*_TLB unit that was generated by the Import Component wizard or by TLIBIMP, not the type library itself. You can add this file directly to a client project, or, if the type library is registered on your system, you can use the Import Type Library dialog (Component ->Import Type Library

).

See Also

Creating a New Type Library (see page 1460)

3.2.2.6.15 Adding an Interface to the Type Library

To add an interface

1. On the toolbar, click on the interface icon. An interface is added to the object list pane prompting you to add a name.
2. Type a name for the interface.

The new interface contains default attributes that you can modify as needed.

You can add properties (represented by getter/setter functions) and methods to suit the purpose of the interface.

See Also

Toolbar (see page 1447)

Adding Properties and Methods to the Type Library (see page 1462)

Modifying an Interface Using the Type Library (see page 1461)

3.2.2.6.16 Modifying an Interface Using the Type Library

There are several ways to modify an interface or dispinterface once it is created.

- You can change the interface's attributes using the page of type information that contains the information you want to change. Select the interface in the **Object List** pane and then use the controls on the appropriate page of type information. For example, you may want to change the parent interface using the attributes page, or use the flags page to change whether or not it is a dual interface.
- You can edit the interface declaration directly by selecting the interface in the object list pane and then editing the declarations on the **Text** page.
- You can Add properties and methods to the interface (see page 1462).

- You can modify the properties and methods already in your interface by changing their type information.
- You can associate it with a CoClass by selecting the CoClass in the object list pane, right-clicking on the Implements page, and choosing Insert Interface.

If the interface is associated with a CoClass that was generated by a wizard, you can tell the **Type Library Editor** to apply your changes to the implementation file by clicking the **Refresh** button on the toolbar. If you have the Apply Updates (see page 1466) dialog enabled, the **Type Library Editor** notifies you before updating the sources and warns you of potential problems. For example, if you rename an event interface by mistake, you may get a warning in your source file that looks like this:

```
Because of the presence of instance variables in your implementation file,
Delphi was not able to update the file to reflect the change in your event
interface name. As Delphi has updated the type library for you, however, you
must update the implementation file by hand.
```

You also get a TODO comment in your source file immediately above it.

Warning: If you ignore this warning and TODO comment, the code will not compile.

See Also

Adding an Interface to the Type Library (see page 1461)

Adding Properties and Methods to the Type Library (see page 1462)

3.2.2.6.17 Adding Properties and Methods to the Type Library

To add properties or methods to an interface or dispinterface

1. Select the interface, and choose either a **property** or **method** icon from the toolbar. If you are adding a property, you can click directly on the property icon to create a read/write property (with both a getter and a setter), or click the down arrow to display a menu of property types. The property access method members or method member is added to the object list pane, prompting you to add a name.
2. Type a name for the member.

The new member contains default settings on its attributes, parameters, and flags pages that you can modify to suit the member. For example, you will probably want to assign a type to a property on the attributes page. If you are adding a method, you will probably want to specify its parameters on the parameters page.

As an alternate approach, you can add properties and methods by typing directly into the text page using Delphi or IDL syntax. For example, if you are working in Delphi syntax, you can type the following property declarations into the text page of an interface:

```
Interface1 = interface(IDispatch)
  [ uuid '{5FD36EEF-70E5-11D1-AA62-00C04FB16F42}',
    version 1.0,
    dual,
    oleautomation ]
 function AutoSelect: Integer [propget, dispid $00000002]; safecall; // Add this
 function AutoSize: WordBool [propget, dispid $00000001]; safecall; // And this
 procedure AutoSize(Value: WordBool) [propput, dispid $00000001]; safecall; // And this
end;
```

If you are working in IDL, you can add the same declarations as follows:

```
[
   uuid(5FD36EEF-70E5-11D1-AA62-00C04FB16F42),
   version(1.0),
   dual,
   oleautomation
]
interface Interface1: IDispatch
{ // Add everything between the curly braces
[propget, id(0x00000002)]
   HRESULT _stdcall AutoSelect([out, retval] long Value );
   [propget, id(0x00000003)]
```

```
    HRESULT _stdcall AutoSize([out, retval] VARIANT_BOOL Value );
    [propput, id(0x00000003)]
    HRESULT _stdcall AutoSize([in] VARIANT_BOOL Value );
};
```

After you have added members to an interface using the interface text page, the members appear as separate items in the object list pane, each with its own attributes, flags, and parameters pages. You can modify each new property or method by selecting it in the object list pane and using these pages, or by making edits directly in the text page.

If the interface is associated with a CoClass that was generated by a wizard, you can tell the **Type Library Editor** to apply your changes to the implementation file by clicking the **Refresh** button on the toolbar. The **Type Library Editor** adds new methods to your implementation class to reflect the new members. You can then locate the new methods in implementation unit's source code and fill in their bodies to complete the implementation.

If you have the Apply Updates (see page 1466) dialog enabled, the **Type Library Editor** notifies you of all changes before updating the sources and warns you of potential problems.

See Also

Modifying an Interface Using the Type Library (see page 1461)

Adding an Interface to the Type Library (see page 1461)

Toolbar (see page 1447)

3.2.2.6.18 Adding a CoClass to the Type Library

The easiest way to add a CoClass to your project is to choose **File** ▸ **New** ▸ **Other** from the main menu in the IDE and use the appropriate wizard (see page 1397) on the ActiveX page of the **New Items** dialog. The advantage to this approach is that, in addition to adding the CoClass and its interface to the type library, the wizard adds an implementation unit and updates the project file to include the new implementation unit in its uses clause.

If you are not using a wizard, however, you can create a CoClass by clicking the CoClass icon on the toolbar and then specifying its attributes. You will probably want to give the new CoClass a name (on the Attributes page), and may want to use the Flags page to indicate information such as whether the CoClass is an application object, whether it represents an ActiveX control, and so on.

Note: When you add a CoClass to a type library using the toolbar instead of a wizard, you must generate the implementation for the CoClass yourself and update it by hand every time you change an element on one of the CoClass' interfaces.

You can't add members directly to a CoClass. Instead, you implicitly add members when you add an interface to the CoClass (see page 1463).

See Also

Adding an Interface to the Type Library (see page 1461)

Code Generated by Wizards (see page 1398)

3.2.2.6.19 Adding an Interface to a CoClass

CoClasses are defined by the interfaces they present to clients. While you can add any number of properties and methods to the implementation class of a CoClass, clients can only see those properties and methods that are exposed by interfaces associated with the CoClass.

To associate an interface with a CoClass, right-click in the **Implements** page for the class and choose Insert Interface to display a list of interfaces from which you can choose. The list includes interfaces that are defined in the current type library and those defined in any type libraries that the current type library references. Choose an interface you want the class to implement. The

interface is added to the page with its GUID and other attributes.

If the CoClass was generated by a wizard, the **Type Library Editor** automatically updates the implementation class to include skeletal methods for the methods (including property access methods) of any interfaces you add this way.If you have the Apply Updates (see page 1466) dialog enabled, the **Type Library Editor** notifies you before updating the sources and warns you of potential problems.

Adding an Interface to the Type Library (see page 1461)

Adding a CoClass to the Type Library (see page 1463)

3.2.2.6.20 Adding an Enumeration to the Type Library

To add enumerations to a type library

1. On the toolbar, click on the enum icon. An enum type is added to the **Object List** pane .
2. Type a name for the enumeration. The new enum is empty and contains default attributes in its attributes page for you to modify.

Add values to the enum by right clicking the enum and selecting the **New** ▸ **Const** button . Then, select each enumerated value and assign it a name (and possibly a value) using the attributes page.

Once you have added an enumeration, the new type is available for use by the type library or any other type library that references it from its uses page. For example, you can use the enumeration as the type for a property or parameter.

See Also

Adding an Alias to the Type Library (see page 1464)

Adding a Record or Union to the Type Library (see page 1464)

Adding a Module to the Type Library (see page 1465)

3.2.2.6.21 Adding an Alias to the Type Library

To add an alias to a type library

1. On the toolbar, click on the alias icon. An alias type is added to the object list pane .
2. Type a name for the alias. By default, the new alias stands for a Long Integer type. Use the **Attributes** page to change this to the type you want the alias to represent.

Once you have added an alias, the new type is available for use by the type library or any other type library that references it from its uses page. For example, you can use the alias as the type for a property or parameter.

See Also

Adding an Enumeration to the Type Library (see page 1464)

Adding a Record or Union to the Type Library (see page 1464)

Adding a Module to the Type Library (see page 1465)

3.2.2.6.22 Adding a Record or Union to the Type Library

To add a record or union to a type library

1. On the toolbar, click on the record icon or the union icon. The selected type element is added to the object list pane .
2. Type a name for the record or union. At this point, the new record or union contains no fields.

3. With the record or union selected in the object list pane, click on the field icon in the toolbar. Specify the field's name and type, using the **Attributes** page.
4. Repeat step 3 for as many fields as you need.

Once you have defined the record or union, the new type is available for use by the type library or any other type library that references it from its uses page. For example, you can use the record or union as the type for a property or parameter.

Adding an Enumeration to the Type Library (see page 1464)

Adding an Alias to the Type Library (see page 1464)

Adding a Module to the Type Library (see page 1465)

3.2.2.6.23 Adding a Module to the Type Library

To add a module to a type library

1. On the toolbar, click on the module icon. The selected module is added to the object list pane .
2. Type a name for the module.
3. On the **Attributes** page, specify the name of the DLL whose entry points the Module represents.
4. Add any methods from the DLL you specified in step 3 by clicking on the **Method** icon in the toolbar and then using the attributes pages to describe the method.
5. Add any constants you want the module to define by clicking on the **Const** icon on the toolbar. For each constant, specify a name, type, and value.

Adding an Enumeration to the Type Library (see page 1464)

Adding an Alias to the Type Library (see page 1464)

3.2.2.6.24 Saving and Registering Type Library Information

After modifying your type library, you'll want to save and register the type library information.

Saving the type library automatically updates:

- Both the text-based type library file (`.ridl` extension) and the binary type library file (`.tlb` extension).
- The *Project*_TLB unit that represents its contents
- The implementation code for any CoClasses that were generated by a wizard.

Note: The type library is stored as separate text (.RIDL) and binary (.TLB) files, but is also linked into the server (.EXE, DLL, or .OCX).

The **Type Library Editor** gives you toolbar buttons for storing your type library information:

- Refresh (see page 1467) updates the type library units in memory only.
- Register (see page 1467) adds an entry for the type library in your system's Windows registry. This is done automatically when the associated server is itself registered.
- Save as TLB (see page 1466) saves the type library as a `.tlb` file.

All the above methods perform syntax checking. When you refresh, register, or save the type library, Delphi automatically updates the implementation unit of any CoClasses that were created using a wizard.

3.2.2.6.25 Apply Updates Dialog

The **Apply Updates** dialog appears when you refresh, register, or save the type library if you have selected **Display updates before refreshing** in the **Tools** ▸ **Options** ▸ **Type Library** page (which is not checked off by default).

Without this option, the **Type Library Editor** automatically updates the sources of the associated object when you make changes in the editor. With this option, you have a chance to veto the proposed changes when you attempt to refresh, save, or register the type library.

The **Apply Updates** dialog will warn you about potential errors, and will insert TODO comments in your source file. For example, if you rename an event by mistake, you will get a warning in your source file that looks like this:

```
Because of the presence of instance variables in your implementation file,
Delphi was not able to update the file to reflect the change in your event
interface name. As Delphi has updated the type library for you, however, you
must update the implementation file by hand.
```

You will also get a TODO comment in your source file immediately above it.

Note: If you ignore this warning and TODO comment, the code will not compile.

See Also

Refreshing the Type Library (see page 1467)

Registering the Type Library (see page 1467)

3.2.2.6.26 Saving a Type Library

For 2009, RAD Studio stores type libraries as separate text-based files (RIDL, or Restricted Interface Definition Language); The RIDL file, which represents the TLB file in the Editor, is also linked into the server (.EXE, DLL, or .OCX). When you build your project, the RIDL file is saved on disk as both a `.tlb` file as well as a `.ridl` file.

There are three ways to save a type library.

- **File>Save Command:** To save the project and the type library, choose **File** ▸ **Save**. Saving a type library saves type information to a `.ridl` file.
- **Save TLB Button in Type Library Editor:** To save the type library as a `.tlb` file, click **Save as TLB** in the toolbar (see page 1447) of the Type Library Editor. Saving as a TLB creates a binary type library file (`.tlb` extension) derived from the `.ridl` file in your type library.
- **Build Your Project or Run GenTLB:** Both building your project and running GenTLB.exe also save the type library as a `.tlb` file.

You might encounter unexpected messages from COM when you save a type library as a TLB file (such as when you perform a project build). No syntax or validity checks are performed while you are working with the `.ridl` file or when you merely save the project.

Apply Updates Dialog (see page 1466)

Refreshing the Type Library (see page 1467)

Registering the Type Library (see page 1467)

Type Library Editor Window

RIDL File (see page 1468)

3.2.2.6.27 Refreshing the Type Library

To refresh the type library, choose the **Refresh Implementation** icon on the **Type Library Editor toolbar**.

Refreshing the type library does the following:

- Updates the xxxx_TLB units that contain a Delphi or C++ representation of the Type Library.
- Notifies the IDE's module manager to update the implementation files that contain the implementation for the CoClasses, if the type library is associated with a CoClass that was generated by a wizard.

On the **Tools ▶ Options ▶ Environment Options ▶ Delphi Options ▶ Type Library** or the **Tools ▶ Options ▶ Environment Options ▶ C++ Options ▶ Type Library** dialog box, you can designate specific instances when the Type Library Editor is to refresh the type library implementation. You can select from the following instances:

- When renaming the type library.
- When .ridl file is saved.

Note: If you have renamed items in the type library, refreshing the implementation may create duplicate entries. In this case, you must move your code to the correct entry and delete any duplicates. Similarly, if you delete items in the type library, refreshing the implementation does not remove them from CoClasses (under the assumption that you are merely removing them from visibility to clients). You must delete these items manually in the implementation unit if they are no longer needed.

Apply Updates Dialog (see page 1466)

Saving a Type Library (see page 1466)

Registering the Type Library (see page 1467)

3.2.2.6.28 Registering the Type Library

To register the type library, click the **Register Type Library** button on the **Type Library Editor toolbar**.

Typically, you do not need to explicitly register a type library because it is registered automatically when you register your COM server application (see Registering a COM object (see page 1440)). However, when you create a type library using the **Type Library wizard**, the type library is not associated with a server object. In this case, you can register the type library directly using the toolbar.

Registering the type library adds an entry to the Windows registry for the type library.

Saving a Type Library (see page 1466)

Refreshing the Type Library (see page 1467)

3.2.2.6.29 Deploying Type Libraries

By default, when you have a type library that was created as part of an Automation server project, the type library is automatically linked into the .DLL, .OCX, or EXE as a resource.

You can, however, deploy your application with the type library as a separate .TLB, as Delphi maintains the type library, if you prefer.

Historically, type libraries for Automation applications were stored as a separate file with the .TLB extension. Now, typical Automation applications compile the type libraries into the .OCX or .EXE file directly. The operating system expects the type library to be the first resource in the executable (.DLL, .OCX, or .EXE) file.

When you make type libraries other than the primary project type library available to application developers, the type libraries can be in any of the following forms:

- Stand-alone binary files. The .TLB file output by the Type Library editor is a binary file.
- A resource. This resource should have the type TYPELIB and an integer ID. If you choose to build type libraries with a resource compiler, it must be declared in the resource (.RC) file as follows:

```
1 typelib mylib1.tlb
2 typelib mylib2.tlb
```

See Also

Deploying Applications (see page 1947)

3.2.2.6.30 GenTLB.exe

A new type library generator (GenTLB.exe) has been added to RAD Studio. When you compile or build a project that contains a type library, the type library generator compiles the text-based RIDL file into the binary `.tlb` file.

You can use GenTLB.exe in your custom builds. If you use MSBuild from the command line, then MSBuild automatically uses GenTLB.exe.

Examples

To create AppName.tlb from the contents of AppName.ridl:

```
C:\> gentlb  AppName.ridl
```

To create a type library based on a differently named .ridl file, use the -T option to specify the name of the type library. To create AppName.tlb from the contents of model.ridl:

```
C:\> gentlb -TAppName.tlb  model.ridl
```

Using the COM Wizards (see page 79)

3.2.2.6.31 RIDL File

A new file type has been added to the COM architecture for 2009 – the RIDL file (Restricted Interface Definition Language). The RIDL file is the storage mechanism that the project uses to persist the type library data to disk. RAD Studio now uses the `.tlb` file as an intermediate file (like a `.res`, `.dcu`, `.obj`, and so forth). This means that you can rebuild the `.tlb` file from the command line (outside the IDE), that `.tlb` files can be edited with a text editor, and the history is stored by the IDE.

The Type Library Editor now works on top of a .text file (the RIDL file) instead of the binary `.tlb`.

This change means that:

- You no longer have to check in the binary `.tlb` file, because the build-system can generate it from the latest .RIDL file.
- Multiple programmers can work on the type library at the same time and then simply merge their changes to the text RIDL file. [Binary files cannot be merged, requiring that the last person always overwrites previous changes.]

The RIDL format offers more flexibility for certain constructs than the Type Library Editor. For example, with a RIDL file you can add and edit custom data on any type, function, or member. You can describe complex types such as safe arrays of safe arrays. You can easily perform diff's of RIDL files and gain insight into the evolution of the model exposed by a server over time.

During a build, the RIDL file is compiled using the new type library generator, GenTLB.exe, to generate the binary `.tlb` file.

3.2.3.1 Working with ADO components

Topics

Name	Description
ADO Connection Events (see page 1474)	In addition to the usual events that occur for all database connection components, *TADOConnection* generates a number of additional events that occur during normal usage.
Accessing the Connection Object (see page 1475)	Use the ConnectionObject property of *TADOConnection* to access the underlying ADO connection object. Using this reference it is possible to access properties and call methods of the underlying ADO Connection object. Using the underlying ADO Connection object requires a good working knowledge of ADO objects in general and the ADO Connection object in particular. It is not recommended that you use the Connection object unless you are familiar with Connection object operations. Consult the Microsoft Data Access SDK help for specific information on using ADO Connection objects.
Accessing the Connection's Datasets (see page 1475)	Like other database connection components, you can access the datasets associated with the connection (see page 1505) using the *DataSets* and *DataSetCount* properties. However, *dbGo* also includes TADOCommand objects, which are not datasets, but which maintain a similar relationship to the connection component. You can use the Commands and CommandCount properties of *TADOConnection* to access the associated ADO command objects in the same way you use the *DataSets* and *DataSetCount* properties to access the associated datasets. Unlike *DataSets* and *DataSetCount*, which only list active datasets, *Commands* and *CommandCount* provide references to all *TADOCommand* components associated with the connection component. *Commands* is a... more (see page 1475)
Applying the Batch Updates to Base Tables (see page 1476)	Apply pending data changes that have not yet been applied or canceled by calling the UpdateBatch method. Rows that have been changed and are applied have their changes put into the base tables on which the recordset is based. A cached row marked for deletion causes the corresponding base table row to be deleted. A record insertion (exists in the cache but not the base table) is added to the base table. Modified rows cause the columns in the corresponding rows in the base tables to be changed to the new column values in the cache. Used alone with no... more (see page 1476)
Canceling Batch Updates (see page 1476)	Cancel pending data changes that have not yet been canceled or applied by calling the CancelBatch method. When you cancel pending batch updates, field values on rows that have been changed revert to the values that existed prior to the last call to *CancelBatch* or *UpdateBatch*, if either has been called, or prior to the current pending batch of changes. Used alone with no parameter, *CancelBatch* cancels all pending updates. A *TAffectRecords* value can optionally be passed as the parameter for *CancelBatch*. If any value except *arAll* is passed, only a subset of the pending changes are canceled.... more (see page 1476)
Canceling Commands (see page 1477)	If you are executing the command asynchronously, then after calling Execute you can abort the execution by calling the Cancel method:
Connecting to ADO Data Stores (see page 1477)	dbGo applications use Microsoft ActiveX Data Objects (ADO) 2.1 to interact with an OLE DB provider that connects to a data store and accesses its data. One of the items a data store can represent is a database. An ADO-based application requires that ADO 2.1 be installed on the client computer. ADO and OLE DB is supplied by Microsoft and installed with Windows. An ADO provider represents one of a number of types of access, from native OLE DB drivers to ODBC drivers. These drivers must be installed on the client computer. OLE DB drivers for... more (see page 1477)
Connecting to a Data Store Using TADOConnection (see page 1478)	One or more ADO dataset and command components can share a single connection to a data store by using TADOConnection. To do so, associated dataset and command components with the connection component through their *Connection* properties. At design-time, select the desired connection component from the drop-down list for the *Connection* property in the **Object Inspector**. At runtime, assign the reference to the *Connection* property. For example, the following line associates a *TADODataSet* component with a *TADOConnection* component.
Connecting an ADO Dataset to a Data Store (see page 1479)	ADO datasets can connect to an ADO data store either collectively or individually. When connecting datasets collectively, set the Connection property of each dataset to a TADOConnection component. Each dataset then uses the ADO connection component's connection.

Controlling Timeouts (see page 1480)	You can control the amount of time that can elapse before attempted commands and connections are considered failed and are aborted using the ConnectionTimeout and CommandTimeout properties. ConnectionTimeout specifies the amount of time, in seconds, before an attempt to connect to the data store times out. If the connection does not successfully compile prior to expiration of the time specified in ConnectionTimeout, the connection attempt is canceled:
Fetching Records Asynchronously (see page 1481)	Unlike other datasets, ADO datasets can fetch their data asynchronously. This allows your application to continue performing other tasks while the dataset populates itself with data from the data store. To control whether the dataset fetches data asynchronously, if it fetches data at all, use the ExecuteOptions property. *ExecuteOptions* governs how the dataset fetches its records when you call *Open* or set *Active* to *True*. If the dataset represents a query or stored procedure that does not return any records, ExecuteOptions governs how the query or stored procedure is executed when you call *ExecSQL* or *ExecProc*. *ExecuteOptions* is... more (see page 1481)
Filtering Multiple Rows Based On Update Status (see page 1481)	Filter a recordset to show only those rows that belong to a group of rows with the same update status using the FilterGroup property. Set *FilterGroup* to the *TFilterGroup* constant that represents the update status of rows to display. A value of *fgNone* (the default value for this property) specifies that no filtering is applied and all rows are visible regardless of update status (except rows marked for deletion). The example below causes only pending batch update rows to be visible.
Filtering Records Based On Bookmarks (see page 1482)	ADO datasets support the common dataset feature of using bookmarks to mark and return to specific records (see page 1599). Also like other datasets, ADO datasets let you use filters to limit the available records in the dataset (see page 1631). ADO datasets provide an additional feature that combines these two common dataset features: the ability to filter on a set of records identified by bookmarks.
Fine-tuning a Connection (see page 1483)	One advantage of using *TADOConnection* for establishing the connection to a data store instead of simply supplying a connection string for your ADO command and dataset components, is that it provides a greater degree of control over the conditions and attributes of the connection. The following topics describe the properties you can use to fine-tune the connection: • Forcing asynchronous connections (see page 1483) • Controlling time-outs (see page 1480) • Indicating the types of operations the connection supports (see page 1485) • Specifying whether the connection automatically initiates transactions (see page 1489)
Forcing Asynchronous Connections (see page 1483)	Use the ConnectOptions property to force the connection to be asynchronous. Asynchronous connections allow your application to continue processing without waiting for the connection to be completely opened. By default, *ConnectionOptions* is set to *coConnectUnspecified* which allows the server to decide the best type of connection. To explicitly make the connection asynchronous, set *ConnectOptions* to *coAsyncConnect*. The example routines below enable and disable asynchronous connections in the specified connection component:

Handling Command Parameters (see page 1484)	There are two ways in which a *TADOCommand* object may use parameters: • The *CommandText* property can specify a query that includes parameters. Working with parameterized queries in *TADOCommand* works like using a parameterized query (see page 1617) in an ADO dataset. • The *CommandText* property can specify a stored procedure that uses parameters. Stored procedure parameters (see page 1625) work much the same using *TADOCommand* as with an ADO dataset. There are two ways to supply parameter values when working with *TADOCommand*: you can supply them when you call the Execute method, or you can specify them ahead of time using the Parameters property. The *Execute... more (see page 1484)*
Indicating the Types of Operations the Connection Supports (see page 1485)	ADO connections are established using a specific mode, similar to the mode you use when opening a file. The connection mode determines the permissions available to the connection, and hence the types of operations (such as reading and writing) that can be performed using that connection. Use the Mode property to indicate the connection mode. The possible values are listed in the following table: ***ADO connection modes***
Inspecting the Update Status of Individual Rows (see page 1485)	Determine the update status of a given row by making it current and then inspecting the RecordStatus property of the ADO data component. *RecordStatus* reflects the update status of the current row and only that row.
Loading Data from and Saving Data to Files (see page 1486)	The data retrieved via an ADO dataset component can be saved to a file for later retrieval on the same or a different computer. The data is saved in one of two proprietary formats: ADTG or XML. These two file formats are the only formats supported by ADO. However, both formats are not necessarily supported in all versions of ADO. Consult the ADO documentation for the version you are using to determine what save file formats are supported. Save the data to a file using the SaveToFile method. *SaveToFile* takes two parameters, the name of the file to which data... more (see page 1486)
Opening the Dataset in Batch Update Mode (see page 1487)	To open an ADO dataset in batch update mode, it must meet these criteria: 1. The component's CursorType property must be *ctKeySet* (the default property value) or *ctStatic*. 2. The LockType property must be *ltBatchOptimistic*. 3. The command must be a SELECT query. Before activating the dataset component, set the *CursorType* and *LockType* properties as indicated above. Assign a SELECT statement to the component's CommandText property (for *TADODataSet*) or the SQL property (for *TADOQuery*). For *TADOStoredProc* components, set the *ProcedureName* to the name of a stored procedure that returns a result set. These properties can be set at design-time... more (see page 1487)
Overview of ADO Components (see page 1487)	The ADO page of the **Tool palette** hosts the *dbGo* components. These components let you connect to an ADO data store, execute commands, and retrieve data from tables in databases using the ADO framework. They require ADO 2.1 (or higher) to be installed on the host computer. Additionally, client software for the target database system (such as Microsoft SQL Server) must be installed, as well as an OLE DB driver or ODBC driver specific to the particular database system. Most *dbGo* components have direct counterparts in the components available for other data access mechanisms: a database connection component (... more (see page 1487)

Retrieving Result Sets with Commands (see page 1488)	Unlike *TADOQuery* components, which use different methods to execute depending on whether they return a result set, *TADOCommand* always uses the Execute command to execute the command, regardless of whether it returns a result set. When the command returns a result set, *Execute* returns an interface to the ADO _RecordSet interface. The most convenient way to work with this interface is to assign it to the RecordSet property of an ADO dataset. For example, the following code uses *TADOCommand* (*ADOCommand1*) to execute a SELECT query, which returns a result set. This result set is then assigned to the... more (see page 1488)
Specifying the Command (see page 1489)	Specify commands for a *TADOCommand* component using the CommandText property. Like *TADODataSet*, *TADOCommand* lets you specify the command in different ways, depending on the CommandType property. Possible values for *CommandType* include: *cmdText* (used if the command is an SQL statement), *cmdTable* (if it is a table name), and *cmdStoredProc* (if the command is the name of a stored procedure). At design-time, select the appropriate command type from the list in the **Object Inspector**. At runtime, assign a value of type *TCommandType* to the *CommandType* property.
Specifying Whether the Connection Automatically Initiates Transactions (see page 1489)	Use the Attributes property to control the connection component's use of retaining commits and retaining aborts. When the connection component uses retaining commits, then every time your application commits a transaction, a new transaction is automatically started. When the connection component uses retaining aborts, then every time your application rolls back a transaction, a new transaction is automatically started. *Attributes* is a set that can contain one, both, or neither of the constants *xaCommitRetaining* and *xaAbortRetaining*. When *Attributes* contains *xaCommitRetaining*, the connection uses retaining commits. When *Attributes* contains *xaAbortRetaining*, it uses retaining aborts. Check whether either retaining... more (see page 1489)
Using ADO datasets (see page 1490)	ADO dataset components encapsulate the ADO Recordset object. They inherit the common dataset capabilities described in Understanding Datasets (see page 1632), using ADO to provide the implementation. In order to use an ADO dataset, you must familiarize yourself with these common features. In addition to the common dataset features, all ADO datasets add properties, events, and methods for the following: • Connecting to an ADO datastore (see page 1479) • Accessing the underlying Recordset object (see page 1494) • Filtering records based on bookmarks (see page 1482) • Fetching records asynchronously (see page 1481) • Performing batch updates (caching updates) (see page 1491) • Using files on disk to store data (see page 1486) There are four ADO datasets: • *TADOTable*, a table-type dataset (see page 1620) that represents... more (see page 1490)
Using Batch Updates (see page 1491)	One approach for caching updates is to connect the ADO dataset to a client dataset using a dataset provider. This approach is discussed in Using a client dataset to cache updates (see page 1731). However, ADO dataset components provide their own support for cached updates, which they call batch updates. The following table lists the correspondences between caching updates using a client dataset and using the batch updates features: ***Comparison of ADO and client dataset cached updates***
Using Command Objects (see page 1492)	In the ADO environment, commands are textual representations of provider-specific action requests. Typically, they are Data Definition Language (DDL) and Data Manipulation Language (DML) SQL statements. The language used in commands is provider-specific, but usually compliant with the SQL-92 standard for the SQL language. Although you can always execute commands using *TADOQuery*, you may not want the overhead of using a dataset component, especially if the command does not return a result set. As an alternative, you can use the TADOCommand component, which is a lighter-weight object designed to execute commands, one command at a time. *TADOCommand* is intended... more (see page 1492)

Using TADODataSet (see page 1492)	TADODataSet is a general-purpose dataset (see page 1632) for working with data from an ADO data store. Unlike the other ADO dataset components, *TADODataSet* is not a table-type (see page 1620), query-type (see page 1618), or stored procedure-type (see page 1618) dataset. Instead, it can function as any of these types: • Like a table-type dataset, *TADODataSet* lets you represent all of the rows and columns of a single database table. To use it in this way, set the CommandType property to *cmdTable* and the CommandText property to the name of the table. *TADODataSet* supports table-type tasks such as • Assigning indexes (see page 1609) to sort records or form the basis of record-based searches.... more (see page 1492)
Using the Execute Method (see page 1493)	Before *TADOCommand* can execute its command, it must have a valid connection to a data store. This is established just as with an ADO dataset. See Connecting an ADO dataset to a data store (see page 1479) for details. To execute the command, call the Execute method. *Execute* is an overloaded method that lets you choose the most appropriate way to execute the command. For commands that do not require any parameters and for which you do not need to know how many records were affected, call *Execute* without any parameters:
Working with ADO Components (see page 1494)	The *dbGo* components provide data access through the ADO framework. ADO, (Microsoft ActiveX Data Objects) is a set of COM objects that access data through an OLE DB provider. The *dbGo* components encapsulate these ADO objects in the Delphi database architecture. The ADO layer of an ADO-based application consists of Microsoft ADO 2.1, an OLE DB provider or ODBC driver for the data store access, client software for the specific database system used (in the case of SQL databases), a database back-end system accessible to the application (for SQL database systems), and a database. All of these must... more (see page 1494)
Working with Record Sets (see page 1494)	The Recordset property provides direct access to the ADO recordset object underlying the dataset component. Using this object, it is possible to access properties and call methods of the recordset object from an application. Use of *Recordset* to directly access the underlying ADO recordset object requires a good working knowledge of ADO objects in general and the ADO recordset object in specific. Using the recordset object directly is not recommended unless you are familiar with recordset object operations. Consult the Microsoft Data Access SDK help for specific information on using ADO recordset objects. The RecordSetState property indicates the current state... more (see page 1494)

3.2.3.1.1 ADO Connection Events

In addition to the usual events that occur for all database connection components, *TADOConnection* generates a number of additional events that occur during normal usage.

Events when establishing a connection

In addition to the *BeforeConnect* and *AfterConnect* events that are common to all database connection components, *TADOConnection* also generates an *OnWillConnect* and *OnConnectComplete* event when establishing a connection. These events occur after the *BeforeConnect* event.

- OnWillConnect occurs before the ADO provider establishes a connection. It lets you make last minute changes to the connection string, provide a user name and password if you are handling your own login support, force an asynchronous connection, or even cancel the connection before it is opened.
- OnConnectComplete occurs after the connection is opened. Because *TADOConnection* can represent asynchronous connections, you should use *OnConnectComplete*, which occurs after the connection is opened or has failed due to an error condition, instead of the *AfterConnect* event, which occurs after the connection component instructs the ADO provider to open a connection, but not necessarily after the connection is opened.

Events when disconnecting

In addition to the *BeforeDisconnect* and *AfterDisconnect* events common to all database connection components,

TADOConnection also generates an OnDisconnect event after closing a connection. *OnDisconnect* occurs after the connection is closed but before any associated datasets are closed and before the *AfterDisconnect* event.

Events when managing transactions

The ADO connection component provides a number of events for detecting when transaction-related processes have been completed. These events indicate when a transaction process initiated by a *BeginTrans*, *CommitTrans*, and *RollbackTrans* method has been successfully completed at the data store.

- The OnBeginTransComplete event occurs when the data store has successfully started a transaction after a call to the BeginTrans method.
- The OnCommitTransComplete event occurs after a transaction is successfully committed due to a call to CommitTrans.
- The OnRollbackTransComplete event occurs after a transaction is successfully aborted due to a call to *RollbackTrans*.

Other events

ADO connection components introduce two additional events you can use to respond to notifications from the underlying ADO connection object:

- The OnExecuteComplete event occurs after the connection component executes a command on the data store (for example, after calling the *Execute* method). *OnExecuteComplete* indicates whether the execution was successful.
- The OnInfoMessage event occurs when the underlying connection object provides detailed information after an operation is completed. The *OnInfoMessage* event handler receives the interface to an ADO Error object that contains the detailed information and a status code indicating whether the operation was successful.

Connecting to a Data Store Using TADOConnection (see page 1478)

Connecting to a Data Store Using TADOConnection (see page 1478)

Accessing the Connection's Datasets (see page 1475)

3.2.3.1.2 Accessing the Connection Object

Use the ConnectionObject property of *TADOConnection* to access the underlying ADO connection object. Using this reference it is possible to access properties and call methods of the underlying ADO Connection object.

Using the underlying ADO Connection object requires a good working knowledge of ADO objects in general and the ADO Connection object in particular. It is not recommended that you use the Connection object unless you are familiar with Connection object operations. Consult the Microsoft Data Access SDK help for specific information on using ADO Connection objects.

3.2.3.1.3 Accessing the Connection's Datasets

Like other database connection components, you can access the datasets associated with the connection (see page 1505) using the *DataSets* and *DataSetCount* properties. However, *dbGo* also includes TADOCommand objects, which are not datasets, but which maintain a similar relationship to the connection component.

You can use the Commands and CommandCount properties of *TADOConnection* to access the associated ADO command objects in the same way you use the *DataSets* and *DataSetCount* properties to access the associated datasets. Unlike *DataSets* and *DataSetCount*, which only list active datasets, *Commands* and *CommandCount* provide references to all *TADOCommand* components associated with the connection component.

Commands is a zero-based array of references to ADO command components. *CommandCount* provides a total count of all of the commands listed in *Commands*. You can use these properties together to iterate through all the commands that use a

connection component, as illustrated in the following code:

```
var
  i: Integer
begin
  for i := 0 to (ADOConnection1.CommandCount - 1) do
    ADOConnection1.Commands[i].Execute;
end;
for (int i = 0; i < ADOConnection2->CommandCount; i++)
  ADOConnection2->Commands[i]->Execute();
```

ADO Connection Events (see page 1474)

3.2.3.1.4 Applying the Batch Updates to Base Tables

Apply pending data changes that have not yet been applied or canceled by calling the UpdateBatch method. Rows that have been changed and are applied have their changes put into the base tables on which the recordset is based. A cached row marked for deletion causes the corresponding base table row to be deleted. A record insertion (exists in the cache but not the base table) is added to the base table. Modified rows cause the columns in the corresponding rows in the base tables to be changed to the new column values in the cache.

Used alone with no parameter, *UpdateBatch* applies all pending updates. A *TAffectRecords* value can optionally be passed as the parameter for *UpdateBatch*. If any value except *arAll* is passed, only a subset of the pending changes are applied. Passing *arAll* is the same as passing no parameter at all and causes all pending updates to be applied. The example below applies only the currently active row to be applied:

```
ADODataSet1.UpdateBatch(arCurrent);
ADODataSet1->UpdateBatch(arCurrent);
```

See Also

Inspecting the Update Status of Individual Rows (see page 1485)

Filtering Multiple Rows Based On Update Status (see page 1481)

Canceling Batch Updates (see page 1476)

3.2.3.1.5 Canceling Batch Updates

Cancel pending data changes that have not yet been canceled or applied by calling the CancelBatch method. When you cancel pending batch updates, field values on rows that have been changed revert to the values that existed prior to the last call to *CancelBatch* or *UpdateBatch*, if either has been called, or prior to the current pending batch of changes.

Used alone with no parameter, *CancelBatch* cancels all pending updates. A *TAffectRecords* value can optionally be passed as the parameter for *CancelBatch*. If any value except *arAll* is passed, only a subset of the pending changes are canceled. Passing *arAll* is the same as passing no parameter at all and causes all pending updates to be canceled. The example below cancels all pending changes:

```
ADODataSet1.CancelBatch;
ADODataSet1->CancelBatch(arAll);
```

See Also

Opening the Dataset in Batch Update Mode (see page 1487)

Inspecting the Update Status of Individual Rows (see page 1485)

Filtering Multiple Rows Based On Update Status (see page 1481)

Applying the Batch Updates to Base Tables (see page 1476)

3.2.3.1.6 Canceling Commands

If you are executing the command asynchronously, then after calling Execute you can abort the execution by calling the Cancel method:

```
procedure TDataForm.ExecuteButtonClick(Sender: TObject);
begin
  ADOCommand1.Execute;
end;
procedure TDataForm.CancelButtonClick(Sender: TObject);
begin
  ADOCommand1.Cancel;
end;
void __fastcall TDataForm::ExecuteButtonClick(TObject *Sender)
{
  ADOCommand1->Execute();
}
void __fastcall TDataForm::CancelButtonClick(TObject *Sender)
{
  ADOCommand1->Cancel();
}
```

The *Cancel* method only has an effect if there is a command pending and it was executed asynchronously (*eoAsynchExecute* is in the *ExecuteOptions* parameter of the *Execute* method). A command is said to be pending if the *Execute* method has been called but the command has not yet been completed or timed out.

A command times out if it is not completed or canceled before the number of seconds specified in the CommandTimeout property expire. By default, commands time out after 30 seconds.

3.2.3.1.7 Connecting to ADO Data Stores

dbGo applications use Microsoft ActiveX Data Objects (ADO) 2.1 to interact with an OLE DB provider that connects to a data store and accesses its data. One of the items a data store can represent is a database. An ADO-based application requires that ADO 2.1 be installed on the client computer. ADO and OLE DB is supplied by Microsoft and installed with Windows.

An ADO provider represents one of a number of types of access, from native OLE DB drivers to ODBC drivers. These drivers must be installed on the client computer. OLE DB drivers for various database systems are supplied by the database vendor or by a third-party. If the application uses an SQL database, such as Microsoft SQL Server or Oracle, the client software for that database system must also be installed on the client computer. Client software is supplied by the database vendor and installed from the database systems CD (or disk).

To connect your application with the data store (see page 1478), use an ADO connection component (TADOConnection). Configure the ADO connection component to use one of the available ADO providers. Although *TADOConnection* is not strictly required, because ADO command and dataset components can establish connections directly using their *ConnectionString* property, you can use *TADOConnection* to share a single connection among several ADO components. This can reduce resource consumption, and allows you to create transactions that span multiple datasets.

Like other database connection components (see page 1506), *TADOConnection* provides support for

- Controlling connections (see page 1497)
- Controlling server login (see page 1507)
- Managing transactions (see page 1498)
- Working with associated datasets (see page 1505)
- Sending commands to the server (see page 1502)
- Obtaining metadata (see page 1501)

In addition to these features that are common to all database connection components, *TADOConnection* provides its own support for

- A wide range of options you can use to fine-tune the connection (see page 1483).
- The ability to list the command objects that use the connection (see page 1475).
- Additional events (see page 1474) when performing common tasks.

3.2.3.1.8 Connecting to a Data Store Using TADOConnection

One or more ADO dataset and command components can share a single connection to a data store by using TADOConnection. To do so, associated dataset and command components with the connection component through their *Connection* properties. At design-time, select the desired connection component from the drop-down list for the *Connection* property in the **Object Inspector**. At runtime, assign the reference to the *Connection* property. For example, the following line associates a *TADODataSet* component with a *TADOConnection* component.

```
ADODataSet1.Connection := ADOConnection1;
ADODataSet1->Connection = ADOConnection1;
```

The connection component represents an ADO connection object (see page 1475). Before you can use the connection object to establish a connection, you must identify the data store to which you want to connect. Typically, you provide information using the ConnectionString property. *ConnectionString* is a semicolon delimited string that lists one or more named connection parameters. These parameters identify the data store by specifying either the name of a file that contains the connection information or the name of an ADO provider and a reference identifying the data store. Use the following, predefined parameter names to supply this information:

Connection parameters

Parameter	Description
Provider	The name of a local ADO provider to use for the connection.
Data Source	The name of the data store.
File name	The name of a file containing connection information.

Remote Provider	The name of an ADO provider that resides on a remote machine.
Remote Server	The name of the remote server when using a remote provider.

Thus, a typical value of *ConnectionString* has the form

```
Provider=MSDASQL.1;Data Source=MQIS
```

Note: The connection parameters in *ConnectionString* do not need to include the *Provider* or *Remote Provider* parameter if you specify an ADO provider using the Provider property. Similarly, you do not need to specify the *Data Source* parameter if you use the DefaultDatabase property.

In addition, to the parameters listed above, *ConnectionString* can include any connection parameters peculiar to the specific ADO provider you are using. These additional connection parameters can include user ID and password if you want to hardcode the login information.

At design-time, you can use the Connection String Editor to build a connection string by selecting connection elements (like the provider and server) from lists. Click the ellipsis button for the *ConnectionString* property in the **Object Inspector** to launch the Connection String Editor, which is an ActiveX property editor supplied by ADO.

Once you have specified the *ConnectionString* property (and, optionally, the *Provider* property), you can use the ADO connection component to connect to (see page 1509) or disconnect from (see page 1497) the ADO data store, although you may first want to use other properties to fine-tune the connection (see page 1483). When connecting to or disconnecting from the data store, *TADOConnection* lets you respond to a few additional events (see page 1474) beyond those common to all database connection components..

Note: If you do not explicitly activate the connection by setting the connection component's *Connected* property to *True*, it automatically establishes the connection when the first dataset component is opened or the first time you use an ADO command component to execute a command.

3.2.3.1.9 Connecting an ADO Dataset to a Data Store

ADO datasets can connect to an ADO data store either collectively or individually.

When connecting datasets collectively, set the Connection property of each dataset to a TADOConnection component. Each dataset then uses the ADO connection component's connection.

```
ADODataSet1.Connection := ADOConnection1;
ADODataSet2.Connection := ADOConnection1;
...
ADODataSet1->Connection = ADOConnection1;
```

```
ADODataSet2->Connection = ADOConnection1;
...
```

Among the advantages of connecting datasets collectively are:

- The datasets share the connection object's attributes.
- Only one connection need be set up: that of the *TADOConnection*.
- The datasets can participate in transactions.

For more information on using *TADOConnection* see Connecting to ADO data stores (see page 1477).

When connecting datasets individually, set the ConnectionString property of each dataset. Each dataset that uses *ConnectionString* establishes its own connection to the data store, independent of any other dataset connection in the application.

The *ConnectionString* property of ADO datasets works the same way as the *ConnectionString* property of *TADOConnection*: it is a set of semicolon-delimited connection parameters such as the following:

```
ADODataSet1.ConnectionString := "Provider=YourProvider;Password=SecretWord;" +
  "User ID=JaneDoe;SERVER=PURGATORY;UID=JaneDoe;PWD=SecretWord;" +
  "Initial Catalog=Employee";
ADODataSet1->ConnectionString = "Provider=YourProvider;Password=SecretWord;";
ADODataSet1->ConnectionString += "User ID=JaneDoe;SERVER=PURGATORY";
ADODataSet1->ConnectionString += "UID=JaneDoe;PWD=SecretWord;"
ADODataSet1->ConnectionString += "Initial Catalog=Employee";
```

At design time you can use the Connection String Editor to help you build the connection string. For more information about connection strings, see Connecting to a data store using TADOConnection (see page 1478).

Fetching Records Asynchronously (see page 1481)

3.2.3.1.10 Controlling Timeouts

You can control the amount of time that can elapse before attempted commands and connections are considered failed and are aborted using the ConnectionTimeout and CommandTimeout properties.

ConnectionTimeout specifies the amount of time, in seconds, before an attempt to connect to the data store times out. If the connection does not successfully compile prior to expiration of the time specified in ConnectionTimeout, the connection attempt is canceled:

```
with ADOConnection1 do begin
  ConnectionTimeout := 10 {seconds};
  Open;
end;
  ADOConnection1->ConnectionTimeout = 10; // seconds
  ADOConnection1->Open();
```

CommandTimeout specifies the amount of time, in seconds, before an attempted command times out. If a command initiated by a call to the Execute method does not successfully complete prior to expiration of the time specified in CommandTimeout, the command is canceled and ADO generates an exception:

```
with ADOConnection1 do begin
  CommandTimeout := 10 {seconds};
  Execute("DROP TABLE Employee1997", cmdText, []);
```

```
end;
  ADOConnection1->ConnectionTimeout = 10;
  ADOConnection1->Execute("DROP TABLE Employee1997", cmdText, TExecuteOptions());
```

3.2.3.1.11 Fetching Records Asynchronously

Unlike other datasets, ADO datasets can fetch their data asynchronously. This allows your application to continue performing other tasks while the dataset populates itself with data from the data store.

To control whether the dataset fetches data asynchronously, if it fetches data at all, use the ExecuteOptions property. *ExecuteOptions* governs how the dataset fetches its records when you call *Open* or set *Active* to *True*. If the dataset represents a query or stored procedure that does not return any records, ExecuteOptions governs how the query or stored procedure is executed when you call *ExecSQL* or *ExecProc*.

ExecuteOptions is a set that includes zero or more of the following values:

Execution options for ADO datasets

Execute Option	Meaning
eoAsyncExecute	The command or data fetch operation is executed asynchronously.
eoAsyncFetch	The dataset first fetches the number of records specified by the *CacheSize* property synchronously, then fetches any remaining rows asynchronously.
eoAsyncFetchNonBlocking	Asynchronous data fetches or command execution do not block the current thread of execution.
eoExecuteNoRecords	A command or stored procedure that does not return data. If any rows are retrieved, they are discarded and not returned.

Working with Record Sets (see page 1494)

Using Batch Updates (see page 1491)

Loading Data from and Saving Data to Files (see page 1486)

Filtering Records Based On Bookmarks (see page 1482)

3.2.3.1.12 Filtering Multiple Rows Based On Update Status

Filter a recordset to show only those rows that belong to a group of rows with the same update status using the FilterGroup property. Set *FilterGroup* to the *TFilterGroup* constant that represents the update status of rows to display. A value of *fgNone* (the default value for this property) specifies that no filtering is applied and all rows are visible regardless of update status (except rows marked for deletion). The example below causes only pending batch update rows to be visible.

```
FilterGroup := fgPendingRecords;
Filtered := True;
FilterGroup = fgPendingRecords;
Filtered = true;
```

Note: For the *FilterGroup* property to have an effect, the ADO dataset component's Filtered property must be set to *True*.

See Also

Inspecting the Update Status of Individual Rows (see page 1485)

Applying the Batch Updates to Base Tables (see page 1476)

Canceling Batch Updates (see page 1476)

3.2.3.1.13 Filtering Records Based On Bookmarks

ADO datasets support the common dataset feature of using bookmarks to mark and return to specific records (see page 1599). Also like other datasets, ADO datasets let you use filters to limit the available records in the dataset (see page 1631). ADO datasets provide an additional feature that combines these two common dataset features: the ability to filter on a set of records identified by bookmarks.

To filter on a set of bookmarks

1. Use the Bookmark method to mark the records you want to include in the filtered dataset.
2. Call the FilterOnBookmarks method to filter the dataset so that only the bookmarked records appear.

This process is illustrated below:

```
procedure TForm1.Button1Click(Sender: TObject);
var
BM1, BM2: TBookmarkStr;
begin
with ADODataSet1 do begin
BM1 := Bookmark;
    BMList.Add(Pointer(BM1));
MoveBy(3);
BM2 := Bookmark;
    BMList.Add(Pointer(BM2));
    FilterOnBookmarks([BM1, BM2]);
end;
end;
void __fastcall TForm1::Button1Click(TObject *Sender)
{
TBookmarkStr BM1;
TBookmarkStr BM2;
BM1 = ADODataSet1->Bookmark;
  BMList->Add(BM1);
ADODataSet1->MoveBy(3);
BM2 = ADODataSet1->Bookmark;
  BMList->Add(BM2);
  ADODataSet1->FilterOnBookmarks(ARRAYOFCONST((BM1,BM2)));
}
```

Note that the example above also adds the bookmarks to a list object named BMList. This is necessary so that the application can later free the bookmarks when they are no longer needed.

Fetching Records Asynchronously (see page 1481)

3.2.3.1.14 Fine-tuning a Connection

One advantage of using *TADOConnection* for establishing the connection to a data store instead of simply supplying a connection string for your ADO command and dataset components, is that it provides a greater degree of control over the conditions and attributes of the connection.

The following topics describe the properties you can use to fine-tune the connection:

- Forcing asynchronous connections (see page 1483)
- Controlling time-outs (see page 1480)
- Indicating the types of operations the connection supports (see page 1485)
- Specifying whether the connection automatically initiates transactions (see page 1489)

See Also

Connecting to Databases (see page 1506)

Connecting to a Data Store Using TADOConnection (see page 1478)

Accessing the Connection's Datasets (see page 1475)

ADO Connection Events (see page 1474)

3.2.3.1.15 Forcing Asynchronous Connections

Use the ConnectOptions property to force the connection to be asynchronous. Asynchronous connections allow your application to continue processing without waiting for the connection to be completely opened.

By default, *ConnectionOptions* is set to *coConnectUnspecified* which allows the server to decide the best type of connection. To explicitly make the connection asynchronous, set *ConnectOptions* to *coAsyncConnect*.

The example routines below enable and disable asynchronous connections in the specified connection component:

```
procedure TForm1.AsyncConnectButtonClick(Sender: TObject);
begin
  with ADOConnection1 do begin
    Close;
    ConnectOptions := coAsyncConnect;
    Open;
  end;
end;
procedure TForm1.ServerChoiceConnectButtonClick(Sender: TObject);
begin
  with ADOConnection1 do begin
    Close;
    ConnectOptions := coConnectUnspecified;
    Open;
  end;
end;
void __fastcall TForm1::AsyncConnectButtonClick(TObject *Sender)
{
  ADOConnection1->Close();
  ADOConnection1->ConnectOptions = coAsyncConnect;
  ADOConnection1->Open();
}
void __fastcall TForm1::ServerChoiceConnectButtonClick(TObject *Sender)
{
  ADOConnection1->Close();
  ADOConnection1->ConnectOptions = coConnectUnspecified;
  ADOConnection1->Open();
}
```

Controlling Timeouts (see page 1480)

Specifying Whether the Connection Automatically Initiates Transactions (see page 1489)

Indicating the Types of Operations the Connection Supports (see page 1485)

3.2.3.1.16 Handling Command Parameters

There are two ways in which a *TADOCommand* object may use parameters:

- The *CommandText* property can specify a query that includes parameters. Working with parameterized queries in *TADOCommand* works like using a parameterized query (see page 1617) in an ADO dataset.
- The *CommandText* property can specify a stored procedure that uses parameters. Stored procedure parameters (see page 1625) work much the same using *TADOCommand* as with an ADO dataset.

There are two ways to supply parameter values when working with *TADOCommand*: you can supply them when you call the Execute method, or you can specify them ahead of time using the Parameters property.

The *Execute* method is overloaded to include versions that take a set of parameter values as a Variant array. This is useful when you want to supply parameter values quickly without the overhead of setting up the *Parameters* property:

```
ADOCommand1.Execute(VarArrayOf([Edit1.Text, Date]));
Variant Values[2];
Values[0] = Edit1->Text;
Values[1] = Date();
ADOCommand1.Execute(VarArrayOf(Values,1));
```

When working with stored procedures that return output parameters, you must use the *Parameters* property instead. Even if you do not need to read output parameters, you may prefer to use the *Parameters* property, which lets you supply parameters at design time and lets you work with *TADOCommand* properties in the same way you work with the parameters on datasets.

When you set the *CommandText* property, the *Parameters* property is automatically updated to reflect the parameters in the query or those used by the stored procedure. At design-time, you can use the Parameter Editor to access parameters, by clicking the ellipsis button for the *Parameters* property in the **Object Inspector**. At runtime, use properties and methods of *TParameter* to set (or get) the values of each parameter.

```
with ADOCommand1 do begin
  CommandText := 'INSERT INTO Talley ' +
    '(Counter) ' +
    'VALUES (:NewValueParam)';
  CommandType := cmdText;
  Parameters.ParamByName("NewValueParam").Value := 57;
  Execute
end;
ADOCommand1->CommandText = "INSERT INTO Talley ";
ADOCommand1->CommandText += "(Counter) ";
ADOCommand1->CommandText += "VALUES (:NewValueParam)";
ADOCommand1->CommandType = cmdText;
ADOCommand1->Parameters->ParamByName("NewValueParam")->Value = 57;
ADOCommand1->Execute()
```

See Also

Specifying the Command (see page 1489)

Using the Execute Method (see page 1493)

Canceling Commands (see page 1477)

Retrieving Result Sets with Commands (see page 1488)

3.2.3.1.17 Indicating the Types of Operations the Connection Supports

ADO connections are established using a specific mode, similar to the mode you use when opening a file. The connection mode determines the permissions available to the connection, and hence the types of operations (such as reading and writing) that can be performed using that connection.

Use the Mode property to indicate the connection mode. The possible values are listed in the following table:

ADO connection modes

Connect Mode	Meaning
cmUnknown	Permissions are not yet set for the connection or cannot be determined.
cmRead	Read-only permissions are available to the connection.
cmWrite	Write-only permissions are available to the connection.
cmReadWrite	Read/write permissions are available to the connection.
cmShareDenyRead	Prevents others from opening connections with read permissions.
cmShareDenyWrite	Prevents others from opening connection with write permissions.
cmShareExclusive	Prevents others from opening connection.
cmShareDenyNone	Prevents others from opening connection with any permissions.

The possible values for *Mode* correspond to the *ConnectModeEnum* values of the *Mode* property on the underlying ADO connection object. See the Microsoft Data Access SDK help for more information on these values.

See Also

Specifying Whether the Connection Automatically Initiates Transactions (see page 1489)

Controlling Timeouts (see page 1480)

3.2.3.1.18 Inspecting the Update Status of Individual Rows

Determine the update status of a given row by making it current and then inspecting the RecordStatus property of the ADO data component. *RecordStatus* reflects the update status of the current row and only that row.

```
if (rsNew in ADOQuery1.RecordStatus) then
begin
...
end;
else
if (rsDeleted in ADOQuery1.RecordStatus) then
begin
...
else
switch (ADOQuery->RecordStatus)
{
  case rsUnmodified:
    StatusBar1->Panels->Items[0]->Text = "Unchanged record";
    break;
  case rsModified:
    StatusBar1->Panels->Items[0]->Text = "Changed record";
    break;
  case rsDeleted:
    StatusBar1->Panels->Items[0]->Text = "Deleted record";
    break;
  case rsNew:
    StatusBar1->Panels->Items[0]->Text = "New record";
```

```
    break;
}
```

Canceling Batch Updates (see page 1476)

3.2.3.1.19 Loading Data from and Saving Data to Files

The data retrieved via an ADO dataset component can be saved to a file for later retrieval on the same or a different computer. The data is saved in one of two proprietary formats: ADTG or XML. These two file formats are the only formats supported by ADO. However, both formats are not necessarily supported in all versions of ADO. Consult the ADO documentation for the version you are using to determine what save file formats are supported.

Save the data to a file using the SaveToFile method. *SaveToFile* takes two parameters, the name of the file to which data is saved, and, optionally, the format (ADTG or XML) in which to save the data. Indicate the format for the saved file by setting the Format parameter to *pfADTG* or *pfXML*. If the file specified by the *FileName* parameter already exists, *SaveToFile* raises an *EOleException*.

Retrieve the data from file using the LoadFromFile method. *LoadFromFile* takes a single parameter, the name of the file to load. If the specified file does not exist, *LoadFromFile* raises an *EOleException* exception. On calling the *LoadFromFile* method, the dataset component is automatically activated.

In the example below, the first procedure saves the dataset retrieved by the *TADODataSet* component *ADODataSet1* to a file. The target file is an ADTG file named SaveFile, saved to a local drive. The second procedure loads this saved file into the *TADODataSet* component *ADODataSet2*.

```
procedure TForm1.SaveBtnClick(Sender: TObject);
begin
  if (FileExists("c:\SaveFile")) then
  begin
    DeleteFile("c:\SaveFile");
    StatusBar1.Panels[0].Text := "Save file deleted!";
  end;
  ADODataSet1.SaveToFile("c:\SaveFile", pfADTG);
end;
procedure TForm1.LoadBtnClick(Sender: TObject);
begin
  if (FileExists("c:\SaveFile")) then
    ADODataSet2.LoadFromFile("c:\SaveFile")
  else
    StatusBar1.Panels[0].Text := "Save file does not exist!";
end;
void __fastcall TForm1::SaveBtnClick(TObject *Sender)
{
  if (FileExists("c:\\SaveFile"))
  {
    DeleteFile("c:\\SaveFile");
    Statusbar1->Panels->Items[0]->Text = "Save file deleted!";
  }
  ADODataSet1->SaveToFile("c:\\SaveFile");
}
void __fastcall TForm1::LoadBtnClick(TObject *Sender)
{
  if (FileExists("c:\\SaveFile"))
    ADODataSet1->LoadFromFile("c:\\SaveFile");
  else
```

```
    Statusbar1->Panels->Items[0]->Text = "Save file does not exist!";
}
```

The datasets that save and load the data need not be on the same form as above, in the same application, or even on the same computer. This allows for the briefcase-style transfer of data from one computer to another.

Working with Record Sets (see page 1494)

Fetching Records Asynchronously (see page 1481)

Using Batch Updates (see page 1491)

Filtering Records Based On Bookmarks (see page 1482)

3.2.3.1.20 Opening the Dataset in Batch Update Mode

To open an ADO dataset in batch update mode, it must meet these criteria:

1. The component's CursorType property must be *ctKeySet* (the default property value) or *ctStatic*.
2. The LockType property must be *ltBatchOptimistic*.
3. The command must be a SELECT query.

Before activating the dataset component, set the *CursorType* and *LockType* properties as indicated above. Assign a SELECT statement to the component's CommandText property (for *TADODataSet*) or the SQL property (for *TADOQuery*). For *TADOStoredProc* components, set the *ProcedureName* to the name of a stored procedure that returns a result set. These properties can be set at design-time through the **Object Inspector** or programmatically at runtime. The example below shows the preparation of a *TADODataSet* component for batch update mode.

```
with ADODataSet1 do begin
  CursorLocation := clUseClient;
  CursorType := ctStatic;
  LockType := ltBatchOptimistic;
  CommandType := cmdText;
  CommandText := 'SELECT * FROM Employee';
  Open;
end;
ADODataSet1->CursorLocation = clUseClient;
ADODataSet1->CursorType = ctStatic;
ADODataSet1->LockType = ltBatchOptimistic;
ADODataSet1->CommandType = cmdText;
ADODataSet1->CommandText = "SELECT * FROM Employee";
```

After a dataset has been opened in batch update mode, all changes to the data are cached rather than applied directly to the base tables.

3.2.3.1.21 Overview of ADO Components

The ADO page of the **Tool palette** hosts the *dbGo* components. These components let you connect to an ADO data store, execute commands, and retrieve data from tables in databases using the ADO framework. They require ADO 2.1 (or higher) to

be installed on the host computer. Additionally, client software for the target database system (such as Microsoft SQL Server) must be installed, as well as an OLE DB driver or ODBC driver specific to the particular database system.

Most *dbGo* components have direct counterparts in the components available for other data access mechanisms: a database connection component (*TADOConnection*) and various types of datasets. In addition, *dbGo* includes *TADOCommand*, a simple component that is not a dataset but which represents an SQL command to be executed on the ADO data store.

The following table lists the ADO components.

ADO components

Component	Use
TADOConnection	A database connection component (see page 1506) that establishes a connection with an ADO data store; multiple ADO dataset and command components can share this connection to execute commands, retrieve data, and operate on metadata.
TADODataSet	The primary dataset (see page 1632) for retrieving and operating on data; *TADODataSet* can retrieve data from a single or multiple tables; can connect directly to a data store or use a *TADOConnection* component.
TADOTable	A table-type dataset (see page 1620) for retrieving and operating on a recordset produced by a single database table; *TADOTable* can connect directly to a data store or use a *TADOConnection* component.
TADOQuery	A query-type dataset (see page 1618) for retrieving and operating on a recordset produced by a valid SQL statement; *TADOQuery* can also execute data definition language (DDL) SQL statements. It can connect directly to a data store or use a *TADOConnection* component
TADOStoredProc	A stored procedure-type dataset (see page 1618) for executing stored procedures; *TADOStoredProc* executes stored procedures that may or may not retrieve data. It can connect directly to a data store or use a *TADOConnection* component.
TADOCommand	A simple component for executing commands (SQL statements that do not return result sets); *TADOCommand* can be used with a supporting dataset component, or retrieve a dataset from a table; It can connect directly to a data store or use a *TADOConnection* component.

3.2.3.1.22 Retrieving Result Sets with Commands

Unlike *TADOQuery* components, which use different methods to execute depending on whether they return a result set, *TADOCommand* always uses the Execute command to execute the command, regardless of whether it returns a result set. When the command returns a result set, *Execute* returns an interface to the ADO _RecordSet interface.

The most convenient way to work with this interface is to assign it to the RecordSet property of an ADO dataset.

For example, the following code uses *TADOCommand* (*ADOCommand1*) to execute a SELECT query, which returns a result set. This result set is then assigned to the *RecordSet* property of a *TADODataSet* component (*ADODataSet1*).

```
with ADOCommand1 do begin
  CommandText := 'SELECT Company, State ' +
    'FROM customer ' +
    'WHERE State = :StateParam';
  CommandType := cmdText;
  Parameters.ParamByName('StateParam').Value := 'HI';
  ADODataSet1.Recordset := Execute;
end;
```

```
ADOCommand1->CommandText = "SELECT Company, State ";
ADOCommand1->CommandText += "FROM customer ";
ADOCommand1->CommandText += "WHERE State = :StateParam";
ADOCommand1->CommandType = cmdText;
ADOCommand1->Parameters->ParamByName("StateParam")->Value = "HI";
ADOCommand1->Recordset = ADOCommand1->Execute();
```

As soon as the result set is assigned to the ADO dataset's *Recordset* property, the dataset is automatically activated and the

data is available.

Using the Execute Method (see page 1493)

Canceling Commands (see page 1477)

Handling Command Parameters (see page 1484)

3.2.3.1.23 Specifying the Command

Specify commands for a *TADOCommand* component using the CommandText property. Like *TADODataSet*, *TADOCommand* lets you specify the command in different ways, depending on the CommandType property. Possible values for *CommandType* include: *cmdText* (used if the command is an SQL statement), *cmdTable* (if it is a table name), and *cmdStoredProc* (if the command is the name of a stored procedure). At design-time, select the appropriate command type from the list in the **Object Inspector**. At runtime, assign a value of type *TCommandType* to the *CommandType* property.

```
with ADOCommand1 do begin
  CommandText := "AddEmployee";
  CommandType := cmdStoredProc;
...
end;
ADOCommand1->CommandText = "AddEmployee";
ADOCommand1->CommandType = cmdStoredProc;
...
```

If no specific type is specified, the server is left to decide as best it can based on the command in *CommandText*.

CommandText can contain the text of an SQL query that includes parameters or the name of a stored procedure that uses parameters. You must then supply parameter values, which are bound to the parameters before executing the command. See Handling command parameters (see page 1484) for details.

3.2.3.1.24 Specifying Whether the Connection Automatically Initiates Transactions

Use the Attributes property to control the connection component's use of retaining commits and retaining aborts. When the connection component uses retaining commits, then every time your application commits a transaction, a new transaction is automatically started. When the connection component uses retaining aborts, then every time your application rolls back a transaction, a new transaction is automatically started.

Attributes is a set that can contain one, both, or neither of the constants *xaCommitRetaining* and *xaAbortRetaining*. When *Attributes* contains *xaCommitRetaining*, the connection uses retaining commits. When *Attributes* contains *xaAbortRetaining*, it uses retaining aborts.

Check whether either retaining commits or retaining aborts is enabled using the in operator. Enable retaining commits or aborts by adding the appropriate value to the attributes property; disable them by subtracting the value. The example routines below respectively enable and disable retaining commits in an ADO connection component.

```
procedure TForm1.RetainingCommitsOnButtonClick(Sender: TObject);
begin
  with ADOConnection1 do begin
    Close;
    if not (xaCommitRetaining in Attributes) then
      Attributes := (Attributes + [xaCommitRetaining])
    Open;
  end;
end;
procedure TForm1.RetainingCommitsOffButtonClick(Sender: TObject);
begin
  with ADOConnection1 do begin
    Close;
    if (xaCommitRetaining in Attributes) then
      Attributes := (Attributes - [xaCommitRetaining]);
    Open;
  end;
end;
void __fastcall TForm1::RetainingCommitsOnButtonClick(TObject *Sender)
{
  ADOConnection1->Close()
  if (!ADOConnection1->Attributes.Contains(xaCommitRetaining))
    ADOConnection1->Attributes = TXactAttributes() << xaCommitRetaining;
  ADOConnection1->Open()
}
void __fastcall TForm1::RetainingCommitsOffButtonClick(TObject *Sender)
{
  ADOConnection1->Close()
  if (ADOConnection1->Attributes.Contains(xaCommitRetaining))
    ADOConnection1->Attributes = TXactAttributes() >> xaCommitRetaining;
  ADOConnection1->Open()
}
```

3.2.3.1.25 Using ADO datasets

ADO dataset components encapsulate the ADO Recordset object. They inherit the common dataset capabilities described in Understanding Datasets (see page 1632), using ADO to provide the implementation. In order to use an ADO dataset, you must familiarize yourself with these common features.

In addition to the common dataset features, all ADO datasets add properties, events, and methods for the following:

- Connecting to an ADO datastore (see page 1479)
- Accessing the underlying Recordset object (see page 1494)
- Filtering records based on bookmarks (see page 1482)
- Fetching records asynchronously (see page 1481)
- Performing batch updates (caching updates) (see page 1491)
- Using files on disk to store data (see page 1486)

There are four ADO datasets:

- *TADOTable*, a table-type dataset (see page 1620) that represents all of the rows and columns of a single database table.
- *TADOQuery*, a query-type dataset (see page 1618) that encapsulates an SQL statement and enables applications to access the resulting records, if any.

- *TADOStoredProc*, a stored procedure-type dataset (see page 1618) that executes a stored procedure defined on a database server.
- *TADODataSet*, a general-purpose dataset that includes the capabilities of the other three types. See Using TADODataSet (see page 1492) for a description of features unique to *TADODataSet*.

  Note: When using ADO to access database information, you do not need to use a dataset such as *TADOQuery* to represent SQL commands that do not return a cursor. Instead, you can use *TADOCommand*, a simple component that is not a dataset. For details on *TADOCommand*, see Using Command Objects (see page 1492).

See Also

Using Command Objects (see page 1492)

Connecting to ADO Data Stores (see page 1477)

3.2.3.1.26 Using Batch Updates

One approach for caching updates is to connect the ADO dataset to a client dataset using a dataset provider. This approach is discussed in Using a client dataset to cache updates (see page 1731).

However, ADO dataset components provide their own support for cached updates, which they call batch updates. The following table lists the correspondences between caching updates using a client dataset and using the batch updates features:

Comparison of ADO and client dataset cached updates

ADO dataset	TClientDataSet	Description
LockType	Not used: client datasets always cache updates	Specifies whether the dataset is opened in batch update mode.
CursorType	Not used: client datasets always work with an in-memory snapshot of data	Specifies how isolated the ADO dataset is from changes on the server.
RecordStatus	UpdateStatus	Indicates what update, if any, has occurred on the current row. *RecordStatus* provides more information than *UpdateStatus*.
FilterGroup	StatusFilter	Specifies which type of records are available. *FilterGroup* provides a wider variety of information.
UpdateBatch	ApplyUpdates	Applies the cached updates back to the database server. Unlike *ApplyUpdates*, *UpdateBatch* lets you limit the types of updates to be applied.
CancelBatch	CancelUpdates	Discards pending updates, reverting to the original values. Unlike *CancelUpdates*, *CancelBatch* lets you limit the types of updates to be canceled.

Using the batch updates features of ADO dataset components is a matter of:

- Opening the dataset in batch update mode (see page 1487)
- Inspecting the update status of individual rows (see page 1485)
- Filtering multiple rows based on update status (see page 1481)
- Applying the batch updates to base tables (see page 1476)
- Canceling batch updates (see page 1476)

3.2.3.1.27 Using Command Objects

In the ADO environment, commands are textual representations of provider-specific action requests. Typically, they are Data Definition Language (DDL) and Data Manipulation Language (DML) SQL statements. The language used in commands is provider-specific, but usually compliant with the SQL-92 standard for the SQL language.

Although you can always execute commands using *TADOQuery*, you may not want the overhead of using a dataset component, especially if the command does not return a result set. As an alternative, you can use the TADOCommand component, which is a lighter-weight object designed to execute commands, one command at a time. *TADOCommand* is intended primarily for executing those commands that do not return result sets, such as Data Definition Language (DDL) SQL statements. Through an overloaded version of its *Execute* method, however, it is capable of returning a result set that can be assigned to the *RecordSet* property of an ADO dataset component.

In general, working with *TADOCommand* is very similar to working with *TADODataSet*, except that you can't use the standard dataset methods to fetch data, navigate records, edit data, and so on. *TADOCommand* objects connect to a data store in the same way as ADO datasets. See Connecting an ADO dataset to a data store (see page 1479) for details.

The following topics provide details on how to specify and execute commands using *TADOCommand*:

- Specifying the command (see page 1489)
- Using Command objects (see page 1493)
- Canceling commands (see page 1477)
- Retrieving result sets with commands (see page 1488)
- Handling command parameters (see page 1484)

Using the Execute Method (see page 1493)

3.2.3.1.28 Using TADODataSet

TADODataSet is a general-purpose dataset (see page 1632) for working with data from an ADO data store. Unlike the other ADO dataset components, *TADODataSet* is not a table-type (see page 1620), query-type (see page 1618), or stored procedure-type (see page 1618) dataset. Instead, it can function as any of these types:

- Like a table-type dataset, *TADODataSet* lets you represent all of the rows and columns of a single database table. To use it in this way, set the CommandType property to *cmdTable* and the CommandText property to the name of the table. *TADODataSet* supports table-type tasks such as
- Assigning indexes (see page 1609) to sort records or form the basis of record-based searches. In addition to the standard index properties and methods, *TADODataSet* lets you sort using temporary indexes by setting the Sort property. Indexed-based searches performed using the Seek method use the current index.
- Emptying the dataset (see page 1592). The DeleteRecordsDeleteRecords method provides greater control than related methods in other table-type datasets, because it lets you specify what records to delete.

The table-type tasks supported by *TADODataSet* are available even when you are not using a *CommandType* of *cmdTable*.

- Like a query-type dataset, *TADODataSet* lets you specify a single SQL command that is executed when you open the

dataset. To use it in this way, set the CommandType property to *cmdText* and the CommandText property to the SQL command you want to execute. At design time, you can double-click on the *CommandText* property in the **Object Inspector** to use the Command Text editor for help in constructing the SQL command. *TADODataSet* supports query-type tasks such as

- Using parameters in the query text (see page 1617).
- Setting up master/detail relationships using parameters (see page 1593).
- Preparing the query in advance to improve performance by setting the Prepared property to *True*.
- Like a stored procedure-type dataset, *TADODataSet* lets you specify a stored procedure that is executed when you open the dataset. To use it in this way, set the CommandType property to *cmdStoredProc* and the CommandText property to the name of the stored procedure. *TADODataSet* supports stored procedure-type tasks such as
- Working with stored procedure parameters (see page 1625).
- Fetching multiple result sets (see page 1597).
- Preparing the stored procedure in advance to improve performance by setting the Prepared property to *True*.

In addition, *TADODataSet* lets you work with data stored in files by setting the *CommandType* property to *cmdFile* and the *CommandText* property to the file name.

Before you set the *CommandText* and *CommandType* properties, you should link the *TADODataSet* to a data store by setting the Connection or ConnectionString property. This process is described in Connecting an ADO dataset to a data store (see page 1479). As an alternative, you can use an RDS DataSpace object to connect the *TADODataSet* to an ADO-based application server. To use an RDS DataSpace object, set the RDSConnection property to a TRDSConnection object.

See Also

Understanding Datasets (see page 1632)

Using TADODataSet

3.2.3.1.29 Using the Execute Method

Before *TADOCommand* can execute its command, it must have a valid connection to a data store. This is established just as with an ADO dataset. See Connecting an ADO dataset to a data store (see page 1479) for details.

To execute the command, call the Execute method. *Execute* is an overloaded method that lets you choose the most appropriate way to execute the command.

For commands that do not require any parameters and for which you do not need to know how many records were affected, call *Execute* without any parameters:

```
with ADOCommand1 do begin
  CommandText := "UpdateInventory";
  CommandType := cmdStoredProc;
  Execute;
end;
ADOCommand1->CommandText = "UpdateInventory";
ADOCommand1->CommandType = cmdStoredProc;
ADOCommand1->Execute();
```

Other versions of *Execute* let you provide parameter values using a Variant array, and to obtain the number of records affected by the command.

For information on executing commands that return a result set, see Retrieving result sets with commands (see page 1488).

Retrieving Result Sets with Commands (see page 1488)

Handling Command Parameters (see page 1484)

3.2.3.1.30 Working with ADO Components

The *dbGo* components provide data access through the ADO framework. ADO, (Microsoft ActiveX Data Objects) is a set of COM objects that access data through an OLE DB provider. The *dbGo* components encapsulate these ADO objects in the Delphi database architecture.

The ADO layer of an ADO-based application consists of Microsoft ADO 2.1, an OLE DB provider or ODBC driver for the data store access, client software for the specific database system used (in the case of SQL databases), a database back-end system accessible to the application (for SQL database systems), and a database. All of these must be accessible to the ADO-based application for it to be fully functional.

The ADO objects that figure most prominently are the Connection, Command, and Recordset objects. These ADO objects are wrapped by the *TADOConnection*, *TADOCommand*, and ADO dataset components. The ADO framework includes other "helper" objects, like the Field and Properties objects, but these are typically not used directly in dbGo applications and are not wrapped by dedicated components.

Before reading about the features peculiar to the *dbGo* components, you should familiarize yourself with the common features of database connection components (see page 1506) and datasets (see page 1632).

The following topics describe the unique features of dbGo components and how to work with them:

- Overview of ADO components (see page 1487)
- Connecting to ADO data stores (see page 1477)
- Using TADODataSet (see page 1492)
- Using Command Objects (see page 1492)

3.2.3.1.31 Working with Record Sets

The Recordset property provides direct access to the ADO recordset object underlying the dataset component. Using this object, it is possible to access properties and call methods of the recordset object from an application. Use of *Recordset* to directly

access the underlying ADO recordset object requires a good working knowledge of ADO objects in general and the ADO recordset object in specific. Using the recordset object directly is not recommended unless you are familiar with recordset object operations. Consult the Microsoft Data Access SDK help for specific information on using ADO recordset objects.

The RecordSetState property indicates the current state of the underlying recordset object. *RecordsetState* corresponds to the *State* property of the ADO recordset object. The value of *RecordsetState* is either *stOpen*, *stExecuting*, or *stFetching*. (*TObjectState*, the type of the *RecordsetState* property, defines other values, but only *stOpen*, *stExecuting,* and *stFetching* pertain to recordsets.) A value of *stOpen* indicates that the recordset is currently idle. A value of stExecuting indicates that it is executing a command. A value of stFetching indicates that it is fetching rows from the associated table (or tables).

Use *RecordsetState* values to perform actions dependent on the current state of the dataset. For example, a routine that updates data might check the RecordsetState property to see whether the dataset is active and not in the process of other activities such as connecting or fetching data.

Fetching Records Asynchronously (see page 1481)

3.2.3.2 Connecting to databases

Topics

Name	Description
Controlling Connections (see page 1497)	Before you can establish a connection to a database server, your application must provide certain key pieces of information that describe the desired server. Each type of connection component surfaces a different set of properties to let you identify the server. In general, however, they all provide a way for you to name the server you want and supply a set of connection parameters that control how the connection is formed. Connection parameters vary from server to server. They can include information such as user name and password, the maximum size of BLOB fields, SQL roles, and so on. Once... more (see page 1497)
Disconnecting from a Database Server (see page 1497)	There are two ways to disconnect a server using a connection component: • Set the Connected property to *False*. • Call the Close method. Calling *Close* sets *Connected* to *False*. When *Connected* is set to *False*, the connection component generates a BeforeDisconnect event, where you can perform any cleanup before the connection closes. For example, you can use this event to cache information about all open datasets before they are closed. After the *BeforeConnect* event, the connection component closes all open datasets and disconnects from the server. Finally, the connection component generates an AfterDisconnect event, where you can respond... more (see page 1497)

Managing Transactions (see page 1498)	A *transaction* is a group of actions that must all be carried out successfully on one or more tables in a database before they are *committed* (made permanent). If one of the actions in the group fails, then all actions are *rolled back* (undone). By using transactions, you ensure that the database is not left in an inconsistent state when a problem occurs completing one of the actions that make up the transaction. For example, in a banking application, transferring funds from one account to another is an operation you would want to protect with a transaction. If, after decrementing... more (see page 1498)
Obtaining Metadata (see page 1501)	All database connection components can retrieve lists of metadata on the database server, although they vary in the types of metadata they retrieve. The methods that retrieve metadata fill a string list with the names of various entities available on the server. You can then use this information, for example, to let your users dynamically select a table at runtime. You can use a *TADOConnection* component to retrieve metadata about the tables and stored procedures available on the ADO data store. You can then use this information, for example, to let your users dynamically select a table or stored procedure... more (see page 1501)
Sending Commands to the Server (see page 1502)	All database connection components except *TIBDatabase* let you execute SQL statements on the associated server by calling the *Execute* method. Although *Execute* can return a cursor when the statement is a SELECT statement, this use is not recommended. The preferred method for executing statements that return data is to use a dataset. The *Execute* method is very convenient for executing simple SQL statements that do not return any records. Such statements include Data Definition Language (DDL) statements, which operate on or create a database's metadata, such as CREATE INDEX, ALTER TABLE, and DROP DOMAIN. Some Data Manipulation Language (DML) SQL... more (see page 1502)
Specifying the Transaction Isolation Level (see page 1504)	Transaction isolation level determines how a transaction interacts with other simultaneous transactions when they work with the same tables. In particular, it affects how much a transaction "sees" of other transactions' changes to a table. Each server type supports a different set of possible transaction isolation levels. There are three possible transaction isolation levels: • *DirtyRead*: When the isolation level is *DirtyRead*, your transaction sees all changes made by other transactions, even if they have not been committed. Uncommitted changes are not permanent, and might be rolled back at any time. This value provides the least isolation, and is... more (see page 1504)
Using Implicit Connections (see page 1505)	No matter what data access mechanism you are using, you can always create the connection component explicitly and use it to manage the connection to and communication with a database server. For BDE-enabled and ADO-based datasets, you also have the option of describing the database connection through properties of the dataset and letting the dataset generate an implicit connection. For BDE-enabled datasets, you specify an implicit connection using the DatabaseName property. For ADO-based datasets, you use the ConnectionString property. When using an implicit connection, you do not need to explicitly create a connection component. This can simplify your application development,... more (see page 1505)
Working with Associated Datasets (see page 1505)	All database connection components maintain a list of all datasets that use them to connect to a database. A connection component uses this list, for example, to close all of the datasets when it closes the database connection. You can use this list as well, to perform actions on all the datasets that use a specific connection component to connect to a particular database.
Connecting to Databases: Overview (see page 1506)	Most dataset components can connect directly to a database server (see page 1560). Once connected, the dataset communicates with the server automatically. When you open the dataset, it populates itself with data from the server, and when you post records, they are sent back the server and applied. A single connection component can be shared by multiple datasets, or each dataset can use its own connection. Each type of dataset connects to the database server using its own type of connection component, which is designed to work with a single data access mechanism. The following table lists these data access mechanisms and... more (see page 1506)

Controlling Server Login (see page 1507)	Most remote database servers include security features to prohibit unauthorized access. Usually, the server requires a user name and password login before permitting database access. At design time, if a server requires a login, a standard login dialog box prompts for a user name and password when you first attempt to connect to the database. At runtime, there are three ways you can handle a server's request for a login: The first way is to let the default login dialog and processes handle the login. This is the default approach. Set the *LoginPrompt property of the connection component to True... more (see page 1507)*
Connecting to a Database Server (see page 1509)	There are two ways to connect to a database server using a connection component: • Call the Open method. • Set the Connected property to *True*. *Calling the Open method sets Connected to True.* ***Note:*** *When a connection component is not connected to a server and an application attempts to open one of its associated datasets, the dataset automatically calls the connection component's Open method.* *When you set Connected to True, the connection component first generates a BeforeConnect event, where you can perform any initialization. For example, you can use this event to alter connection parameters.* *After the BeforeConnect... more (see page 1509)*

3.2.3.2.1 Controlling Connections

Before you can establish a connection to a database server, your application must provide certain key pieces of information that describe the desired server. Each type of connection component surfaces a different set of properties to let you identify the server. In general, however, they all provide a way for you to name the server you want and supply a set of connection parameters that control how the connection is formed. Connection parameters vary from server to server. They can include information such as user name and password, the maximum size of BLOB fields, SQL roles, and so on.

Once you have identified the desired server and any connection parameters, you can use the connection component to explicitly open or close a connection. The connection component generates events when it opens or closes a connection that you can use to customize the response of your application to changes in the database connection.

The following topics provide details about opening and closing database connections:

- Connecting to a Database Server (see page 1509)
- Disconnecting From a Database Server (see page 1497)

Working with Associated Datasets (see page 1505)

Sending Commands to the Server (see page 1502)

3.2.3.2.2 Disconnecting from a Database Server

There are two ways to disconnect a server using a connection component:

- Set the Connected property to *False*.
- Call the Close method.

Calling *Close* sets *Connected* to *False*.

When *Connected* is set to *False*, the connection component generates a BeforeDisconnect event, where you can perform any cleanup before the connection closes. For example, you can use this event to cache information about all open datasets before they are closed.

After the *BeforeConnect* event, the connection component closes all open datasets and disconnects from the server.

Finally, the connection component generates an AfterDisconnect event, where you can respond to the change in connection status, such as enabling a Connect button in your user interface.

Note: Calling *Close* or setting *Connected* to *False* disconnects from a database server even if the connection component has a *KeepConnection* property that is *True*.

Connecting to a Database Server (see page 1509)

3.2.3.2.3 Managing Transactions

A *transaction* is a group of actions that must all be carried out successfully on one or more tables in a database before they are *committed* (made permanent). If one of the actions in the group fails, then all actions are *rolled back* (undone). By using transactions, you ensure that the database is not left in an inconsistent state when a problem occurs completing one of the actions that make up the transaction.

For example, in a banking application, transferring funds from one account to another is an operation you would want to protect with a transaction. If, after decrementing the balance in one account, an error occurred incrementing the balance in the other, you want to roll back the transaction so that the database still reflects the correct total balance.

It is always possible to manage transactions by sending SQL commands directly to the database (see page 1502). Most databases provide their own transaction management model, although some have no transaction support at all. For servers that support it, you may want to code your own transaction management directly, taking advantage of advanced transaction management capabilities on a particular database server, such as schema caching.

If you do not need to use any advanced transaction management capabilities, connection components provide a set of methods and properties you can use to manage transactions without explicitly sending any SQL commands. Using these properties and methods has the advantage that you do not need to customize your application for each type of database server you use, as long as the server supports transactions. (The BDE also provides limited transaction support for local tables with no server transaction support. When not using the BDE, trying to start transactions on a database that does not support them causes connection components to raise an exception.)

Warning: When a dataset provider component applies updates, it implicitly generates transactions for any updates. Be careful that any transactions you explicitly start do not conflict with those generated by the provider.

Starting a transaction

When you start a transaction, all subsequent statements that read from or write to the database occur in the context of that transaction, until the transaction is explicitly terminated or (in the case of overlapping transactions) until another transaction is started. Each statement is considered part of a group. Changes must be successfully committed to the database, or every change made in the group must be undone.

While the transaction is in process, your view of the data in database tables is determined by your transaction isolation level (see page 1504).

For *TADOConnection*, start a transaction by calling the *BeginTrans* method:

```
Level := ADOConnection1.BeginTrans;
Level = ADOConnection1->BeginTrans();
```

BeginTrans returns the level of nesting for the transaction that started. A nested transaction is one that is nested within another, parent, transaction. After the server starts the transaction, the ADO connection receives an *OnBeginTransComplete* event.

For *TDatabase,* use the *StartTransaction* method instead. *TDataBase* does not support nested or overlapped transactions: If you call a *TDatabase* component's *StartTransaction* method while another transaction is underway, it raises an exception. To avoid calling *StartTransaction*, you can check the *InTransaction* property:

```
if not Database1.InTransaction then
  Database1.StartTransaction;
if (!Database1->InTransaction)
  Database1->StartTransaction();
```

TSQLConnection also uses the *StartTransaction* method, but it uses a version that gives you a lot more control. Specifically, *StartTransaction* takes a transaction descriptor, which lets you manage multiple simultaneous transactions and specify the transaction isolation level (see page 1504) on a per-transaction basis. In order to manage multiple simultaneous transactions, set the *TransactionID* field of the transaction descriptor to a unique value. *TransactionID* can be any value you choose, as long as it is unique (does not conflict with any other transaction currently underway). Depending on the server, transactions started by *TSQLConnection* can be nested (as they can be when using ADO) or they can be overlapped.

```
var
  TD: TTransactionDesc;
begin
  TD.TransactionID := 1;
  TD.IsolationLevel := xilREADCOMMITTED;
  SQLConnection1.StartTransaction(TD);
TTransactionDesc TD;
TD.TransactionID = 1;
TD.IsolationLevel = xilREADCOMMITTED;
SQLConnection1->StartTransaction(TD);
```

By default, with overlapped transactions, the first transaction becomes inactive when the second transaction starts, although you can postpone committing or rolling back the first transaction until later. If you are using *TSQLConnection* with an InterBase database, you can identify each dataset in your application with a particular active transaction, by setting its TransactionLevel property. That is, after starting a second transaction, you can continue to work with both transactions simultaneously, simply by associating a dataset with the transaction you want.

Note: Unlike *TADOConnection*, *TSQLConnection* and *TDatabase* do not receive any events when the transactions starts.

InterBase express offers you even more control than *TSQLConnection* by using a separate transaction component rather than starting transactions using the connection component. You can, however, use *TIBDatabase* to start a default transaction:

```
if not IBDatabase1.DefaultTransaction.InTransaction then
  IBDatabase1.DefaultTransaction.StartTransaction;
if (!IBDatabase1->DefaultTransaction->InTransaction)
  IBDatabase1->DefaultTransaction->StartTransaction();
```

You can have overlapped transactions by using two separate transaction components. Each transaction component has a set of parameters that let you configure the transaction. These let you specify the transaction isolation level, as well as other properties of the transaction.

Ending a transaction

Ideally, a transaction should only last as long as necessary. The longer a transaction is active, the more simultaneous users that access the database, and the more concurrent, simultaneous transactions that start and end during the lifetime of your transaction, the greater the likelihood that your transaction will conflict with another when you attempt to commit any changes.

When the actions that make up the transaction have all succeeded, you can make the database changes permanent by committing the transaction. For *TDatabase*, you commit a transaction using the *Commitmethod:*

```
MyOracleConnection.Commit;
MyOracleConnection->Commit();
```

For *TSQLConnection*, you also use the *Commitmethod, but you must specify which transaction you are committing by supplying*

the transaction descriptor you gave to the StartTransaction method:

```
MyOracleConnection.Commit(TD);
MyOracleConnection->Commit(TD);
```

For *TIBDatabase*, you commit a transaction object using its *Commit* method:

```
IBDatabase1.DefaultTransaction.Commit;
IBDatabase1->DefaultTransaction->Commit();
```

For *TADOConnection*, you commit a transaction using the *CommitTrans* method:

```
ADOConnection1.CommitTrans;
ADOConnection1->CommitTrans();
```

Note: It is possible for a nested transaction to be committed, only to have the changes rolled back later if the parent transaction is rolled back.

After the transaction is successfully committed, an ADO connection component receives an *OnCommitTransComplete* event. Other connection components do not receive any similar events.

A call to commit the current transaction is usually attempted in a **try...except** statement. That way, if the transaction cannot commit successfully, you can use the **except** block to handle the error and retry the operation or to roll back the transaction.

If an error occurs when making the changes that are part of the transaction or when trying to commit the transaction, you will want to discard all changes that make up the transaction. Discarding these changes is called rolling back the transaction.

For *TDatabase*, you roll back a transaction by calling the *Rollback* method:

```
MyOracleConnection.Rollback;
MyOracleConnection->Rollback();
```

For *TSQLConnection*, you also use the *Rollback* method, but you must specify which transaction you are rolling back by supplying the transaction descriptor you gave to the *StartTransaction* method:

```
MyOracleConnection.Rollback(TD);
MyOracleConnection->Rollback(TD);
```

For *TIBDatabase*, you roll back a transaction object by calling its *Rollback* method:

```
IBDatabase1.DefaultTransaction.Rollback;
IBDatabase1->DefaultTransaction->Rollback();
```

For *TADOConnection*, you roll back a transaction by calling the *RollbackTrans* method:

```
ADOConnection1.RollbackTrans;
ADOConnection1->RollbackTrans();
```

After the transaction is successfully rolled back, an ADO connection component receives an *OnRollbackTransComplete* event. Other connection components do not receive any similar events.

A call to roll back the current transaction usually occurs in

- Exception handling code when you can't recover from a database error.
- Button or menu event code, such as when a user clicks a Cancel button.

Obtaining Metadata (see page 1501)

3.2.3.2.4 Obtaining Metadata

All database connection components can retrieve lists of metadata on the database server, although they vary in the types of metadata they retrieve. The methods that retrieve metadata fill a string list with the names of various entities available on the server. You can then use this information, for example, to let your users dynamically select a table at runtime.

You can use a *TADOConnection* component to retrieve metadata about the tables and stored procedures available on the ADO data store. You can then use this information, for example, to let your users dynamically select a table or stored procedure at runtime.

Listing available tables

The *GetTableNames* method copies a list of table names to an already-existing string list object. This can be used, for example, to fill a list box with table names that the user can then use to choose a table to open. The following line fills a listbox with the names of all tables on the database:

```
MyDBConnection.GetTableNames(ListBox1.Items, False);
MyDBConnection->GetTableNames(ListBox1->Items, false);
```

GetTableNames has two parameters: the string list to fill with table names, and a boolean that indicates whether the list should include system tables, or ordinary tables. Note that not all servers use system tables to store metadata, so asking for system tables may result in an empty list.

Note: For most database connection components, *GetTableNames* returns a list of all available non-system tables when the second parameter is *False*. For *TSQLConnection*, however, you have more control over what type is added to the list when you are not fetching only the names of system tables. When using *TSQLConnection*, the types of names added to the list are controlled by the *TableScope* property. *TableScope* indicates whether the list should contain any or all of the following: ordinary tables, system tables, synonyms, and views.

Listing the fields in a table

The *GetFieldNames* method fills an existing string list with the names of all fields (columns) in a specified table. *GetFieldNames* takes two parameters, the name of the table for which you want to list the fields, and an existing string list to be filled with field names:

```
MyDBConnection.GetFieldNames('Employee', ListBox1.Items);
MyDBConnection->GetTableNames("Employee", ListBox1->Items);
```

Listing available stored procedures

To get a listing of all of the stored procedures contained in the database, use the *GetProcedureNames* method. This method takes a single parameter: an already-existing string list to fill:

```
MyDBConnection.GetProcedureNames(ListBox1.Items);
MyDBConnection->GetProcedureNames(ListBox1->Items);
```

Note: *GetProcedureNames* is only available for *TADOConnection* and *TSQLConnection*.

Listing available indexes

To get a listing of all indexes defined for a specific table, use the *GetIndexNames* method. This method takes two parameters: the table whose indexes you want, and an already-existing string list to fill:

```
SQLConnection1.GetIndexNames('Employee', ListBox1.Items);
MyDBConnection1->GetIndexNames("Employee", ListBox1->Items);
```

Note: *GetIndexNames* is only available for *TSQLConnection*, although most table-type datasets have an equivalent method.

Listing stored procedure parameters

To get a list of all parameters defined for a specific stored procedure, use the *GetProcedureParams* method. *GetProcedureParams* fills a *TList* object with pointers to parameter description records, where each record describes a parameter of a specified stored procedure, including its name, index, parameter type, field type, and so on.

GetProcedureParams takes two parameters: the name of the stored procedure, and an already-existing *TList* object to fill:

```
SQLConnection1.GetProcedureParams('GetInterestRate', List1);
MyDBConnection1->GetIndexNames("GetInterestRate", List1);
```

To convert the parameter descriptions that are added to the list into the more familiar *TParams* object, call the global *LoadParamListItems* procedure. Because *GetProcedureParams* dynamically allocates the individual records, your application must free them when it is finished with the information. The global *FreeProcParams* routine can do this for you.

Note: *GetProcedureParams* is only available for *TSQLConnection*.

3.2.3.2.5 Sending Commands to the Server

All database connection components except *TIBDatabase* let you execute SQL statements on the associated server by calling the *Execute* method. Although *Execute* can return a cursor when the statement is a SELECT statement, this use is not recommended. The preferred method for executing statements that return data is to use a dataset.

The *Execute* method is very convenient for executing simple SQL statements that do not return any records. Such statements include Data Definition Language (DDL) statements, which operate on or create a database's metadata, such as CREATE INDEX, ALTER TABLE, and DROP DOMAIN. Some Data Manipulation Language (DML) SQL statements also do not return a result set. The DML statements that perform an action on data but do not return a result set are: INSERT, DELETE, and UPDATE.

The syntax for the *Execute* method varies with the connection type:

- For *TDatabase*, *Execute* takes four parameters: a string that specifies a single SQL statement that you want to execute, a TParams object that supplies any parameter values for that statement, a boolean that indicates whether the statement should be cached because you will call it again, and a pointer to a BDE cursor that can be returned (It is recommended that you pass nil).
- For *TADOConnection*, there are two versions of *Execute.* The first takes a WideString that specifies the SQL statement and a second parameter that specifies a set of options that control whether the statement is executed asynchronously and whether it returns any records. This first syntax returns an interface for the returned records. The second syntax takes a WideString that specifies the SQL statement, a second parameter that returns the number of records affected when the statement executes, and a third that specifies options such as whether the statement executes asynchronously. Note that neither syntax provides for passing parameters.
- For *TSQLConnection*, *Execute* takes three parameters: a string that specifies a single SQL statement that you want to execute, a TParams object that supplies any parameter values for that statement, and a pointer that can receive a *TCustomSQLDataSet* that is created to return records.

Note: *Execute* can only execute one SQL statement at a time. It is not possible to execute multiple SQL statements with a single call to *Execute*, as you can with SQL scripting utilities. To execute more than one statement, call *Execute* repeatedly.

It is relatively easy to execute a statement that does not include any parameters. For example, the following code executes a CREATE TABLE statement (DDL) without any parameters on a *TSQLConnection* component:

```
procedure TForm1.CreateTableButtonClick(Sender: TObject);
var
  SQLstmt: String;
begin
  SQLConnection1.Connected := True;
  SQLstmt := 'CREATE TABLE NewCusts ' +
    '( " +
    '  CustNo INTEGER, ' +
    '  Company CHAR(40), ' +
    '  State CHAR(2), ' +
    '  PRIMARY KEY (CustNo) ' +
    ')';
  SQLConnection1.Execute(SQLstmt, nil, nil);
end;
void __fastcall TDataForm::CreateTableButtonClick(TObject *Sender)
{
  SQLConnection1->Connected = true;
  AnsiString SQLstmt = "CREATE TABLE NewCusts " +
    "( " +
    " CustNo INTEGER, " +
    " Company CHAR(40), " +
    " State CHAR(2), " +
    " PRIMARY KEY (CustNo) " +
    ")";
  SQLConnection1->Execute(SQLstmt, NULL, NULL);
}
```

To use parameters, you must create a TParams object. For each parameter value, use the *TParams*.*CreateParam* method to add a *TParam* object. Then use properties of *TParam* to describe the parameter and set its value.

This process is illustrated in the following example, which uses *TDatabase* to execute an INSERT statement. The INSERT statement has a single parameter named: *StateParam*. A *TParams* object (called *stmtParams*) is created to supply a value of "CA" for that parameter.

```
procedure TForm1.INSERT_WithParamsButtonClick(Sender: TObject);
var
  SQLstmt: String;
  stmtParams: TParams;
begin
  stmtParams := TParams.Create;
  try
    Database1.Connected := True;
    stmtParams.CreateParam(ftString, 'StateParam', ptInput);
    stmtParams.ParamByName('StateParam').AsString := 'CA';
    SQLstmt := 'INSERT INTO "Custom.db" '+
      '(CustNo, Company, State) ' +
      'VALUES (7777, "Robin Dabank Consulting", :StateParam)';
    Database1.Execute(SQLstmt, stmtParams, False, nil);
  finally
    stmtParams.Free;
  end;
end;
void __fastcall TForm1::INSERT_WithParamsButtonClick(TObject *Sender)
{
  AnsiString SQLstmt;
  TParams *stmtParams = new TParams;
  try
  {
    Database1->Connected = true;
    stmtParams->CreateParam(ftString, "StateParam", ptInput);
```

```
    stmtParams->ParamByName("StateParam")->AsString = "CA";
    SQLstmt = "INSERT INTO "Custom.db" ";
    SQLstmt += "(CustNo, Company, State) ";
    SQLstmt += "VALUES (7777, "Robin Dabank Consulting", :StateParam)";
    Database1->Execute(SQLstmt, stmtParams, false, NULL);
  }
  __finally
  {
    delete stmtParams;
  }
}
```

If the SQL statement includes a parameter but you do not supply a *TParam* object to provide its value, the SQL statement may cause an error when executed (this depends on the particular database back-end used). If a *TParam* object is provided but there is no corresponding parameter in the SQL statement, an exception is raised when the application attempts to use the *TParam*.

Using Implicit Connections (see page 1505)

Working with Associated Datasets (see page 1505)

Managing Transactions (see page 1498)

3.2.3.2.6 Specifying the Transaction Isolation Level

Transaction isolation level determines how a transaction interacts with other simultaneous transactions when they work with the same tables. In particular, it affects how much a transaction "sees" of other transactions' changes to a table.

Each server type supports a different set of possible transaction isolation levels. There are three possible transaction isolation levels:

- *DirtyRead*: When the isolation level is *DirtyRead*, your transaction sees all changes made by other transactions, even if they have not been committed. Uncommitted changes are not permanent, and might be rolled back at any time. This value provides the least isolation, and is not available for many database servers (such as Oracle, Sybase, MS-SQL, and InterBase).
- *ReadCommitted*: When the isolation level is *ReadCommitted*, only committed changes made by other transactions are visible. Although this setting protects your transaction from seeing uncommitted changes that may be rolled back, you may still receive an inconsistent view of the database state if another transaction is committed while you are in the process of reading. This level is available for all transactions except local transactions managed by the BDE.
- *RepeatableRead*: When the isolation level is *RepeatableRead*, your transaction is guaranteed to see a consistent state of the database data. Your transaction sees a single snapshot of the data. It cannot see any subsequent changes to data by other simultaneous transactions, even if they are committed. This isolation level guarantees that once your transaction reads a record, its view of that record will not change. At this level your transaction is most isolated from changes made by other transactions. This level is not available on some servers, such as Sybase and MS-SQL and is unavailable on local transactions managed by the BDE.

In addition, *TSQLConnection* lets you specify database-specific custom isolation levels. Custom isolation levels are defined by the *dbExpress* driver. See your driver documentation for details.

Note: For a detailed description of how each isolation level is implemented, see your server documentation.

TDatabase and *TADOConnection* let you specify the transaction isolation level by setting the *TransIsolation* property. When you set *TransIsolation* to a value that is not supported by the database server, you get the next highest level of isolation (if available). If there is no higher level available, the connection component raises an exception when you try to start a transaction.

When using *TSQLConnection*, transaction isolation level is controlled by the *IsolationLevel* field of the transaction descriptor.

When using InterBase express, transaction isolation level is controlled by a transaction parameter.

Managing Transactions (see page 1498)

3.2.3.2.7 Using Implicit Connections

No matter what data access mechanism you are using, you can always create the connection component explicitly and use it to manage the connection to and communication with a database server. For BDE-enabled and ADO-based datasets, you also have the option of describing the database connection through properties of the dataset and letting the dataset generate an implicit connection. For BDE-enabled datasets, you specify an implicit connection using the DatabaseName property. For ADO-based datasets, you use the ConnectionString property.

When using an implicit connection, you do not need to explicitly create a connection component. This can simplify your application development, and the default connection you specify can cover a wide variety of situations. For complex, mission-critical client/server applications with many users and different requirements for database connections, however, you should create your own connection components to tune each database connection to your application's needs. Explicit connection components give you greater control. For example, you need to access the connection component to perform the following tasks:

- Customize database server login support (see page 1507). (Implicit connections display a default login dialog to prompt the user for a user name and password.)
- Control transactions and specify transaction isolation levels (see page 1498).
- Execute SQL commands on the server without using a dataset (see page 1502).
- Perform actions on all open datasets that are connected to the same database (see page 1505).

In addition, if you have multiple datasets that all use the same server, it can be easier to use an connection component, so that you only have to specify the server to use in one place. That way, if you later change the server, you do not need to update several dataset components: only the connection component.

Sending Commands to the Server (see page 1502)

3.2.3.2.8 Working with Associated Datasets

All database connection components maintain a list of all datasets that use them to connect to a database. A connection component uses this list, for example, to close all of the datasets when it closes the database connection.

You can use this list as well, to perform actions on all the datasets that use a specific connection component to connect to a particular database.

Closing all datasets without disconnecting from the server

The connection component automatically closes all datasets when you close its connection. There may be times, however, when you want to close all datasets without disconnecting from the database server.

To close all open datasets without disconnecting from a server, you can use the *CloseDataSets* method.

For *TADOConnection* and *TIBDatabase*, calling *CloseDataSets* always leaves the connection open. For *TDatabase* and

TSQLConnection, you must also set the *KeepConnection* property to *True*.

Iterating through the associated datasets

To perform any actions (other than closing them all) on all the datasets that use a connection component, use the DataSets and DataSetCount properties. *DataSets* is an indexed array of all datasets that are linked to the connection component. For all connection components except *TADOConnection*, this list includes only the active datasets. *TADOConnection* lists the inactive datasets as well. *DataSetCount* is the number of datasets in this array.

Note: When you use a specialized client dataset to cache updates (as opposed to the generic client dataset, *TClientDataSet*), the *DataSets* property lists the internal dataset owned by the client dataset, not the client dataset itself.

You can use *DataSets* with *DataSetCount* to cycle through all currently active datasets in code. For example, the following code cycles through all active datasets and disables any controls that use the data they provide:

```
var
  I: Integer;
begin
  with MyDBConnection do
  begin
    for I := 0 to DataSetCount - 1 do
      DataSets[I].DisableControls;
  end;
end;
for (int i = 0; i < MyDBConnection->DataSetCount; i++)
  MyDBConnection->DataSets[i]->DisableControls();
```

Note: *TADOConnection* supports command objects as well as datasets. You can iterate through these much like you iterate through the datasets, by using the *Commands* and *CommandCount* properties.

3.2.3.2.9 Connecting to Databases: Overview

Most dataset components can connect directly to a database server (see page 1560). Once connected, the dataset communicates with the server automatically. When you open the dataset, it populates itself with data from the server, and when you post records, they are sent back the server and applied. A single connection component can be shared by multiple datasets, or each dataset can use its own connection.

Each type of dataset connects to the database server using its own type of connection component, which is designed to work with a single data access mechanism. The following table lists these data access mechanisms and the associated connection components:

Database connection components

Data Access Mechanism	Connection Component
Borland Database Engine (BDE)	TDatabase

ActiveX Data Objects (ADO)	TADOConnection
dbExpress	TSQLConnection
InterBase Express	TIBDatabase

Note: For a discussion of some pros and cons of each of these mechanisms, see Using Databases (see page 1572).

The connection component provides all the information necessary to establish a database connection. This information is different for each type of connection component:

- For information about describing a BDE-based connection, see Identifying the Database (see page 1648).
- For information about describing an ADO-based connection, see Connecting to a Data Store Using TADOConnection (see page 1478).
- For information about describing a dbExpress connection, see Setting up TSQLConnection (see page 1834).
- For information about describing an InterBase Express connection, see TIBDatabase.

Although each type of dataset uses a different connection component, they are all descendants of TCustomConnection. They all perform many of the same tasks and surface many of the same properties, methods, and events.

The following topics discuss many of these common tasks:

- Using Implicit Connections (see page 1505)
- Controlling Connections (see page 1497)
- Controlling Server Login (see page 1507)
- Managing Transactions (see page 1498)
- Working with Associated Datasets (see page 1505)
- Sending Commands to the Server (see page 1502)
- Obtaining Metadata (see page 1501)

Using Decision Support Components (see page 1800)

Using XML in Database Applications (see page 1847)

3.2.3.2.10 Controlling Server Login

Most remote database servers include security features to prohibit unauthorized access. Usually, the server requires a user

name and password login before permitting database access.

At design time, if a server requires a login, a standard login dialog box prompts for a user name and password when you first attempt to connect to the database.

At runtime, there are three ways you can handle a server's request for a login:

The first way is to let the default login dialog and processes handle the login. This is the default approach. Set the *LoginPrompt property of the connection component to True (the default) and add DBLogDlg to the uses clause of the unit that declares the connection component. Your application displays the standard login dialog box when the server requests a user name and password.*

The second way is to supply the login information before the login attempt. Each type of connection component uses a different mechanism for specifying the user name and password:

- For BDE, dbExpress, and InterBase express datasets, the user name and password connection parameters can be accessed through the *Params* property. (For BDE datasets, the parameter values can also be associated with a BDE alias, while for dbExpress datasets, they can also be associated with a connection name).
- For ADO datasets, the user name and password can be included in the *C*onnectionString property (or provided as parameters to the *Open* method).

If you specify the user name and password before the server requests them, be sure to set the *LoginPrompt* to *False*, so that the default login dialog does not appear. For example, the following code sets the user name and password on a SQL connection component in the *BeforeConnect* event handler, decrypting an encrypted password that is associated with the current connection name:

```
procedure TForm1.SQLConnectionBeforeConnect(Sender: TObject);
begin
  with Sender as TSQLConnection do
  begin
    if LoginPrompt = False then
    begin
      Params.Values['User_Name'] := 'SYSDBA';
      Params.Values['Password'] := Decrypt(Params.Values['Password']);
    end;
  end;
end;
void __fastcall TForm1::SQLConnectionBeforeConnect(TObject *Sender)
{
  if (SQLConnection1->LoginPrompt == false)
  {
    SQLConnection1->Params->Values["User_Name"] = "SYSDBA";
    SQLConnection1->Params->Values["Password"] =
        Decrypt(SQLConnection1->Params->Values["Password"]);
  }
}
```

Note that setting the user name and password at design-time or using hard-coded strings in code causes the values to be embedded in the application's executable file. This still leaves them easy to find, compromising server security:

The third way is to provide your own custom handling for the login event. The connection component generates an event when it needs the user name and password.

- For *TDatabase*, *TSQLConnection*, and *TIBDatabase*, this is an *OnLogin* event. The event handler has two parameters, the connection component, and a local copy of the user name and password parameters in a string list. (*TSQLConnection* includes the database parameter as well). You must set the LoginPrompt property to *True* for this event to occur. Having a LoginPrompt value of False and assigning a handler for the OnLogin event creates a situation where it is impossible to log in to the database because the default dialog does not appear and the OnLogin event handler never executes.
- For *TADOConnection*, the event is an *On*WillConnect event. The event handler has five parameters, the connection component and four parameters that return values to influence the connection (including two for user name and password). This event always occurs, regardless of the value of *LoginPrompt*.

Write an event handler for the event in which you set the login parameters. Here is an example where the values for the USER

NAME and PASSWORD parameters are provided from a global variable (*UserName*) and a method that returns a password given a user name (*PasswordSearch*)

```
procedure TForm1.Database1Login(Database: TDatabase; LoginParams: TStrings);
begin
  LoginParams.Values['USER NAME'] := UserName;
  LoginParams.Values['PASSWORD'] := PasswordSearch(UserName);
end;
void __fastcall TForm1::Database1Login(TDatabase *Database, TStrings *LoginParams)
{
  LoginParams->Values["USER NAME"] = UserName;
  LoginParams->Values["PASSWORD"] = PasswordSearch(UserName);
}
```

As with the other methods of providing login parameters, when writing an *OnLogin* or *OnWillConnect* event handler, avoid hard coding the password in your application code. It should appear only as an encrypted value, an entry in a secure database your application uses to look up the value, or be dynamically obtained from the user.

Using Implicit Connections (see page 1505)

Controlling Connections (see page 1497)

Managing Transactions (see page 1498)

Working with Associated Datasets (see page 1505)

Sending Commands to the Server (see page 1502)

3.2.3.2.11 Connecting to a Database Server

There are two ways to connect to a database server using a connection component:

- Call the Open method.
- Set the Connected property to *True*.

Calling the Open method sets Connected to True.

Note: *When a connection component is not connected to a server and an application attempts to open one of its associated datasets, the dataset automatically calls the connection component's Open method.*

When you set Connected to True, the connection component first generates a BeforeConnect event, where you can perform any initialization. For example, you can use this event to alter connection parameters.

After the BeforeConnect event, the connection component may display a default login dialog, depending on how you choose to control server login (see page 1507). It then passes the user name and password to the driver, opening a connection.

Once the connection is open, the connection component generates an AfterConnect event, where you can perform any tasks that require an open connection.

Note: *Some connection components generate additional events as well when establishing a connection.*

Once a connection is established, it is maintained as long as there is at least one active dataset using it. When there are no more active datasets, the connection component drops the connection. Some connection components surface a KeepConnection property that allows the connection to remain open even if all the datasets that use it are closed. If KeepConnection is True, the connection is maintained. For connections to remote database servers, or for applications that frequently open and close datasets, setting KeepConnection to True reduces network traffic and speeds up the application. If KeepConnection is False, the connection is dropped when there are no active datasets using the database. If a dataset that uses the database is later opened, the connection must be reestablished and initialized.

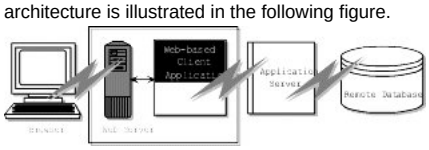
Disconnecting from a Database Server (see page 1497)

3.2.3.3 Creating multi-tiered applications

Topics

Name	Description
Connecting to the Application Server (see page 1517)	To establish and maintain a connection to an application server, a client application uses one or more connection components. You can find these components on the DataSnap or WebServices category of the Tool Palette. Use a connection component to • Identify the protocol for communicating with the application server. Each type of connection component represents a different communication protocol. See Choosing a connection protocol (see page 1523) for details on the benefits and limitations of the available protocols. • Indicate how to locate the server machine. The details of identifying the server machine vary depending on the protocol. See the following topics for details: • Specifying (see page 1537)... more (see page 1517)
Creating Multi-tiered Applications: Overview (see page 1518)	A multi-tiered client/server application is partitioned into logical units, called tiers, which run in conjunction on separate machines. Multi-tiered applications share data and communicate with one another over a local-area network or even over the Internet. They provide many benefits (see page 1519), such as centralized business logic and thin client applications. In its simplest form, sometimes called the "three-tiered model," a multi-tiered application is partitioned into thirds: • **Client application:** provides a user interface on the user's machine. • **Application server:** resides in a central networking location accessible to all clients and provides common data services. • **Remote database server:** provides the relational database... more (see page 1518)
Connecting to the Server (see page 1519)	To locate and connect to the application server, you must first set the properties of the connection component to identify the application server. This process is described in Connecting to the application server (see page 1517). Before opening the connection, any client datasets that use the connection component to communicate with the application server should indicate this by setting their *RemoteServer* property to specify the connection component. The connection is opened automatically when client datasets try to access the application server. For example, setting the *Active* property of the client dataset to *True* opens the connection, as long as the *RemoteServer* property... more (see page 1519)
Advantages of the Multi-tiered Database Model (see page 1519)	The multi-tiered database model breaks a database application into logical pieces. The client application can focus on data display and user interactions. Ideally, it knows nothing about how the data is stored or maintained. The application server (middle tier) coordinates and processes requests and updates from multiple clients. It handles all the details of defining datasets and interacting with the database server. The advantages of this multi-tiered model include the following: • **Encapsulation of business logic in a shared middle tier**. Different client applications all access the same middle tier. This allows you to avoid the redundancy (and maintenance cost)... more (see page 1519)

Brokering Connections (see page 1520)	If you have multiple COM-based servers that your client application can choose from, you can use an Object Broker to locate an available server system. The object broker maintains a list of servers from which the connection component can choose. When the connection component needs to connect to an application server, it asks the Object Broker for a computer name (or IP address, host name, or URL). The broker supplies a name, and the connection component forms a connection. If the supplied name does not work (for example, if the server is down), the broker supplies another name, and so... more (see page 1520)
Building a Multi-tiered Application (see page 1520)	
Building an InternetExpress Application (see page 1521)	The following steps describe one way to build a Web application using InternetExpress. The result is an application that creates HTML pages that let users interact with the data from an application server via a javascript-enabled Web browser. You can also build an InternetExpress application using the Site Express architecture by using the InternetExpress page producer (*TInetXPageProducer*).
Building Web Applications Using InternetExpress (see page 1522)	A client application can request that the application server provide data packets that are coded in XML instead of OleVariants. By combining XML-coded data packets, special javascript libraries (see page 1549) of database functions, and the Web server application support, you can create thin client applications that can be accessed using a Web browser that supports javascript. This combination of features is called InternetExpress. Before building an InternetExpress application (see page 1521), you should understand the Web server application architecture and the multi-tiered database architecture. These are described in Creating Internet Server Applications (see page 2251) and Creating multi-tiered Applications (see page 1518) An InternetExpress application extends the basic Web server... more (see page 1522)
Calling Server Interfaces (see page 1522)	Applications do not need to call the *IAppServer* or *IAppServerSOAP* interface directly because the appropriate calls are made automatically when you use the properties and methods of the client dataset. However, while it is not necessary to work directly with the *IAppServer* or *IAppServerSOAP* interface, you may have added your own extensions to the remote data module's interface. When you extend the application server's interface (see page 1531), you need a way to call those extensions using the connection created by your connection component. Unless you are using SOAP, you can do this using the AppServer property of the connection component. *AppServer... more (see page 1522)*
Choosing a Connection Protocol (see page 1523)	Each communications protocol you can use to connect your client applications to the application server provides its own unique benefits. Before choosing a protocol, consider how many clients you expect, how you are deploying your application, and future development plans. The following topics describe the unique features for each connection protocol: • Using DCOM Connections (see page 1546) • Using Socket Connections (see page 1548) • Using Web Connections (see page 1550) • Using SOAP Connections (see page 1548)
Configuring TMTSDataModule (see page 1524)	To add a *TMTSDataModule* component to your application, choose **File** ▶ **New** ▶ **Other** and select Transactional Data Module from the Multitier page of the new items dialog. You will see the Transactional Data Module wizard. You must supply a class name for your remote data module. This is the base name of a descendant of *TMTSDataModule* that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name *MyDataServer*, the wizard creates a new unit declaring *TMyDataServer*, a descendant of *TMTSDataModule*, which implements *IMyDataServer*, a... more (see page 1524)
Configuring TRemoteDataModule (see page 1525)	To add a *TRemoteDataModule* component to your application, choose **File** ▶ **New** ▶ **Other** and select Remote Data Module from the ActiveX page of the new items dialog. You will see the Remote Data Module wizard. You must supply a class name for your remote data module. This is the base name of a descendant of *TRemoteDataModule* that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name *MyDataServer*, the wizard creates a new unit declaring *TMyDataServer*, a descendant of *TRemoteDataModule*, which implements *IMyDataServer*, a... more (see page 1525)



Configuring TSOAPDataModule (see page 1525)	To add a *TSoapDataModule* component to your application, choose **File** ▶ **New** ▶ **Other** and select SOAP Server Data Module from the WebServices page of the new items dialog. The SOAP data module wizard appears. You must supply a class name for your SOAP data module. This is the base name of a *TSoapDataModule* descendant*that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name MyDataServer, the wizard creates a new unit declaring TMyDataServer, a descendant of TSoapDataModule, which implements IMyDataServer, a descendant of... more (see page 1525)*
Connecting to an Application Server That Uses Multiple Data Modules (see page 1526)	If a COM-based application server uses a main "parent" remote data module and several child remote data modules, as described in Using multiple remote data modules (see page 1547), then you need a separate connection component for every remote data module on the application server. Each connection component represents the connection to a single remote data module. While it is possible to have your client application form independent connections to each remote data module on the application server, it is more efficient to use a single connection to the application server that is shared by all the connection components. That is, you... more (see page 1526)
Creating an Active Form for the Client Application (see page 1526)	
Creating the Application Server (see page 1527)	You create an application server very much as you create most database applications. The major difference is that the application server uses a remote data module.
Creating the Client Application (see page 1528)	In most regards, creating a multi-tiered client application is similar to creating a two-tiered client that uses a client dataset to cache updates. The major difference is that a multi-tiered client uses a connection component to establish a conduit to the application server.
Creating Web Pages with an InternetExpress Page Producer (see page 1529)	Each InternetExpress page producer generates an HTML document that appears in the browsers of your application's clients. If your application includes several separate Web documents, use a separate page producer for each of them. The InternetExpress page producer (*TInetXPageProducer*) is a special page producer component (see page 2270). As with other page producers, you can assign it as the Producer property of an action item or call it explicitly from an OnAction event handler. For more information about using content producers with action items, see Responding to request messages with action items (see page 2278). The InternetExpress page producer has a default... more (see page 1529)
Customizing the InternetExpress Page Producer Template (see page 1529)	The template of an InternetExpress page producer is an HTML document with extra embedded tags that your application translates dynamically. Initially, the page producer generates a default template as the value of the HTMLDoc property. This default template has the form
Distributing a Client Application as an ActiveX Control (see page 1530)	The multi-tiered database architecture can be combined with ActiveX features to distribute a client application as an ActiveX control. When you distribute your client application as an ActiveX control, create the application server (see page 1527) as you would for any other multi-tiered application. When creating the client application, you must use an Active Form as the basis instead of an ordinary form. See Creating an Active Form for the Client Application (see page 1526) for details. Once you have built and deployed your client application, it can be accessed from any ActiveX-enabled Web browser on another machine. For a Web browser to successfully launch your... more (see page 1530)
Dropping or Changing a Server Connection (see page 1531)	A connection component drops a connection to the application server when you • set the *Connected* property to *False*. • free the connection component. A connection object is automatically freed when a user closes the client application. • change any of the properties that identify the application server (*ServerName*, *ServerGUID*, *ComputerName*, and so on). Changing these properties allows you to switch among available application servers at runtime. The connection component drops the current connection and establishes a new one. **Note:** Instead of using a single connection component to switch among available application servers, a client application can instead... more (see page 1531)

Extending the Interface of the Application Server (see page 1531)	Client applications interact with the application server by creating or connecting to an instance of the remote data module. They use its interface as the basis of all communication with the application server. You can add to your remote data module's interface to provide additional support for your client applications. This interface is a descendant of *IAppServer* and is created for you automatically by the wizard when you create the remote data module (see page 1536). To add to the remote data module's interface, you can • Choose the Add to Interface command from the Edit menu in the IDE. Indicate whether you... more (see page 1531)
Granting Permission to Access and Launch the Application Server (see page 1532)	Requests from the InternetExpress application appear to the application server as originating from a guest account with the name IUSR_computername, where computername is the name of the system running the Web application. By default, this account does not have access or launch permission for the application server. If you try to use the Web application without granting these permissions, when the Web browser tries to load the requested page it times out with EOLE_ACCESS_ERROR. **Note:** Because the application server runs under this guest account, it can't be shut down by other accounts. To grant the Web application access and launch... more (see page 1532)
Managing Server Connections (see page 1533)	The main purpose of connection components is to locate and connect to the application server. Because they manage server connections, you can also use connection components to call the methods of the application server's interface. The following topics describe how to use a connection component for • Connecting to the Server (see page 1519). • Dropping or Changing a Server Connection (see page 1531). • Calling Server Interfaces (see page 1522). • Connecting to an Application Server that Uses Multiple Data Modules (see page 1526).
Managing Transactions in Multi-tiered Applications (see page 1533)	When client applications apply updates to the application server, the provider component automatically wraps the process of applying updates and resolving errors in a transaction. This transaction is committed if the number of problem records does not exceed the *MaxErrors* value specified as an argument to the *ApplyUpdates* method. Otherwise, it is rolled back. In addition, you can add transaction support to your server application by adding a database connection component or managing the transaction directly by sending SQL to the database server. This works the same way that you would manage transactions in a two-tiered application. For more information... more (see page 1533)
Overview of a Three-tiered Application (see page 1534)	The following numbered steps illustrate a normal sequence of events for a provider-based three-tiered application: 1. A user starts the client application. The client connects to the application server (which can be specified at design time or runtime). If the application server is not already running, it starts. The client receives an *IAppServer* interface for communicating with the application server. 2. The client requests data from the application server. A client may request all data at once, or may request chunks of data throughout the session (fetch on demand). 3. The application server retrieves the data (first establishing a database connection, if necessary),... more (see page 1534)

Pooling Remote Data Modules (see page 1535)	Object pooling allows you to create a cache of remote data modules that are shared by their clients, thereby conserving resources. How this works depends on the type of remote data module and on the connection protocol (see page 1523). If you are creating a transactional data module (see page 1546) that will be installed to COM+, you can use the COM+ Component Manager to install the application server as a pooled object. Even if you are not using a transactional data module, you can take advantage of object pooling if the connection is formed using *TWebConnection*. Under this second type of object pooling,... more (see page 1535)
Registering the Application Server (see page 1535)	Before client applications can locate and use an application server, it must be registered or installed. • If the application server uses DCOM, HTTP, or sockets as a communication protocol, it acts as an Automation server and must be registered like any other COM server. For information about registering a COM server, see Registering a COM Object (see page 1440). • If you are using a transactional data module, you do not register the application server. Instead, you install it with COM+ or MTS. . • When the application server uses SOAP, the application must be a Web Service application. As such, it must be... more (see page 1535)
Setting Up the Remote Data Module (see page 1536)	When you create the remote data module, you must provide certain information that indicates how it responds to client requests. This information varies, depending on the type of remote data module. See The Structure of the Application Server (see page 1542) for information on what type of remote data module you need. The following topics describe how to configure each type of remote data module: • Configuring TRemoteDataModule (see page 1525) • Configuring TMTSDataModule (see page 1524) • Configuring TSoapDataModule (see page 1525)
Setting Web Item Properties (see page 1536)	The Web items that you add using the Web page editor are specialized components that generate HTML. Each Web item class is designed to produce a specific control or section of the final HTML document, but a common set of properties influences the appearance of the final HTML. When a Web item represents information from the XML data packet (for example, when it generates a set of field or parameter display controls or a button that manipulates the data), the XMLBroker property associates the Web item with the XML broker that manages the data packet. You can further specify a... more (see page 1536)
Specifying a Connection Using HTTP (see page 1537)	You can establish a connection to the application server using HTTP from any machine that has a TCP/IP address. Unlike sockets, however, HTTP allows you to take advantage of SSL security and to communicate with a server that is protected behind a firewall. When using HTTP, include a TWebConnection component for connecting to the application server. The Web connection component establishes a connection to the Web server application (httpsrvr.dll), which in turn communicates with the application server. *TWebConnection* locates httpsrvr.dll using a Uniform Resource Locator (URL). The URL specifies the protocol (http or, if you are using SSL security, https),... more (see page 1537)
Specifying a Connection Using DCOM (see page 1537)	When using DCOM to communicate with the application server, client applications include a TDCOMConnection component for connecting to the application server. *TDCOMConnection* uses the ComputerName property to identify the machine on which the server resides. When *ComputerName* is blank, the DCOM connection component assumes that the application server resides on the client machine or that the application server has a system registry entry. If you do not provide a system registry entry for the application server on the client when using DCOM, and the server resides on a different machine from the client, you must supply *ComputerName*. **Note:** Even... more (see page 1537)

Specifying a Connection Using SOAP (see page 1538)	You can establish a connection to a SOAP application server using the TSoapConnection component. *TSoapConnection* is very similar to *TWebConnection*, because it also uses HTTP as a transport protocol. Thus, you can use *TSoapConnection* from any machine that has a TCP/IP address, and it can take advantage of SSL security and to communicate with a server that is protected by a firewall. The SOAP connection component establishes a connection to a Web Service provider that implements the *IAppServerSOAP* or *IAppServer* interface. (The UseSOAPAdapter property specifies which interface it expects the server to support.) If the server implements the *IAppServerSOAP... more (see page 1538)*
Specifying a Connection Using Sockets (see page 1538)	You can establish a connection to the application server using sockets from any machine that has a TCP/IP address. This method has the advantage of being applicable to more machines, but does not provide for using any security protocols. When using sockets, include a TSocketConnection component for connecting to the application server. *TSocketConnection* identifies the server machine using the IP Address or host name of the server system, and the port number of the socket dispatcher program (Scktsrvr.exe) that is running on the server machine. For more information about IP addresses and port values, see Describing sockets (see page 2336). Three properties... more (see page 1538)
Supporting Master/detail Relationships (see page 1539)	You can create master/detail relationships between client datasets in your client application in the same way you set them up using any table-type dataset. For more information about setting up master/detail relationships in this way, see Creating Master/detail Relationships (see page 1590). However, this approach has two major drawbacks: • The detail table must fetch and store all of its records from the application server even though it only uses one detail set at a time. (This problem can be mitigated by using parameters. For more information, see Limiting records with parameters (see page 1720).) • It is very difficult to apply updates, because client datasets... more (see page 1539)
Supporting State Information in Remote Data Modules (see page 1540)	The *IAppServer* interface, which client datasets use to communicate with providers on the application server, is mostly stateless. When an application is stateless, it does not "remember" anything that happened in previous calls by the client. This stateless quality is useful if you are pooling database connections in a transactional data module, because your application server does not need to distinguish between database connections for persistent information such as record currency. Similarly, this stateless quality is important when you are sharing remote data module instances between many clients, as occurs with just-in-time activation or object pooling. SOAP data modules must... more (see page 1540)
The Structure of the Application Server (see page 1542)	When you set up and run an application server, it does not establish any connection with client applications. Rather, client applications initiate and maintain the connection. The client application uses a connection component to connect to the application server, and uses the interface of the application server to communicate with a selected provider. All of this happens automatically, without your having to write code to manage incoming requests or supply interfaces. The basis of an application server is a remote data module, which is a specialized data module that supports the *IAppServer* interface (for application servers that also function as... more (see page 1542)
The Structure of the Client Application (see page 1543)	To the end user, the client application of a multi-tiered application looks and behaves no differently than a two-tiered application that uses cached updates. User interaction takes place through standard data-aware controls that display data from a TClientDataSet component. For detailed information about using the properties, events, and methods of client datasets, see Using Client Datasets (see page 1740). TClientDataSet fetches data from and applies updates to a provider component, just as in two-tiered applications that use a client dataset with an external provider. For details about providers, see Using Provider Components (see page 1819). For details about client dataset features that facilitate its... more (see page 1543)

Understanding Multi-tiered Database Applications (see page 1544)	Multi-tiered applications use the components on the DataSnap page, the Data Access page, and possibly the WebServices page of the **Tool palette**, plus a remote data module that is created by a wizard on the Multitier or WebServices page of the New Items dialog. They are based on the ability of provider components to package data into transportable data packets and handle updates received as transportable delta packets. The components needed for a multi-tiered application are described in the following table: ***Components used in multi-tiered applications***
Using an XML Broker (see page 1544)	The XML broker serves two major functions: • It fetches XML data packets from the application server and makes them available to the Web Items that generate HTML for the InternetExpress application. • It receives updates in the form of XML delta packets from browsers and applies them to the application server.
Using DCOM Connections (see page 1546)	DCOM provides the most direct approach to communication, requiring no additional runtime applications on the server. DCOM provides the only approach that lets you use security services when writing a transactional data module. These security services are based on assigning roles to the callers of transactional objects. When using DCOM, DCOM identifies the caller to the system that calls your application server (COM+ or MTS). Therefore, it is possible to accurately determine the role of the caller. When using other protocols, however, there is a runtime executable, separate from the application server, that receives client calls. This runtime executable makes... more (see page 1546)
Using Transactional Data Modules (see page 1546)	You can write an application server that takes advantage of special services for distributed applications that are supplied by COM+ (under Windows 2000 and later) or MTS (before Windows 2000). To do so, create a transactional data module instead of an ordinary remote data module. When you use a transactional data module, your application can take advantage of the following special services: • **Security.** COM+ (or MTS) provides role-based security for your application server. Clients are assigned roles, which determine how they can access the MTS data module's interface. The MTS data module implements the IsCallerInRole method, which you lets you... more (see page 1546)
Using Multiple Remote Data Modules (see page 1547)	You may want to structure your application server so that it uses multiple remote data modules. Using multiple remote data modules lets you partition your code, organizing a large application server into multiple units, where each unit is relatively self-contained. Although you can always create multiple remote data modules on the application server that function independently, a special connection component on the DataSnap category of the **Tool palette** provides support for a model where you have one main "parent" remote data module that dispatches connections from clients to other "child" remote data modules. This model requires that you use a... more (see page 1547)
Using SOAP Connections (see page 1548)	SOAP is the protocol that underlies the built-in support for Web Service applications. SOAP marshals method calls using an XML encoding. SOAP connections use HTTP as a transport protocol. SOAP connections have the advantage that they work in cross-platform applications because they are supported on both the Windows and Linux. Because SOAP connections use HTTP, they have the same advantages as Web connections: HTTP provides a lowest common denominator that you know is available on all clients, and clients can communicate with an application server that is protected by a "firewall." For more information about using SOAP to distribute applications,... more (see page 1548)
Using Socket Connections (see page 1548)	TCP/IP Sockets let you create lightweight clients. For example, if you are writing a Web-based client application (see page 1551), you can't be sure that client systems support DCOM. Sockets provide a lowest common denominator that you know will be available for connecting to the application server. For more information about sockets, see Working with Sockets. (see page 2337) Instead of instantiating the remote data module directly from the client (as happens with DCOM), sockets use a separate application on the server (ScktSrvr.exe), which accepts client requests and instantiates the remote data module using COM. The connection component on the client and ScktSrvr.exe... more (see page 1548)

Using the Javascript Libraries (see page 1549)	The HTML pages generated by the InternetExpress components and the Web items they contain make use of several javascript libraries that ship in the source/webmidas directory: ***Javascript libraries***
Using the Web Page Editor (see page 1549)	The Web page editor lets you add Web items to your InternetExpress page producer and view the resulting HTML page. Display the Web page editor by double-clicking on a InternetExpress page producer component. **Note:** You must have Internet Explorer 4 or better installed to use the Web page editor. The top of the Web page editor displays the Web items that generate the HTML document. These Web items are nested, where each type of Web item assembles the HTML generated by its subitems. Different types of items can contain different subitems. On the left, a tree view displays all of... more (see page 1549)
Using Web Connections (see page 1550)	HTTP lets you create clients that can communicate with an application server that is protected by a firewall. HTTP messages provide controlled access to internal applications so that you can distribute your client applications safely and widely. Like socket connections, HTTP messages provide a lowest common denominator that you know will be available for connecting to the application server. For more information about HTTP messages, see Creating Internet Server Applications (see page 2251) Instead of instantiating the remote data module directly from the client (as happens with DCOM), HTTP-based connections use a Web server application on the server (httpsrvr.dll) that accepts client requests... more (see page 1550)
Writing Web-based Client Applications (see page 1551)	If you want to create Web-based clients for your multi-tiered database application, you must replace the client tier with a special Web application that acts simultaneously as a client to an application server and as a Web server application that is installed with a Web server on the same machine. This architecture is illustrated in the following figure.  There are two approaches that you can take to build the Web application: • You can combine the multi-tiered database architecture with an ActiveX form to distribute the client application as an ActiveX control (see page 1530). This allows any browser that supports ActiveX to... more (see page 1551)

3.2.3.3.1 Connecting to the Application Server

To establish and maintain a connection to an application server, a client application uses one or more connection components. You can find these components on the DataSnap or WebServices category of the Tool Palette.

Use a connection component to

- Identify the protocol for communicating with the application server. Each type of connection component represents a different communication protocol. See Choosing a connection protocol (see page 1523) for details on the benefits and limitations of the available protocols.
- Indicate how to locate the server machine. The details of identifying the server machine vary depending on the protocol. See the following topics for details:
- Specifying a connection using DCOM (see page 1537)
- Specifying a connection using sockets (see page 1538)
- Specifying a connection using HTTP (see page 1537)
- Specifying a connection using SOAP (see page 1538)
- Identify the application server on the server machine.
- If you are not using SOAP, identify the server using the ServerName or ServerGUID property. *ServerName* identifies the base name of the class you specify when creating the remote data module on the application server. See Setting up the remote

data module (see page 1536) for details on how this value is specified on the server. If the server is registered or installed on the client machine, or if the connection component is connected to the server machine, you can set the *ServerName* property at design time by choosing from a drop-down list in the **Object Inspector**. *ServerGUID* specifies the GUID of the remote data module's interface. You can look up this value using the type library editor.

- Manage server connections (see page 1533). Connection components can be used to create or drop connections and to call application server interfaces.

If you are using SOAP, the server is identified in the URL you use to locate the server machine. Follow the steps in Specifying a connection using SOAP (see page 1538).

Usually the application server is on a different machine from the client application, but even if the server resides on the same machine as the client application (for example, during the building and testing of the entire multi-tier application), you can still use the connection component to identify the application server by name, specify a server machine, and use the application server interface.

3.2.3.3.2 Creating Multi-tiered Applications: Overview

A multi-tiered client/server application is partitioned into logical units, called tiers, which run in conjunction on separate machines. Multi-tiered applications share data and communicate with one another over a local-area network or even over the Internet. They provide many benefits (see page 1519), such as centralized business logic and thin client applications.

In its simplest form, sometimes called the "three-tiered model," a multi-tiered application is partitioned into thirds:

- **Client application:** provides a user interface on the user's machine.
- **Application server:** resides in a central networking location accessible to all clients and provides common data services.
- **Remote database server:** provides the relational database management system (RDBMS).

In this three-tiered model, the application server manages the flow of data between clients and the remote database server, so it is sometimes called a "data broker." You usually only create the application server and its clients, although, if you are really ambitious, you could create your own database back end as well.

In more complex multi-tiered applications, additional services reside between a client and a remote database server. For example, there might be a security services broker to handle secure Internet transactions, or bridge services to handle sharing of data with databases on other platforms.

Support for developing multi-tiered applications is an extension of the way client datasets communicate with a provider component using transportable data packets. See Understanding multi-tiered database applications (see page 1544) for an overview of this technology and the architecture of a typical three-tiered application. Once you understand how to create and manage a three-tiered application, you can create and add additional service layers based on your needs.

Building a multi-tiered application (see page 1520) provides details on how to apply this architecture to build a three-tiered application. Writing Web-based client applications (see page 1551) describes how to combine this architecture with other technologies to create a Web-based multi-tiered application.

3.2.3.3.3 Connecting to the Server

To locate and connect to the application server, you must first set the properties of the connection component to identify the application server. This process is described in Connecting to the application server (see page 1517). Before opening the connection, any client datasets that use the connection component to communicate with the application server should indicate this by setting their *RemoteServer* property to specify the connection component.

The connection is opened automatically when client datasets try to access the application server. For example, setting the *Active* property of the client dataset to *True* opens the connection, as long as the *RemoteServer* property has been set.

If you do not link any client datasets to the connection component, you can open the connection by setting the *Connected* property of the connection component to *True*.

Before a connection component establishes a connection to an application server, it generates a *BeforeConnect* event. You can perform any special actions prior to connecting in a *BeforeConnect* handler that you code. After establishing a connection, the connection component generates an *AfterConnect* event for any special actions.

3.2.3.3.4 Advantages of the Multi-tiered Database Model

The multi-tiered database model breaks a database application into logical pieces. The client application can focus on data display and user interactions. Ideally, it knows nothing about how the data is stored or maintained. The application server (middle tier) coordinates and processes requests and updates from multiple clients. It handles all the details of defining datasets and interacting with the database server.

The advantages of this multi-tiered model include the following:

- **Encapsulation of business logic in a shared middle tier**. Different client applications all access the same middle tier. This allows you to avoid the redundancy (and maintenance cost) of duplicating your business rules for each separate client application.
- **Thin client applications**. Your client applications can be written to make a small footprint by delegating more of the processing to middle tiers. Not only are client applications smaller, but they are easier to deploy because they don't need to worry about installing, configuring, and maintaining the database connectivity software (such as the database server's client-side software). Thin client applications can be distributed over the Internet for additional flexibility.
- **Distributed data processing**. Distributing the work of an application over several machines can improve performance because of load balancing, and allow redundant systems to take over when a server goes down.
- **Increased opportunity for security**. You can isolate sensitive functionality into tiers that have different access restrictions.

This provides flexible and configurable levels of security. Middle tiers can limit the entry points to sensitive material, allowing you to control access more easily. If you are using HTTP or COM+, you can take advantage of the security models they support.

3.2.3.3.5 Brokering Connections

If you have multiple COM-based servers that your client application can choose from, you can use an Object Broker to locate an available server system. The object broker maintains a list of servers from which the connection component can choose. When the connection component needs to connect to an application server, it asks the Object Broker for a computer name (or IP address, host name, or URL). The broker supplies a name, and the connection component forms a connection. If the supplied name does not work (for example, if the server is down), the broker supplies another name, and so on, until a connection is formed.

Once the connection component has formed a connection with a name supplied by the broker, it saves that name as the value of the appropriate property (*ComputerName*, *Address*, *Host,RemoteHost*, or *URL*). If the connection component closes the connection later, and then needs to reopen the connection, it tries using this property value, and only requests a new name from the broker if the connection fails.

Use an Object Broker by specifying the ObjectBroker property of your connection component. When the *ObjectBroker* property is set, the connection component does not save the value of *ComputerName*, *Address*, *Host*, *RemoteHost*, or *URL* to disk.

Note: You can not use the *ObjectBroker* property with SOAP connections.

Specifying a Connection Using Sockets (see page 1538)

3.2.3.3.6 Building a Multi-tiered Application

To create a multi-tiered database application

1. Create the application server (see page 1527).
2. Register or install the application server (see page 1535).
3. Create a client application (see page 1528).

The order of creation is important. You should create and run the application server before you create a client. At design time, you can then connect to the application server to test your client. You can, of course, create a client without specifying the application server at design time, and only supply the server name at runtime. However, doing so prevents you from seeing if your application works as expected when you code at design time, and you will not be able to choose servers and providers using the **Object Inspector**.

Note: If you are not creating the client application on the same system as the server, and you are using a DCOM connection, you may want to register the application server on the client system. This makes the connection component aware of the application server at design time so that you can choose server names and provider names from a drop-down list in the Object Inspector

. (If you are using a Web connection, SOAP connection, or socket connection, the connection component fetches the names of registered providers from the server machine.)

3.2.3.3.7 Building an InternetExpress Application

The following steps describe one way to build a Web application using InternetExpress. The result is an application that creates HTML pages that let users interact with the data from an application server via a javascript-enabled Web browser. You can also build an InternetExpress application using the Site Express architecture by using the InternetExpress page producer (*TInetXPageProducer*).

To build a Web application using InternetExpress

1. Choose **File** ▶ **New** ▶ **Other** to display the New Items dialog box, and on the New page select Web Server application. This process is described in Creating Web server applications with Web Broker.
2. From the DataSnap category of the **Tool palette**, add a connection component to the Web Module that appears when you create a new Web server application. The type of connection component you add depends on the communication protocol you want to use. See Choosing a connection protocol (see page 1523) for details.
3. Set properties on your connection component to specify the application server with which it should establish a connection. To learn more about setting up the connection component, see Connecting to the application server (see page 1517).
4. Instead of a client dataset, add an TXMLBroker from the InternetExpress category of the **Tool palette** to the Web module. Like *TClientDataSet*, *TXMLBroker* represents the data from a provider on the application server and interacts with the application server through an *IAppServer* interface. However, unlike client datasets, XML brokers request data packets as XML instead of as OleVariants and interact with InternetExpress components instead of data controls.
5. Set the *RemoteServer* property of the XML broker to point to the connection component you added in step 2. Set the *ProviderName* property to indicate the provider on the application server that provides data and applies updates. For more information about setting up the XML broker, see Using an XML broker (see page 1544).
6. Add an InternetExpress page producer (*TInetXPageProducer*) to the Web module for each separate page that users will see in their browsers. For each page producer, you must set the *IncludePathURL* property to indicate where it can find the javascript libraries (see page 1549) that augment its generated HTML controls with data management capabilities.
7. Right-click a Web page and choose Action Editor to display the Action editor. Add action items for every message you want to handle from browsers. Associate the page producers you added in step 6 with these actions by setting their *Producer* property or writing code in an *OnAction* event handler. For more information on adding action items using the Action editor, see Adding actions to the dispatcher (see page 2277).
8. Double-click each Web page to display the Web Page editor. (You can also display this editor by clicking the ellipsis button in the **Object Inspector** next to the *WebPageItems* property.) In this editor you can add Web Items to design the pages that users see in their browsers. For more information about designing Web pages for your InternetExpress application, see Creating Web pages with an InternetExpress page producer (see page 1529).
9. Build your Web application. Once you install this application with your Web server, browsers can call it by specifying the name of the application as the script name portion of the URL (see page 2253) and the name of the Web Page component as the pathinfo portion.

Creating the Application Server (see page 1527)

Using the Javascript Libraries (see page 1549)

3.2.3.3.8 Building Web Applications Using InternetExpress

A client application can request that the application server provide data packets that are coded in XML instead of OleVariants. By combining XML-coded data packets, special javascript libraries (see page 1549) of database functions, and the Web server application support, you can create thin client applications that can be accessed using a Web browser that supports javascript. This combination of features is called InternetExpress.

Before building an InternetExpress application (see page 1521), you should understand the Web server application architecture and the multi-tiered database architecture. These are described in Creating Internet Server Applications (see page 2251) and Creating multi-tiered Applications (see page 1518)

An InternetExpress application extends the basic Web server application architecture to act as the client of an application server. InternetExpress applications generate HTML pages that contain a mixture of HTML, XML, and javascript. The HTML governs the layout and appearance of the pages seen by end users in their browsers. The XML encodes the data packets and delta packets that represent database information. The javascript allows the HTML controls to interpret and manipulate the data in these XML data packets on the client machine.

If the InternetExpress application uses DCOM to connect to the application server, you must take additional steps to ensure that the application server grants access and launch permissions (see page 1532) to its clients.

Tip: You can create an InternetExpress application to provide Web browsers with "live" data even if you do not have an application server. Simply add the provider and its dataset to the Web module.

Building a Multi-tiered Application (see page 1520)

Distributing a Client Application as an ActiveX Control (see page 1530)

3.2.3.3.9 Calling Server Interfaces

Applications do not need to call the *IAppServer* or *IAppServerSOAP* interface directly because the appropriate calls are made automatically when you use the properties and methods of the client dataset. However, while it is not necessary to work directly with the *IAppServer* or *IAppServerSOAP* interface, you may have added your own extensions to the remote data module's interface. When you extend the application server's interface (see page 1531), you need a way to call those extensions using the connection created by your connection component. Unless you are using SOAP, you can do this using the AppServer property of the connection component.

AppServer is a Variant that represents the application server's interface. If you are not using SOAP, you can call an interface method using *AppServer* by writing a statement such as

```
MyConnection.AppServer.SpecialMethod(x,y);
```

However, this technique provides late (dynamic) binding of the interface call. That is, the *SpecialMethod* procedure call is not bound until runtime when the call is executed. Late binding is very flexible, but by using it you lose many benefits such as code insight and type checking. In addition, late binding is slower than early binding, because the compiler generates additional calls to the server to set up interface calls before they are invoked.

Using early binding with DCOM

When you are using DCOM as a communications protocol, you can use early binding of *AppServer* calls. Use the as operator to cast the *AppServer* variable to the *IAppServer* descendant you created when you created the remote data module (see page 1536). For example:

```
with MyConnection.AppServer as IMyAppServer do
SpecialMethod(x,y);
```

To use early binding under DCOM, the server's type library must be registered on the client machine. You can use TRegsvr.exe,

which ships with Delphi to register the type library.

Note: See the TRegSvr demo (which provides the source for TRegsvr.exe) for an example of how to register the type library programmatically.

Using dispatch interfaces with TCP/IP or HTTP

When you are using TCP/IP or HTTP, you can't use true early binding, but because the remote data module uses a dual interface, you can use the application server's dispinterface to improve performance over simple late binding. The dispinterface has the same name as the remote data module's interface, with the string 'Disp' appended. You can assign the *AppServer* property to a variable of this type to obtain the dispinterface. Thus:

```
var
TempInterface: IMyAppServerDisp;
begin
  TempInterface :=IMyAppServerDisp(IDispatch(MyConnection.AppServer));
...
TempInterface.SpecialMethod(x,y);
...
end;
```

Note: To use the dispinterface, you must add the _TLB unit that is generated when you save the type library to the **uses** clause of your client module.

Calling the interface of a SOAP-based server

If you are using SOAP, you can't use the *AppServer* property. Instead, you must obtain the server's interface by calling the *GetSOAPServer* method. Before you call *GetSOAPServer*, however, you must take the following steps:

- Your client application must include the definition of the application server's interface and register it with the invocation registry. You can add the definition of this interface to your client application by referencing a WSDL document that describes the interface you want to call. For information on importing a WSDL document that describes the server interface, see Importing WSDL documents (see page 2307). When you import the interface definition, the WSDL importer automatically adds code to register it with the invocation registry. For more information about interfaces and the invocation registry, see Understanding invokable interfaces (see page 2292).
- The *TSOAPConnection* component must have its UseSOAPAdapter property set to *True*. This means that the server must support the *IAppServerSOAP* interface. If the application server is built using Delphi 6 or Kylix 1, it does not support *IAppServerSOAP* and you must use a separate *THTTPRio* component instead. For details on how to call an interface using a *THTTPRio* component, see Calling invokable interfaces (see page 2307).
- You must set the SOAPServerIID property of the SOAP connection component to the GUID of the server interface. You must set this property before your application connects to the server, because it tells the *TSOAPConnection* component what interface to fetch from the server.

Assuming the previous three conditions are met, you can fetch the server interface as follows:

```
with MyConnection.GetSOAPServer as IMyAppServer do
SpecialMethod(x,y);
IDispatch* disp = (IDispatch*)(MyConnection->AppServer)
IMyAppServerDisp TempInterface( (IMyAppServer*)disp);
TempInterface.SpecialMethod(x,y);
```

3.2.3.3.10 Choosing a Connection Protocol

Each communications protocol you can use to connect your client applications to the application server provides its own unique benefits. Before choosing a protocol, consider how many clients you expect, how you are deploying your application, and future

development plans.

The following topics describe the unique features for each connection protocol:

- Using DCOM Connections (see page 1546)
- Using Socket Connections (see page 1548)
- Using Web Connections (see page 1550)
- Using SOAP Connections (see page 1548)

The Structure of the Application Server (see page 1542)

Pooling Application Servers (see page 1535)

3.2.3.3.11 Configuring TMTSDataModule

To add a *TMTSDataModule* component to your application, choose **File ▸ New ▸ Other** and select Transactional Data Module from the Multitier page of the new items dialog. You will see the Transactional Data Module wizard.

You must supply a class name for your remote data module. This is the base name of a descendant of *TMTSDataModule* that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name *MyDataServer*, the wizard creates a new unit declaring *TMyDataServer*, a descendant of *TMTSDataModule*, which implements *IMyDataServer*, a descendant of *IAppServer*.

Note: You can add your own properties and methods to your new interface. For more information, see Extending the application server's interface (see page 1531).

You must specify the threading model in the Transactional Data Module wizard. Choose Single, Apartment, or Both.

- If you choose Single, client requests are serialized so that your application services only one at a time. You do not need to worry about client requests interfering with each other.
- If you choose Apartment, the system ensures that any instance of your remote data module services one request at a time, and calls always use the same thread. You must guard against thread conflicts if you use global variables or objects not contained in the remote data module. Instead of using global variables, you can use the shared property manager.
- If you choose Both, MTS calls into the remote data module's interface in the same way as when you choose Apartment. However, any callbacks you make to client applications are serialized, so that you don't need to worry about them interfering with each other.

  Note: The Apartment model under MTS or COM+ is different from the corresponding model under DCOM.

  You must also specify the transaction attributes of your remote data module. You can choose from the following options:

- Requires a transaction. When you select this option, every time a client uses your remote data module's interface, that call is executed in the context of a transaction. If the caller supplies a transaction, a new transaction need not be created.
- Requires a new transaction. When you select this option, every time a client uses your remote data module's interface, a new transaction is automatically created for that call.
- Supports transactions. When you select this option, your remote data module can be used in the context of a transaction, but the caller must supply the transaction when it invokes the interface.
- Does not support transactions. When you select this option, your remote data module can't be used in the context of transactions.

See Also

Configuring TSOAPDataModule (see page 1525)

3.2.3.3.12 Configuring TRemoteDataModule

To add a *TRemoteDataModule* component to your application, choose **File** ▶ **New** ▶ **Other** and select Remote Data Module from the ActiveX page of the new items dialog. You will see the Remote Data Module wizard.

You must supply a class name for your remote data module. This is the base name of a descendant of *TRemoteDataModule* that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name *MyDataServer*, the wizard creates a new unit declaring *TMyDataServer*, a descendant of *TRemoteDataModule*, which implements *IMyDataServer*, a descendant of *IAppServer*.

Note: You can add your own properties and methods to the new interface. For more information, see Extending the application server's interface (see page 1531).

You must specify the threading model in the Remote Data Module wizard. You can choose Single-threaded, Apartment-threaded, Free-threaded, or Both.

- If you choose Single-threaded, COM ensures that only one client request is serviced at a time. You do not need to worry about client requests interfering with each other.
- If you choose Apartment-threaded, COM ensures that any instance of your remote data module services one request at a time. When writing code in an Apartment-threaded library, you must guard against thread conflicts if you use global variables or objects not contained in the remote data module. This is the recommended model if you are using BDE-enabled datasets. (Note that you will need a session component with its *AutoSessionName* property set to *True* to handle threading issues on BDE-enabled datasets).
- If you choose Free-threaded, your application can receive simultaneous client requests on several threads. You are responsible for ensuring your application is thread-safe. Because multiple clients can access your remote data module simultaneously, you must guard your instance data (properties, contained objects, and so on) as well as global variables. This is the recommended model if you are using ADO datasets.
- If you choose Both, your library works the same as when you choose Free-threaded, with one exception: all callbacks (calls to client interfaces) are serialized for you.
- If you choose Neutral, the remote data module can receive simultaneous calls on separate threads, as in the Free-threaded model, but COM guarantees that no two threads access the same method at the same time.

If you are creating an EXE, you must also specify what type of instancing to use. You can choose Single instance or Multiple instance (Internal instancing applies only if the client code is part of the same process space.)

- If you choose Single instance, each client connection launches its own instance of the executable. That process instantiates a single instance of the remote data module, which is dedicated to the client connection.
- If you choose Multiple instance, a single instance of the application (process) instantiates all remote data modules created for clients. Each remote data module is dedicated to a single client connection, but they all share the same process space.

See Also

Configuring TSOAPDataModule (see page 1525)

3.2.3.3.13 Configuring TSOAPDataModule

To add a *TSoapDataModule* component to your application, choose **File** ▶ **New** ▶ **Other** and select SOAP Server Data Module from the WebServices page of the new items dialog. The SOAP data module wizard appears.

You must supply a class name for your SOAP data module. This is the base name of a *TSoapDataModule* descendant*that your application creates. It is also the base name of the interface for that class. For example, if you specify the class name MyDataServer, the wizard creates a new unit declaring TMyDataServer, a descendant of TSoapDataModule, which implements IMyDataServer, a descendant of IAppServerSOAP.*

Note: *To use TSoapDataModule, the new data module should be added to a Web Service application. The IAppServerSOAP interface is an invokable interface, which is registered in the initialization section of the new unit. This allows the invoker*

component in the main Web module to forward all incoming calls to your data module.

You may want to edit the definitions of the generated interface and TSoapDataModule descendant, adding your own properties and methods. These properties and methods are not called automatically, but client applications that request your new interface by name or GUID can use any of the properties and methods that you add.

Configuring TRemoteDataModule (see page 1525)

3.2.3.3.14 Connecting to an Application Server That Uses Multiple Data Modules

If a COM-based application server uses a main "parent" remote data module and several child remote data modules, as described in Using multiple remote data modules (see page 1547), then you need a separate connection component for every remote data module on the application server. Each connection component represents the connection to a single remote data module.

While it is possible to have your client application form independent connections to each remote data module on the application server, it is more efficient to use a single connection to the application server that is shared by all the connection components. That is, you add a single connection component that connects to the "main" remote data module on the application server, and then, for each "child" remote data module, add an additional component that shares the connection to the main remote data module.

To use a single shared connection

1. For the connection to the main remote data module, add and set up a connection component as described in Connecting to the Application Server (see page 1517). The only limitation is that you can't use a SOAP connection.
2. For each child remote data module, use a TSharedConnection component.

- Set its *ParentConnection* property to the connection component you added in step 1. The *TSharedConnection* component shares the connection that this main connection establishes.
- Set its *ChildName* property to the name of the property on the main remote data module's interface that exposes the interface of the desired child remote data module.

When you assign the *TSharedConnection* component placed in step 2 as the value of a client dataset's *RemoteServer* property, it works as if you were using an entirely independent connection to the child remote data module. However, the *TSharedConnection* component uses the connection established by the component you placed in step 1.

3.2.3.3.15 Creating an Active Form for the Client Application

To create an Active Form for the Client Application

1. Because the client application will be deployed as an ActiveX control, you must have a Web server that runs on the same system as the client application. You can use a ready-made server such as Microsoft's Personal Web server or you can write your own using the socket components described in "Working with Sockets." (see page 2337)
2. Create the client application following the steps described in Creating the client application (see page 1528) except start by choosing **File** ▸ **New** ▸ **ActiveX** ▸ **Active Form**, rather than beginning an ordinary client project.

3. If your client application uses a data module, add a call to explicitly create the data module in the active form initialization.
4. When your client application is finished, compile the project, and select **Project ▸ Web Deployment Options**. In the Web Deployment Options dialog, you must do the following: On the Project page, specify the Target directory, the URL for the target directory, and the HTML directory. Typically, the Target directory and the HTML directory will be the same as the projects directory for your Web Server. The target URL is typically the name of the server machine. On the Additional Files page, include midas.dll with your client application.
5. Finally, select **Project ▸ WebDeploy** to deploy the client application as an active form.

Any Web browser that can run Active forms can run your client application by specifying the .HTM file that was created when you deployed the client application. This .HTM file has the same name as your client application project, and appears in the directory specified as the Target directory.

See Also

Generating an ActiveX Control Based On a VCL Form (see page 1410)

3.2.3.3.16 Creating the Application Server

You create an application server very much as you create most database applications. The major difference is that the application server uses a remote data module.

To create an application server

1. Start a new project:

- If you are using SOAP as a transport protocol, this should be a new Web Service application. Choose **File ▸ New ▸ Other**, and on the WebServices page of the new items dialog, choose SOAP Server application. Select the type of Web Server you want to use, and when prompted whether you want to define a new interface for the SOAP module, say no.
- For any other transport protocol, you need only choose **File ▸ New ▸ Application**. Save the new project.

2. Add a new remote data module to the project. From the main menu, choose **File ▸ New ▸ Other**, and on the ActiveX, Delphi Files, or WebServices page of the new items dialog, select

- **Remote Data Module** if you are creating a COM Automation server that clients access using DCOM, HTTP, or sockets.
- **Transactional Data Module** if you are creating a remote data module that runs under COM+ (or MTS). Connections can be formed using DCOM, HTTP, or sockets. However, only DCOM supports the security services.
- **SOAP Server Data Module** if you are creating a SOAP server in a Web Service application. For more detailed information about setting up a remote data module, see Setting up the remote data module (see page 1536).

  Note: Remote data modules are more than simple data modules. The SOAP data module implements an invokable interface in a Web Service application. Other data modules are COM Automation objects.

3. Place the appropriate dataset components on the data module and set them up to access the database server.
4. Place a *TDataSetProvider* component on the data module for each dataset you want to expose to clients. This provider is required for brokering client requests and packaging data. Set the *DataSet* property for each provider to the name of the dataset to access. You can set additional properties for the provider. See Using provider components (see page 1819) for more detailed information about setting up a provider. If you are working with data from XML documents, you can use a *TXMLTransformProvider* component instead of a dataset and *TDataSetProvider* component. When using *TXMLTransformProvider*, set the *XMLDataFile* property to specify the XML document from which data is provided and to which updates are applied.
5. Write application server code to implement events, shared business rules, shared data validation, and shared security. When writing this code, you may want to

- Extend the application server's interface (see page 1531) to provide additional ways for the client application to call the server.
- Provide transaction support (see page 1533) beyond the transactions automatically created when applying updates.

- Create master/detail relationships (see page 1539) between the datasets in your application server.
- Ensure your application server is stateless (see page 1540).
- Divide your application server into multiple remote data modules (see page 1547).

6. Save, compile, and register or install the application server (see page 1535).
7. If your server application does not use DCOM or SOAP, you must install the runtime software that receives client messages, instantiates the remote data module, and marshals interface calls.

- For TCP/IP sockets this is a socket dispatcher application, Scktsrvr.exe.
- For HTTP connections this is httpsrvr.dll, an ISAPI/NSAPI DLL that must be installed with your Web server.

The Structure of the Application Server (see page 1542)

3.2.3.3.17 Creating the Client Application

In most regards, creating a multi-tiered client application is similar to creating a two-tiered client that uses a client dataset to cache updates. The major difference is that a multi-tiered client uses a connection component to establish a conduit to the application server.

To create a multi-tiered client application

1. Add a new data module to the project.
2. Place a connection component on the data module. The type of connection component you add depends on the communication protocol you want to use. See The Structure of the Client Application (see page 1543) for details.
3. Set properties on your connection component to specify the application server with which it should establish a connection. To learn more about setting up the connection component, see Connecting to the Application Server (see page 1517).
4. Set the other connection component properties as needed for your application. For example, you might set the *ObjectBroker* property to allow the connection component to choose dynamically from several servers. For more information about using the connection components, see Managing Server Connections (see page 1533).
5. Place as many *TClientDataSet* components as needed on the data module, and set the *RemoteServer* property for each component to the name of the connection component you placed in Step 2. For a full introduction to client datasets, see Using Client Datasets (see page 1740).
6. Set the *ProviderName* property for each *TClientDataSet* component. If your connection component is connected to the application server at design time, you can choose available application server providers from the *ProviderName* property's drop-down list.
7. Continue in the same way you would create any other database application. There are a few additional features available to clients of multi-tiered applications:

- Your application may want to make direct calls to the application server. Calling Server Interfaces (see page 1522) describes how to do this.
- You may want to use the special features of client datasets that support their interaction with the provider components. These are described in Using a Client Dataset with a Provider (see page 1732).

3.2.3.3.18 Creating Web Pages with an InternetExpress Page Producer

Each InternetExpress page producer generates an HTML document that appears in the browsers of your application's clients. If your application includes several separate Web documents, use a separate page producer for each of them.

The InternetExpress page producer (*TInetXPageProducer*) is a special page producer component (see page 2270). As with other page producers, you can assign it as the Producer property of an action item or call it explicitly from an OnAction event handler. For more information about using content producers with action items, see Responding to request messages with action items (see page 2278).

The InternetExpress page producer has a default template as the value of its HTMLDoc property. This template contains a set of HTML-transparent tags that the InternetExpress page producer uses to assemble an HTML document (with embedded javascript and XML) including content produced by other components. Before it can translate all of the HTML-transparent tags and assemble this document, you must indicate the location of the javascript libraries (see page 1549) used for the embedded javascript on the page. This location is specified by setting the IncludePathURL property.

You can specify the components that generate parts of the Web page using the Web page editor (see page 1549). Display the Web page editor by double-clicking the Web page component or clicking the ellipsis button next to the *WebPageItems* property in the **Object Inspector**.

The components you add in the Web page editor generate the HTML that replaces one of the HTML-transparent tags in the InternetExpress page producer's default template. These components become the value of the WebPageItems property. After adding the components in the order you want them, you can customize the template (see page 1529) to add your own HTML or change the default tags.

See Also

Using an XML Broker (see page 1544)

3.2.3.3.19 Customizing the InternetExpress Page Producer Template

The template of an InternetExpress page producer is an HTML document with extra embedded tags that your application translates dynamically. Initially, the page producer generates a default template as the value of the HTMLDoc property. This default template has the form

```
<HTML>
<HEAD>
</HEAD>
<BODY>
<#INCLUDES> <#STYLES> <#WARNINGS> <#FORMS> <#SCRIPT>
</BODY>
</HTML>
```

The HTML-transparent tags in the default template are translated as follows:

<#INCLUDES> generates the statements that include the javascript libraries. These statements have the form

```
<SCRIPT language=Javascript type="text/javascript" SRC="IncludePathURL/xmldom.js"> </SCRIPT>
<SCRIPT language=Javascript type="text/javascript" SRC="IncludePathURL/xmldb.js"> </SCRIPT>
<SCRIPT language=Javascript type="text/javascript" SRC="IncludePathURL/xmlbind.js"> </SCRIPT>
```

<#STYLES> generates the statements that defines a style sheet from definitions listed in the Styles or StylesFile property of the InternetExpress page producer.

<#WARNINGS> generates nothing at runtime. At design time, it adds warning messages for problems detected while generating the HTML document. You can see these messages in the Web page editor.

<#FORMS> generates the HTML produced by the components that you add in the Web page editor. The HTML from each component is generated in the order it appears in *WebPageItems*.

<#SCRIPT> generates a block of javascript declarations that are used in the HTML generated by the components added in the Web page editor.

You can replace the default template by changing the value of *HTMLDoc* or setting the HTMLFile property. The customized HTML template can include any of the HTML-transparent tags that make up the default template. The InternetExpress page producer automatically translates these tags when you call the Content method. In addition, The InternetExpress page producer automatically translates three additional tags:

<#BODYELEMENTS> is replaced by the same HTML as results from the 5 tags in the default template. It is useful when generating a template in an HTML editor when you want to use the default layout but add additional elements using the editor.

<#COMPONENT Name=WebComponentName> is replaced by the HTML that the component named *WebComponentName* generates. This component can be one of the components added in the Web page editor, or it can be any component that supports the IWebContent interface and has the same Owner as the InternetExpress page producer.

<#DATAPACKET XMLBroker=BrokerName> is replaced with the XML data packet obtained from the XML broker specified by *BrokerName*. When, in the Web page editor, you see the HTML that the InternetExpress page producer generates, you see this tag instead of the actual XML data packet.

In addition, the customized template can include any other HTML-transparent tags that you define. When the InternetExpress page producer encounters a tag that is not one of the seven types it translates automatically, it generates an OnHTMLTag event, where you can write code to perform your own translations. For more information about HTML templates in general, see HTML templates (see page 2269).

Tip: The components that appear in the Web page editor generate static code. That is, unless the application server changes the metadata that appears in data packets, the HTML is always the same, no matter when it is generated. You can avoid the overhead of generating this code dynamically at runtime in response to every request message by copying the generated HTML in the Web page editor and using it as a template. Because the Web page editor displays a <#DATAPACKET> tag instead of the actual XML, using this as a template still allows your application to fetch data packets from the application server dynamically.

3.2.3.3.20 Distributing a Client Application as an ActiveX Control

The multi-tiered database architecture can be combined with ActiveX features to distribute a client application as an ActiveX control.

When you distribute your client application as an ActiveX control, create the application server (see page 1527) as you would for any other multi-tiered application.

When creating the client application, you must use an Active Form as the basis instead of an ordinary form. See Creating an Active Form for the Client Application (see page 1526) for details.

Once you have built and deployed your client application, it can be accessed from any ActiveX-enabled Web browser on another machine. For a Web browser to successfully launch your client application, the Web server must be running on the machine that has the client application.

If the client application uses DCOM to communicate between the client application and the application server, the machine with the Web browser must be enabled to work with DCOM. If the machine with the Web browser is a Windows 95 machine, it must

have installed DCOM95, which is available from Microsoft.

3.2.3.3.21 Dropping or Changing a Server Connection

A connection component drops a connection to the application server when you

- set the *Connected* property to *False*.
- free the connection component. A connection object is automatically freed when a user closes the client application.
- change any of the properties that identify the application server (*ServerName*, *ServerGUID*, *ComputerName*, and so on). Changing these properties allows you to switch among available application servers at runtime. The connection component drops the current connection and establishes a new one.

  Note: Instead of using a single connection component to switch among available application servers, a client application can instead have more than one connection component, each of which is connected to a different application server.

  Before a connection component drops a connection, it automatically calls its *BeforeDisconnect* event handler, if one is provided. To perform any special actions prior to disconnecting, write a *BeforeDisconnect* handler. Similarly, after dropping the connection, the *AfterDisconnect* event handler is called. If you want to perform any special actions after disconnecting, write an *AfterDisconnect* handler.

Calling Server Interfaces (see page 1522)

Connecting to an Application Server That Uses Multiple Data Modules (see page 1526)

3.2.3.3.22 Extending the Interface of the Application Server

Client applications interact with the application server by creating or connecting to an instance of the remote data module. They use its interface as the basis of all communication with the application server.

You can add to your remote data module's interface to provide additional support for your client applications. This interface is a descendant of *IAppServer* and is created for you automatically by the wizard when you create the remote data module (see page 1536).

To add to the remote data module's interface, you can

- Choose the Add to Interface command from the Edit menu in the IDE. Indicate whether you are adding a procedure, function, or property, and enter its syntax. When you click OK, you will be positioned in the code editor on the implementation of your new interface member.
- Use the type library editor. Select the interface for your application server in the type library editor, and click the tool button for the type of interface member (method or property) that you are adding. Give your interface member a name in the Attributes page, specify parameters and type in the Parameters page, and then refresh the type library. See Working with type libraries (see page 1445) for more information about using the type library editor .

  Note: Neither of these approaches works if you are implementing *TSoapDataModule*. For *TSoapDataModule* descendants, you must edit the server interface directly.

  When you add to a COM interface, your changes are added to your unit source code and the type library file (.TLB).

  Note: You must explicitly save the TLB file by choosing Refresh in the type library editor and then saving the changes from the IDE.

  Once you have added to your remote data module's interface, locate the properties and methods that were added to your

remote data module's implementation. Add code to finish this implementation by filling in the bodies of the new methods.

If you are not writing a SOAP data module, client applications call your interface extensions using the *AppServer* property of their connection component. With SOAP data modules, they call the connection component's *GetSOAPServer* method. For more information on how to call your interface extensions, see Calling server interfaces (see page 1522).

Adding callbacks to the application server's interface

You can allow the application server to call your client application by introducing a callback. To do this, the client application passes an interface to one of the application server's methods, and the application server later calls this method as needed. However, if your extensions to the remote data module's interface include callbacks, you can't use an HTTP or SOAP-based connection. TWebConnection and TSoapConnection do not support callbacks. If you are using a socket-based connection, client applications must indicate whether they are using callbacks by setting the SupportCallbacks property. All other types of connection automatically support callbacks.

Extending a transactional application server's interface

When using transactions or just-in-time activation, you must be sure all new methods call SetComplete to indicate when they are finished. This allows transactions to complete and permits the remote data module to be deactivated.

Furthermore, you can't return any values from your new methods that allow the client to communicate directly with objects or interfaces on the application server unless they provide a safe reference. If you are using a stateless MTS data module, neglecting to use a safe reference can lead to crashes because you can't guarantee that the remote data module is active.

3.2.3.3.23 Granting Permission to Access and Launch the Application Server

Requests from the InternetExpress application appear to the application server as originating from a guest account with the name IUSR_computername, where computername is the name of the system running the Web application. By default, this account does not have access or launch permission for the application server. If you try to use the Web application without granting these permissions, when the Web browser tries to load the requested page it times out with EOLE_ACCESS_ERROR.

Note: Because the application server runs under this guest account, it can't be shut down by other accounts.

To grant the Web application access and launch permissions, run DCOMCnfg.exe, which is located in the System32 directory of the machine that runs the application server.

To configure your application server

1. When you run DCOMCnfg, select your application server in the list of applications on the Applications page.
2. Click the Properties button. When the dialog changes, select the Security page.
3. Select Use Custom Access Permissions, and press the Edit button. Add the name IUSR_computername to the list of accounts with access permission, where computername is the name of the machine that runs the Web application.
4. Select Use Custom Launch Permissions, and press the Edit button. Add IUSR_computername to this list as well.
5. Click the Apply button.

3.2.3.3.24 Managing Server Connections

The main purpose of connection components is to locate and connect to the application server. Because they manage server connections, you can also use connection components to call the methods of the application server's interface.

The following topics describe how to use a connection component for

- Connecting to the Server (see page 1519).
- Dropping or Changing a Server Connection (see page 1531).
- Calling Server Interfaces (see page 1522).
- Connecting to an Application Server that Uses Multiple Data Modules (see page 1526).

See Also

Connecting to the Application Server (see page 1517)

The Structure of the Client Application (see page 1543)

Using a Client dataset with a data provider (see page 1732)

3.2.3.3.25 Managing Transactions in Multi-tiered Applications

When client applications apply updates to the application server, the provider component automatically wraps the process of applying updates and resolving errors in a transaction. This transaction is committed if the number of problem records does not exceed the *MaxErrors* value specified as an argument to the *ApplyUpdates* method. Otherwise, it is rolled back.

In addition, you can add transaction support to your server application by adding a database connection component or managing the transaction directly by sending SQL to the database server. This works the same way that you would manage transactions in a two-tiered application. For more information about this sort of transaction control, see Managing transactions (see page 1498).

If you have a transactional data module, you can broaden your transaction support by using COM+ (or MTS) transactions. These transactions can include any of the business logic on your application server, not just the database access. In addition, because they support two-phase commits, they can span multiple databases.

Only the BDE- and ADO-based data access components support two-phase commit. Do not use InterbaseExpress or dbExpress components if you want to have transactions that span multiple databases.

Warning: When using the BDE, two-phase commit is fully implemented only on Oracle7 and MS-SQL databases. If your transaction involves multiple databases, and some of them are remote servers other than Oracle7 or MS-SQL, your transaction runs a small risk of only partially succeeding. Within any one database, however, you will always have transaction support.

By default, all *IAppServer* calls on a transactional data module are transactional. You need only set the transaction attribute of your data module (see page 1524) to indicate that it must participate in transactions. In addition, you can extend the application server's interface (see page 1531) to include method calls that encapsulate transactions that you define.

If your transaction attribute indicates that the remote data module requires a transaction, then every time a client calls a method on its interface, it is automatically wrapped in a transaction. All client calls to your application server are then enlisted in that transaction until you indicate that the transaction is complete. These calls either succeed as a whole or are rolled back.

Note: Do not combine COM+ or MTS transactions with explicit transactions created by a database connection component or using explicit SQL commands. When your transactional data module is enlisted in a transaction, it automatically enlists all of your database calls in the transaction as well.

3.2.3.3.26 Overview of a Three-tiered Application

The following numbered steps illustrate a normal sequence of events for a provider-based three-tiered application:

1. A user starts the client application. The client connects to the application server (which can be specified at design time or runtime). If the application server is not already running, it starts. The client receives an *IAppServer* interface for communicating with the application server.
2. The client requests data from the application server. A client may request all data at once, or may request chunks of data throughout the session (fetch on demand).
3. The application server retrieves the data (first establishing a database connection, if necessary), packages it for the client, and returns a data packet to the client. Additional information, (for example, field display characteristics) can be included in the metadata of the data packet. This process of packaging data into data packets is called "providing."
4. The client decodes the data packet and displays the data to the user.
5. As the user interacts with the client application, the data is updated (records are added, deleted, or modified). These modifications are stored in a change log by the client.
6. Eventually the client applies its updates to the application server, usually in response to a user action. To apply updates, the client packages its change log and sends it as a data packet to the server.
7. The application server decodes the package and posts updates (in the context of a transaction if appropriate). If a record can't be posted (for example, because another application changed the record after the client requested it and before the client applied its updates), the application server either attempts to reconcile the client's changes with the current data, or saves the records that could not be posted. This process of posting records and caching problem records is called "resolving."
8. When the application server finishes the resolving process, it returns any unposted records to the client for further resolution.
9. The client reconciles unresolved records. There are many ways a client can reconcile unresolved records. Typically the client attempts to correct the situation that prevented records from being posted or discards the changes. If the error situation can be rectified, the client applies updates again.
10. The client refreshes its data from the server.

The Structure of the Client Application (see page 1543)

The Structure of the Application Server (see page 1542)

Choosing a Connection Protocol (see page 1523)

Using a Multi-tiered Architecture (see page 1564)

3.2.3.3.27 Pooling Remote Data Modules

Object pooling allows you to create a cache of remote data modules that are shared by their clients, thereby conserving resources. How this works depends on the type of remote data module and on the connection protocol (see page 1523).

If you are creating a transactional data module (see page 1546) that will be installed to COM+, you can use the COM+ Component Manager to install the application server as a pooled object.

Even if you are not using a transactional data module, you can take advantage of object pooling if the connection is formed using *TWebConnection*. Under this second type of object pooling, you limit the number of instances of your remote data module that are created. This limits the number of database connections that you must hold, as well as any other resources used by the remote data module.

When the Web Server application (which passes calls to your remote data module) receives client requests, it passes them on to the first available remote data module in the pool. If there is no available remote data module, it creates a new one (up to a maximum number that you specify). This provides a middle ground between routing all clients through a single remote data module instance (which can act as a bottleneck), and creating a separate instance for every client connection (which can consume many resources).

If a remote data module instance in the pool does not receive any client requests for a while, it is automatically freed. This prevents the pool from monopolizing resources unless they are used.

To set up object pooling when using a Web connection (HTTP), your remote data module must override the UpdateRegistry method. In the overridden method, call RegisterPooled when the remote data module registers and UnregisterPooled when the remote data module unregisters.

When using either method of object pooling, your remote data module must be stateless. This is because a single instance potentially handles requests from several clients. If it relied on persistent state information, clients could interfere with each other. See Supporting State Information in Remote Data Modules (see page 1540) for more information on how to ensure that your remote data module is stateless.

See Also

Choosing a Connection Protocol (see page 1523)

3.2.3.3.28 Registering the Application Server

Before client applications can locate and use an application server, it must be registered or installed.

- If the application server uses DCOM, HTTP, or sockets as a communication protocol, it acts as an Automation server and must be registered like any other COM server. For information about registering a COM server, see Registering a COM Object (see page 1440).
- If you are using a transactional data module, you do not register the application server. Instead, you install it with COM+ or MTS. .
- When the application server uses SOAP, the application must be a Web Service application. As such, it must be registered with your Web Server, so that it receives incoming HTTP messages. In addition, you need to publish a WSDL document that describes the invokable interfaces in your application. For information about exporting a WSDL document for a Web Service application, see Generating WSDL Documents for a Web Service Application (see page 2306).

Creating the Client Application (see page 1528)

Creating the Application Server (see page 1527)

Writing Web-based client applications (see page 1551)

3.2.3.3.29 Setting Up the Remote Data Module

When you create the remote data module, you must provide certain information that indicates how it responds to client requests. This information varies, depending on the type of remote data module. See The Structure of the Application Server (see page 1542) for information on what type of remote data module you need.

The following topics describe how to configure each type of remote data module:

- Configuring TRemoteDataModule (see page 1525)
- Configuring TMTSDataModule (see page 1524)
- Configuring TSoapDataModule (see page 1525)

Supporting State Information in Remote Data Modules (see page 1540)

Using Multiple Remote Data Modules (see page 1547)

3.2.3.3.30 Setting Web Item Properties

The Web items that you add using the Web page editor are specialized components that generate HTML. Each Web item class is designed to produce a specific control or section of the final HTML document, but a common set of properties influences the appearance of the final HTML.

When a Web item represents information from the XML data packet (for example, when it generates a set of field or parameter display controls or a button that manipulates the data), the XMLBroker property associates the Web item with the XML broker that manages the data packet. You can further specify a dataset that is contained in a dataset field of that data packet using the XMLDataSetField property. If the Web item represents a specific field or parameter value, the Web item has a FieldName or ParamName property.

You can apply a style attribute to any Web item, thereby influencing the overall appearance of all the HTML it generates. Styles and style sheets are part of the HTML 4 standard. They allow an HTML document to define a set of display attributes that apply to a tag and everything in its scope. Web items offer a flexible selection of ways to use them:

The simplest way to use styles is to define a style attribute directly on the Web item. To do this, use the Style property. The value of *Style* is simply the attribute definition portion of a standard HTML style definition, such as,

```
color: red.
```

You can define a style sheet that defines a set of style definitions. Each definition includes a style selector (the name of a tag to which the style always applies or a user-defined style name) and the attribute definition in curly braces,

```
H2 B  {color: red}
.MyStyle  {font-family: arial; font-weight: bold; font-size: 18px }
```

The entire set of definitions is maintained by the InternetExpress page producer as its Styles property. Each Web item can then reference the styles with user-defined names by setting its StyleRule property.

If you are sharing a style sheet with other applications, you can also supply the style definitions as the value of the InternetExpress page producer's StylesFile property instead of the *Styles* property. Individual Web items still reference styles using the *StyleRule* property.

Another common property of Web items is the *Custom* property. *Custom* includes a set of options that you add to the generated

HTML tag. HTML defines a different set of options for each type of tag. The VCL reference for the *Custom* property of most Web items gives an example of possible options. For more information on possible options, use an HTML reference.

3.2.3.3.31 Specifying a Connection Using HTTP

You can establish a connection to the application server using HTTP from any machine that has a TCP/IP address. Unlike sockets, however, HTTP allows you to take advantage of SSL security and to communicate with a server that is protected behind a firewall. When using HTTP, include a TWebConnection component for connecting to the application server.

The Web connection component establishes a connection to the Web server application (httpsrvr.dll), which in turn communicates with the application server. *TWebConnection* locates httpsrvr.dll using a Uniform Resource Locator (URL). The URL specifies the protocol (http or, if you are using SSL security, https), the host name for the machine that runs the Web server and httpsrvr.dll, and the path to the Web server application (httpsrvr.dll). Specify this value using the URL property.

Note: When using *TWebConnection*, wininet.dll must be installed on the client machine. If you have IE3 or higher installed, wininet.dll can be found in the Windows system directory.

If the Web server requires authentication, or if you are using a proxy server that requires authentication, you must set the values of the UserName and Password properties so that the connection component can log on.

If you have multiple servers that your client application can choose from, you can use the ObjectBroker property instead of specifying a value for URL. For more information, see Brokering connections (see page 1520).

Using Web Connections (see page 1550)

Parts of a Uniform Resource Locator (see page 2253)

3.2.3.3.32 Specifying a Connection Using DCOM

When using DCOM to communicate with the application server, client applications include a TDCOMConnection component for connecting to the application server. *TDCOMConnection* uses the ComputerName property to identify the machine on which the server resides.

When *ComputerName* is blank, the DCOM connection component assumes that the application server resides on the client machine or that the application server has a system registry entry. If you do not provide a system registry entry for the application server on the client when using DCOM, and the server resides on a different machine from the client, you must supply *ComputerName*.

Note: Even when there is a system registry entry for the application server, you can specify *ComputerName* to override this entry. This can be especially useful during development, testing, and debugging.

If you have multiple servers that your client application can choose from, you can use the ObjectBroker property instead of specifying a value for *ComputerName*. For more information, see Brokering connections (see page 1520).

If you supply the name of a host computer or server that cannot be found, the DCOM connection component raises an exception when you try to open the connection.

3.2.3.3.33 Specifying a Connection Using SOAP

You can establish a connection to a SOAP application server using the TSoapConnection component. *TSoapConnection* is very similar to *TWebConnection*, because it also uses HTTP as a transport protocol. Thus, you can use *TSoapConnection* from any machine that has a TCP/IP address, and it can take advantage of SSL security and to communicate with a server that is protected by a firewall.

The SOAP connection component establishes a connection to a Web Service provider that implements the *IAppServerSOAP* or *IAppServer* interface. (The UseSOAPAdapter property specifies which interface it expects the server to support.) If the server implements the *IAppServerSOAP* interface, *TSoapConnection* converts that interface to an *IAppServer* interface for client datasets. *TSoapConnection* locates the Web Server application using a Uniform Resource Locator (URL). The URL specifies the protocol (http or, if you are using SSL security, https), the host name for the machine that runs the Web server, the name of the Web Service application, and a path that matches the path name of the *THTTPSoapDispatcher* on the application server. Specify this value using the URL property.

By default, *TSOAPConnection* automatically looks for an *IAppServerSOAP* (or *IAppServer*) interface. If the server includes more than one remote data module, you must indicate the target data module's interface (an *IAppServerSOAP* descendant) so that *TSOAPConnection* can identify the remote data module you want to use. There are two ways to do this:

- Set the SOAPServerIID property to indicate the interface of the target remote data module. This method works for any server that implements an *IAppServerSOAP* descendant. *SOAPServerIID* identifies the target interface by its GUID. At runtime, you can use the interface name, and the compiler automatically extracts the GUID. However, at design time, in the **Object Inspector**, you must specify the GUID string.
- If the server is written using the Delphi language, you can simply include the name of the SOAP data module's interface following a slash at the end of the path portion of the URL. This lets you specify the interface by name rather than GUID, but is only available when both client and server are written in Delphi.

  Tip: The first approach, using the *SOAPServerIID* method, has the added advantage that it lets you call extensions to the remote data module's interface (see page 1522).

  If you are using a proxy server, you must indicate the name of the proxy server using the Proxy property. If that proxy requires authentication, you must also set the values of the UserName and Password properties so that the connection component can log on.

  Note: When using *TSoapConnection*, wininet.dll must be installed on the client machine. If you have IE3 or higher installed, wininet.dll can be found in the Windows system directory.

Specifying a Connection Using DCOM (see page 1537)

Specifying a Connection Using Sockets (see page 1538)

3.2.3.3.34 Specifying a Connection Using Sockets

You can establish a connection to the application server using sockets from any machine that has a TCP/IP address. This method has the advantage of being applicable to more machines, but does not provide for using any security protocols. When using sockets, include a TSocketConnection component for connecting to the application server.

TSocketConnection identifies the server machine using the IP Address or host name of the server system, and the port number

of the socket dispatcher program (Scktsrvr.exe) that is running on the server machine. For more information about IP addresses and port values, see Describing sockets (see page 2336).

Three properties of *TSocketConnection* specify this information:

- Address specifies the IP Address of the server.
- Host specifies the host name of the server.
- Port specifies the port number of the socket dispatcher program on the application server.

Address and *Host* are mutually exclusive. Setting one unsets the value of the other. For information on which one to use, see Describing the host (see page 2336).

If you have multiple servers that your client application can choose from, you can use the ObjectBroker property instead of specifying a value for *Address* or *Host*. For more information, see Brokering connections (see page 1520).

By default, the value of *Port* is 211, which is the default port number of the socket dispatcher program that forwards incoming messages to your application server. If the socket dispatcher has been configured to use a different port, set the *Port* property to match that value.

Note: You can configure the port of the socket dispatcher while it is running by right-clicking the CodeGear Socket Server tray icon and choosing Properties.

Although socket connections do not provide for using security protocols, you can customize the socket connection to add your own encryption.

To add your own encryption

1. Create a COM object that supports the IDataIntercept interface. This is an interface for encrypting and decrypting data.
2. Use TPacketInterceptFactory as the class factory for this object. If you are using a wizard to create the COM object in step 1, replace the line in the initialization section that says `TComponentFactory.Create(...)` with `TPacketInterceptFactory.Create(...)`.
3. Register your new COM server on the client machine.
4. Set the InterceptName or InterceptGUID property of the socket connection component to specify this COM object. If you used *TPacketInterceptFactory* in step 2, your COM server appears in the drop-down list of the **Object Inspector** for the *InterceptName* property.
5. Finally, right click the CodeGear Socket Server tray icon, choose Properties, and on the properties tab set the Intercept Name or Intercept GUID to the ProgId or GUID for the interceptor.

This mechanism can also be used for data compression and decompression.

3.2.3.3.35 Supporting Master/detail Relationships

You can create master/detail relationships between client datasets in your client application in the same way you set them up using any table-type dataset. For more information about setting up master/detail relationships in this way, see Creating Master/detail Relationships (see page 1590).

However, this approach has two major drawbacks:

- The detail table must fetch and store all of its records from the application server even though it only uses one detail set at a time. (This problem can be mitigated by using parameters. For more information, see Limiting records with parameters (see page 1720).)

- It is very difficult to apply updates, because client datasets apply updates at the dataset level and master/detail updates span multiple datasets. Even in a two-tiered environment, where you can use the database connection component to apply updates for multiple tables in a single transaction, applying updates in master/detail forms is tricky.

In multi-tiered applications, you can avoid these problems by using nested tables to represent the master/detail relationship. To do this when providing from datasets, set up a master/detail relationship between the datasets on the application server. Then set the *DataSet* property of your provider component to the master table. To use nested tables to represent master/detail relationships when providing from XML documents, use a transformation file that defines the nested detail sets.

When clients call the *GetRecords* method of the provider, it automatically includes the detail dataset as a DataSet field in the records of the data packet. When clients call the *ApplyUpdates* method of the provider, it automatically handles applying updates in the proper order.

Using Multiple Remote Data Modules (see page 1547)

3.2.3.3.36 Supporting State Information in Remote Data Modules

The *IAppServer* interface, which client datasets use to communicate with providers on the application server, is mostly stateless. When an application is stateless, it does not "remember" anything that happened in previous calls by the client. This stateless quality is useful if you are pooling database connections in a transactional data module, because your application server does not need to distinguish between database connections for persistent information such as record currency. Similarly, this stateless quality is important when you are sharing remote data module instances between many clients, as occurs with just-in-time activation or object pooling. SOAP data modules must be stateless.

However, there are times when you want to maintain state information between calls to the application server. For example, when requesting data using incremental fetching (see page 1725), the provider on the application server must "remember" information from previous calls (the current record).

Before and after any calls to the *IAppServer* interface that the client dataset makes (*AS_ApplyUpdates*, *AS_Execute*, *AS_GetParams*, *AS_GetRecords*, or *AS_RowRequest*), it receives an event where it can send or retrieve custom state information. Similarly, before and after providers respond to these client-generated calls, they receive events where they can retrieve or send custom state information. Using this mechanism, you can communicate persistent state information between client applications and the application server, even if the application server is stateless.

For example, consider a dataset that represents the following parameterized query:

```
SELECT * from CUSTOMER WHERE CUST_NO > :MinVal ORDER BY CUST_NO
```

To enable incremental fetching in a stateless application server, you can do the following:

When the provider packages a set of records in a data packet, it notes the value of CUST_NO on the last record in the packet:

```
TRemoteDataModule1.DataSetProvider1GetData(Sender: TObject; DataSet: TCustomClientDataSet);
begin
  DataSet.Last; { move to the last record }
  with Sender as TDataSetProvider do
    Tag := DataSet.FieldValues['CUST_NO']; {save the value of CUST_NO }
end;
TRemoteDataModule1::DataSetProvider1GetData(TObject *Sender, TCustomClientDataSet *DataSet)
{
  DataSet->Last(); // move to the last record
```

```
  TComponent *pProvider = dynamic_cast<TComponent *>(Sender);
  pProvider->Tag = DataSet->FieldValues["CUST_NO"];
}
```

The provider sends this last CUST_NO value to the client after sending the data packet:

```
TRemoteDataModule1.DataSetProvider1AfterGetRecords(Sender: TObject;
                  var OwnerData: OleVariant);
begin
  with Sender as TDataSetProvider do
    OwnerData := Tag; {send the last value of CUST_NO }
end;
TRemoteDataModule1::DataSetProvider1AfterGetRecords(TObject *Sender, OleVariant &OwnerData)
{
  TComponent *pProvider = dynamic_cast<TComponent *>(Sender);
  OwnerData = pProvider->Tag;
}
```

On the client, the client dataset saves this last value of CUST_NO:

```
TDataModule1.ClientDataSet1AfterGetRecords(Sender: TObject; var OwnerData: OleVariant);
begin
  with Sender as TClientDataSet do
    Tag := OwnerData; {save the last value of CUST_NO }
end;
TDataModule1::ClientDataSet1AfterGetRecords(TObject *Sender, OleVariant &OwnerData)
{
  TComponent *pDS = dynamic_cast<TComponent *>(Sender);
  pDS->Tag = OwnerData;
}
```

Before fetching a data packet, the client sends the last value of CUST_NO it received:

```
TDataModule1.ClientDataSet1BeforeGetRecords(Sender: TObject; var OwnerData: OleVariant);
begin
  with Sender as TClientDataSet do
  begin
    if not Active then Exit;
    OwnerData := Tag; { Send last value of CUST_NO to application server }
  end;
end;
TDataModule1::ClientDataSet1BeforeGetRecords(TObject *Sender, OleVariant &OwnerData)
{
  TClientDataSet *pDS = dynamic_cast<TClientDataSet *>(Sender);
  if (!pDS->Active)
    return;
  OwnerData = pDS->Tag;
}
```

Finally, on the server, the provider uses the last CUST_NO sent as a minimum value in the query:

```
TRemoteDataModule1.DataSetProvider1BeforeGetRecords(Sender: TObject;
                   var OwnerData: OleVariant);
begin
  if not VarIsEmpty(OwnerData) then
    with Sender as TDataSetProvider do
      with DataSet as TSQLDataSet do
      begin
        Params.ParamValues['MinVal'] := OwnerData;
        Refresh; { force the query to reexecute }
    end;
end;
TRemoteDataModule1::DataSetProvider1BeforeGetRecords(TObject *Sender, OleVariant &OwnerData)
{
if (!VarIsEmpty(OwnerData))
{
  TDataSetProvider *pProv = dynamic_cast<TDataSetProvider *>(Sender);
  TSQLDataSet *pDS = (dynamic_cast<TSQLDataSet *>(pProv->DataSet);
```

```
  pDS->Params->ParamValues["MinVal"] = OwnerData;
  pDS->Refresh(); // force the query to reexecute
}
}
```

3.2.3.3.37 The Structure of the Application Server

When you set up and run an application server, it does not establish any connection with client applications. Rather, client applications initiate and maintain the connection. The client application uses a connection component to connect to the application server, and uses the interface of the application server to communicate with a selected provider. All of this happens automatically, without your having to write code to manage incoming requests or supply interfaces.

The basis of an application server is a remote data module, which is a specialized data module that supports the *IAppServer* interface (for application servers that also function as a Web Service, the remote data module supports the *IAppServerSOAP* interface as well, and uses it in preference to *IAppServer*.) Client applications use the remote data module's interface to communicate with providers (see page 1811) on the application server. When the remote data module uses *IAppServerSOAP*, the connection component adapts this to an *IAppServer* interface that client datasets can use.

There are three types of remote data modules:

- **TRemoteDataModule**: This is a dual-interface Automation server. Use this type of remote data module if clients use DCOM, HTTP, sockets, or OLE to connect to the application server, unless you want to install the application server with COM+.
- **TMTSDataModule**: This is a dual-interface Automation server. Use this type of remote data module if you are creating the application server as an Active Library (.DLL) that is installed with COM+ (or MTS). You can use MTS remote data modules with DCOM, HTTP, sockets, or OLE. See Using transactional data modules (see page 1546) for information about the benefits and limitations of using MTS or COM+ with the application server.
- **TSoapDataModule**: This is a data module that implements an *IAppServerSOAP* interface in a Web Service application. Use this type of remote data module to provide data to clients that access data as a Web Service.

  Note: If the application server is to be deployed under COM+ (or MTS), the remote data module includes events for when the application server is activated or deactivated. This allows it to acquire database connections when activated and release them when deactivated.

The contents of the remote data module

As with any data module, you can include any nonvisual component in the remote data module. There are certain components, however, that you must include:

It must include a dataset component to represent the records from that database server if the remote data module is exposing information from a database server. Other components, such as a database connection component (see page 1506) of some type, may be required to allow the dataset to interact with a database server.

For every dataset that the remote data module exposes to clients, it must include a dataset provider (see page 1819). A

dataset provider packages data into data packets that are sent to client datasets and applies updates received from client datasets back to a source dataset or a database server.

It must include an XML provider (see page 1846) for every XML document that the remote data module exposes to clients. An XML provider acts like a dataset provider, except that it fetches data from and applies updates to an XML document rather than a database server.

Note: Do not confuse database connection components, which connect datasets to a database server, with the connection components used by client applications in a multi-tiered application. The connection components in multi-tiered applications can be found on the DataSnap category or WebServices category of the Tool palette

.

Overview of AMIDAS Based MultiTiered Applications

The Structure of the Client Application (see page 1543)

Creating the Application Server (see page 1527)

3.2.3.3.38 The Structure of the Client Application

To the end user, the client application of a multi-tiered application looks and behaves no differently than a two-tiered application that uses cached updates. User interaction takes place through standard data-aware controls that display data from a TClientDataSet component. For detailed information about using the properties, events, and methods of client datasets, see Using Client Datasets (see page 1740).

TClientDataSet fetches data from and applies updates to a provider component, just as in two-tiered applications that use a client dataset with an external provider. For details about providers, see Using Provider Components (see page 1819). For details about client dataset features that facilitate its communication with a provider, see Using a Client Dataset with a Provider (see page 1732).

The client dataset communicates with the provider through the IAppServer interface. It gets this interface from a connection component. The connection component establishes the connection to the application server. Different connection components are available for using different communications protocols (see page 1523).

These connection components are summarized in the following table:

Connection components

Component	Protocol
TDCOMConnection	DCOM
TSocketConnection	Windows sockets (TCP/IP)
TWebConnection	HTTP
TSOAPConnection	SOAP (HTTP and XML)

Note: The DataSnap category of the Tool palette

also includes a connection component that does not connect to an application server at all, but instead supplies an IAppServer interface for client datasets to use when communicating with providers in the same application. This component, TLocalConnection, is not required, but makes it easier to scale up to a multi-tiered application later. For more information about using connection components, see Connecting to the Application Server (see page 1517).

3.2.3.3.39 Understanding Multi-tiered Database Applications

Multi-tiered applications use the components on the DataSnap page, the Data Access page, and possibly the WebServices page of the **Tool palette**, plus a remote data module that is created by a wizard on the Multitier or WebServices page of the New Items dialog. They are based on the ability of provider components to package data into transportable data packets and handle updates received as transportable delta packets.

The components needed for a multi-tiered application are described in the following table:

Components used in multi-tiered applications

Component	Description
Remote data modules	Specialized data modules that can act as a COM Automation server or implement a Web Service to give client applications access to any providers they contain. Used on the application server.
Provider component	A data broker that provides data by creating data packets and resolves client updates. Used on the application server.
Client dataset component	A specialized dataset that uses midas.dll or midaslib.dcu to manage data stored in data packets. The client dataset is used in the client application. It caches updates locally, and applies them in delta packets to the application server.
Connection components	A family of components that locate the server, form connections, and make the *IAppServer* interface available to client datasets. Each connection component is specialized to use a particular communications protocol.

The provider and client dataset components require midas.dll or midaslib.dcu, which manages datasets stored as data packets. (Note that, because the provider is used on the application server and the client dataset is used on the client application, if you are using midas.dll, you must deploy it on both application server and client application.)

An overview of the architecture into which these components fit is described in Using a multi-tiered architecture (see page 1564). For more information on how these components fit together to create a multi-tiered application, see

- Overview of a Three-tiered Application (see page 1534)
- The Structure of the Client Application (see page 1543)
- The Structure of the Application Server (see page 1542)
- Choosing a Connection Protocol (see page 1523)

Writing Web-based Client Applications (see page 1551)

3.2.3.3.40 Using an XML Broker

The XML broker serves two major functions:

- It fetches XML data packets from the application server and makes them available to the Web Items that generate HTML for the InternetExpress application.
- It receives updates in the form of XML delta packets from browsers and applies them to the application server.

Fetching XML data packets

Before the XML broker can supply XML data packets to the components that generate HTML pages, it must fetch them from the application server. To do this, it uses the *IAppServer* interface, which it acquires from a connection component.

Note: Even when using SOAP, where the application server supports *IAppServerSOAP*, the XML broker uses *IAppServer* because the connection component acts as an adapter between the two interfaces.

You must set the following properties so that the XML producer can use the *IAppServer* interface:

- Set the RemoteServer property to the connection component that establishes the connection to the application server and gets its *IAppServer* interface. At design time, you can select this value from a drop-down list in the **Object Inspector**.
- Set the ProviderName property to the name of the provider component on the application server that represents the dataset for which you want XML data packets. This provider both supplies XML data packets and applies updates from XML delta packets. At design time, if the *RemoteServer* property is set and the connection component has an active connection, the **Object Inspector** displays a list of available providers. (If you are using a DCOM connection the application server must also be registered on the client machine).

Two properties let you indicate what you want to include in data packets:

- You can limit the number of records that are added to the data packet by setting the MaxRecords property. This is especially important for large datasets because InternetExpress applications send the entire data packet to client Web browsers. If the data packet is too large, the download time can become prohibitively long.
- If the provider on the application server represents a query or stored procedure, you may want to provide parameter values before obtaining an XML data packet. You can supply these parameter values using the Params property.

The components that generate HTML and javascript for the InternetExpress application automatically use the XML broker's XML data packet once you set their *XMLBroker* property. To obtain the XML data packet directly in code, use the RequestRecords method.

Note: When the XML broker supplies a data packet to another component (or when you call *RequestRecords*), it receives an OnRequestRecords event. You can use this event to supply your own XML string instead of the data packet from the application server. For example, you could fetch the XML data packet from the application server using GetXMLRecords and then edit it before supplying it to the emerging Web page.

Applying updates from XML delta packets

When you add the XML broker to the Web module (or data module containing a *TWebDispatcher*), it automatically registers itself with the Web dispatcher as an auto-dispatching object. This means that, unlike other components, you do not need to create an action item for the XML broker in order for it to respond to update messages from a Web browser. These messages contain XML delta packets that should be applied to the application server. Typically, they originate from a button that you create on one of the HTML pages produced by the Web client application.

So that the dispatcher can recognize messages for the XML broker, you must describe them using the WebDispatch property. Set the *PathInfo* property to the path portion of the URL to which messages for the XML broker are sent. Set *MethodType* to the value of the method header of update messages addressed to that URL (typically *mtPost*). If you want to respond to all messages with the specified path, set *MethodType* to *mtAny*. If you don't want the XML broker to respond directly to update messages (for example, if you want to handle them explicitly using an action item), set the *Enabled* property to *False*. For more information on how the Web dispatcher determines which component handles messages from the Web browser, see Dispatching request messages (see page 2281).

When the dispatcher passes an update message on to the XML broker, it passes the updates on to the application server and, if there are update errors, receives an XML delta packet describing all update errors. Finally, it sends a response message back to the browser, which either redirects the browser to the same page that generated the XML delta packet or sends it some new content.

A number of events allow you to insert custom processing at all steps of this update process:

1. When the dispatcher first passes the update message to the XML broker, it receives a BeforeDispatch event, where you can preprocess the request or even handle it entirely. This event allows the XML broker to handle messages other than update messages.

2. If the *BeforeDispatch* event handler does not handle the message, the XML broker receives an OnRequestUpdate event, where you can apply the updates yourself rather than using the default processing.
3. If the *OnRequestUpdate* event handler does not handle the request, the XML broker applies the updates and receives a delta packet containing any update errors.
4. If there are no update errors, the XML broker receives an OnGetResponse event, where you can create a response message that indicates the updates were successfully applied or sends refreshed data to the browser. If the *OnGetResponse* event handler does not complete the response (does not set the *Handled* parameter to *True*), the XML broker sends a response that redirects the browser back to the document that generated the delta packet.
5. If there are update errors, the XML broker receives an OnGetErrorResponse event instead. You can use this event to try to resolve update errors or to generate a Web page that describes them to the end user. If the *OnGetErrorResponse* event handler does not complete the response (does not set the *Handled* parameter to *True*), the XML broker calls on a special content producer called the ReconcileProducer to generate the content of the response message.
6. Finally, the XML broker receives an AfterDispatch event, where you can perform any final actions before sending a response back to the Web browser.

Creating Web Pages with an InternetExpress Page Producer (see page 1529)

3.2.3.3.41 Using DCOM Connections

DCOM provides the most direct approach to communication, requiring no additional runtime applications on the server.

DCOM provides the only approach that lets you use security services when writing a transactional data module. These security services are based on assigning roles to the callers of transactional objects. When using DCOM, DCOM identifies the caller to the system that calls your application server (COM+ or MTS). Therefore, it is possible to accurately determine the role of the caller. When using other protocols, however, there is a runtime executable, separate from the application server, that receives client calls. This runtime executable makes COM calls into the application server on behalf of the client. Because of this, it is impossible to assign roles to separate clients: The runtime executable is, effectively, the only client.

See Also

Using Transactional Data Modules (see page 1546)

Using Socket Connections (see page 1548)

Using SOAP Connections (see page 1548)

3.2.3.3.42 Using Transactional Data Modules

You can write an application server that takes advantage of special services for distributed applications that are supplied by COM+ (under Windows 2000 and later) or MTS (before Windows 2000). To do so, create a transactional data module instead of an ordinary remote data module.

When you use a transactional data module, your application can take advantage of the following special services:

- **Security.** COM+ (or MTS) provides role-based security for your application server. Clients are assigned roles, which determine how they can access the MTS data module's interface. The MTS data module implements the IsCallerInRole method, which you lets you check the role of the currently connected client and conditionally allow certain functions based on that role. .
- **Database handle pooling.** Transactional data modules automatically pool database connections that are made via ADO or (if you are using MTS and turn on MTS POOLING) the BDE. When one client is finished with a database connection, another client can reuse it. This cuts down on network traffic, because your middle tier does not need to log off of the remote database server and then log on again. When pooling database handles, your database connection component should set its *KeepConnection* property to *False*, so that your application maximizes the sharing of connections. .
- **Transactions**. When using a transactional data module, you can provide enhanced transaction support beyond that available

with a single database connection. Transactional data modules can participate in transactions that span multiple databases, or include functions that do not involve databases at all. For more information about the transaction support provided by transactional objects such as transactional data modules, see Managing transactions in multi-tiered applications (see page 1533).

- **Just-in-time activation and as-soon-as-possible deactivation.** You can write your server so that remote data module instances are activated and deactivated on an as-needed basis. When using just-in-time activation and as-soon-as-possible deactivation, your remote data module is instantiated only when it is needed to handle client requests. This prevents it from tying up resources such as database handles when they are not in use.

Using just-in-time activation and as-soon-as-possible deactivation provides a middle ground between routing all clients through a single remote data module instance, and creating a separate instance for every client connection. With a single remote data module instance, the application server must handle all database calls through a single database connection. This acts as a bottleneck, and can impact performance when there are many clients. With multiple instances of the remote data module, each instance can maintain a separate database connection, thereby avoiding the need to serialize database access. However, this monopolizes resources because other clients can't use the database connection while it is associated with another client's remote data module.

To take advantage of transactions, just-in-time activation, and as-soon-as-possible deactivation, remote data module instances must be stateless. This means you must provide additional support if your client relies on state information. For example, the client must pass information about the current record when performing incremental fetches. For more information about state information and remote data modules in multi-tiered applications, see Supporting state information in remote data modules (see page 1540).

By default, all automatically generated calls to a transactional data module are transactional (that is, they assume that when the call exits, the data module can be deactivated and any current transactions committed or rolled back). You can write a transactional data module that depends on persistent state information by setting the AutoComplete property to *False*, but it will not support transactions, just-in-time activation, or as-soon-as-possible deactivation unless you use a custom interface.

Warning: Application servers containing transactional data modules should not open database connections until the data module is activated. While developing your application, be sure that all datasets are not active and the database is not connected before running your application. In the application itself, add code to open database connections when the data module is activated and close them when it is deactivated.

Pooling Remote Data Modules (see page 1535)

3.2.3.3.43 Using Multiple Remote Data Modules

You may want to structure your application server so that it uses multiple remote data modules. Using multiple remote data modules lets you partition your code, organizing a large application server into multiple units, where each unit is relatively self-contained.

Although you can always create multiple remote data modules on the application server that function independently, a special connection component on the DataSnap category of the **Tool palette** provides support for a model where you have one main "parent" remote data module that dispatches connections from clients to other "child" remote data modules. This model requires that you use a COM-based application server (that is, not *TSoapDataModule*).

To create the parent remote data module, you must extend its *IAppServer* interface, adding properties that expose the interfaces of the child remote data modules. That is, for each child remote data module, add a property to the parent data module's interface whose value is the *IAppServer* interface for the child data module. The property getter should look something like the following:

```
function ParentRDM.Get_ChildRDM: IChildRDM;
begin
  if not Assigned(ChildRDMFactory) then
    ChildRDMFactory :=
      TComponentFactory.Create(ComServer, TChildRDM, Class_ChildRDM,
                               ciInternal, tmApartment);
```

```
  Result := ChildRDMFactory.CreateCOMObject(nil) as IChildRDM;
  Result.MainRDM := Self;
end;
```

For information about extending the parent remote data module's interface, see Extending the application server's interface (see page 1531).

Tip: You may also want to extend the interface for each child data module, exposing the parent data module's interface, or the interfaces of the other child data modules. This lets the various data modules in your application server communicate more freely with each other.

Once you have added properties that represent the child remote data modules to the main remote data module, client applications do not need to form separate connections to each remote data module on the application server. Instead, they share a single connection to the parent remote data module, which then dispatches messages to the "child" data modules. Because each client application uses the same connection for every remote data module, the remote data modules can share a single database connection, conserving resources. For information on how child applications share a single connection, see Connecting to an Application Server That Uses Multiple Data Modules (see page 1526).

3.2.3.3.44 Using SOAP Connections

SOAP is the protocol that underlies the built-in support for Web Service applications. SOAP marshals method calls using an XML encoding. SOAP connections use HTTP as a transport protocol.

SOAP connections have the advantage that they work in cross-platform applications because they are supported on both the Windows and Linux. Because SOAP connections use HTTP, they have the same advantages as Web connections: HTTP provides a lowest common denominator that you know is available on all clients, and clients can communicate with an application server that is protected by a "firewall." For more information about using SOAP to distribute applications, see Using Web Services. (see page 2291).

As with HTTP connections, you can't use callbacks when the connection is formed via SOAP.

See Also

Using DCOM Connections (see page 1546)

Using Socket Connections (see page 1548)

3.2.3.3.45 Using Socket Connections

TCP/IP Sockets let you create lightweight clients. For example, if you are writing a Web-based client application (see page 1551), you can't be sure that client systems support DCOM. Sockets provide a lowest common denominator that you know will be available for connecting to the application server. For more information about sockets, see Working with Sockets. (see page 2337)

Instead of instantiating the remote data module directly from the client (as happens with DCOM), sockets use a separate application on the server (ScktSrvr.exe), which accepts client requests and instantiates the remote data module using COM. The connection component on the client and ScktSrvr.exe on the server are responsible for marshaling *IAppServer* calls.

Note: ScktSrvr.exe can run as an NT service application. Register it with the Service manager by starting it using the -install command line option. You can unregister it using the -uninstall command line option.

Before you can use a socket connection, the application server must register its availability to clients using a socket connection. By default, all new remote data modules automatically register themselves by adding a call to EnableSocketTransport in the *UpdateRegistry* method. You can remove this call to prevent socket connections to your application server.

Note: Because older servers did not add this registration, you can disable the check for whether an application server is registered by unchecking the Connections->Registered Objects Only

menu item on ScktSrvr.exe. When using sockets, there is no protection on the server against client systems failing before they release a reference to interfaces on the application server. While this results in less message traffic than when using DCOM (which sends periodic keep-alive messages), this can result in an application server that can't release its resources because it is unaware that the client has gone away.

Using DCOM Connections (see page 1546)

Using SOAP Connections (see page 1548)

3.2.3.3.46 Using the Javascript Libraries

The HTML pages generated by the InternetExpress components and the Web items they contain make use of several javascript libraries that ship in the source/webmidas directory:

Javascript libraries

Library	Description
xmldom.js	This library is a DOM-compatible XML parser written in javascript. It allows parsers that do not support XML to use XML data packets. Note that this does not include support for XML Islands, which are supported by IE5 and later.
xmldb.js	This library defines data access classes that manage XML data packets and XML delta packets.
xmldisp.js	This library defines classes that associate the data access classes in xmldb with HTML controls in the HTML page.
xmlerrdisp.js	This library defines classes that can be used when reconciling update errors. These classes are not used by any of the built-in InternetExpress components, but are useful when writing a Reconcile producer.
xmlshow.js	This library includes functions to display formatted XML data packets and XML delta packets. This library is not used by any of the InternetExpress components, but is useful when debugging.

Once you have installed these libraries, you must set the *IncludePathURL* property of all InternetExpress page producers to indicate where they can be found.

It is possible to write your own HTML pages using the javascript classes provided in these libraries instead of using Web items to generate your Web pages. However, you must ensure that your code does not do anything illegal, as these classes include minimal error checking (so as to minimize the size of the generated Web pages).

See Also

Building an InternetExpress Application (see page 1521)

Granting Permission to Access and Launch the Application Server (see page 1532)

3.2.3.3.47 Using the Web Page Editor

The Web page editor lets you add Web items to your InternetExpress page producer and view the resulting HTML page. Display

the Web page editor by double-clicking on a InternetExpress page producer component.

Note: You must have Internet Explorer 4 or better installed to use the Web page editor.

The top of the Web page editor displays the Web items that generate the HTML document. These Web items are nested, where each type of Web item assembles the HTML generated by its subitems. Different types of items can contain different subitems. On the left, a tree view displays all of the Web items, indicating how they are nested. On the right, you can see the Web items included by the currently selected item. When you select a component in the top of the Web page editor, you can set its properties (see page 1536) using the **Object Inspector**.

Click the New Item button to add a subitem to the currently selected item. The Add Web Component dialog lists only those items that can be added to the currently selected item.

The InternetExpress page producer can contain one of two types of item, each of which generates an HTML form:

TDataForm, which generates an HTML form for displaying data and the controls that manipulate that data or submit updates.

Items you add to *TDataForm* display data in a multi-record grid (TDataGrid) or in a set of controls each of which represents a single field from a single record (TFieldGroup). In addition, you can add a set of buttons to navigate through data or post updates (TDataNavigator), or a button to apply updates back to the Web client (TApplyUpdatesButton). Each of these items contains subitems to represent individual fields or buttons. Finally, as with most Web items, you can add a layout grid (TLayoutGroup), that lets you customize the layout of any items it contains.

TQueryForm, which generates an HTML form for displaying or reading application-defined values. For example, you can use this form for displaying and submitting parameter values.

Items you add to *TQueryForm* display application-defined values(TQueryFieldGroup) or a set of buttons to submit or reset those values (TQueryButtons). Each of these items contains subitems to represent individual values or buttons. You can also add a layout grid to a query form, just as you can to a data form.

The bottom of the Web page editor displays the generated HTML code and lets you see what it looks like in a browser (Internet Explorer).

Customizing the InternetExpress Page Producer Template (see page 1529)

Setting Web Item Properties (see page 1536)

3.2.3.3.48 Using Web Connections

HTTP lets you create clients that can communicate with an application server that is protected by a firewall. HTTP messages provide controlled access to internal applications so that you can distribute your client applications safely and widely. Like socket connections, HTTP messages provide a lowest common denominator that you know will be available for connecting to the application server. For more information about HTTP messages, see Creating Internet Server Applications (see page 2251)

Instead of instantiating the remote data module directly from the client (as happens with DCOM), HTTP-based connections use a Web server application on the server (httpsrvr.dll) that accepts client requests and instantiates the remote data module using COM. Because of this, they are also called Web connections. The connection component on the client and httpsrvr.dll on the server are responsible for marshaling *IAppServer* calls.

Web connections can take advantage of the SSL security provided by wininet.dll (a library of Internet utilities that runs on the client system). Once you have configured the Web server on the server system to require authentication, you can specify the user name and password using the properties of the Web connection component.

As an additional security measure, the application server must register its availability to clients using a Web connection. By default, all new remote data modules automatically register themselves by adding a call to EnableWebTransport in the *UpdateRegistry* method. You can remove this call to prevent Web connections to your application server.

Web connections can take advantage of object pooling (see page 1535). This allows your server to create a limited pool of remote data module instances that are available for client requests. By pooling the remote data modules, your server does not consume the resources for the data module and its database connection except when they are needed.

Unlike most other connection components, you can't use callbacks when the connection is formed via HTTP.

Using DCOM Connections (see page 1546)

Using SOAP Connections (see page 1548)

3.2.3.3.49 Writing Web-based Client Applications

If you want to create Web-based clients for your multi-tiered database application, you must replace the client tier with a special Web application that acts simultaneously as a client to an application server and as a Web server application that is installed with a Web server on the same machine. This architecture is illustrated in the following figure.

There are two approaches that you can take to build the Web application:

- You can combine the multi-tiered database architecture with an ActiveX form to distribute the client application as an ActiveX control (see page 1530). This allows any browser that supports ActiveX to run your client application as an in-process server.
- You can use XML data packets to build an InternetExpress application (see page 1522). This allows browsers that supports javascript to interact with your client application through html pages.

These two approaches are very different. Which one you choose depends on the following considerations:

- Each approach relies on a different technology (ActiveX vs. javascript and XML). Consider what systems your end users will use. The first approach requires a browser to support ActiveX (which limits clients to a Windows platform). The second approach requires a browser to support javascript and the DHTML capabilities introduced by Netscape 4 and Internet Explorer 4.
- ActiveX controls must be downloaded to the browser to act as an in-process server. As a result, the clients using an ActiveX approach require much more memory than the clients of an HTML-based application.
- The InternetExpress approach can be integrated with other HTML pages. An ActiveX client must run in a separate window.
- The InternetExpress approach uses standard HTTP, thereby avoiding any firewall issues that confront an ActiveX application.
- The ActiveX approach provides greater flexibility in how you program your application. You are not limited by the capabilities of the javascript libraries. The client datasets used in the ActiveX approach surface more features (such as filters, ranges, aggregation, optional parameters, delayed fetching of BLOBs or nested details, and so on) than the XML brokers used in the InternetExpress approach.

  Warning: Your Web client application may look and act differently when viewed from different browsers. Test your application with the browsers you expect your end-users to use.

3.2.3.4 Creating reports with Rave Reports

Topics

Name	Description
Rave Component Overview (see page 1552)	This section provides an overview of the Rave Reports components. For detailed component information, see the documentation listed in Getting more information (see page 1555).

Getting More Information (see page 1555)	Delphi includes the following Nevrona Designs documentation for Rave Reports. ***Rave Reports documentation***
Getting Started with Rave Reports (see page 1555)	You can use Rave Reports in VCL applications to generate reports from database and non-database data.
Rave Reports: Overview (see page 1556)	Rave Reports is a component-based visual report design tool that simplifies the process of adding reports to an application. You can use Rave Reports to create a variety of reports, from simple banded reports to more complex, highly customized reports. Report features include: • Word wrapped memos • Full graphics • Justification • Precise page positioning • Printer configuration • Font control • Print preview • Reuse of report content • PDF, HTML, RTF, and text report renditions
Rave Visual Designer (see page 1556)	To launch the Rave Visual Designer, do one of the following: • Choose **Tools** ▸ **Rave Designer**. • Double-click a TRvProject component on a form. • Right-click a TRvProject component on a form, and choose Rave Visual Designer. For a detailed information on using the Rave Visual Designer, use the Help menu or see the Rave Reports documentation listed in Getting more information (see page 1555).

3.2.3.4.1 Rave Component Overview

This section provides an overview of the Rave Reports components. For detailed component information, see the documentation listed in Getting more information (see page 1555).

VCL components

The VCL components for Rave Reports are non-visual components that you add to a form in your VCL application. They are available on the Rave category of the **Tool palette**. There are four categories of components: engine, render, data connection and Rave project.

Engine components

The Engine components are used to generate reports. Reports can be generated from a pre-defined visual definition (using the *Engine* property of TRvProject) or by making calls to the Rave code-based API library from within the OnPrint event. The engine components are:

1. TRvNDRWriter
2. TRvSystem

Render components

The Render components are used to convert an NDR file (Rave snapshot report file) or a stream generated from TRvNDRWriter to a variety of formats. Rendering can be done programmatically or added to the standard setup and preview dialogs of TRvSystem by dropping a render component on an active form or data module within your application. The render components

are:

1. TRvRenderPreview
2. TRvRenderPrinter
3. TRvRenderPDF
4. TRvRenderHTML
5. TRvRenderRTF
6. TRvRenderText

Data connection components

The Data Connection components provide the link between application data and the Direct Data Views in visually designed Rave reports. The data connection components are:

1. TRvCustomConnection
2. TRvDataSetConnection
3. TRvTableConnection
4. TRvQueryConnection

Rave project component

The TRvProject component interfaces with and executes visually designed Rave reports within an application. Normally a TRvSystem component would be assigned to the *Engine* property. The reporting project (.rav) should be specified in the *ProjectFile* property or loaded into the DFM using the *StoreRAV* property. Project parameters can be set using the SetParam method and reports can be executed using the ExecuteReport method.

Reporting components

The following components are available in the Rave Visual Designer.

Project components

The Project toolbar provides the essential building blocks for all reports. The project components are:

1. TRaveProjectManager
2. TRaveReport
3. TRavePage

Data objects

Data objects connect to data or control access to reports from the Rave Reporting Server. The **File ▸ New Data Object** menu command displays the Data Connections dialog box, which you can use to create each of the data objects. The data object components are:

1. TRaveDatabase
2. TRaveDriverDataView
3. TRaveDirectDataView
4. TRaveSimpleSecurity
5. TRaveLookupSecurity

Standard components

The Standard toolbar provides components that are frequently used when designing reports. The standard components are:

1. TRaveText
2. TRaveMemo
3. TRaveSection

4. TRaveBitmap
5. TRaveMetaFile
6. TRaveFontMaster
7. TRavePageNumInit

Drawing components

The Drawing toolbar provides components to create lines and shapes in a report. To color and style the components, use the Fills, Lines, and Colors toolbars. The drawing components are:

1. TRaveLine
2. TRaveHLine
3. TRaveVLine
4. TRaveSquare
5. TRaveRectangle
6. TRaveCircle
7. TRaveEllipse

Report components

The Report toolbar provides components that are used most often in data-aware reports. The report components are:

1. TRaveRegion
2. TRaveDataBand
3. TRaveBand
4. Band Style Edito
5. TRaveDataText
6. DataText Editor
7. TRaveDataMemo
8. TRaveCalcText
9. TRaveDataCycle
10. TRaveDataMirrorSection
11. TRaveCalcOp Component
12. TRaveCalcController
13. TRaveCalcTotal

Bar code components

The Bar Code toolbar provides different types of bar codes in a report. The bar code components are:

1. TRavePostNetBarCode
2. TRaveI2of5Bar Code
3. TRaveCode39BarCode
4. TRaveCode128BarCode
5. TRaveUPCBarCode
6. TRaveEANBarCode

3.2.3.4.2 Getting More Information

Delphi includes the following Nevrona Designs documentation for Rave Reports.

Rave Reports documentation

Title	Description
Rave Visual Designer Manual for Reference and Learning	Provides detailed information about using the Rave Visual Designer to create reports.
Rave Tutorial and Reference	Provides step-by-step instructions on using the Rave Reports components and includes a reference of classes, components, and units.
Rave Application Interface Technology Specification	Explains how to create custom Rave Reports components, property editors, component editors, project editors, and control the Rave environment.

These books are distributed as PDF files on the Delphi Companion Tools CD.

Most of the information in the PDF files is also available in the online Help. To display online Help for a Rave Reports component on a form, select the component and press `F1`. To display online Help for the Rave Visual Designer, use the Help menu.

3.2.3.4.3 Getting Started with Rave Reports

You can use Rave Reports in VCL applications to generate reports from database and non-database data.

To add a simple report to an existing database application

1. Open a database application in Delphi.
2. From the Rave category of the **Tool palette**, add the TRvDataSetConnection component to a form in the application.
3. In the **Object Inspector**, set the *DataSet* property to a dataset component that is already defined in your application.
4. Use the Rave Visual Designer:
5. From the Rave category of the **Tool palette**, add the Rave project component, TRvProject, to the form.
6. In the **Object Inspector**, set the *ProjectFile* property to the report project file (MyRave.rav) that you created in step 8 in using the Rave Visual Designer.
7. From the Standard category of the **Tool palette**, add the TButton component.
8. In the **Object Inspector**, click the Events tab and double-click the OnClick event.
9. Write an event handler that uses the ExecuteReport method to execute the Rave project component.

To design your report and create a report project file (.rav file) using the Rave Visual Designer

1. Choose **Tools** ▸ **Rave Designer** to launch the Rave Visual Designer.
2. Choose **File** ▸ **New Data Object** to display the Data Connections dialog box, and in the Data Object Type list, select Direct Data View and click Next.
3. In the Active Data Connections list, select RVDataSetConnection1 and click Finish. In the Project Tree on the left side of the Rave Visual Designer window, expand the Data View Dictionary node, then expand the newly created DataView1 node. Your application data fields are displayed under the DataView1 node.
4. Choose **Tools** ▸ **Report Wizards** ▸ **Simple Table** to display the Simple Table wizard, and select DataView1 and click Next.
5. Select two or three fields that you want to display in the report and click Next.
6. Follow the prompts on the subsequent wizard pages to set the order of the fields, margins, heading text, and fonts to be used in the report.

7. On the final wizard page, click Generate to complete the wizard and display the report in the Page Designer.
8. Choose **File** ▸ **Save** as to display the Save As dialog box. Navigate to the directory in which your Delphi application is located and save the Rave project file as MyRave.rav.
9. Minimize the Rave Visual Designer window and return to Delphi.

For a more information on using the Rave Visual Designer, use the Help menu or see the Rave Reports documentation listed in Getting more information (see page 1555).

3.2.3.4.4 Rave Reports: Overview

Rave Reports is a component-based visual report design tool that simplifies the process of adding reports to an application. You can use Rave Reports to create a variety of reports, from simple banded reports to more complex, highly customized reports. Report features include:

- Word wrapped memos
- Full graphics
- Justification
- Precise page positioning
- Printer configuration
- Font control
- Print preview
- Reuse of report content
- PDF, HTML, RTF, and text report renditions

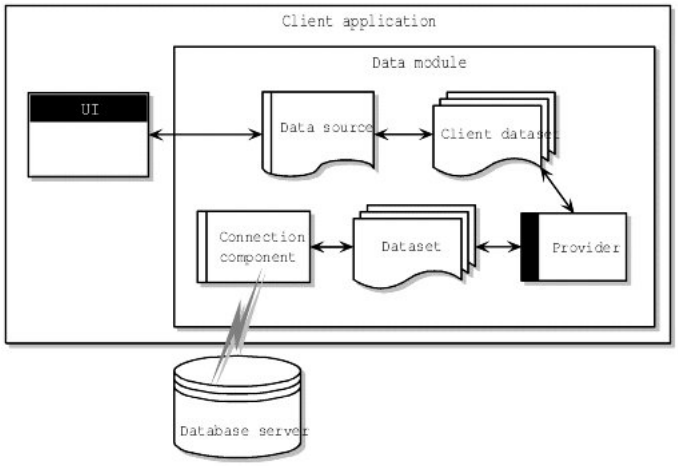
3.2.3.4.5 Rave Visual Designer

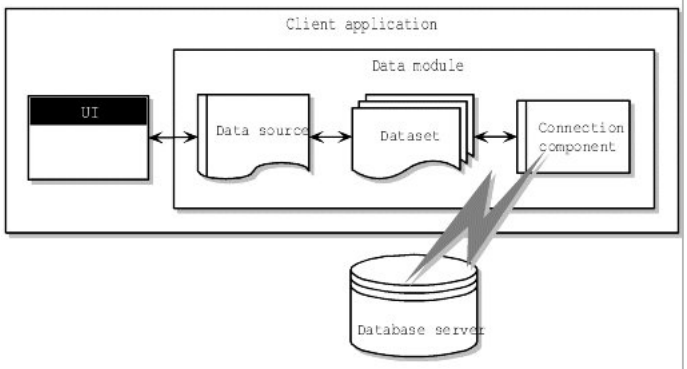
To launch the Rave Visual Designer, do one of the following:

- Choose **Tools** ▸ **Rave Designer**.
- Double-click a TRvProject component on a form.
- Right-click a TRvProject component on a form, and choose Rave Visual Designer.

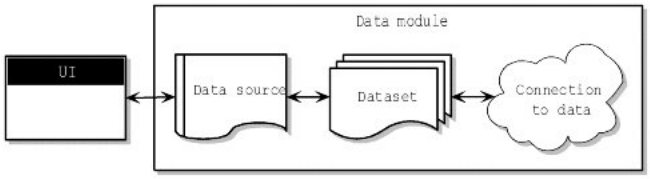
For a detailed information on using the Rave Visual Designer, use the Help menu or see the Rave Reports documentation listed in Getting more information (see page 1555).

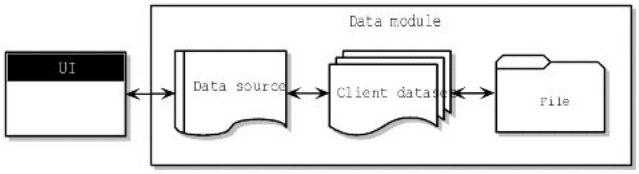
3.2.3.5 Designing database applications



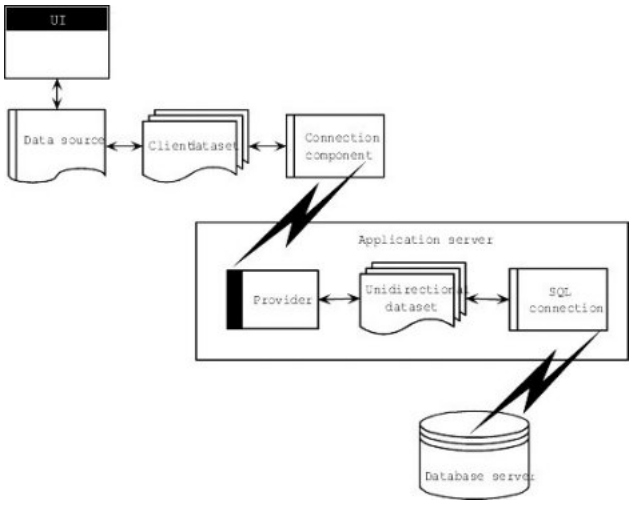


Topics





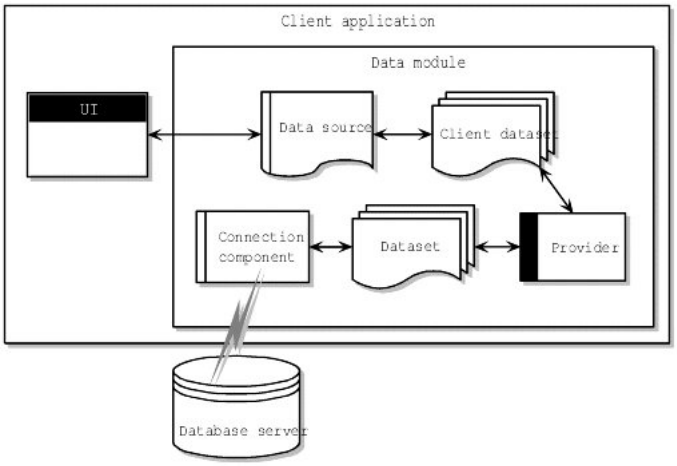
Name	Description
Database architecture (see page 1557)	
Designing Database Applications: Overview (see page 1566)	Database applications let users interact with information that is stored in databases. Databases provide structure for the information, and allow it to be shared among different applications. Delphi provides support for relational database applications. Relational databases organize information into tables, which contain rows (records) and columns (fields). These tables can be manipulated by simple operations known as the relational calculus. When designing a database application, you must understand how the data is structured. Based on that structure, you can then design a user interface to display data to the user and allow the user to enter new information or modify... more (see page 1566)
Designing the user interface (see page 1567)	



Using databases (see page 1568)	

3.2.3.5.1 Database architecture

Topics



Name	Description
Connecting a Client Dataset to Another Dataset in the Same Application (see page 1559)	By using a provider component (see page 1819), you can connect *TClientDataSet* to another (source) dataset. The provider packages database information into transportable data packets (which can be used by client datasets) and applies updates received in delta packets (which client datasets create) back to a database server. The architecture for this is illustrated in the following figure.  This architecture represents either a single-tiered or two-tiered application, depending on whether the database server is a local database or a remote database server (see page 1571). The logic that manipulates database information is in the same application that implements the user interface, although isolated into... more (see page 1559)
Connecting Directly to a Database Server (see page 1560)	The most common database architecture is the one where the dataset uses a connection component to establish a connection to a database server. The dataset then fetches data directly from the server and posts edits directly to the server. This is illustrated in the following figure. Connecting directly to the database server  Each type of dataset uses its own type of connection component, which represents a single data access mechanism: • If the dataset is a BDE dataset such as *TTable*, *TQuery*, or *TStoredProc*, the connection component is a TDataBase*object. You connect the dataset to the database... more (see page 1560)*

Connecting to Another Dataset (see page 1561)	There are specialized client datasets that use the BDE or *dbExpress* to connect to a database server. These specialized client datasets are, in fact, composite components that include another dataset internally to access the data and an internal provider component to package the data from the source dataset and to apply updates back to the database server. These composite components require some additional overhead, but provide certain benefits: • Client datasets provide the most robust way to work with cached updates. By default, other types of datasets post edits directly to the database server. You can reduce network traffic by using... more (see page 1561)
Database Architecture (see page 1562)	Database applications are built from user interface elements, components that represent database information (datasets), and components that connect these to each other and to the source of the database information. How you organize these pieces is the architecture of your database application. While there are many distinct ways to organize the components in a database application, most follow the general scheme illustrated in the following figure: 
Using a Dedicated File on Disk (see page 1564)	The simplest form of database application you can write does not use a database server at all. Instead, it uses MyBase, the ability of client datasets to save themselves to a file and to load the data from a file. This architecture is illustrated in the following figure:  When using this file-based approach, your application writes changes to disk using the client dataset's SaveToFile method. *SaveToFile* takes one parameter, the name of the file which is created (or overwritten) containing the table. When you want to read a table previously written using the *SaveToFile* method, use the LoadFromFile method. *LoadFromFile... more (see page 1564)*

Using a Multi-Tiered Architecture (see page 1564)	When the database information includes complicated relationships between several tables, or when the number of clients grows, you may want to use a multi-tiered application. Multi-tiered applications have middle tiers between the client application and database server. The architecture for this is illustrated in the following figure.  The preceding figure represents three-tiered application. The logic that manipulates database information is on a separate system, or tier. This middle tier centralizes the logic that governs your database interactions so there is centralized control over data relationships. This allows different client applications to use the same data, while ensuring consistent data logic.... more (see page 1564)
Combining Approaches (see page 1565)	There is no reason why you can't combine two or more of the available architectures in a single application. In fact, some combinations can be extremely powerful. For example, you can combine the disk-based architecture described in Using a dedicated file on disk (see page 1564) with another approach such as those described in Connecting to another dataset (see page 1561) or Using a multi-tiered architecture (see page 1564). These combinations are easy because all models use a client dataset to represent the data that appears in the user interface. The result is called the briefcase model (or sometimes the disconnected model, or mobile computing). The briefcase model... more (see page 1565)

3.2.3.5.1.1 Connecting a Client Dataset to Another Dataset in the Same Application

By using a provider component (see page 1819), you can connect *TClientDataSet* to another (source) dataset. The provider packages database information into transportable data packets (which can be used by client datasets) and applies updates received in delta packets (which client datasets create) back to a database server. The architecture for this is illustrated in the following figure.

This architecture represents either a single-tiered or two-tiered application, depending on whether the database server is a local database or a remote database server (see page 1571). The logic that manipulates database information is in the same application that implements the user interface, although isolated into a data module.

To link the client dataset to the provider, set its ProviderName property to the name of the provider component. The provider must be in the same data module as the client dataset. To link the provider to the source dataset, set its DataSet property.

Once the client dataset is linked to the provider and the provider is linked to the source dataset, these components automatically handle all the details necessary for fetching, displaying, and navigating through the database records (assuming the source dataset is connected to a database). To apply user edits back to the database, you need only call the client dataset's ApplyUpdates method.

For more information on using a client dataset with a provider, see Using a client dataset with a provider (see page 1732).

Using a multi-tiered architecture (see page 1564)

3.2.3.5.1.2 Connecting Directly to a Database Server

The most common database architecture is the one where the dataset uses a connection component to establish a connection to a database server. The dataset then fetches data directly from the server and posts edits directly to the server. This is illustrated in the following figure.

Connecting directly to the database server

Each type of dataset uses its own type of connection component, which represents a single data access mechanism:

- If the dataset is a BDE dataset such as *TTable*, *TQuery*, or *TStoredProc*, the connection component is a TDataBase*object.*

You connect the dataset to the database component by setting its Databaseproperty. You do not need to explicitly add a database component when using BDE dataset. If you set the dataset's DatabaseName property, a database component is created for you automatically at runtime.

- If the dataset is an ADO dataset such as *TADODataSet*, *TADOTable*, *TADOQuery*, or *TADOStoredProc*, the connection component is a TADOConnection*object. You connect the dataset to the ADO connection component by setting its Connectionproperty. As with BDE datasets, you do not need to explicitly add the connection component: instead you can set the dataset's ConnectionStringproperty.*
- If the dataset is a dbExpress dataset such as *TSQLDataSet*, *TSQLTable*, *TSQLQuery*, or *TSQLStoredProc*, the connection component is a TSQLConnection object. You connect the dataset to the SQL connection component by setting its SQLConnection property. When using dbExpress datasets, you must explicitly add the connection component. Another difference between dbExpress datasets and the other datasets is that dbExpress datasets are always read-only and unidirectional: This means you can only navigate by iterating through the records in order, and you can't use the dataset methods that support editing.
- If the dataset is an InterBase Express dataset such as *TIBDataSet*, *TIBTable*, *TIBQuery*, or *TIBStoredProc*, the connection component is a TIBDatabase*object. You connect the dataset to the IB database component by setting its Database_Database">Databaseproperty. As with dbExpress datasets, you must explicitly add the connection component.*

In addition to the components listed above, you can use a specialized client dataset such as *TBDEClientDataSet, TSimpleDataSet*, or *TIBClientDataSet* with a database connection component. When using one of these client datasets, specify the appropriate type of connection component as the value of the *DBConnection* property.

Although each type of dataset uses a different connection component, they all perform many of the same tasks and surface many of the same properties, methods, and events. For more information on the commonalities among the various database connection components, see Connecting to databases (see page 1506)

This architecture represents either a single-tiered or two-tiered application, depending on whether the database server is a local database such or a remote database server (see page 1571). The logic that manipulates database information is in the same application that implements the user interface, although isolated into a data module.

Note: The connection components or drivers needed to create two-tiered applications are not available in all version of Delphi.

3.2.3.5.1.3 Connecting to Another Dataset

There are specialized client datasets that use the BDE or *dbExpress* to connect to a database server. These specialized client datasets are, in fact, composite components that include another dataset internally to access the data and an internal provider component to package the data from the source dataset and to apply updates back to the database server. These composite components require some additional overhead, but provide certain benefits:

- Client datasets provide the most robust way to work with cached updates. By default, other types of datasets post edits directly to the database server. You can reduce network traffic by using a dataset that caches updates locally and applies them all later in a single transaction. For information on the advantages of using client datasets to cache updates, see Using a client dataset to cache updates (see page 1731).
- Client datasets can apply edits directly to a database server when the dataset is read-only. When using *dbExpress*, this is the only way to edit the data in the dataset (it is also the only way to navigate freely in the data when using *dbExpress*). Even when not using *dbExpress*, the results of some queries and all stored procedures are read-only. Using a client dataset provides a standard way to make such data editable.
- Because client datasets can work directly with dedicated files on disk, using a client dataset can be combined with a file-based model (see page 1565) to allow for a flexible "briefcase" application.

In addition to these specialized client datasets, there is a generic client dataset (*TClientDataSet*), which does not include an

internal dataset and dataset provider. Although *TClientDataSet* has no built-in database access mechanism, you can connect it to another, external, dataset from which it fetches data and to which it sends updates. Although this approach is a bit more complicated, there are times when it is preferable:

- Because the source dataset and dataset provider are external, you have more control over how they fetch data and apply updates. For example, the provider component surfaces a number of events that are not available when using a specialized client dataset to access data.
- When the source dataset is external, you can link it in a master/detail relationship with another dataset. An external provider automatically converts this arrangement into a single dataset with nested details. When the source dataset is internal, you can't create nested detail sets this way.
- Connecting a client dataset to an external dataset is an architecture that easily scales up to multiple tiers. Because the development process can get more involved and expensive as the number of tiers increases, you may want to start developing your application as a single-tiered or two-tiered application. As the amount of data, the number of users, and the number of different applications accessing the data grows, you may later need to scale up to a multi-tiered architecture. If you think you may eventually use a multi-tiered architecture, it can be worthwhile to start by using a client dataset with an external source dataset. This way, when you move the data access and manipulation logic to a middle tier, you protect your development investment because the code can be reused as your application grows.
- *TClientDataSet* can link to any source dataset. This means you can use custom datasets (third-party components) for which there is no corresponding specialized client dataset. Some versions of Delphi even include special provider components that connect a client dataset to an XML document rather than another dataset. (This works the same way as connecting a client dataset to another (source) dataset, except that the XML provider uses an XML document rather than a dataset. For information about these XML providers, see Using an XML document as the source (see page 1846) for a provider.)

There are two versions of the architecture that connects a client dataset to an external dataset:

- Connecting a client dataset to another dataset in the same application (see page 1559).
- Using a multi-tiered architecture (see page 1564).

3.2.3.5.1.4 Database Architecture

Database applications are built from user interface elements, components that represent database information (datasets), and components that connect these to each other and to the source of the database information. How you organize these pieces is the architecture of your database application.

While there are many distinct ways to organize the components in a database application, most follow the general scheme illustrated in the following figure:

The user interface form

It is a good idea to isolate the user interface on a form that is completely separate from the rest of the application. This has several advantages. By isolating the user interface from the components that represent the database information itself, you introduce a greater flexibility into your design: Changes to the way you manage the database information do not require you to rewrite your user interface, and changes to the user interface do not require you to change the portion of your application that

works with the database. In addition, this type of isolation lets you develop common forms that you can share between multiple applications, thereby providing a consistent user interface. By storing links to well-designed forms in the Object Repository (see page 1916), you and other developers can build on existing foundations rather than starting over from scratch for each new project. Sharing forms also makes it possible for you to develop corporate standards for application interfaces. For more information about creating the user interface for a database application, see Designing the user interface (see page 1567).

The data module

If you have isolated your user interface into its own form, you can use a data module (see page 1911) to house the components that represent database information (datasets), and the components that connect these datasets to the other parts of your application. Like the user interface forms, you can share data modules in the Object Repository so that they can be reused or shared between applications.

The data source

The first item in the data module is a data source (see page 1746). The data source acts as a conduit between the user interface and a dataset that represents information from a database. Several data-aware controls on a form can share a single data source, in which case the display in each control is synchronized so that as the user scrolls through records, the corresponding value in the fields for the current record is displayed in each control.

The dataset

The heart of your database application is the dataset. This component represents a set of records from the underlying database. These records can be the data from a single database table, a subset of the fields or records in a table, or information from more than one table joined into a single view. By using datasets, your application logic is buffered from restructuring of the physical tables in your databases. When the underlying database changes, you might need to alter the way the dataset component specifies the data it contains, but the rest of your application can continue to work without alteration. For more information on the common properties and methods of datasets, see Understanding datasets (see page 1632)

The data connection

Different types of datasets use different mechanisms for connecting to the underlying database information. These different mechanisms, in turn, make up the major differences in the architecture of the database applications you can build. There are four basic mechanisms for connecting to the data:

- Connecting directly to a database server (see page 1560). Most datasets use a descendant of *TCustomConnection* to represent the connection to a database server.
- Using a dedicated file on disk (see page 1564). Client datasets support the ability to work with a dedicated file on disk. No separate connection component is needed when working with a dedicated file because the client dataset itself knows how to read from and write to the file.
- Connecting to another dataset (see page 1561). Client datasets can work with data provided by another dataset. A *TDataSetProvider* component serves as an intermediary between the client dataset and its source dataset. This dataset provider can reside in the same data module as the client dataset, or it can be part of an application server running on another machine. If the provider is part of an application server, you also need a special descendant of *TCustomConnection* to represent the connection to the application server.
- Obtaining data from an RDS DataSpace object. ADO datasets can use a TRDSConnection component to marshal data in multi-tier database applications that are built using ADO-based application servers.

Sometimes, these mechanisms can be combined in a single application (see page 1565).

Using Databases (see page 1572)

Types of Databases (see page 1571)

3.2.3.5.1.5 Using a Dedicated File on Disk

The simplest form of database application you can write does not use a database server at all. Instead, it uses MyBase, the ability of client datasets to save themselves to a file and to load the data from a file. This architecture is illustrated in the following figure:

When using this file-based approach, your application writes changes to disk using the client dataset's SaveToFile method. *SaveToFile* takes one parameter, the name of the file which is created (or overwritten) containing the table. When you want to read a table previously written using the *SaveToFile* method, use the LoadFromFile method. *LoadFromFile* also takes one parameter, the name of the file containing the table.

If you always load to and save from the same file, you can use the FileName property instead of the *SaveToFile* and *LoadFromFile* methods. When *FileName* is set to a valid file name, the data is automatically loaded from the file when the client dataset is opened and saved to the file when the client dataset is closed.

This simple file-based architecture is a single-tiered application. The logic that manipulates database information is in the same application that implements the user interface, although isolated into a data module.

The file-based approach has the benefit of simplicity. There is no database server to install, configure, or deploy (If you do not statically link in midaslib.dcu, the client dataset does require midas.dll). There is no need for site licenses or database administration.

In addition, some versions of Delphi let you convert between arbitrary XML documents and the data packets that are used by a client dataset. Thus, the file-based approach can be used to work with XML documents as well as dedicated datasets. For information about converting between XML documents and client dataset data packets, see Using XML in database applications (see page 1847)

The file-based approach offers no support for multiple users. The dataset should be dedicated entirely to the application. Data is saved to files on disk, and loaded at a later time, but there is no built-in protection to prevent multiple users from overwriting each other's data files.

For more information about using a client dataset with data stored on disk, see Using a client dataset with file-based data (see page 1733).

3.2.3.5.1.6 Using a Multi-Tiered Architecture

When the database information includes complicated relationships between several tables, or when the number of clients grows, you may want to use a multi-tiered application. Multi-tiered applications have middle tiers between the client application and database server. The architecture for this is illustrated in the following figure.

The preceding figure represents three-tiered application. The logic that manipulates database information is on a separate system, or tier. This middle tier centralizes the logic that governs your database interactions so there is centralized control over data relationships. This allows different client applications to use the same data, while ensuring consistent data logic. It also allows for smaller client applications because much of the processing is off-loaded onto the middle tier. These smaller client applications are easier to install, configure, and maintain. Multi-tiered applications can also improve performance by spreading data-processing over several systems.

The multi-tiered architecture is very similar to the model described in Connecting a client dataset to another dataset in the same application (see page 1559). It differs mainly in that source dataset that connects to the database server and the provider that acts as an intermediary between that source dataset and the client dataset have both moved to a separate application. That separate application is called the application server (or sometimes the "remote data broker").

Because the provider has moved to a separate application, the client dataset can no longer connect to the source dataset by simply setting its ProviderName property. In addition, it must use some type of connection component to locate and connect to the application server.

There are several types of connection components that can connect a client dataset to an application server. They are all descendants of TCustomRemoteServer, and differ primarily in the communication protocol they use (TCP/IP, HTTP, DCOM, or SOAP). Link the client dataset to its connection component by setting the RemoteServer property.

The connection component establishes a connection to the application server and returns an interface that the client dataset uses to call the provider specified by its *ProviderName* property. Each time the client dataset calls the application server, it passes the value of *ProviderName*, and the application server forwards the call to the provider.

For more information about connecting a client dataset to an application server, see Creating multi-tiered applications (see page 1518)

See Also

Connecting a Client Dataset to Another Dataset in the Same Application (see page 1559)

Using a client dataset with a data provider (see page 1732)

3.2.3.5.1.7 Combining Approaches

There is no reason why you can't combine two or more of the available architectures in a single application. In fact, some combinations can be extremely powerful.

For example, you can combine the disk-based architecture described in Using a dedicated file on disk (see page 1564) with another approach such as those described in Connecting to another dataset (see page 1561) or Using a multi-tiered

architecture (see page 1564). These combinations are easy because all models use a client dataset to represent the data that appears in the user interface. The result is called the briefcase model (or sometimes the disconnected model, or mobile computing).

The briefcase model is useful in a situation such as the following: An onsite company database contains customer contact data that sales representatives can use and update in the field. While onsite, sales representatives download information from the database. Later, they work with it on their laptops as they fly across the country, and even update records at existing or new customer sites. When the sales representatives return onsite, they upload their data changes to the company database for everyone to use.

When operating on site, the client dataset in a briefcase model application fetches its data from a provider. The client dataset is therefore connected to the database server and can, through the provider, fetch server data and send updates back to the server. Before disconnecting from the provider, the client dataset saves its snapshot of the information to a file on disk. While offsite, the client dataset loads its data from the file, and saves any changes back to that file. Finally, back onsite, the client dataset reconnects to the provider so that it can apply its updates to the database server or refresh its snapshot of the data.

3.2.3.5.2 Designing Database Applications: Overview

Database applications let users interact with information that is stored in databases. Databases provide structure for the information, and allow it to be shared among different applications.

Delphi provides support for relational database applications. Relational databases organize information into tables, which contain rows (records) and columns (fields). These tables can be manipulated by simple operations known as the relational calculus.

When designing a database application, you must understand how the data is structured. Based on that structure, you can then design a user interface to display data to the user and allow the user to enter new information or modify existing data.

The following topics introduce common considerations when designing a database application:

- Using Databases (see page 1572)
- Database Architecture (see page 1562)
- Designing the User Interface (see page 1567)

3.2.3.5.3 Designing the user interface

Topics

Name	Description
Analyzing Data (see page 1567)	Some database applications do not present database information directly to the user. Instead, they analyze and summarize information from databases so that users can draw conclusions from the data. The TDBChart component on the Data Controls category of the **Tool Palette** lets you present database information in a graphical format that enables users to quickly grasp the import of database information. In addition, some versions of Delphi include a Decision Cube category on the **Tool Palette**. It contains six components that let you perform data analysis and cross-tabulations on data when building decision support applications. For more information... more (see page 1567)
Designing the User Interface (see page 1567)	The Data Controls category of the **Tool Palette** provides a set of data-aware controls that represent data from fields in a database record, and can permit users to edit that data and post changes back to the database. Using data-aware controls, you can build your database application's user interface (UI) so that information is visible and accessible to users. For more information on data-aware controls see Using data controls (see page 1778). In addition to the basic data controls, you may also want to introduce other elements into your user interface: • You may want your application to analyze the data (see page 1567) contained... more (see page 1567)
Writing Reports (see page 1568)	If you want to let your users print database information from the datasets in your application, you can use Rave Reports, as described in Creating reports with Rave Reports. (see page 1556)

3.2.3.5.3.1 Analyzing Data

Some database applications do not present database information directly to the user. Instead, they analyze and summarize information from databases so that users can draw conclusions from the data.

The TDBChart component on the Data Controls category of the **Tool Palette** lets you present database information in a graphical format that enables users to quickly grasp the import of database information.

In addition, some versions of Delphi include a Decision Cube category on the **Tool Palette**. It contains six components that let you perform data analysis and cross-tabulations on data when building decision support applications. For more information about using the Decision Cube components, see Using decision support components (see page 1800)

If you want to build your own components that display data summaries based on various grouping criteria, you can use maintained aggregates (see page 1735) with a client dataset.

See Also

Writing Reports (see page 1568)

Using Data Controls (see page 1778)

3.2.3.5.3.2 Designing the User Interface

The Data Controls category of the **Tool Palette** provides a set of data-aware controls that represent data from fields in a database record, and can permit users to edit that data and post changes back to the database. Using data-aware controls, you can build your database application's user interface (UI) so that information is visible and accessible to users. For more information on data-aware controls see Using data controls (see page 1778).

In addition to the basic data controls, you may also want to introduce other elements into your user interface:

- You may want your application to analyze the data (see page 1567) contained in a database. Applications that analyze data do more than just display the data in a database, they also summarize the information in useful formats to help users grasp

the impact of that data.

- You may want to print reports (see page 1568) that provide a hard copy of the information displayed in your user interface.
- You may want to create a user interface that can be viewed from Web browsers. The simplest Web-based database applications are described in Using database information in responses (see page 2266). In addition, you can combine the Web-based approach with the multi-tiered architecture, as described in Writing Web-based client applications. (see page 1551)

3.2.3.5.4 Using databases

Topics

Name	Description
Database Security (see page 1569)	Databases often contain sensitive information. Different databases provide security schemes for protecting that information. Some databases, such as Paradox and dBASE, only provide security at the table or field level. When users try to access protected tables, they are required to provide a password. Once users have been authenticated, they can see only those fields (columns) for which they have permission. Most SQL servers require a password and user name to use the database server at all. Once the user has logged in to the database, that username and password determine which tables can be used. For information on providing... more (see page 1569)
Referential Integrity, Stored Procedures, and Triggers (see page 1570)	All relational databases have certain features in common that allow applications to store and manipulate data. In addition, databases often provide other, database-specific, features that can prove useful for ensuring consistent relationships between the tables in a database. These include • **Referential integrity.** Referential integrity provides a mechanism to prevent master/detail relationships between tables from being broken. When the user attempts to delete a field in a master table which would result in orphaned detail records, referential integrity rules prevent the deletion or automatically delete the orphaned detail records. • **Stored procedures.** Stored procedures are sets of SQL statements that are named... more (see page 1570)

Transactions (see page 1570)	A transaction is a group of actions that must all be carried out successfully on one or more tables in a database before they are committed (made permanent). If any of the actions in the group fails, then all actions are rolled back (undone). Transactions ensure that • All updates in a single transaction are either committed or aborted and rolled back to their previous state. This is referred to as **atomicity**. • A transaction is a correct transformation of the system state, preserving the state invariants. This is referred to as **consistency**. • Concurrent transactions do not see each other's... more (see page 1570)
Types of Databases (see page 1571)	Relational database servers vary in the way they store information and in the way they allow multiple users to access that information simultaneously. Delphi provides support for two types of relational database server: • **Remote database servers** reside on a separate machine. Sometimes, the data from a remote database server does not even reside on a single machine, but is distributed over several servers. Although remote database servers vary in the way they store information, they provide a common logical interface to clients. This common interface is Structured Query Language (SQL). Because you access them using SQL, they are sometimes called... more (see page 1571)
Using Databases (see page 1572)	Delphi includes many components for accessing databases and representing the information they contain. They are grouped according to the data access mechanism: • The BDE page of the Component palette contains components that use the Borland Database Engine (BDE). The BDE defines a large API for interacting with databases. Of all the data access mechanisms, the BDE supports the broadest range of functions and comes with the most supporting utilities. It is the best way to work with data in Paradox or dBASE tables. However, it is also the most complicated mechanism to deploy. For more information about using the... more (see page 1572)

3.2.3.5.4.1 Database Security

Databases often contain sensitive information. Different databases provide security schemes for protecting that information. Some databases, such as Paradox and dBASE, only provide security at the table or field level. When users try to access protected tables, they are required to provide a password. Once users have been authenticated, they can see only those fields (columns) for which they have permission.

Most SQL servers require a password and user name to use the database server at all. Once the user has logged in to the database, that username and password determine which tables can be used. For information on providing passwords to SQL servers, see Controlling server login (see page 1507).

When designing database applications, you must consider what type of authentication is required by your database server. Often, applications are designed to hide the explicit database login from users, who need only log in to the application itself. If you do not want to require your users to provide a database password, you must either use a database that does not require one or you must provide the password and username to the server programmatically. When providing the password programmatically, care must be taken that security can't be breached by reading the password from the application.

If you require your user to supply a password, you must consider when the password is required. If you are using a local database but intend to scale up to a larger SQL server later, you may want to prompt for the password at the point when you will

eventually log in to the SQL database, rather than when opening individual tables.

If your application requires multiple passwords because you must log in to several protected systems or databases, you can have your users provide a single master password that is used to access a table of passwords required by the protected systems. The application then supplies passwords programmatically, without requiring the user to provide multiple passwords.

In multi-tiered applications, you may want to use a different security model altogether. You can use HTTPs or COM+ to control access to middle tiers, and let the middle tiers handle all details of logging into database servers.

Types of Databases (see page 1571)

Transactions (see page 1570)

The Data Dictionary (see page 1680)

Referential Integrity (see page 1570)

3.2.3.5.4.2 Referential Integrity, Stored Procedures, and Triggers

All relational databases have certain features in common that allow applications to store and manipulate data. In addition, databases often provide other, database-specific, features that can prove useful for ensuring consistent relationships between the tables in a database. These include

- **Referential integrity.** Referential integrity provides a mechanism to prevent master/detail relationships between tables from being broken. When the user attempts to delete a field in a master table which would result in orphaned detail records, referential integrity rules prevent the deletion or automatically delete the orphaned detail records.
- **Stored procedures.** Stored procedures are sets of SQL statements that are named and stored on an SQL server. Stored procedures usually perform common database-related tasks on the server, and sometimes return sets of records (datasets).
- **Triggers.** Triggers are sets of SQL statements that are automatically executed in response to a particular command.

See Also

Types of Databases (see page 1571)

Database Security (see page 1569)

Transactions (see page 1570)

The Data Dictionary (see page 1680)

3.2.3.5.4.3 Transactions

A transaction is a group of actions that must all be carried out successfully on one or more tables in a database before they are committed (made permanent). If any of the actions in the group fails, then all actions are rolled back (undone).

Transactions ensure that

- All updates in a single transaction are either committed or aborted and rolled back to their previous state. This is referred to as **atomicity**.
- A transaction is a correct transformation of the system state, preserving the state invariants. This is referred to as **consistency**.
- Concurrent transactions do not see each other's partial or uncommitted results, which might create inconsistencies in the application state. This is referred to as **isolation**.
- Committed updates to records survive failures, including communication failures, process failures, and server system failures. This is referred to as **durability**.

Thus, transactions protect against hardware failures that occur in the middle of a database command or set of commands. Transactional logging allows you to recover the durable state after disk media failures. Transactions also form the basis of

multi-user concurrency control on SQL servers. When each user interacts with the database only through transactions, one user's commands can't disrupt the unity of another user's transaction. Instead, the SQL server schedules incoming transactions, which either succeed as a whole or fail as a whole.

Transaction support is not part of most local databases, although it is provided by local InterBase. In addition, the BDE drivers provide limited transaction support for some local databases. Database transaction support is provided by the component that represents the database connection. For details on managing transactions using a database connection component, see Managing transactions (see page 1498).

In multi-tiered applications, you can create transactions that include actions other than database operations or that span multiple databases. For details on using transactions in multi-tiered applications, see Managing transactions in multi-tiered applications (see page 1533).

The Data Dictionary (see page 1680)

Referential Integrity (see page 1570)

3.2.3.5.4.4 Types of Databases

Relational database servers vary in the way they store information and in the way they allow multiple users to access that information simultaneously. Delphi provides support for two types of relational database server:

- **Remote database servers** reside on a separate machine. Sometimes, the data from a remote database server does not even reside on a single machine, but is distributed over several servers. Although remote database servers vary in the way they store information, they provide a common logical interface to clients. This common interface is Structured Query Language (SQL). Because you access them using SQL, they are sometimes called SQL servers. (Another name is Remote Database Management system, or RDBMS.) In addition to the common commands that make up SQL, most remote database servers support a unique "dialect" of SQL. Examples of SQL servers include InterBase, Oracle, Sybase, Informix, Microsoft SQL server, and DB2.
- **Local databases** reside on your local drive or on a local area network. They often have proprietary APIs for accessing the data. When they are shared by several users, they use file-based locking mechanisms. Because of this, they are sometimes called file-based databases. Examples of local databases include Paradox, dBASE, FoxPro, and Access.

Applications that use local databases are called **single-tiered applications** because the application and the database share a single file system. Applications that use remote database servers are called **two-tiered applications** or **multi-tiered** applications because the application and the database operate on independent systems (or tiers).

Choosing the type of database to use depends on several factors. For example, your data may already be stored in an existing database. If you are creating the database tables your application uses, you may want to consider the following questions:

- How many users will be sharing these tables? Remote database servers are designed for access by several users at the same time. They provide support for multiple users through a mechanism called transactions (see page 1570). Some local databases (such as Local InterBase) also provide transaction support, but many only provide file-based locking mechanisms, and some (such as client dataset files) provide no multi-user support at all.
- How much data will the tables hold? Remote database servers can hold more data than local databases. Some remote database servers are designed for warehousing large quantities of data while others are optimized for other criteria (such as fast updates).
- What type of performance (speed) do you require from the database? Local databases are usually faster than remote database servers because they reside on the same system as the database application. Different remote database servers are optimized to support different types of operations, so you may want to consider performance when choosing a remote database server.
- What type of support will be available for database administration? Local databases require less support than remote database servers. Typically, they are less expensive to operate because they do not require separately installed servers or expensive site licenses.

3.2.3.5.4.5 Using Databases

Delphi includes many components for accessing databases and representing the information they contain. They are grouped according to the data access mechanism:

- The BDE page of the Component palette contains components that use the Borland Database Engine (BDE). The BDE defines a large API for interacting with databases. Of all the data access mechanisms, the BDE supports the broadest range of functions and comes with the most supporting utilities. It is the best way to work with data in Paradox or dBASE tables. However, it is also the most complicated mechanism to deploy. For more information about using the BDE components, see Using the Borland Database Engine (see page 1643).
- The ADO page (see page 1494) of the Component palette contains components that use ActiveX Data Objects (ADO) to access database information through OLEDB. ADO is a Microsoft Standard. There is a broad range of ADO drivers available for connecting to different database servers. Using ADO-based components lets you integrate your application into an ADO-based environment (for example, making use of ADO-based application servers). For more information about using the ADO components, see Working with ADO Components (see page 1494)
- The dbExpress page (see page 16) of the Component palette contains components that use dbExpress to access database information. dbExpress is a lightweight set of drivers that provide the fastest access to database information. However, dbExpress database components also support the narrowest range of data manipulation functions. For more information about using the dbExpress components, see Using unidirectional datasets (see page 1823)
- The InterBase page of the Component palette contains components that access InterBase databases directly, without going through a separate engine layer.
- The Data Access page of the Component palette contains components that can be used with any data access mechanism. This page includes *TClientDataset*, which can work with data stored on disk or, using the *TDataSetProvider* component also on this page, with components from one of the other groups. For more information about using client datasets, see Using client datasets (see page 1740) For more information about *TDataSetProvider*, see Using provider components (see page 1819)

  Note: Different versions of Delphi include different drivers for accessing database servers using the BDE, ADO, or dbExpress.

  When designing a database application, you must decide which set of components to use. Each data access mechanism differs in its range of functional support, the ease of deployment, and the availability of drivers to support different database servers.

  In addition to choosing a data access mechanism, you must choose a database server. There are different types of databases (see page 1571) and you will want to consider the advantages and disadvantages of each type before settling on a particular database server.

  All types of databases contain tables which store information. In addition, most (but not all) servers support additional features such as

- Database security (see page 1569)
- Transactions (see page 1570)
- Referential integrity (see page 1570)

3.2.3.6 Understanding datasets

Topics

Name	Description
Creating an Index with IndexFieldNames (see page 1581)	If there is no defined index that implements the sort order you want, you can create a pseudo-index using the *IndexFieldNames* property. **Note:** *IndexName and IndexFieldNames are mutually exclusive. Setting one property clears values set for the other. For information about IndexName, see Specifying an index with IndexName (see page 1630).* *The value of IndexFieldNames is a string. To specify a sort order, list each column name to use in the order it should be used, and delimit the names with semicolons. Sorting is by ascending order only. Case-sensitivity of the sort depends on the capabilities of your server. See your... more (see page 1581)*
Supplying Parameters at Design Time (see page 1582)	At design time, you can specify parameter values using the parameter collection editor. To display the parameter collection editor, click on the ellipsis button for the *Params* or *Parameters* property in the **Object Inspector**. If the SQL statement does not contain any parameters, no objects are listed in the collection editor. **Note:** The parameter collection editor is the same collection editor that appears for other collection properties. Because the editor is shared with other properties, its right-click context menu contains the Add and Delete commands. However, they are never enabled for query parameters. The only way to add or... more (see page 1582)
Supplying Parameters at Runtime (see page 1583)	To create parameters at runtime, you can use the • *ParamByName* method to assign values to a parameter based on its name (not available for *TADOQuery*) • *Params* or *Parameters* property to assign values to a parameter based on the parameter's ordinal position within the SQL statement. • *Params.ParamValues* or *Parameters.ParamValues* property to assign values to one or more parameters in a single command line, based on the name of each parameter set. The following code uses *ParamByName* to assign the text of an edit box to the :Capital parameter:
Adding New Records (see page 1583)	A dataset must be in *dsInsert* mode before an application can add new records. In code, you can use the Insert or Append methods to put a dataset into *dsInsert* mode if the read-only CanModify property for the dataset is *True*. When a dataset transitions to *dsInsert* mode, it first receives a *BeforeInsert* event. After the transition to insert mode is successfully completed, the dataset receives first an *OnNewRecord* event hand then an *AfterInsert* event. You can use these events, for example, to provide initial values to newly inserted records:
Applying or Canceling a Range (see page 1585)	When you call *SetRangeStart* or *EditRangeStart* to specify the start of a range, or *SetRangeEnd* or *EditRangeEnd* to specify the end of a range, the dataset enters the *dsSetKey* state. It stays in that state until you apply or cancel the range.

Calculating Fields (see page 1585)	Using the Fields editor, you can define calculated fields (see page 1872) for your datasets. When a dataset contains calculated fields, you provide the code to calculate those field's values in an OnCalcFields event handler. The AutoCalcFields property determines when *OnCalcFields* is called. If *AutoCalcFields* is *True*, *OnCalcFields* is called when • A dataset is opened. • The dataset enters edit mode. • A record is retrieved from the database. • Focus moves from one visual component to another, or from one column to another in a data-aware grid control and the current record has been modified. If *AutoCalcFields* is *False*, then *OnCalcFields* is not... more (see page 1585)
Canceling Changes (see page 1586)	An application can undo changes made to the current record at any time, if it has not yet directly or indirectly called Post. For example, if a dataset is in *dsEdit* mode, and a user has changed the data in one or more fields, the application can return the record back to its original values by calling the Cancel method for the dataset. A call to Cancel always returns a dataset to *dsBrowse* state. If the dataset was in *dsEdit* or *dsInsert* mode when your application called *Cancel*, it receives *BeforeCancel* and *AfterCancel* events before and after the current... more (see page 1586)
Controlling Read/Write Access to Tables (see page 1587)	By default when a table type dataset is opened, it requests read and write access for the underlying database table. Depending on the characteristics of the underlying database table, the requested write privilege may not be granted (for example, when you request write access to an SQL table on a remote server and the server restricts the table's access to read only). **Note:** This is not true for *TClientDataSet*, which determines whether users can edit data from information that the dataset provider supplies with data packets. It is also not true for *TSQLTable*, which is a unidirectional dataset,... more (see page 1587)
Creating and Deleting Tables (see page 1587)	Some table type datasets let you create and delete the underlying tables at design time or at runtime. Typically, database tables are created and deleted by a database administrator. However, it can be handy during application development and testing to create and destroy database tables that your application can use.
Creating Filters (see page 1590)	There are two ways to create a filter for a dataset: • Set the Filter property (see page 1608). Filter is especially useful for creating and applying filters at runtime. • Write an OnFilterRecord event handler (see page 1635) for simple or complex filter conditions. With OnFilterRecord, you specify filter conditions at design time. Unlike the *Filter* property, which is restricted to a single string containing filter logic, an *OnFilterRecord* event can take advantage of branching and looping logic to create complex, multi-level filter conditions. The main advantage to creating filters using the *Filter* property is that your application can create, change, and apply filters dynamically, (for... more (see page 1590)

Creating Master/detail Relationships (see page 1590)	Table type datasets can be linked into master/detail relationships. When you set up a master/detail relationship, you link two datasets so that all the records of one (the detail) always correspond to the single current record in the other (the master). Table type datasets support master/detail relationships in two very distinct ways: • All table type datasets can act as the detail of another dataset by linking cursors. This process is described in Making the table a detail of another dataset (see page 1598). • *TTable*, *TSQLTable*, and all client datasets can act as the master in a master/detail relationship that uses... more (see page 1590)
Deleting Records (see page 1591)	Use the Delete method to delete the current record in an active dataset. When the *Delete* method is called, • The dataset receives a *BeforeDelete* event. • The dataset attempts to delete the current record. • The dataset returns to the *dsBrowse* state. • The dataset receives an *AfterDelete* event. If want to prevent the deletion in the *BeforeDelete* event handler, you can call the global *Abort* procedure:
Editing Records (see page 1591)	A dataset must be in *dsEdit* mode before an application can modify records. In your code you can use the *Edit method to put a dataset into dsEdit mode if the read-only CanModify property for the dataset is True.* *When a dataset transitions to dsEdit mode, it first receives a BeforeEdit event. After the transition to edit mode is successfully completed, the dataset receives an AfterEdit event. Typically, these events are used for updating the user interface to indicate the current state of the dataset. If the dataset can't be put into edit mode for some reason, an... more (see page 1591)*
Emptying Tables (see page 1592)	Many table type datasets supply a single method that lets you delete all rows of data in the table.
Enabling and Disabling Filtering (see page 1593)	
Establishing Master/detail Relationships Using Parameters (see page 1593)	To set up a master/detail relationship where the detail set is a query-type dataset, you must specify a query that uses parameters. These parameters refer to current field values on the master dataset. Because the current field values on the master dataset change dynamically at runtime, you must rebind the detail set's parameters every time the master record changes. Although you could write code to do this using an event handler, all query-type datasets except *TIBQuery* provide an easier mechanism using the DataSource property. If parameter values for a parameterized query are not bound at design time or specified at... more (see page 1593)
Executing a Search with Find Methods (see page 1594)	The *Find* methods do the same thing as the Goto methods (see page 1595), except that you do not need to explicitly put the dataset in *dsSetKey* state to specify the key field values on which to search.
Executing a Search with Goto Methods (see page 1595)	
Executing Queries That Don't Return a Result Set (see page 1596)	When a query returns a set of records (such as a SELECT query), you execute the query the same way you populate any dataset with records: by setting *Active* to *True* or calling the *Open* method. However, often SQL commands do not return any records. Such commands include statements that use Data Definition Language (DDL) or Data Manipulation Language (DML) statements other than SELECT statements (For example, INSERT, DELETE, UPDATE, CREATE INDEX, and ALTER TABLE commands do not return any records). For all query-type datasets, you can execute a query that does not return a result set by calling *ExecSQL... more (see page 1596)*
Executing Stored Procedures That Don't Return a Result Set (see page 1596)	When a stored procedure returns a cursor, you execute it the same way you populate any dataset with records: by setting *Active* to *True* or calling the *Open* method. However, often stored procedures do not return any data, or only return results in output parameters. You can execute a stored procedure that does not return a result set by calling *ExecProc*. After executing the stored procedure, you can use the *ParamByName* method to read the value of the result parameter or of any output parameters:

Fetching Multiple Result Sets (see page 1597)	Some stored procedures return multiple sets of records. The dataset only fetches the first set when you open it. If you are using *TSQLStoredProc* or *TADOStoredProc*, you can access the other sets of records by calling the *NextRecordSet* method:
Limiting Records with Ranges (see page 1597)	You can temporarily view and edit a subset of data for any dataset by using filters (see page 1631). Some table type datasets support an additional way to access a subset of available records, called ranges. Ranges only apply to *TTable* and to client datasets. Despite their similarities, ranges and filters have different uses. The following topics discuss the differences between ranges and filters and how to use ranges: • Understanding the differences between ranges and filters (see page 1615) • Specifying ranges (see page 1610) • Modifying a range (see page 1601) • Applying or canceling a range (see page 1585)
Making the Table a Detail of Another Dataset (see page 1598)	A table type dataset's *MasterSource* and *MasterFields* properties can be used to establish one-to-many relationships between two datasets. The *MasterSource* property is used to specify a data source from which the table gets data from the master table. This data source can be linked to any type of dataset. For instance, by specifying a query's data source in this property, you can link a client dataset as the detail of the query, so that the client dataset tracks events occurring in the query. The dataset is linked to the master table based on its current index. Before you specify the... more (see page 1598)
Marking and Returning to Records (see page 1599)	In addition to moving from record to record in a dataset (or moving from one record to another by a specific number of records), it is often also useful to mark a particular location in a dataset so that you can return to it quickly when desired. TDataSet introduces a bookmarking feature that consists of a Bookmark property and five bookmark methods. *TDataSet* implements **virtual** bookmark methods. While these methods ensure that any dataset object derived from *TDataSet* returns a value if a bookmark method is called, the return values are merely defaults that do not keep track of the... more (see page 1599)
Modifying a Range (see page 1601)	Two functions enable you to modify the existing boundary conditions for a range: *EditRangeStart*, for changing the starting values for a range; and *EditRangeEnd*, for changing the ending values for the range.
Modifying Entire Records (see page 1601)	On forms, all data-aware controls except for grids and the navigator provide access to a single field in a record. In code, however, you can use the following methods that work with entire record structures provided that the structure of the database tables underlying the dataset is stable and does not change. The following table summarizes the methods available for working with entire records rather than individual fields in those records: ***Methods that work with entire records***
Navigating Records in a Filtered Dataset (see page 1603)	There are four dataset methods that navigate among records in a filtered dataset. The following table lists these methods and describes what they do: ***Filtered dataset navigational methods***
Obtaining Information About Indexes (see page 1603)	Your application can obtain information about server-defined indexes from all table type datasets. To obtain a list of available indexes for the dataset, call the *GetIndexNames* method. *GetIndexNames* fills a string list with valid index names. For example, the following code fills a listbox with the names of all indexes defined for the *CustomersTable* dataset:
Opening and Closing Datasets (see page 1604)	To read or write data in a dataset, an application must first open it. You can open a dataset in two ways:

Posting Data (see page 1606)	After you finish editing a record, you must call the Post method to write out your changes. The *Post* method behaves differently, depending on the dataset's state and on whether you are caching updates. • If you are not caching updates, and the dataset is in the *dsEdit* or *dsInsert* state, *Post* writes the current record to the database and returns the dataset to the *dsBrowse* state. • If you are caching updates, and the dataset is in the *dsEdit* or *dsInsert* state, *Post* writes the current record to an internal cache and returns the dataset to the *dsBrowse* state. The edits... more (see page 1606)
Preparing Queries (see page 1606)	Preparing a query is an optional step that precedes query execution. Preparing a query submits the SQL statement and its parameters, if any, to the data access layer and the database server for parsing, resource allocation, and optimization. In some datasets, the dataset may perform additional setup operations when preparing the query. These operations improve query performance, making your application faster, especially when working with updatable queries. An application can prepare a query by setting the *Prepared* property to *True*. If you do not prepare a query before executing it, the dataset automatically prepares it for you each time... more (see page 1606)
Preparing Stored Procedures (see page 1607)	As with query-type datasets, stored procedure-type datasets must be prepared before they execute the stored procedure. Preparing a stored procedure tells the data access layer and the database server to allocate resources for the stored procedure and to bind parameters. These operations can improve performance. If you attempt to execute a stored procedure before preparing it, the dataset automatically prepares it for you, and then unprepares it after it executes. If you plan to execute a stored procedure a number of times, it is more efficient to explicitly prepare it by setting the *Prepared* property to *True*.
Searching On Partial Keys (see page 1607)	Each time you call *SetKey* or *FindKey*, the method clears any previous values in the *Fields* property. If you want to repeat a search using previously set fields, or you want to add to the fields used in a search, call *EditKey* in place of *SetKey* and *FindKey*. For example, suppose you have already executed a search of the Employee table based on the City field of the "CityIndex" index. Suppose further that "CityIndex" includes both the *City* and *Company* fields. To find a record with a specified company name in a specified city, use the following code:... more (see page 1607)
Searching On Partial Keys (see page 1608)	If the dataset has more than one key column, and you want to search for values in a subset of that key, set *KeyFieldCount* to the number of columns on which you are searching. For example, if the dataset's current index has three columns, and you want to search for values using just the first column, set *KeyFieldCount* to 1. For table type datasets with multiple-column keys, you can search only for values in contiguous columns, beginning with the first. For example, for a three-column key you can search for values in the first column, the first and second, or... more (see page 1608)
Setting Filter Options (see page 1608)	The FilterOptions property lets you specify whether a filter that compares string-based fields accepts records based on partial comparisons and whether string comparisons are case-sensitive. *FilterOptions* is a set property that can be an empty set (the default), or that can contain either or both of the following values: ***FilterOptions values***
Setting the Filter Property (see page 1608)	To create a filter using the Filter property, set the value of the property to a string that contains the filter's test condition. For example, the following statement creates a filter that tests a dataset's *State* field to see if it contains a value for the state of California:

Sorting Records with Indexes (see page 1609)	An index determines the display order of records in a table. Typically, records appear in ascending order based on a primary, or default, index. This default behavior does not require application intervention. If you want a different sort order, however, you must specify either • An alternate index. • A list of columns on which to sort (not available on servers that aren't SQL-based). Indexes let you present the data from a table in different orders. On SQL-based tables, this sort order is implemented by using the index to generate an ORDER BY clause in a query that fetches the table's records.... more (see page 1609)
Specifying Ranges (see page 1610)	There are two mutually exclusive ways to specify a range: • Specify the beginning and ending separately using *SetRangeStart* and *SetRangeEnd*. • Specify both endpoints at once using *SetRange*.
Specifying the Current Record After a Successful Search (see page 1612)	By default, a successful search positions the cursor on the first record that matches the search criteria. If you prefer, you can set the *KeyExclusive* property to *True* to position the cursor on the next record after the first matching record. By default, *KeyExclusive* is *False*, meaning that successful searches position the cursor on the first matching record.
Specifying the Query (see page 1613)	For true query-type datasets, you use the *SQL* property to specify the SQL statement for the dataset to execute. Some datasets, such as *TADODataSet*, *TSQLDataSet,* and client datasets, use a *CommandText* property to accomplish the same thing. Most queries that return records are SELECT commands. Typically, they define the fields to include, the tables from which to select those fields, conditions that limit what records to include, and the order of the resulting dataset. For example:
Synchronizing Tables (see page 1614)	If you have two or more datasets that represent the same database table but do not share a data source component, then each dataset has its own view on the data and its own current record. As users access records through each datasets, the components' current records will differ. If the datasets are all instances of *TTable*, or all instances of *TIBTable*, or all client datasets, you can force the current record for each of these datasets to be the same by calling the *GotoCurrent* method. *GotoCurrent* sets its own dataset's current record to the current record of... more (see page 1614)
Understanding the Differences Between Ranges and Filters (see page 1615)	Both ranges and filters restrict visible records to a subset of all available records, but the way they do so differs. A range is a set of contiguously indexed records that fall between specified boundary values. For example, in an employee database indexed on last name, you might apply a range to display all employees whose last names are greater than "Jones" and less than "Smith". Because ranges depend on indexes, you must set the current index to one that can be used to define the range. As with specifying an index to sort records (see page 1609), you can assign the... more (see page 1615)
Using Indexes to Search for Records (see page 1615)	You can search against any dataset using the Locate and Lookup methods of *TDataSet*. However, by explicitly using indexes, some table type datasets can improve over the searching performance provided by the *Locate* and *Lookup* methods. ADO datasets all support the Seek method, which moves to a record based on a set of field values for fields in the current index. *Seek* lets you specify where to move the cursor relative to the first or last matching record. *TTable* and all types of client dataset support similar indexed-based searches, but use a combination of related methods. The following table... more (see page 1615)
Using Nested Detail Tables (see page 1616)	A nested table is a detail dataset that is the value of a single dataset field in another (master) dataset. For datasets that represent server data, a nested detail dataset can only be used for a dataset field on the server. *TClientDataSet* components do not represent server data, but they can also contain dataset fields if you create a dataset for them that contains nested details, or if they receive data from a provider that is linked to the master table of a master/detail relationship. **Note:** For *TClientDataSet*, using nested detail sets is necessary if you want to apply... more (see page 1616)

Using Parameters in Queries (see page 1617)	A parameterized SQL statement contains parameters, or variables, the values of which can be varied at design time or runtime. Parameters can replace data values, such as those used in a WHERE clause for comparisons, that appear in an SQL statement. Ordinarily, parameters stand in for data values passed to the statement. For example, in the following INSERT statement, values to insert are passed as parameters:
Using Query-type Datasets (see page 1618)	
Using Stored Procedure-type Datasets (see page 1618)	How your application uses a stored procedure depends on how the stored procedure was coded, whether and how it returns data, the specific database server used, or a combination of these factors.
Using TDataSet Descendants (see page 1619)	*TDataSet* has several immediate descendants, each of which corresponds to a different data access mechanism. You do not work directly with any of these descendants. Rather, each descendant introduces the properties and methods for using a particular data access mechanism. These properties and methods are then exposed by descendant classes that are adapted to different types of server data. The immediate descendants of *TDataSet* include • *TBDEDataSet*, which uses the Borland Database Engine (BDE) to communicate with the database server. The *TBDEDataSet* descendants you use are *TTable*, *TQuery*, *TStoredProc*, and *TNestedTable*. The unique features of... more (see page 1619)
Using Table Type Datasets (see page 1620)	
Using the Eof and Bof Properties (see page 1621)	Two read-only, runtime properties, *Eof* (End-of-file) and *Bof(Beginning-of-file), are useful when you want to iterate through all records in a dataset.*
Using the First and Last Methods (see page 1623)	The First method moves the cursor to the first row in a dataset and sets the BOF property to *True*. If the cursor is already at the first row in the dataset, *First* does nothing. For example, the following code moves to the first record in *CustTable*:
Using the MoveBy Method (see page 1623)	MoveBy lets you specify how many rows forward or back to move the cursor in a dataset. Movement is relative to the current record at the time that *MoveBy* is called. *MoveBy* also sets the BOF and EOF properties for the dataset as appropriate. This function takes an integer parameter, the number of records to move. Positive integers indicate a forward move and negative integers indicate a backward move. **Note:** *MoveBy* raises an exception in unidirectional datasets if you use a negative argument. *MoveBy* returns the number of rows it moves. If you attempt to move past the beginning or... more (see page 1623)
Using the Next and Prior Methods (see page 1624)	The Next method moves the cursor forward one row in the dataset and sets the BOF property to *False* if the dataset is not empty. If the cursor is already at the last row in the dataset when you call *Next*, nothing happens. For example, the following code moves to the next record in *CustTable*:
Using Unidirectional Result Sets (see page 1624)	When a query-type dataset returns a result set, it also receives a cursor, or pointer to the first record in that result set. The record pointed to by the cursor is the currently active record. The current record is the one whose field values are displayed in data-aware components associated with the result set's data source. Unless you are using dbExpress, this cursor is bi-directional by default. A bi-directional cursor can navigate both forward and backward through its records. Bi-directional cursor support requires some additional processing overhead, and can slow some queries. If you do not need to be able... more (see page 1624)

Working with Stored Procedure Parameters (see page 1625)	There are four types of parameters that can be associated with stored procedures: • *Input p*arameters, used to pass values to a stored procedure for processing. • *Output* parameters, used by a stored procedure to pass return values to an application. • *Input/output parameters*, used to pass values to a stored procedure for processing, and used by the stored procedure to pass return values to the application. • *A result parameter*, used by some stored procedures to return an error or status value to an application. A stored procedure can only return one result parameter. Whether a stored procedure uses a... more (see page 1625)
Using Locate (see page 1627)	Locate moves the cursor to the first row matching a specified set of search criteria. In its simplest form, you pass *Locate* the name of a column to search, a field value to match, and an options flag specifying whether the search is case-insensitive or if it can use partial-key matching. (Partial-key matching is when the criterion string need only be a prefix of the field value.) For example, the following code moves the cursor to the first row in the *CustTable* where the value in the *Company* column is "Professional Divers, Ltd.":
Using Lookup (see page 1628)	Lookup searches for the first row that matches specified search criteria. If it finds a matching row, it forces the recalculation of any calculated fields and lookup fields associated with the dataset, then returns one or more fields from the matching row. *Lookup* does not move the cursor to the matching row; it only returns values from it. In its simplest form, you pass *Lookup* the name of field to search, the field value to match, and the field or fields to return. For example, the following code looks for the first record in the *CustTable* where the value of... more (see page 1628)
Modifying Data (see page 1629)	You can use the following dataset methods to insert, update, and delete data if the read-only *CanModify* property is *True*. *CanModify* is *True* unless the dataset is unidirectional, the database underlying the dataset does not permit read and write privileges, or some other factor intervenes. (Intervening factors include the *ReadOnly* property on some datasets or the *RequestLive* property on *TQuery* components.) ***Dataset methods for inserting, updating, and deleting data***
Searching Datasets (see page 1630)	If a dataset is not unidirectional, you can search against it using the *Locate* and *Lookup* methods. These methods enable you to search on any type of columns in any dataset. The following topics discuss Locate and Lookup in greater detail: • Using Locate (see page 1627) • Using Lookup (see page 1628) **Note:** Some *TDataSet* descendants introduce an additional family of methods for searching based on an index. For information about these additional methods, see Using Indexes to Search for Records (see page 1615).
Specifying an Index with IndexName (see page 1630)	Use the *IndexName* property to cause an index to be active. Once active, an index determines the order of records in the dataset. (It can also be used as the basis for a master-detail link, an index-based search, or index-based filtering.) To activate an index, set the *IndexName* property to the name of the index. In some database systems, primary indexes do not have names. To activate one of these indexes, set *IndexName* to a blank string. At design-time, you can select an index from a list of available indexes by clicking the property's ellipsis button in the **Object Inspector... more (see page 1630)**

Displaying and Editing a Subset of Data Using Filters (see page 1631)	An application is frequently interested in only a subset of records from a dataset. For example, you may be interested in retrieving or viewing only those records for companies based in California in your customer database, or you may want to find a record that contains a particular set of field values. In each case, you can use filters to restrict an application's access to a subset of all records in the dataset. With unidirectional datasets, you can only limit the records in the dataset by using a query that restricts the records in the dataset. With other *TDataSet* descendants,... more (see page 1631)
Understanding Datasets: Overview (see page 1632)	The fundamental unit for accessing data is the dataset family of objects. Your application uses datasets for all database access. A dataset object represents a set of records from a database organized into a logical table. These records may be the records from a single database table, or they may represent the results of executing a query or stored procedure. All dataset objects that you use in your database applications descend from TDataSet, and they inherit data fields, properties, events, and methods from this class. *TDataSet* is a virtualized dataset, meaning that many of its properties and methods are **virtual... more (see page 1632)**
Determining Dataset States (see page 1633)	The *state*—or *mode*—of a dataset determines what can be done to its data. For example, when a dataset is closed, its state is *dsInactive*, meaning that nothing can be done to its data. At runtime, you can examine a dataset's read-only State property to determine its current state. The following table summarizes possible values for the *State* property and what they mean: ***Values for the dataset State property***
Navigating Datasets (see page 1634)	Each active dataset has a *cursor*, or pointer, to the current row in the dataset. The *current row* in a dataset is the one whose field values currently show in single-field, data-aware controls on a form, such as TDBEdit, *TDBLabel*, and TDBMemo. If the dataset supports editing, the current record contains the values that can be manipulated by edit, insert, and delete methods. You can change the current row by moving the cursor to point at a different row. The following table lists methods you can use in application code to move to different records: ***Navigational methods of... more (see page 1634)***
Writing an OnFilterRecord Event Handler (see page 1635)	You can write code to filter records using the OnFilterRecord events generated by the dataset for each record it retrieves. This event handler implements a test that determines if a record should be included in those that are visible to the application. To indicate whether a record passes the filter condition, your *OnFilterRecord* handler sets its *Accept* parameter to *True* to include a record, or *False* to exclude it. For example, the following filter displays only those records with the State field set to "CA":
Types of Datasets (see page 1635)	Using TDataSet descendants (see page 1619) classifies *TDataSet* descendants by the method they use to access their data. Another useful way to classify *TDataSet* descendants is to consider the type of server data they represent. Viewed this way, there are three basic classes of datasets: Table type datasets (see page 1620): Table type datasets represent a single table from the database server, including all of its rows and columns. Table type datasets include TTable, TADOTable, TSQLTable, and TIBTable. Table type datasets let you take advantage of indexes defined on the server. Because there is a one-to-one correspondence between database table and dataset, you can use... more (see page 1635)

3.2.3.6.1 Creating an Index with IndexFieldNames

If there is no defined index that implements the sort order you want, you can create a pseudo-index using the *IndexFieldNames* property.

Note: *IndexName and IndexFieldNames are mutually exclusive. Setting one property clears values set for the other. For information about IndexName, see Specifying an index with IndexName (see page 1630).*

The value of IndexFieldNames is a string. To specify a sort order, list each column name to use in the order it should be used, and delimit the names with semicolons. Sorting is by ascending order only. Case-sensitivity of the sort depends on the capabilities of your server. See your server documentation for more information.

The following code sets the sort order for PhoneTable based on LastName, then FirstName:

```
PhoneTable.IndexFieldNames := 'LastName;FirstName';
```

```
PhoneTable->IndexFieldNames = "LastName;FirstName";
```

Note: If you use *IndexFieldNames* on Paradox and dBASE tables, the dataset attempts to find an index that uses the columns you specify. If it cannot find such an index, it raises an exception.

3.2.3.6.2 Supplying Parameters at Design Time

At design time, you can specify parameter values using the parameter collection editor. To display the parameter collection editor, click on the ellipsis button for the *Params* or *Parameters* property in the **Object Inspector**. If the SQL statement does not contain any parameters, no objects are listed in the collection editor.

Note: The parameter collection editor is the same collection editor that appears for other collection properties. Because the editor is shared with other properties, its right-click context menu contains the Add and Delete commands. However, they are never enabled for query parameters. The only way to add or delete parameters is in the SQL statement itself.

For each parameter, select it in the parameter collection editor. Then use the **Object Inspector** to modify its properties.

When using the *Params* property (*TParam* objects), you will want to inspect or modify the following,

The DataType property lists the data type for the parameter's value. For some datasets, this value may be correctly initialized. If the dataset did not deduce the type, *DataType* is *ftUnknown*, and you must change it to indicate the type of the parameter value.

The *DataType* property lists the logical data type for the parameter. In general, these data types conform to server data types. For specific logical type-to-server data type mappings, see the documentation for the data access mechanism (BDE, dbExpress, InterBase).

The ParamType property lists the type of the selected parameter. For queries, this is always *ptInput*, because queries can only contain input parameters. If the value of *ParamType* is *ptUnknown*, change it to *ptInput*.

The Value property specifies a value for the selected parameter. You can leave *Value* blank if your application supplies parameter values at runtime.

When using the *Parameters* property (*TParameter* objects), you will want to inspect or modify the following:

The DataType property lists the data type for the parameter's value. For some data types, you must provide additional information:

- The NumericScale property indicates the number of decimal places for numeric parameters.
- The Precision property indicates the total number of digits for numeric parameters.
- The Size property indicates the number of characters in string parameters.

The Direction property lists the type of the selected parameter. For queries, this is always *pdInput*, because queries can only contain input parameters.

The Attributes property controls the type of values the parameter will accept. *Attributes* may be set to a combination of *psSigned*, *psNullable*, and *psLong*.

The Value property specifies a value for the selected parameter. You can leave *Value* blank if your application supplies parameter values at runtime.

See Also

Supplying Parameters at Runtime (see page 1583)

Establishing Master/detail Relationships Using Parameters (see page 1593)

3.2.3.6.3 Supplying Parameters at Runtime

To create parameters at runtime, you can use the

- *ParamByName* method to assign values to a parameter based on its name (not available for *TADOQuery*)
- *Params* or *Parameters* property to assign values to a parameter based on the parameter's ordinal position within the SQL statement.
- *Params.ParamValues* or *Parameters.ParamValues* property to assign values to one or more parameters in a single command line, based on the name of each parameter set.

The following code uses *ParamByName* to assign the text of an edit box to the :Capital parameter:

```
SQLQuery1.ParamByName('Capital').AsString := Edit1.Text;
SQLQuery1->ParamByName("Capital")->AsString = Edit1->Text;
```

The same code can be rewritten using the *Params* property, using an index of 0 (assuming the :Capital parameter is the first parameter in the SQL statement):

```
SQLQuery1.Params[0].AsString := Edit1.Text;
SQLQuery1->Params->Items[0]->AsString = Edit1->Text;
```

The command line below sets three parameters at once, using the *Params.ParamValues* property:

```
Query1.Params.ParamValues['Name;Capital;Continent'] :=
  VarArrayOf([Edit1.Text, Edit2.Text, Edit3.Text]);
Query1->Params->ParamValues["Name;Capital;Continent"] =
  VarArrayOf(OPENARRAY(Variant, (Edit1->Text, Edit2->Text, Edit3->Text)));
```

Note that *ParamValues* uses Variants, avoiding the need to cast values.

3.2.3.6.4 Adding New Records

A dataset must be in *dsInsert* mode before an application can add new records. In code, you can use the Insert or Append methods to put a dataset into *dsInsert* mode if the read-only CanModify property for the dataset is *True*.

When a dataset transitions to *dsInsert* mode, it first receives a *BeforeInsert* event. After the transition to insert mode is successfully completed, the dataset receives first an *OnNewRecord* event hand then an *AfterInsert* event. You can use these events, for example, to provide initial values to newly inserted records:

```
procedure TForm1.OrdersTableNewRecord(DataSet: TDataSet);
begin
  DataSet.FieldByName('OrderDate').AsDateTime := Date;
end;
void __fastcall TForm1::OrdersTableNewRecord(TDataSet *DataSet)
{
```

```
  DataSet->FieldByName("OrderDate")->AsDateTime = Date();
}
```

On forms in your application, the data-aware grid and navigator controls can put a dataset into *dsInsert* state if

- The control's *ReadOnly* property is *False* (the default), and
- *CanModify* is *True* for the dataset.

Note: Even if a dataset is in *dsInsert* state, adding records may not succeed for SQL-based databases if your application's user does not have proper SQL access privileges.

Once a dataset is in *dsInsert* mode, a user or application can enter values into the fields associated with the new record. Except for the grid and navigational controls, there is no visible difference to a user between *Insert* and *Append*. On a call to *Insert*, an empty row appears in a grid above what was the current record. On a call to *Append*, the grid is scrolled to the last record in the dataset, an empty row appears at the bottom of the grid, and the Next and Last buttons are dimmed on any navigator component associated with the dataset.

Data-aware controls for which inserting is enabled automatically call Post when a user executes any action that changes which record is current (such as moving to a different record in a grid). Otherwise you must call *Post* in your code.

Post writes the new record to the database, or, if you are caching updates, *Post* writes the record to an in-memory cache. To write cached inserts and appends to the database, call the dataset's *ApplyUpdates* method.

Inserting records

Insert opens a new, empty record before the current record, and makes the empty record the current record so that field values for the record can be entered either by a user or by your application code.

When an application calls Post (or *ApplyUpdates* when using cached updates), a newly inserted record is written to a database in one of three ways:

- For indexed Paradox and dBASE tables, the record is inserted into the dataset in a position based on its index.
- For unindexed Paradox and dBASE tables, the record is inserted into the dataset at its current position.
- For SQL databases, the physical location of the insertion is implementation-specific. If the table is indexed, the index is updated with the new record information.

Appending records

Append opens a new, empty record at the end of the dataset, and makes the empty record the current one so that field values for the record can be entered either by a user or by your application code.

When an application calls Post (or *ApplyUpdates* when using cached updates), a newly appended record is written to a database in one of three ways:

- For indexed Paradox and dBASE tables, the record is inserted into the dataset in a position based on its index.
- For unindexed Paradox and dBASE tables, the record is added to the end of the dataset.
- For SQL databases, the physical location of the append is implementation-specific. If the table is indexed, the index is updated with the new record information.

3.2.3.6.5 Applying or Canceling a Range

When you call *SetRangeStart* or *EditRangeStart* to specify the start of a range, or *SetRangeEnd* or *EditRangeEnd* to specify the end of a range, the dataset enters the *dsSetKey* state. It stays in that state until you apply or cancel the range.

Applying a range

When you specify a range, the boundary conditions you define are not put into effect until you apply the range. To make a range take effect, call the *ApplyRange* method. *ApplyRange* immediately restricts a user's view of and access to data in the specified subset of the dataset.

Canceling a range

The *CancelRange* method ends application of a range and restores access to the full dataset. Even though canceling a range restores access to all records in the dataset, the boundary conditions for that range are still available so that you can reapply the range at a later time. Range boundaries are preserved until you provide new range boundaries or modify the existing boundaries. For example, the following code is valid:

```
.
.
.
MyTable.CancelRange;
.
.
.
{later on, use the same range again. No need to call SetRangeStart, etc.}
MyTable.ApplyRange;
.
.
.
.
.
.
MyTable->CancelRange();
.
.
.
// later on, use the same range again. No need to call SetRangeStart, etc.
MyTable->ApplyRange();
.
.
.
```

3.2.3.6.6 Calculating Fields

Using the Fields editor, you can define calculated fields (see page 1872) for your datasets. When a dataset contains

calculated fields, you provide the code to calculate those field's values in an OnCalcFields event handler.

The AutoCalcFields property determines when *OnCalcFields* is called. If *AutoCalcFields* is *True*, *OnCalcFields* is called when

- A dataset is opened.
- The dataset enters edit mode.
- A record is retrieved from the database.
- Focus moves from one visual component to another, or from one column to another in a data-aware grid control and the current record has been modified.

If *AutoCalcFields* is *False*, then *OnCalcFields* is not called when individual fields within a record are edited (the fourth condition above).

Warning: *OnCalcFields* is called frequently, so the code you write for it should be kept short. Also, if *AutoCalcFields* is *True*, *OnCalcFields* should not perform any actions that modify the dataset (or a linked dataset if it is part of a master-detail relationship), because this leads to recursion. For example, if *OnCalcFields* performs a Post, and *AutoCalcFields* is *True*, then *OnCalcFields* is called again, causing another Post, and so on.

When *OnCalcFields* executes, a dataset enters *dsCalcFields* mode. This state prevents modifications or additions to the records except for the calculated fields the handler is designed to modify. The reason for preventing other modifications is because *OnCalcFields* uses the values in other fields to derive calculated field values. Changes to those other fields might otherwise invalidate the values assigned to calculated fields. After *OnCalcFields* is completed, the dataset returns to *dsBrowse* state.

3.2.3.6.7 Canceling Changes

An application can undo changes made to the current record at any time, if it has not yet directly or indirectly called Post. For example, if a dataset is in *dsEdit* mode, and a user has changed the data in one or more fields, the application can return the record back to its original values by calling the Cancel method for the dataset. A call to Cancel always returns a dataset to *dsBrowse* state.

If the dataset was in *dsEdit* or *dsInsert* mode when your application called *Cancel*, it receives *BeforeCancel* and *AfterCancel* events before and after the current record is restored to its original values.

On forms, you can allow users to cancel edit, insert, or append operations by including the Cancel button on a navigator component associated with the dataset, or you can provide code for your own Cancel button on the form.

3.2.3.6.8 Controlling Read/Write Access to Tables

By default when a table type dataset is opened, it requests read and write access for the underlying database table. Depending on the characteristics of the underlying database table, the requested write privilege may not be granted (for example, when you request write access to an SQL table on a remote server and the server restricts the table's access to read only).

Note: This is not true for *TClientDataSet*, which determines whether users can edit data from information that the dataset provider supplies with data packets. It is also not true for *TSQLTable*, which is a unidirectional dataset, and hence always read-only.

When the table opens, you can check the CanModify property to ascertain whether the underlying database (or the dataset provider) allows users to edit the data in the table. If *CanModify* is *False*, the application cannot write to the database. If *CanModify* is *True*, your application can write to the database provided the table's *ReadOnly* property is *False*.

ReadOnly determines whether a user can both view and edit data. When *ReadOnly* is *False* (the default), a user can both view and edit data. To restrict a user to viewing data, set *ReadOnly* to *True* before opening the table.

Note: *ReadOnly* is implemented on all table type datasets except *TSQLTable*, which is always read-only.

3.2.3.6.9 Creating and Deleting Tables

Some table type datasets let you create and delete the underlying tables at design time or at runtime. Typically, database tables are created and deleted by a database administrator. However, it can be handy during application development and testing to create and destroy database tables that your application can use.

Creating tables

TTable and *TIBTable* both let you create the underlying database table without using SQL. Similarly, *TClientDataSet* lets you create a dataset when you are not working with a dataset provider. Using *TTable* and *TClientDataSet*, you can create the table at design time or runtime. *TIBTable* only lets you create tables at runtime.

Before you can create the table, you must be set properties to specify the structure of the table you are creating. In particular, you must specify

- The database that will host the new table. For *TTable*, you specify the database using the DatabaseName property. For *TIBTable*, you must use a *TIBDatabase* component, which is assigned to the Database property. (Client datasets do not use a database.)
- The type of database (*TTable* only). Set the TableType property to the desired type of table. For Paradox, dBASE, or ASCII tables, set *TableType* to *ttParadox*, *ttDBase*, or *ttASCII*, respectively. For all other table types, set *TableType* to *ttDefault*.

- The name of the table you want to create. Both *TTable* and *TIBTable* have a *TableName* property for the name of the new table. Client datasets do not use a table name, but you should specify the *FileName* property before you save the new table. If you create a table that duplicates the name of an existing table, the existing table and all its data are overwritten by the newly created table. The old table and its data cannot be recovered. To avoid overwriting an existing table, you can check the *Exists* property at runtime. *Exists* is only available on *TTable* and *TIBTable*.
- Indexes for the new table (optional). At design time, double-click the *IndexDefs* property in the **Object Inspector** to bring up the collection editor. Use the collection editor to add, remove, or change the properties of index definitions. At runtime, clear any existing index definitions, and then use the AddIndexDef method to add each new index definition. For each new index definition, set the properties of the TIndexDef object to specify the desired attributes of the index.
- The fields for the new table. There are two ways to do this:
- You can add field definitions to the FieldDefs property. At design time, double-click the *FieldDefs* property in the **Object Inspector** to bring up the collection editor. Use the collection editor to add, remove, or change the properties of the field definitions. At runtime, clear any existing field definitions and then use the AddFieldDef method to add each new field definition. For each new field definition, set the properties of the TFieldDef object to specify the desired attributes of the field.
- You can use persistent field components instead. At design time, double-click on the dataset to bring up the *Fields* editor. In the Fields editor, right-click and choose the New Field command. Describe the basic properties of your field. Once the field is created, you can alter its properties in the **Object Inspector** by selecting the field in the Fields editor.

  Note: You can't define indexes for the new table if you are using persistent field components instead of field definition objects.

  To create the table at design time, right-click the dataset and choose Create Table (*TTable*) or Create Data Set (*TClientDataSet*). This command does not appear on the context menu until you have specified all the necessary information.

  To create the table at runtime, call the *CreateTable* method (*TTable* and *TIBTable*) or the *CreateDataSet* method (*TClientDataSet*).

  Note: You can set up the definitions at design time and then call the *CreateTable* (or *CreateDataSet*) method at runtime to create the table. However, to do so you must indicate that the definitions specified at runtime should be saved with the dataset component. (by default, field and index definitions are generated dynamically at runtime). Specify that the definitions should be saved with the dataset by setting its *StoreDefs* property to *True*.

  Tip: If you are using *TTable*, you can preload the field definitions and index definitions of an existing table at design time. Set the *DatabaseName* and *TableName* properties to specify the existing table. Right click the table component and choose Update Table Definition. This automatically sets the values of the *FieldDefs* and *IndexDefs* properties to describe the fields and indexes of the existing table. Next, reset the *DatabaseName* and *TableName* to specify the table you want to create, canceling any prompts to rename the existing table.

  Note: When creating Oracle8 tables, you can't create object fields (ADT fields, array fields, and dataset fields).

  The following code creates a new table at runtime and associates it with the DBDEMOS alias. Before it creates the new table, it verifies that the table name provided does not match the name of an existing table:

```
var
  TableFound: Boolean;
begin
  with TTable.Create(nil) do // create a temporary TTable component
  begin
    try
      { set properties of the temporary TTable component }
      Active := False;
      DatabaseName := 'DBDEMOS';
      TableName := Edit1.Text;
      TableType := ttDefault;
      { define fields for the new table }
      FieldDefs.Clear;
      with FieldDefs.AddFieldDef do begin
        Name := 'First';
        DataType := ftString;
        Size := 20;
```

```
        Required := False;
      end;
      with FieldDefs.AddFieldDef do begin
        Name := 'Second';
        DataType := ftString;
        Size := 30;
        Required := False;
      end;
      { define indexes for the new table }
      IndexDefs.Clear;
      with IndexDefs.AddIndexDef do begin
        Name := '';
        Fields := 'First';
        Options := [ixPrimary];
      end;
      TableFound := Exists; // check whether the table already exists
      if TableFound then
        if MessageDlg('Overwrite existing table ' + Edit1.Text + '?',
             mtConfirmation, mbYesNoCancel, 0) = mrYes then
          TableFound := False;
      if not TableFound then
        CreateTable; // create the table
    finally
      Free; // destroy the temporary TTable when done
    end;
  end;
end;
TTable *NewTable = new TTable(Form1);
NewTable->Active = false;
NewTable->DatabaseName = "BCDEMOS";
NewTable->TableName = Edit1->Text;
NewTable->TableType = ttDefault;
NewTable->FieldDefs->Clear();
TFieldDef *NewField = NewTable->FieldDefs->AddFieldDef(); // define first field
NewField->DataType = ftInteger;
NewField->Name = Edit2->Text;
NewField = NewTable->FieldDefs->AddFieldDef(); // define second field
NewField->DataType = ftString;
NewField->Size = StrToInt(Edit3->Text);
NewField->Name = Edit4->Text;
NewTable->IndexDefs->Clear();
TIndexDef *NewIndex = NewTable->IndexDefs->AddIndexDef(); // add an index
NewIndex->Name = "PrimaryIndex";
NewIndex->Fields = Edit2->Text;
NewIndex->Options << ixPrimary << ixUnique;
// Now check for prior existence of this table
bool CreateIt = (!NewTable->Exists);
if (!CreateIt)
   if (Application->MessageBox((AnsiString("Overwrite table ") + Edit1->Text +
                                AnsiString("?")).c_str(),
                                "Table Exists", MB_YESNO) == IDYES)
    CreateIt = true;
if (CreateIt)
  NewTable->CreateTable(); // create the table
```

Deleting tables

TTable and *TIBTable* let you delete tables from the underlying database table without using SQL. To delete a table at runtime, call the dataset's *DeleteTable* method. For example, the following statement removes the table underlying a dataset:

```
CustomersTable.DeleteTable;
CustomersTable->DeleteTable();
```

Warning: When you delete a table with *DeleteTable*, the table and all its data are gone forever.

If you are using *TTable*, you can also delete tables at design time: Right-click the table component and select Delete Table from the context menu. The Delete Table menu pick is only present if the table component represents an existing database table (the

DatabaseName and TableName properties specify an existing table).

3.2.3.6.10 Creating Filters

There are two ways to create a filter for a dataset:

- Set the Filter property (see page 1608). Filter is especially useful for creating and applying filters at runtime.
- Write an OnFilterRecord event handler (see page 1635) for simple or complex filter conditions. With OnFilterRecord, you specify filter conditions at design time. Unlike the *Filter* property, which is restricted to a single string containing filter logic, an *OnFilterRecord* event can take advantage of branching and looping logic to create complex, multi-level filter conditions.

The main advantage to creating filters using the *Filter* property is that your application can create, change, and apply filters dynamically, (for example, in response to user input). Its main disadvantages are that filter conditions must be expressible in a single text string, cannot make use of branching and looping constructs, and cannot test or compare its values against values not already in the dataset.

The strengths of the *OnFilterRecord* event are that a filter can be complex and variable, can be based on multiple lines of code that use branching and looping constructs, and can test dataset values against values outside the dataset, such as the text in an edit box. The main weakness of using *OnFilterRecord* is that you set the filter at design time and it cannot be modified in response to user input. (You can, however, create several filter handlers and switch among them in response to general application conditions.)

The following sections describe how to create filters using the *Filter* property and the *OnFilterRecord* event handler.

3.2.3.6.11 Creating Master/detail Relationships

Table type datasets can be linked into master/detail relationships. When you set up a master/detail relationship, you link two datasets so that all the records of one (the detail) always correspond to the single current record in the other (the master).

Table type datasets support master/detail relationships in two very distinct ways:

- All table type datasets can act as the detail of another dataset by linking cursors. This process is described in Making the table a detail of another dataset (see page 1598).
- *TTable*, *TSQLTable*, and all client datasets can act as the master in a master/detail relationship that uses nested detail tables. This process is described in Using nested detail tables (see page 1616).

Each of these approaches has its unique advantages. Linking cursors lets you create master/detail relationships where the master table is any type of dataset. With nested details, the type of dataset that can act as the detail table is limited, but they provide for more options in how to display the data. If the master is a client dataset, nested details provide a more robust mechanism for applying cached updates.

Synchronizing Tables (see page 1614)

3.2.3.6.12 Deleting Records

Use the Delete method to delete the current record in an active dataset. When the *Delete* method is called,

- The dataset receives a *BeforeDelete* event.
- The dataset attempts to delete the current record.
- The dataset returns to the *dsBrowse* state.
- The dataset receives an *AfterDelete* event.

If want to prevent the deletion in the *BeforeDelete* event handler, you can call the global *Abort* procedure:

```
procedure TForm1.TableBeforeDelete (Dataset: TDataset)
begin
  if MessageDlg('Delete This Record?', mtConfirmation, mbYesNoCancel, 0) <> mrYes then
    Abort;
end;
void __fastcall TForm1::TableBeforeDelete (TDataSet *Dataset)
{
  if (MessageBox(0, "Delete This Record?", "CONFIRM", MB_YESNO) != IDYES)
Abort();
}
```

If *Delete* fails, it generates an *OnDeleteError* event. If the *OnDeleteError* event handler can't correct the problem, the dataset remains in *dsEdit* state. If *Delete* succeeds, the dataset reverts to the *dsBrowse* state and the record that followed the deleted record becomes the current record.

If you are caching updates, the deleted record is not removed from the underlying database table until you call *ApplyUpdates*.

If you provide a navigator component on your forms, users can delete the current record by clicking the navigator's Delete button. In code, you must call *Delete* explicitly to remove the current record.

Posting Data to the Database (see page 1606)

Canceling Changes (see page 1586)

Modifying Entire Records (see page 1601)

3.2.3.6.13 Editing Records

A dataset must be in *dsEdit* mode before an application can modify records. In your code you can use the *Edit method to put a*

dataset into dsEdit mode if the read-only CanModify property for the dataset is True.

When a dataset transitions to dsEdit mode, it first receives a BeforeEdit event. After the transition to edit mode is successfully completed, the dataset receives an AfterEdit event. Typically, these events are used for updating the user interface to indicate the current state of the dataset. If the dataset can't be put into edit mode for some reason, an OnEditError event occurs, where you can inform the user of the problem or try to correct the situation that prevented the dataset from entering edit mode.

On forms in your application, some data-aware controls can automatically put a dataset into dsEdit state if

- The control's *ReadOnly* property is *False* (the default),
- The *AutoEdit* property of the data source for the control is *True*, and
- *CanModify* is *True* for the dataset.

Note: Even if a dataset is in *dsEdit* state, editing records may not succeed for SQL-based databases if your application's user does not have proper SQL access privileges.

Once a dataset is in *dsEdit* mode, a user can modify the field values for the current record that appears in any data-aware controls on a form. Data-aware controls for which editing is enabled automatically call *Post* when a user executes any action that changes the current record (such as moving to a different record in a grid).

If you have a navigator component on your form, users can cancel edits by clicking the navigator's Cancel button. Canceling edits returns a dataset to *dsBrowse* state.

In code, you must write or cancel edits by calling the appropriate methods. You write changes by calling Post. You cancel them by calling Cancel. In code, Edit and Post are often used together. For example,

```
with CustTable do
begin
  Edit;
  FieldValues['CustNo'] := 1234;
  Post;
end;
```

```
Table1->Edit();
Table1->FieldValues["CustNo"] = 1234;
Table1->Post();
```

In the previous example, the first line of code places the dataset in *dsEdit* mode. The next line of code assigns the number 1234 to the *CustNo* field of the current record. Finally, the last line writes, or posts, the modified record. If you are not caching updates, posting writes the change back to the database. If you are caching updates, the change is written to a temporary buffer, where it stays until the dataset's *ApplyUpdates* method is called.

Modifying Entire Records (see page 1601)

3.2.3.6.14 Emptying Tables

Many table type datasets supply a single method that lets you delete all rows of data in the table.

Table Type	Method
TTable and *TIBTable*	You can delete all the records by calling the *EmptyTable* method at runtime: PhoneTable.EmptyTable; PhoneTable->EmptyTable();
TADOTable	You can use the *DeleteRecords* method: PhoneTable.DeleteRecords; PhoneTable->DeleteRecords(arAll);

TSQLTable	You can use the *DeleteRecords* method. Note, that the *TSQLTable* version of *DeleteRecords* never takes any parameters: PhoneTable.DeleteRecords; PhoneTable->DeleteRecords();
EmptyDataSet	For client datasets, you can use the *EmptyDataSet* method: PhoneTable.EmptyDataSet; PhoneTable->EmptyDataSet();

Note: For tables on SQL servers, these methods only succeed if you have DELETE privilege for the table.

Warning: When you empty a dataset, the data you delete is gone forever.

3.2.3.6.15 Enabling and Disabling Filtering

To enable filters on a dataset

1. Create a filter (see page 1590).
2. Set filter options (see page 1608) for string-based filter tests, if necessary.
3. Set the Filtered property to *True*.

When filtering is enabled, only those records that meet the filter criteria are available to an application. Filtering is always a temporary condition. You can turn off filtering by setting the *Filtered* property to *False*.

Navigating Records in a Filtered Dataset (see page 1603)

3.2.3.6.16 Establishing Master/detail Relationships Using Parameters

To set up a master/detail relationship where the detail set is a query-type dataset, you must specify a query that uses parameters. These parameters refer to current field values on the master dataset. Because the current field values on the master dataset change dynamically at runtime, you must rebind the detail set's parameters every time the master record changes. Although you could write code to do this using an event handler, all query-type datasets except *TIBQuery* provide an easier mechanism using the DataSource property.

If parameter values for a parameterized query are not bound at design time or specified at runtime, query-type datasets attempt to supply values for them based on the *DataSource* property. *DataSource* identifies a different dataset that is searched for field names that match the names of unbound parameters. This search dataset can be any type of dataset. The search dataset must be created and populated before you create the detail dataset that uses it. If matches are found in the search dataset, the detail dataset binds the parameter values to the values of the fields in the current record pointed to by the data source.

To illustrate how this works, consider two tables: a customer table and an orders table. For every customer, the orders table contains a set of orders that the customer made. The Customer table includes an ID field that specifies a unique customer ID. The orders table includes a CustID field that specifies the ID of the customer who made an order.

To set up the Customer dataset

1. Add a table type dataset to your application and bind it to the Customer table.
2. Add a *TDataSource* component named *CustomerSource*. Set its *DataSet* property to the dataset added in step 1. This data source now represents the Customer dataset.
3. Add a query-type dataset and set its *SQL* property to

```
SELECT CustID, OrderNo, SaleDate
FROM Orders
WHERE CustID = :ID
```

Note that the name of the parameter is the same as the name of the field in the master (Customer) table.

4. Set the detail dataset's *DataSource* property to *CustomerSource*. Setting this property makes the detail dataset a linked query.

At runtime the *:ID* parameter in the SQL statement for the detail dataset*is not assigned a value, so the dataset tries to match the parameter by name against a column in the dataset identified by CustomersSource. CustomersSource gets its data from the master dataset, which, in turn, derives its data from the Customer table. Because the Customer table contains a column called "ID," the value from the ID field in the current record of the master dataset is assigned to the :ID parameter for the detail dataset's SQL statement. The datasets are linked in a master-detail relationship. Each time the current record changes in the Customers dataset, the detail dataset's SELECT statement executes to retrieve all orders based on the current customer id.*

Using Unidirectional Result Sets (see page 1624)

3.2.3.6.17 Executing a Search with Find Methods

The *Find* methods do the same thing as the Goto methods (see page 1595), except that you do not need to explicitly put the dataset in *dsSetKey* state to specify the key field values on which to search.

To execute a search using Find methods

1. Specify the index to use for the search. This is the same index that sorts the records in the dataset (see page 1609). To specify the index, use the *IndexName* or *IndexFieldNames* property.
2. Open the dataset.
3. Search for and move to the first or nearest record with *FindKey* or *FindNearest*. Both methods take a single parameter, a comma-delimited list of field values, where each value corresponds to an indexed column in the underlying table.

   Note: *FindNearest* can only be used for string fields.

FindKey

FindKey

FindNearest

FindNearest

3.2.3.6.18 Executing a Search with Goto Methods

To execute a search using Goto methods

1. Specify the index to use for the search. This is the same index that sorts the records in the dataset (see page 1609). To specify the index, use the *IndexName* or *IndexFieldNames* property.
2. Open the dataset.
3. Put the dataset in *dsSetKey* state by calling the *SetKey* method.
4. Specify the value(s) to search on in the Fields property. *Fields* is a *TFields* object, which maintains an indexed list of field components you can access by specifying ordinal numbers corresponding to columns. The first column number in a dataset is 0.
5. Search for and move to the first matching record found with *GotoKey* or *GotoNearest*.

For example, the following code, attached to a button's *OnClick* event, uses the *GotoKey* method to move to the first record where the first field in the index has a value that exactly matches the text in an edit box:

```
procedure TSearchDemo.SearchExactClick(Sender: TObject);
begin
  ClientDataSet1.SetKey;
  ClientDataSet1.Fields[0].AsString := Edit1.Text;
  if not ClientDataSet1.GotoKey then
    ShowMessage('Record not found');
end;
void __fastcall TSearchDemo::SearchExactClick(TObject *Sender)
{
  ClientDataSet1->SetKey();
  ClientDataSet1->Fields->Fields[0]->AsString = Edit1->Text;
  if (!ClientDataSet1->GotoKey())
    ShowMessage("Record not found");
}
```

GotoNearest is similar. It searches for the nearest match to a partial field value. It can be used only for string fields. For example,

```
Table1.SetKey;
Table1.Fields[0].AsString := 'Sm';
Table1.GotoNearest;
Table1->SetKey();
Table1->Fields->Fields[0]->AsString = "Sm";
Table1->GotoNearest();
```

If a record exists with "Sm" as the first two characters of the first indexed field's value, the cursor is positioned on that record. Otherwise, the position of the cursor does not change and *GotoNearest* returns *False*.

3.2.3.6.19 Executing Queries That Don't Return a Result Set

When a query returns a set of records (such as a SELECT query), you execute the query the same way you populate any dataset with records: by setting *Active* to *True* or calling the *Open* method.

However, often SQL commands do not return any records. Such commands include statements that use Data Definition Language (DDL) or Data Manipulation Language (DML) statements other than SELECT statements (For example, INSERT, DELETE, UPDATE, CREATE INDEX, and ALTER TABLE commands do not return any records).

For all query-type datasets, you can execute a query that does not return a result set by calling *ExecSQL*:

```
CustomerQuery.ExecSQL;  { query does not return a result set }
CustomerQuery->ExecSQL(); // Does not return a result set
```

Tip: If you are executing the query multiple times, it is a good idea to set the *Preparedproperty to True.*

Although the query does not return any records, you may want to know the number of records it affected (for example, the number of records deleted by a DELETE query). The RowsAffected property gives the number of affected records after a call to ExecSQL.

Tip: *When you do not know at design time whether the query returns a result set (for example, if the user supplies the query dynamically at runtime), you can code both types of query execution statements in a* ***try...except*** *block. Put a call to the Open method in the* ***try*** *clause. An action query is executed when the query is activated with the Open method, but an exception occurs in addition to that. Check the exception, and suppress it if it merely indicates the lack of a result set. (For example, TQuery indicates this by an ENoResultSet exception.)*

3.2.3.6.20 Executing Stored Procedures That Don't Return a Result Set

When a stored procedure returns a cursor, you execute it the same way you populate any dataset with records: by setting *Active* to *True* or calling the *Open* method.

However, often stored procedures do not return any data, or only return results in output parameters. You can execute a stored procedure that does not return a result set by calling *ExecProc*. After executing the stored procedure, you can use the *ParamByName* method to read the value of the result parameter or of any output parameters:

```
MyStoredProcedure.ExecProc;  { does not return a result set }
Edit1.Text := MyStoredProcedure.ParamByName('OUTVAR').AsString;
MyStoredProcedure->ExecProc(); // Does not return a result set
Edit1->Text = MyStoredProcedure->ParamByName("OUTVAR")->AsString;
```

Note: *TADOStoredProc* does not have a *ParamByName* method. To obtain output parameter values when using ADO, access parameter objects using the *Parameters* property.

Tip: If you are executing the procedure multiple times, it is a good idea to set the *Prepared* property to *True*.

See Also

Fetching Multiple Result Sets (see page 1597)

Preparing Stored Procedures (see page 1607)

Working with Stored Procedure Parameters (see page 1625)

3.2.3.6.21 Fetching Multiple Result Sets

Some stored procedures return multiple sets of records. The dataset only fetches the first set when you open it. If you are using *TSQLStoredProc* or *TADOStoredProc*, you can access the other sets of records by calling the *NextRecordSet* method:

```
var
  DataSet2: TCustomSQLDataSet;
begin
  DataSet2 := SQLStoredProc1.NextRecordSet;
  ...
TCustomSQLDataSet *DataSet2 = SQLStoredProc1->NextRecordSet();
```

In *TSQLStoredProc, NextRecordSet* returns a newly created *TCustomSQLDataSet* component that provides access to the next set of records. In *TADOStoredProc*, *NextRecordset* returns an interface that can be assigned to the *RecordSet* property of an existing ADO dataset. For either class, the method returns the number of records in the returned dataset as an output parameter.

The first time you call *NextRecordSet*, it returns the second set of records. Calling *NextRecordSet* again returns a third dataset, and so on, until there are no more sets of records. When there are no additional cursors, *NextRecordSet* returns **nil**.

Working with Stored Procedure Parameters (see page 1625)

3.2.3.6.22 Limiting Records with Ranges

You can temporarily view and edit a subset of data for any dataset by using filters (see page 1631). Some table type datasets support an additional way to access a subset of available records, called ranges.

Ranges only apply to *TTable* and to client datasets. Despite their similarities, ranges and filters have different uses. The following topics discuss the differences between ranges and filters and how to use ranges:

- Understanding the differences between ranges and filters (see page 1615)
- Specifying ranges (see page 1610)
- Modifying a range (see page 1601)
- Applying or canceling a range (see page 1585)

Creating and Deleting Tables (see page 1587)

Emptying Tables (see page 1592)

Synchronizing Tables (see page 1614)

3.2.3.6.23 Making the Table a Detail of Another Dataset

A table type dataset's *MasterSource* and *MasterFields* properties can be used to establish one-to-many relationships between two datasets.

The *MasterSource* property is used to specify a data source from which the table gets data from the master table. This data source can be linked to any type of dataset. For instance, by specifying a query's data source in this property, you can link a client dataset as the detail of the query, so that the client dataset tracks events occurring in the query.

The dataset is linked to the master table based on its current index. Before you specify the fields in the master dataset that are tracked by the detail dataset, first specify the index in the detail dataset that starts with the corresponding fields. You can use either the *IndexName* or the *IndexFieldNames* property.

Once you specify the index to use, use the *MasterFields* property to indicate the column(s) in the master dataset that correspond to the index fields in the detail table. To link datasets on multiple column names, separate field names with semicolons:

```
Parts.MasterFields := 'OrderNo;ItemNo';
Parts->MasterFields = "OrderNo;ItemNo";
```

To help create meaningful links between two datasets, you can use the Field Link designer. To use the Field Link designer, double click on the *MasterFields* property in the **Object Inspector** after you have assigned a *MasterSource* and an index.

The following steps create a simple form in which a user can scroll through customer records and display all orders for the current customer. The master table is the CustomersTable table, and the detail table is OrdersTable. The example uses the BDE-based TTable component, but you can use the same methods to link any table type datasets.

To create a simple form

1. Place two *TTable* components and two *TDataSource* components in a data module.
2. Set the properties of the following components,

Component	Property
First *TTable*	*DatabaseName*: DBDEMOS *TableName*: CUSTOMER *Name*: CustomersTable
Second *TTable*	*DatabaseName*: DBDEMOS *TableName*: ORDERS *Name*: OrdersTable
First *TDataSource*	*Name*: CustSource *DataSet*: CustomersTable
Second *TDataSource*	*Name*: OrdersSource *DataSet*: OrdersTable

3. Place two *TDBGrid* components on a form.
4. Choose **File** ▸ **Use Unit** to specify that the form should use the data module.
5. Set the DataSource property of the first grid component to "CustSource", and set the *DataSource* property of the second grid to "OrdersSource".
6. Set the MasterSource property of *OrdersTable* to "CustSource". This links the CUSTOMER table (the master table) to the ORDERS table (the detail table).
7. Double-click the MasterFields property value box in the **Object Inspector** to invoke the Field Link Designer to set the following properties:

- In the Available Indexes field, choose *CustNo* to link the two tables by the *CustNo* field.
- Select *CustNo* in both the Detail Fields and Master Fields field lists.
- Click the Add button to add this join condition. In the Joined Fields list,"CustNo -> CustNo" appears.

- Choose OK to commit your selections and exit the Field Link Designer.

8. Set the Active properties of *CustomersTable* and *OrdersTable* to *True* to display data in the grids on the form.
9. Compile and run the application.

If you run the application now, you will see that the tables are linked together, and that when you move to a new record in the CUSTOMER table, you see only those records in the ORDERS table that belong to the current customer.

3.2.3.6.24 Marking and Returning to Records

In addition to moving from record to record in a dataset (or moving from one record to another by a specific number of records), it is often also useful to mark a particular location in a dataset so that you can return to it quickly when desired. TDataSet introduces a bookmarking feature that consists of a Bookmark property and five bookmark methods.

TDataSet implements **virtual** bookmark methods. While these methods ensure that any dataset object derived from *TDataSet* returns a value if a bookmark method is called, the return values are merely defaults that do not keep track of the current location. *TDataSet* descendants vary in the level of support they provide for bookmarks. None of the dbExpress datasets add any support for bookmarks. ADO datasets can support bookmarks, depending on the underlying database tables. BDE datasets, InterBase express datasets, and client datasets always support bookmarks.

The Bookmark property

The *Bookmark* property indicates which bookmark among any number of bookmarks in your application is current. *Bookmark* is a string that identifies the current bookmark. Each time you add another bookmark, it becomes the current bookmark.

The GetBookmark method

To create a bookmark, you must declare a variable of type *TBookmark* in your application, then call GetBookmark to allocate storage for the variable and set its value to a particular location in a dataset. The *TBookmark* type is a Pointer.

The GotoBookmark and BookmarkValid methods

When passed a bookmark, *GotoBookmark* moves the cursor for the dataset to the location specified in the bookmark. Before calling *GotoBookmark*, you can call *BookmarkValid to determine if the bookmark points to a record. BookmarkValid returns True*

if a specified bookmark points to a record.

The CompareBookmarks method

You can also call *CompareBookmarks to see if a bookmark you want to move to is different from another (or the current) bookmark. If the two bookmarks refer to the same record (or if both are* ***nil****), CompareBookmarks returns 0.*

The FreeBookmark method

FreeBookmark frees the memory allocated for a specified bookmark when you no longer need it. You should also call FreeBookmark before reusing an existing bookmark.

A bookmarking example

The following code illustrates one use of bookmarking:

```
procedure DoSomething (const Tbl: TTable)
var
  Bookmark: TBookmark;
begin
  Bookmark := Tbl.GetBookmark; { Allocate memory and assign a value }
  Tbl.DisableControls; { Turn off display of records in data controls }
  try
    Tbl.First; { Go to first record in table }
    while not Tbl.Eof do {Iterate through each record in table }
    begin
      { Do your processing here }
      .
      .
      .
      Tbl.Next;
    end;
  finally
    Tbl.GotoBookmark(Bookmark);
    Tbl.EnableControls; { Turn on display of records in data controls, if necessary }
    Tbl.FreeBookmark(Bookmark); {Deallocate memory for the bookmark }
  end;
end;
void DoSomething (const TTable *Tbl)
{
  TBookmark Bookmark = Tbl->GetBookmark(); // Allocate memory and assign a value
  Tbl->DisableControls(); // Turn off display of records in data controls
  try
  {
    for (Tbl->First(); !Tbl->Eof; Tbl->Next()) // Iterate through each record in table
    {
      // Do your processing here
      .
      .
      .
    }
  }
  __finally
  {
    Tbl->GotoBookmark(Bookmark);
    Tbl->EnableControls(); // Turn on display of records in data controls
    Tbl->FreeBookmark(Bookmark); // Deallocate memory for the bookmark
  }
}
```

Before iterating through records, controls are disabled. Should an error occur during iteration through records, the **finally** clause ensures that controls are always enabled and that the bookmark is always freed even if the loop terminates prematurely.

3.2.3.6.25 Modifying a Range

Two functions enable you to modify the existing boundary conditions for a range: *EditRangeStart*, for changing the starting values for a range; and *EditRangeEnd*, for changing the ending values for the range.

To edit and apply a range

1. Putting the dataset into *dsSetKey* state and modifying the starting index value for the range.
2. Modifying the ending index value for the range.
3. Applying the range to the dataset.

You can modify either the starting or ending values of the range, or you can modify both boundary conditions. If you modify the boundary conditions for a range that is currently applied to the dataset, the changes you make are not applied until you call *ApplyRange* again.

Editing the start of a range

Call the *EditRangeStart* procedure to put the dataset into *dsSetKey* state and begin modifying the current list of starting values for the range. Once you call *EditRangeStart*, subsequent assignments to the Fields property overwrite the current index values to use when applying the range.

Tip: If you initially created a start range based on a partial key, you can use *EditRangeStart* to extend the starting value for a range.

Editing the end of a range

Call the *EditRangeEnd* procedure to put the dataset into *dsSetKey* state and start creating a list of ending values for the range. Once you call *EditRangeEnd*, subsequent assignments to the Fields property are treated as ending index values to use when applying the range.

3.2.3.6.26 Modifying Entire Records

On forms, all data-aware controls except for grids and the navigator provide access to a single field in a record.

In code, however, you can use the following methods that work with entire record structures provided that the structure of the

database tables underlying the dataset is stable and does not change. The following table summarizes the methods available for working with entire records rather than individual fields in those records:

Methods that work with entire records

Method	Description
AppendRecord([array of values])	Appends a record with the specified column values at the end of a table; analogous to *Append*. Performs an implicit Post.
InsertRecord([array of values])	Inserts the specified values as a record before the current cursor position of a table; analogous to *Insert*. Performs an implicit *Post*.
SetFields([array of values])	Sets the values of the corresponding fields; analogous to assigning values to *TField*s. The application must perform an explicit *Post*.

These method take an array of values as an argument, where each value corresponds to a column in the underlying dataset. The values can be literals, variables, or NULL. If the number of values in an argument is less than the number of columns in a dataset, then the remaining values are assumed to be NULL.

For unindexed datasets, AppendRecord adds a record to the end of the dataset and InsertRecord inserts a record after the current cursor position. For indexed datasets, both methods place the record in the correct position in the table, based on the index. In both cases, the methods move the cursor to the record's position.

SetFields assigns the values specified in the array of parameters to fields in the dataset. To use *SetFields*, an application must first call Edit to put the dataset in *dsEdit* mode. To apply the changes to the current record, it must perform a Post.

If you use *SetFields* to modify some, but not all fields in an existing record, you can pass NULL values for fields you do not want to change. If you do not supply enough values for all fields in a record, *SetFields* assigns NULL values to them. NULL values overwrite any existing values already in those fields.

For example, suppose a database has a COUNTRY table with columns for Name, Capital, Continent, Area, and Population. If a TTable component called *CountryTable* were linked to the COUNTRY table, the following statement would insert a record into the COUNTRY table:

```
CountryTable.InsertRecord(['Japan', 'Tokyo', 'Asia']);
CountryTable->InsertRecord(ARRAYOFCONST(("Japan", "Tokyo", "Asia")));
```

This statement does not specify values for Area and Population, so NULL values are inserted for them. The table is indexed on Name, so the statement would insert the record based on the alphabetic collation of "Japan".

To update the record, an application could use the following code:

```
with CountryTable do
begin
  if Locate('Name', 'Japan', loCaseInsensitive) then;
  begin
    Edit;
    SetFields(nil, nil, nil, 344567, 164700000);
    Post;
  end;
end;
TLocateOptions SearchOptions;
SearchOptions->Clear();
SearchOptions << loCaseInsensitive;
if (CountryTable->Locate("Name", "Japan", SearchOptions))
{
  CountryTable->Edit();
  CountryTable->SetFields(ARRAYOFCONST(((void *)NULL, (void *)NULL, (void *)NULL,
        344567, 164700000)));
  CountryTable->Post();
}
```

This code assigns values to the Area and Population fields and then posts them to the database. The three NULL pointers act as

place holders for the first three columns to preserve their current contents.

3.2.3.6.27 Navigating Records in a Filtered Dataset

There are four dataset methods that navigate among records in a filtered dataset. The following table lists these methods and describes what they do:

Filtered dataset navigational methods

Method	Purpose
FindFirst	Move to the first record that matches the current filter criteria. The search for the first matching record always begins at the first record in the unfiltered dataset.
FindLast	Move to the last record that matches the current filter criteria.
FindNext	Moves from the current record in the filtered dataset to the next one.
FindPrior	Move from the current record in the filtered dataset to the previous one.

For example, the following statement finds the first filtered record in a dataset:

```
DataSet1.FindFirst;
DataSet1->FindFirst();
```

Provided that you set the Filter property or create an OnFilterRecord event handler for your application, these methods position the cursor on the specified record regardless of whether filtering is currently enabled. If you call these methods when filtering is not enabled, then they

- Temporarily enable filtering.
- Position the cursor on a matching record if one is found.
- Disable filtering.

  Note: If filtering is disabled and you do not set the *Filter* property or create an *OnFilterRecord* event handler, these methods do the same thing as *First*, *Last*, *Next*, and *Prior*.

  All navigational filter methods position the cursor on a matching record (if one is found), make that record the current one, and return *True*. If a matching record is not found, the cursor position is unchanged, and these methods return False. You can check the status of the Found property to wrap these calls, and only take action when *Found* is *True*. For example, if the cursor is already on the last matching record in the dataset and you call FindNext, the method returns *False*, and the current record is unchanged.

Enabling and Disabling Filtering (see page 1593)

Navigating Datasets (see page 1634)

3.2.3.6.28 Obtaining Information About Indexes

Your application can obtain information about server-defined indexes from all table type datasets. To obtain a list of available

indexes for the dataset, call the *GetIndexNames* method. *GetIndexNames* fills a string list with valid index names. For example, the following code fills a listbox with the names of all indexes defined for the *CustomersTable* dataset:

```
CustomersTable.GetIndexNames(ListBox1.Items);
CustomersTable->GetIndexNames(ListBox1->Items);
```

Note: For Paradox tables, the primary index is unnamed, and is therefore not returned by *GetIndexNames*. You can still change the index back to a primary index on a Paradox table after using an alternative index, however, by setting the *IndexName* property to a blank string.

To obtain information about the fields of the current index, use the

- *IndexFieldCount* property, to determine the number of columns in the index.
- *IndexFields* property, to examine a list the field components for the columns that comprise the index.

The following code illustrates how you might use *IndexFieldCount* and *IndexFields* to iterate through a list of column names in an application:

```
var
  I: Integer;
  ListOfIndexFields: array[0 to 20} of string;
begin
with CustomersTable do
  begin
  for I := 0 to IndexFieldCount - 1 do
     ListOfIndexFields[I] := IndexFields[I].FieldName;
  end;
end;
AnsiString ListOfIndexFields[20];
for (int i = 0; i < CustomersTable->IndexFieldCount; i++)
  ListOfIndexFields[i] = CustomersTable->IndexFields[i]->FieldName;
```

Note: *IndexFieldCount* is not valid for a dBASE table opened on an expression index.

3.2.3.6.29 Opening and Closing Datasets

To read or write data in a dataset, an application must first open it. You can open a dataset in two ways:

Open Method	Sample Code
Set theActiveproperty of the dataset to *True*, either at design time in the **Object Inspector**, or in code at runtime.	CustTable.Active := True; CustTable->Active = true;
Call the Open method for the dataset at runtime.	CustQuery.Open; CustQuery->Open();

When you open the dataset, the dataset first receives a BeforeOpen event, then it opens a cursor, populating itself with data, and finally, it receives an AfterOpen event.

The newly-opened dataset is in browse mode, which means your application can read the data and navigate through it.

You can close a dataset in two ways:

Close Method	Sample Code
Set the *Active* property of the dataset to *False*, either at design time in the **Object Inspector**, or in code at runtime.	CustQuery.Active := False; CustQuery->Active = false;
Call the Close method for the dataset at runtime.	CustTable.Close; CustTable->Close();

Just as the dataset receives *BeforeOpen* and *AfterOpen* events when you open it, it receives a BeforeClose and AfterClose event when you close it. You can use these events, for example, to prompt the user to post pending changes or cancel them before closing the dataset. The following code illustrates such a handler:

```
procedure TForm1.CustTableVerifyBeforeClose(DataSet: TDataSet);
begin
  if (CustTable.State in [dsEdit, dsInsert]) then begin
    case MessageDlg('Post changes before closing?', mtConfirmation, mbYesNoCancel, 0) of
      mrYes:    CustTable.Post;   { save the changes }
      mrNo:     CustTable.Cancel; { abandon the changes}
      mrCancel: Abort;            { abort closing the dataset }
    end;
  end;
end;
void __fastcall TForm1::VerifyBeforeClose(TDataSet *DataSet)
{
if (DataSet->State == dsEdit || DataSet->State == dsInsert)
{
TMsgDlgButtons btns;
btns << mbYes << mbNo;
    if (MessageDlg("Post changes before closing?", mtConfirmation, btns, 0) == mrYes)
DataSet->Post();
else
DataSet->Cancel();
}
}
```

Note: You may need to close a dataset when you want to change certain of its properties, such as TableName on a TTable component. When you reopen the dataset, the new property value takes effect.

Using TDataSet Descendants (see page 1619)

3.2.3.6.30 Posting Data

After you finish editing a record, you must call the Post method to write out your changes. The *Post* method behaves differently, depending on the dataset's state and on whether you are caching updates.

- If you are not caching updates, and the dataset is in the *dsEdit* or *dsInsert* state, *Post* writes the current record to the database and returns the dataset to the *dsBrowse* state.
- If you are caching updates, and the dataset is in the *dsEdit* or *dsInsert* state, *Post* writes the current record to an internal cache and returns the dataset to the *dsBrowse* state. The edits are not written to the database until you call *ApplyUpdates*.
- If the dataset is in the *dsSetKey* state, *Post* returns the dataset to the *dsBrowse* state.

Regardless of the initial state of the dataset, *Post* generates *BeforePost* and *AfterPost* events, before and after writing the current changes. You can use these events to update the user interface, or prevent the dataset from posting changes by calling the *Abort* procedure. If the call to *Post* fails, the dataset receives an *OnPostError* event, where you can inform the user of the problem or attempt to correct it.

Posting can be done explicitly, or implicitly as part of another procedure. When an application moves off the current record, *Post* is called implicitly. Calls to the First, Next, Prior, and Last methods perform a *Post* if the table is in *dsEdit* or *dsInsert* modes. The Append and Insert methods also implicitly post any pending data.

Warning: The Close method does not call *Post* implicitly. Use the BeforeClose event to post any pending edits explicitly.

3.2.3.6.31 Preparing Queries

Preparing a query is an optional step that precedes query execution. Preparing a query submits the SQL statement and its parameters, if any, to the data access layer and the database server for parsing, resource allocation, and optimization. In some datasets, the dataset may perform additional setup operations when preparing the query. These operations improve query performance, making your application faster, especially when working with updatable queries.

An application can prepare a query by setting the *Prepared* property to *True*. If you do not prepare a query before executing it, the dataset automatically prepares it for you each time you call *Open* or *ExecSQL*. Even though the dataset prepares queries for you, you can improve performance by explicitly preparing the dataset before you open it the first time.

```
CustQuery.Prepared := True;
CustQuery->Prepared = true;
```

When you explicitly prepare the dataset, the resources allocated for executing the statement are not freed until you set *Prepared* to *False*.

Set the *Prepared* property to *False* if you want to ensure that the dataset is re-prepared before it executes (for example, if you add a parameter).

Note: When you change the text of the *SQL* property for a query, the dataset automatically closes and unprepares the query.

See Also

Establishing Master/detail Relationships Using Parameters (see page 1593)

Executing Queries That Don't Return a Result Set (see page 1596)

Using Unidirectional Result Sets (see page 1624)

3.2.3.6.32 Preparing Stored Procedures

As with query-type datasets, stored procedure-type datasets must be prepared before they execute the stored procedure. Preparing a stored procedure tells the data access layer and the database server to allocate resources for the stored procedure and to bind parameters. These operations can improve performance.

If you attempt to execute a stored procedure before preparing it, the dataset automatically prepares it for you, and then unprepares it after it executes. If you plan to execute a stored procedure a number of times, it is more efficient to explicitly prepare it by setting the *Prepared* property to *True*.

```
MyProc.Prepared := True;
MyProc->Prepared = true;
```

When you explicitly prepare the dataset, the resources allocated for executing the stored procedure are not freed until you set *Prepared* to *False*.

Set the *Prepared* property to *False* if you want to ensure that the dataset is re-prepared before it executes (for example, if you change the parameters when using Oracle overloaded procedures).

Working with Stored Procedure Parameters (see page 1625)

3.2.3.6.33 Searching On Partial Keys

Each time you call *SetKey* or *FindKey*, the method clears any previous values in the *Fields* property. If you want to repeat a search using previously set fields, or you want to add to the fields used in a search, call *EditKey* in place of *SetKey* and *FindKey*.

For example, suppose you have already executed a search of the Employee table based on the City field of the "CityIndex" index. Suppose further that "CityIndex" includes both the *City* and *Company* fields. To find a record with a specified company name in a specified city, use the following code:

```
Employee.KeyFieldCount := 2;
Employee.EditKey;
Employee['Company'] := Edit2.Text;
Employee.GotoNearest;
Employee->KeyFieldCount = 2;
Employee->EditKey();
Employee->FieldValues["Company"] = Variant(Edit2->Text);
Employee->GotoNearest();
```

Specifying the Current Record After a Successful Search (see page 1612)

Searching on Partial Keys (see page 1608)

3.2.3.6.34 Searching On Partial Keys

If the dataset has more than one key column, and you want to search for values in a subset of that key, set *KeyFieldCount* to the number of columns on which you are searching. For example, if the dataset's current index has three columns, and you want to search for values using just the first column, set *KeyFieldCount* to 1.

For table type datasets with multiple-column keys, you can search only for values in contiguous columns, beginning with the first. For example, for a three-column key you can search for values in the first column, the first and second, or the first, second, and third, but not just the first and third.

3.2.3.6.35 Setting Filter Options

The FilterOptions property lets you specify whether a filter that compares string-based fields accepts records based on partial comparisons and whether string comparisons are case-sensitive. *FilterOptions* is a set property that can be an empty set (the default), or that can contain either or both of the following values:

FilterOptions values

Value	Meaning
foCaseInsensitive	Ignore case when comparing strings.
foNoPartialCompare	Disable partial string matching; that is, don't match strings that end with an asterisk (*).

For example, the following statements set up a filter that ignores case when comparing values in the *State* field:

```
FilterOptions := [foCaseInsensitive];
Filter := 'State = ' + QuotedStr('CA');
TFilterOptions FilterOptions;
FilterOptions->Clear();
FilterOptions << foCaseInsensitive;
Table1->FilterOptions = FilterOptions;
Table1->Filter = "State = "CA"";
```

See Also

Creating Filters (see page 1590)

3.2.3.6.36 Setting the Filter Property

To create a filter using the Filter property, set the value of the property to a string that contains the filter's test condition. For example, the following statement creates a filter that tests a dataset's *State* field to see if it contains a value for the state of California:

```
Dataset1.Filter := 'State = ' + QuotedStr('CA');
Dataset1->Filter = "State = 'CA'";
```

You can also supply a value for *Filter* based on text supplied by the user. For example, the following statement assigns the text in from edit box to *Filter*:

```
Dataset1.Filter := Edit1.Text;
Dataset1->Filter = Edit1->Text;
```

You can, of course, create a string based on both hard-coded text and user-supplied data:

```
Dataset1.Filter := 'State = ' + QuotedStr(Edit1.Text);
Dataset1->Filter = AnsiString("State = '") + Edit1->Text + "'";
```

Blank field values do not appear unless they are explicitly included in the filter:

```
Dataset1.Filter := 'State <> ''CA'' or State = BLANK';
Dataset1->Filter = "State <> 'CA' or State = BLANK";
```

Note: After you specify a value for *Filter*, to apply the filter to the dataset, set the Filtered property to *True*.

Filters can compare field values to literals and to constants using the following comparison and logical operators:

Comparison and logical operators that can appear in a filter

Operator	Meaning
<	Less than
>	Greater than
>=	Greater than or equal to
<=	Less than or equal to
=	Equal to
<>	Not equal to
AND	Tests two statements are both *True*
NOT	Tests that the following statement is not *True*
OR	Tests that at least one of two statements is *True*
+	Adds numbers, concatenates strings, adds numbers to date/time values (only available for some drivers)
-	Subtracts numbers, subtracts dates, or subtracts a number from a date (only available for some drivers)
*	Multiplies two numbers (only available for some drivers)
/	Divides two numbers (only available for some drivers)
*	wildcard for partial comparisons (*FilterOptions* must include *foPartialCompare*)

By using combinations of these operators, you can create fairly sophisticated filters. For example, the following statement checks to make sure that two test conditions are met before accepting a record for display:

```
(Custno > 1400) AND (Custno < 1500);
```

Note: When filtering is on, user edits to a record may mean that the record no longer meets a filter's test conditions. The next time the record is retrieved from the dataset, it may therefore "disappear." If that happens, the next record that passes the filter condition becomes the current record.

See Also

Writing an OnFilterRecord Event Handler (see page 1635)

3.2.3.6.37 Sorting Records with Indexes

An index determines the display order of records in a table. Typically, records appear in ascending order based on a primary, or default, index. This default behavior does not require application intervention. If you want a different sort order, however, you must specify either

- An alternate index.

- A list of columns on which to sort (not available on servers that aren't SQL-based).

Indexes let you present the data from a table in different orders. On SQL-based tables, this sort order is implemented by using the index to generate an ORDER BY clause in a query that fetches the table's records. On other tables (such as Paradox and dBASE tables), the index is used by the data access mechanism to present records in the desired order.

The following topics provide details on how to obtain information about available indexes and how to specify which index the dataset uses to sort records:

- Obtaining Information about Indexes (see page 1603)
- Specifying an Index with IndexName (see page 1630)
- Creating an Index with IndexFieldNames (see page 1581)

See Also

Using Indexes to Search for Records (see page 1615)

Controlling Read/Write Access to Tables (see page 1587)

Creating and Deleting Tables (see page 1587)

Emptying Tables (see page 1592)

Synchronizing Tables (see page 1614)

3.2.3.6.38 Specifying Ranges

There are two mutually exclusive ways to specify a range:

- Specify the beginning and ending separately using *SetRangeStart* and *SetRangeEnd*.
- Specify both endpoints at once using *SetRange*.

Setting the beginning of a range

Call the *SetRangeStart* procedure to put the dataset into *dsSetKey* state and begin creating a list of starting values for the range. Once you call *SetRangeStart*, subsequent assignments to the Fields property are treated as starting index values to use when applying the range. Fields specified must apply to the current index.

For example, suppose your application uses a *TSimpleDataSet* component named *Customers*, linked to the CUSTOMER table, and that you have created persistent field components for each field in the *Customers* dataset. CUSTOMER is indexed on its first column (*CustNo*). A form in the application has two edit components named *StartVal* and *EndVal*, used to specify start and ending values for a range. The following code can be used to create and apply a range:

```
with Customers do
begin
  SetRangeStart;
  FieldByName('CustNo').AsString := StartVal.Text;
  SetRangeEnd;
  if (Length(EndVal.Text) > 0) then
    FieldByName('CustNo').AsString := EndVal.Text;
  ApplyRange;
end;
Customers->SetRangeStart();
Customers->FieldValues["CustNo"] = StrToInt(StartVal->Text);
Customers->SetRangeEnd();
if (!EndVal->Text.IsEmpty())
  Customers->FieldValues["CustNo"] = StrToInt(EndVal->Text);
Customers->ApplyRange();
```

This code checks that the text entered in *EndVal* is not null before assigning any values to *Fields*. If the text entered for *StartVal*

is null, then all records from the beginning of the dataset are included, since all values are greater than null. However, if the text entered for *EndVal* is null, then no records are included, since none are less than null.

For a multi-column index, you can specify a starting value for all or some fields in the index. If you do not supply a value for a field used in the index, a null value is assumed when you apply the range. If you try to set a value for a field that is not in the index, the dataset raises an exception.

Tip: To start at the beginning of the dataset, omit the call to *SetRangeStart*.

To finish specifying the start of a range, call *SetRangeEnd* or apply or cancel the range (see page 1585).

Setting the end of a range

Call the *SetRangeEnd* procedure to put the dataset into *dsSetKey* state and start creating a list of ending values for the range. Once you call *SetRangeEnd*, subsequent assignments to the Fields property are treated as ending index values to use when applying the range. Fields specified must apply to the current index.

Warning: Always specify the ending values for a range, even if you want a range to end on the last record in the dataset. If you do not provide ending values, Delphi assumes the ending value of the range is a null value. A range with null ending values is always empty.

The easiest way to assign ending values is to call the *FieldByName method. For example,*

```
with Contacts do
begin
  SetRangeStart;
  FieldByName('LastName').AsString := Edit1.Text;
  SetRangeEnd;
  FieldByName('LastName').AsString := Edit2.Text;
  ApplyRange;
end;
Contacts->SetRangeStart();
Contacts->FieldByName("LastName")->Value = Edit1->Text;
Contacts->SetRangeEnd();
Contacts->FieldByName("LastName")->Value = Edit2->Text;
Contacts->ApplyRange();
```

As with specifying start of range values, if you try to set a value for a field that is not in the index, the dataset raises an exception.

To finish specifying the end of a range, apply or cancel the range (see page 1585).

Setting start- and end-range values

Instead of using separate calls to *SetRangeStart* and *SetRangeEnd* to specify range boundaries, you can call the *SetRange* procedure to put the dataset into *dsSetKey* state and set the starting and ending values for a range with a single call.

SetRange takes two constant array parameters: a set of starting values, and a set of ending values. For example, the following statement establishes a range based on a two-column index:

```
SetRange([Edit1.Text, Edit2.Text], [Edit3.Text, Edit4.Text]);
TVarRec StartVals[2];
TVarRec EndVals[2];
StartVals[0] = Edit1->Text;
StartVals[1] = Edit2->Text;
EndVals[0] = Edit3->Text;
EndVals[1] = Edit4->Text;
Table1->SetRange(StartVals, 1, EndVals, 1);
```

For a multi-column index, you can specify starting and ending values for all or some fields in the index. If you do not supply a value for a field used in the index, a null value is assumed when you apply the range. To omit a value for the first field in an index, and specify values for successive fields, pass a null value for the omitted field.

Always specify the ending values for a range, even if you want a range to end on the last record in the dataset. If you do not provide ending values, the dataset assumes the ending value of the range is a null value. A range with null ending values is

always empty because the starting range is greater than or equal to the ending range.

Specifying a range based on partial keys

If a key is composed of one or more string fields, the *SetRange* methods support partial keys. For example, if an index is based on the *LastName* and *FirstName* columns, the following range specifications are valid:

```
Contacts.SetRangeStart;
Contacts['LastName'] := 'Smith';
Contacts.SetRangeEnd;
Contacts['LastName'] := 'Zzzzzz';
Contacts.ApplyRange;
Contacts->SetRangeStart();
Contacts->FieldValues["LastName"] = "Smith";
Contacts->SetRangeEnd();
Contacts->FieldValues["LastName"] = "Zzzzzz";
Contacts->ApplyRange();
```

This code includes all records in a range where *LastName* is greater than or equal to "Smith." The value specification could also be:

```
Contacts['LastName'] := 'Sm';
Contacts->FieldValues["LastName"] = "Sm";
```

This statement includes records that have *LastName* greater than or equal to "Sm."

Including or excluding records that match boundary values

By default, a range includes all records that are greater than or equal to the specified starting range, and less than or equal to the specified ending range. This behavior is controlled by the *KeyExclusive* property. *KeyExclusive* is *False* by default.

If you prefer, you can set the *KeyExclusive* property for a dataset to *True* to exclude records equal to ending range. For example,

```
Contacts.KeyExclusive := True;
Contacts.SetRangeStart;
Contacts['LastName'] := 'Smith';
Contacts.SetRangeEnd;
Contacts['LastName'] := 'Tyler';
Contacts.ApplyRange;
Contacts->SetRangeStart();
Contacts->KeyExclusive = true;
Contacts->FieldValues["LastName"] = "Smith";
Contacts->SetRangeEnd();
Contacts->FieldValues["LastName"] = "Tyler";
Contacts->ApplyRange();
```

This code includes all records in a range where *LastName* is greater than or equal to "Smith" and less than "Tyler".

Applying or Canceling a Range (see page 1585)

Modifying a Range (see page 1601)

3.2.3.6.39 Specifying the Current Record After a Successful Search

By default, a successful search positions the cursor on the first record that matches the search criteria. If you prefer, you can set the *KeyExclusive* property to *True* to position the cursor on the next record after the first matching record.

By default, *KeyExclusive* is *False*, meaning that successful searches position the cursor on the first matching record.

Executing a Search with Find Methods (see page 1594)

Searching on Partial Keys (see page 1608)

Searching on Partial Keys (see page 1607)

3.2.3.6.40 Specifying the Query

For true query-type datasets, you use the *SQL* property to specify the SQL statement for the dataset to execute. Some datasets, such as *TADODataSet*, *TSQLDataSet,* and client datasets, use a *CommandText* property to accomplish the same thing.

Most queries that return records are SELECT commands. Typically, they define the fields to include, the tables from which to select those fields, conditions that limit what records to include, and the order of the resulting dataset. For example:

```
SELECT CustNo, OrderNo, SaleDate
FROM Orders
WHERE CustNo = 1225
ORDER BY SaleDate
```

Queries that do not return records include statements that use Data Definition Language (DDL) or Data Manipulation Language (DML) statements other than SELECT statements (For example, INSERT, DELETE, UPDATE, CREATE INDEX, and ALTER TABLE commands do not return any records). The language used in commands is server-specific, but usually compliant with the SQL-92 standard for the SQL language.

The SQL command you execute must be acceptable to the server you are using. Datasets neither evaluate the SQL nor execute it. They merely pass the command to the server for execution. In most cases, the SQL command must be only one complete SQL statement, although that statement can be as complex as necessary (for example, a SELECT statement with a WHERE clause that uses several nested logical operators such as AND and OR). Some servers also support "batch" syntax that permits multiple statements; if your server supports such syntax, you can enter multiple statements when you specify the query.

The SQL statements used by queries can be verbatim, or they can contain replaceable parameters. Queries that use parameters are called *parameterized queries*. When you use parameterized queries, the actual values assigned to the parameters are inserted into the query before you execute, or run, the query. Using parameterized queries is very flexible, because you can change a user's view of and access to data on the fly at runtime without having to alter the SQL statement. For more information about parameterized queries, see Using parameters in queries (see page 1617).

Specifying a query using the SQL property

When using a true query-type dataset *(TQuery, TADOQuery, TSQLQuery,* or *TIBQuery)*, assign the query to the *SQL* property. The *SQL* property is a *TStrings* object. Each separate string in this *TStrings* object is a separate line of the query. Using multiple lines does not affect the way the query executes on the server, but can make it easier to modify and debug the query if you divide the statement into logical units:

```
MyQuery.Close;
MyQuery.SQL.Clear;
MyQuery.SQL.Add('SELECT CustNo, OrderNO, SaleDate');
MyQuery.SQL.Add(' FROM Orders');
MyQuery.SQL.Add('ORDER BY SaleDate');
MyQuery.Open;
MyQuery->Close();
MyQuery->SQL->Clear();
MyQuery->SQL->Add("SELECT CustNo, OrderNO, SaleDate");
MyQuery->SQL->Add("FROM Orders");
MyQuery->SQL->Add("ORDER BY SaleDate");
MyQuery->Open();
```

The code below demonstrates modifying only a single line in an existing SQL statement. In this case, the ORDER BY clause already exists on the third line of the statement. It is referenced via the *SQL* property using an index of 2.

```
MyQuery.SQL[2] := 'ORDER BY OrderNo';
MyQuery->SQL->Strings[2] = "ORDER BY OrderNO";
```

Note: The dataset must be closed when you specify or modify the SQL property.

At design time, use the String List editor to specify the query. Click the ellipsis button by the *SQL* property in the **Object Inspector** to display the String List editor.

Note: With some versions of Delphi, if you are using *TQuery*, you can also use the SQL Builder to construct a query based on a visible representation of tables and fields in a database. To use the SQL Builder, select the query component, right-click it to invoke the context menu, and choose Graphical Query Editor. To learn how to use SQL Builder, open it and use its online help.

Because the *SQL* property is a *TStrings* object, you can load the text of the query from a file by calling the *TStrings*.*LoadFromFile* method:

```
MyQuery.SQL.LoadFromFile('custquery.sql');
MyQuery->SQL->LoadFromFile("custquery.sql");
```

You can also use the *Assign* method of the *SQL* property to copy the contents of a string list object into the *SQL* property. The *Assign* method automatically clears the current contents of the *SQL* property before copying the new statement:

```
MyQuery.SQL.Assign(Memo1.Lines);
MyQuery->SQL->Assign(Memo1->Lines);
```

Specifying a query using the CommandText property

When using *TADODataSet*, *TSQLDataSet,* or a client dataset, assign the text of the query statement to the *CommandText* property:

```
MyQuery.CommandText := 'SELECT CustName, Address FROM Customer';
MyQuery->CommandText = "SELECT CustName, Address FROM Customer";
```

At design time, you can type the query directly into the **Object Inspector**, or, if the dataset already has an active connection to the database, you can click the ellipsis button by the *CommandText* property to display the Command Text editor. The Command Text editor lists the available tables, and the fields in those tables, to make it easier to compose your queries.

3.2.3.6.41 Synchronizing Tables

If you have two or more datasets that represent the same database table but do not share a data source component, then each dataset has its own view on the data and its own current record. As users access records through each datasets, the components' current records will differ.

If the datasets are all instances of *TTable*, or all instances of *TIBTable*, or all client datasets, you can force the current record for each of these datasets to be the same by calling the *GotoCurrent* method. *GotoCurrent* sets its own dataset's current record to the current record of a matching dataset. For example, the following code sets the current record of *CustomerTableOne* to be the same as the current record of *CustomerTableTwo*:

```
CustomerTableOne.GotoCurrent(CustomerTableTwo);
CustomerTableOne->GotoCurrent(CustomerTableTwo);
```

Tip: If your application needs to synchronize datasets in this manner, put the datasets in a data module and add the unit for the data module to the uses clause of each unit that accesses the tables.

To synchronize datasets from separate forms, you must add one form's unit to the uses clause of the other, and you must

qualify at least one of the dataset names with its form name. For example:

```
CustomerTableOne.GotoCurrent(Form2.CustomerTableTwo);
CustomerTableOne->GotoCurrent(Form2->CustomerTableTwo);
```

3.2.3.6.42 Understanding the Differences Between Ranges and Filters

Both ranges and filters restrict visible records to a subset of all available records, but the way they do so differs. A range is a set of contiguously indexed records that fall between specified boundary values. For example, in an employee database indexed on last name, you might apply a range to display all employees whose last names are greater than "Jones" and less than "Smith". Because ranges depend on indexes, you must set the current index to one that can be used to define the range. As with specifying an index to sort records (see page 1609), you can assign the index on which to define a range using either the *IndexName* or the *IndexFieldNames* property.

A filter, on the other hand, is any set of records that share specified data points, regardless of indexing. For example, you might filter an employee database to display all employees who live in California and who have worked for the company for five or more years. While filters can make use of indexes if they apply, filters are not dependent on them. Filters are applied record-by-record as an application scrolls through a dataset.

In general, filters are more flexible than ranges. Ranges, however, can be more efficient when datasets are large and the records of interest to an application are already blocked in contiguously indexed groups. For very large datasets, it may be still more efficient to use the WHERE clause of a query-type dataset to select data. For details on specifying a query, see Using query-type datasets (see page 1618).

Applying or Canceling a Range (see page 1585)

Modifying a Range (see page 1601)

Displaying and Editing a Subset of Data Using Filters (see page 1631)

3.2.3.6.43 Using Indexes to Search for Records

You can search against any dataset using the Locate and Lookup methods of *TDataSet*. However, by explicitly using indexes, some table type datasets can improve over the searching performance provided by the *Locate* and *Lookup* methods.

ADO datasets all support the Seek method, which moves to a record based on a set of field values for fields in the current index. *Seek* lets you specify where to move the cursor relative to the first or last matching record.

TTable and all types of client dataset support similar indexed-based searches, but use a combination of related methods. The following table summarizes the six related methods provided by *TTable* and client datasets to support index-based searches:

Index-based search methods

Method	Purpose
EditKey	Preserves the current contents of the search key buffer and puts the dataset into *dsSetKey* state so your application can modify existing search criteria prior to executing a search.
FindKey	Combines the *SetKey* and *GotoKey* methods in a single method.
FindNearest	Combines the *SetKey* and *GotoNearest* methods in a single method.
GotoKey	Searches for the first record in a dataset that exactly matches the search criteria, and moves the cursor to that record if one is found.
GotoNearest	Searches on string-based fields for the closest match to a record based on partial key values, and moves the cursor to that record.
SetKey	Clears the search key buffer and puts the table into *dsSetKey* state so your application can specify new search criteria prior to executing a search.

GotoKey and *FindKey* are boolean functions that, if successful, move the cursor to a matching record and return *True*. If the search is unsuccessful, the cursor is not moved, and these functions return *False*.

GotoNearest and *FindNearest* always reposition the cursor either on the first exact match found or, if no match is found, on the first record that is greater than the specified search criteria.

The following topics discuss the Goto and Find methods in greater detail:

- Executing a Search with Goto Methods (see page 1595)
- Executing a Search with Find Methods (see page 1594)
- Specifying the Current Record After a Successful Search (see page 1612)
- Searching on Partial Keys (see page 1608)
- Repeating or Extending a Search (see page 1607)

3.2.3.6.44 Using Nested Detail Tables

A nested table is a detail dataset that is the value of a single dataset field in another (master) dataset. For datasets that represent server data, a nested detail dataset can only be used for a dataset field on the server. *TClientDataSet* components do not represent server data, but they can also contain dataset fields if you create a dataset for them that contains nested details, or if they receive data from a provider that is linked to the master table of a master/detail relationship.

Note: For *TClientDataSet*, using nested detail sets is necessary if you want to apply updates from master and detail tables to a database server.

To use nested detail sets, the ObjectView property of the master dataset must be *True*. When your table type dataset contains nested detail datasets, *TDBGrid* provides support for displaying the nested details in a popup window. For more information on

how this works, see Working with dataset fields (see page 1867).

Alternately, you can display and edit detail datasets in data-aware controls by using a separate dataset component for the detail set. At design time, create persistent fields for the fields in your (master) dataset, using the Fields Editor: right click the master dataset and choose Fields Editor. Add a new persistent field to your dataset by right-clicking and choosing Add Fields. Define your new field with type DataSet Field. In the Fields Editor, define the structure of the detail table. You must also add persistent fields for any other fields used in your master dataset.

The dataset component for the detail table is a dataset descendant of a type allowed by the master table. *TTable* components only allow *TNestedDataSet* components as nested datasets. *TSQLTable* components allow other *TSQLTable* components. *TClientDataset* components allow other client datasets. Choose a dataset of the appropriate type from the **Tool palette** and add it to your form or data module. Set this detail dataset's DataSetField property to the persistent DataSet field in the master dataset. Finally, place a data source component on the form or data module and set its *DataSet* property to the detail dataset. Data-aware controls can use this data source to access the data in the detail set.

Making the Table a Detail of Another Dataset (see page 1598)

3.2.3.6.45 Using Parameters in Queries

A parameterized SQL statement contains parameters, or variables, the values of which can be varied at design time or runtime. Parameters can replace data values, such as those used in a WHERE clause for comparisons, that appear in an SQL statement. Ordinarily, parameters stand in for data values passed to the statement. For example, in the following INSERT statement, values to insert are passed as parameters:

```
INSERT INTO Country (Name, Capital, Population)
VALUES (:Name, :Capital, :Population)
```

In this SQL statement, *:Name*, *:Capital*, and *:Population* are placeholders for actual values supplied to the statement at runtime by your application. Note that the names of parameters begin with a colon. The colon is required so that the parameter names can be distinguished from literal values. You can also include unnamed parameters by adding a question mark (?) to your query. Unnamed parameters are identified by position, because they do not have unique names.

Before the dataset can execute the query, you must supply values for any parameters in the query text. *TQuery*, *TIBQuery*, *TSQLQuery*, and client datasets use the *P*arams property to store these values. *TADOQuery* uses the *Parameters* property instead. *Params* (or *Parame*ters) is a collection of parameter objects (TParam or TParameter), where each object represents a single parameter. When you specify the text for the query, the dataset generates this set of parameter objects, and (depending on the dataset type) initializes any of their properties that it can deduce from the query.

Note: You can suppress the automatic generation of parameter objects in response to changing the query text by setting the *ParamCheck* property to *False*. This is useful for data definition language (DDL) statements that contain parameters as part of the DDL statement that are not parameters for the query itself. For example, the DDL statement to create a stored procedure may define parameters that are part of the stored procedure. By setting *ParamCheck* to *False*, you prevent these parameters from being mistaken for parameters of the query.

Parameter values must be bound into the SQL statement before it is executed for the first time. Query components do this automatically for you even if you do not explicitly call the *Prepare* method before executing a query.

Tip: It is a good programming practice to provide variable names for parameters that correspond to the actual name of the column with which it is associated. For example, if a column name is "Number," then its corresponding parameter would be ":Number". Using matching names is especially important if the dataset uses a data source to obtain parameter values from another dataset. This process is described in Establishing master/detail relationships using parameters (see page 1593).

The following topics describe how to specify the datatypes and values of parameters for your query:

- Supplying Parameters at Design Time (see page 1582)

- Supplying Parameters at Runtime (see page 1583)

See Also

Specifying the Query (see page 1613)

Establishing Master/detail Relationships Using Parameters (see page 1593)

Preparing Queries (see page 1606)

Executing Queries That Don't Return a Result Set (see page 1596)

Using Unidirectional Result Sets (see page 1624)

3.2.3.6.46 Using Query-type Datasets

To use a query-type dataset

1. Place the appropriate dataset component in a data module or on a form, and set its Name property to a unique value appropriate to your application.
2. Identify the database server to query. Each query-type dataset does this differently, but typically you specify a database connection component:

- For *TQuery*, specify a *TDatabase* component or a BDE alias using the DatabaseName property.
- For *TADOQuery*, specify a *TADOConnection* component using the Connection property.
- For *TSQLQuery*, specify a *TSQLConnection* component using the SQLConnection property.
- For *TIBQuery*, specify a *TIBConnection* component using the Database property. For information about using database connection components, see Connecting to databases (see page 1506)

3. Specify an SQL statement (see page 1613) in the *SQL* property of the dataset, and optionally specify any parameters (see page 1617) for the statement.
4. If the query data is to be used with visual data controls, add a data source component to the data module, and set its *DataSet* property to the query-type dataset. The data source component forwards the results of the query (called a *result set*) to data-aware components for display. Connect data-aware components to the data source using their *DataSource* and *DataField* properties.
5. Activate the query component. For queries that return a result set, use the *Active* property or the *Open* method. To execute queries that only perform an action on a table and return no result set (see page 1596), use the *ExecSQL* method at runtime. If you plan to execute the query more than once, you may want to call *Prepare* to initialize the data access layer and bind parameter values into the query. For information about preparing a query, see Preparing queries (see page 1606).

In addition to the basic steps described above, the following topics describe how to establish master/detsil relationships when using query-type datasets and how to improve performance when you only need a unidirectional cursor:

- Establishing master/detail relationships using parameters (see page 1593)
- Using unidirectional result sets (see page 1624)

See Also

Using Table Type Datasets (see page 1620)

Using Stored Procedure-type Datasets (see page 1618)

3.2.3.6.47 Using Stored Procedure-type Datasets

How your application uses a stored procedure depends on how the stored procedure was coded, whether and how it returns data, the specific database server used, or a combination of these factors.

To access a stored procedure on a server

1. Place the appropriate dataset component in a data module or on a form, and set its Name property to a unique value appropriate to your application.
2. Identify the database server that defines the stored procedure. Each stored procedure-type dataset does this differently, but typically you specify a database connection component:

- For *TStoredProc*, specify a *TDatabase* component or a BDE alias using the DatabaseName property.
- For *TADOStoredProc*, specify a *TADOConnection* component using the Connection property.
- For *TSQLStoredProc*, specify a *TSQLConnection* component using the SQLConnection property.
- For *TIBStoredProc*, specify a *TIBConnection* component using the Database property. For information about using database connection components, see Connecting to databases (see page 1506)

3. Specify the stored procedure to execute. For most stored procedure-type datasets, you do this by setting the *StoredProcName* property. The one exception is *TADOStoredProc*, which has a *ProcedureName* property instead.
4. If the stored procedure returns a cursor to be used with visual data controls, add a data source component to the data module, and set its *DataSet* property to the stored procedure-type dataset. Connect data-aware components to the data source using their *DataSource* and *DataField* properties.
5. Provide input parameter values for the stored procedure, if necessary. If the server does not provide information about all stored procedure parameters, you may need to provide additional input parameter information, such as parameter names and data types. For information about working with stored procedure parameters, see Working with stored procedure parameters (see page 1625).
6. Execute the stored procedure. For stored procedures that return a cursor, use the *Active* property or the *Open* method. To execute stored procedures that do not return any results or that only return output parameters (see page 1596), use the *ExecProc* method at runtime. If you plan to execute the stored procedure more than once, you may want to call *Prepare* to initialize the data access layer and bind parameter values into the stored procedure. For information about preparing a query, see Preparing stored procedures (see page 1607).
7. Process any results. These results can be returned as result and output parameters, or they can be returned as a result set that populates the stored procedure-type dataset. Some stored procedures return multiple cursors. For details on how to access the additional cursors, see Fetching multiple result sets (see page 1597).

Using Query-type Datasets (see page 1618)

3.2.3.6.48 Using TDataSet Descendants

TDataSet has several immediate descendants, each of which corresponds to a different data access mechanism. You do not work directly with any of these descendants. Rather, each descendant introduces the properties and methods for using a particular data access mechanism. These properties and methods are then exposed by descendant classes that are adapted to different types of server data. The immediate descendants of *TDataSet* include

- *TBDEDataSet*, which uses the Borland Database Engine (BDE) to communicate with the database server. The *TBDEDataSet* descendants you use are *TTable*, *TQuery*, *TStoredProc*, and *TNestedTable*. The unique features of BDE-enabled datasets are described in Using the Borland Database Engine (see page 1643)
- *TCustomADODataSet*, which uses ActiveX Data Objects (ADO) to communicate with an OLEDB data store. The *TCustomADODataSet* descendants you use are *TADODataSet*, *TADOTable*, *TADOQuery*, and *TADOStoredProc*. The unique features of ADO-based datasets are described in Working with ADO components. (see page 1494)
- *TCustomSQLDataSet*, which uses dbExpress to communicate with a database server. The *TCustomSQLDataSet* descendants you use are *TSQLDataSet*, *TSQLTable*, *TSQLQuery*, and *TSQLStoredProc*. The unique features of dbExpress datasets are described in Using Unidirectional Datasets. (see page 1823)
- *TIBCustomDataSet*, which communicates directly with an InterBase database server. The *TIBCustomDataSet* descendants

you use are *TIBDataSet*, *TIBTable*, *TIBQuery*, and *TIBStoredProc*.

- *TCustomClientDataSet*, which represents the data from another dataset component or the data from a dedicated file on disk. The *TCustomClientDataSet* descendants you use are *TClientDataSet*, which can connect to an external (source) dataset, and the client datasets that are specialized to a particular data access mechanism (*TBDEClientDataSet,TSimpleDataSet*, and *TIBClientDataSet*), which use an internal source dataset. The unique features of client datasets are described in Using client datasets (see page 1740)

Some pros and cons of the various data access mechanisms employed by these *TDataSet* descendants are described in Using databases (see page 1572).

In addition to the built-in datasets, you can create your own custom *TDataSet* descendants—for example to supply data from a process other than a database server, such as a spreadsheet. Writing custom datasets allows you the flexibility of managing the data using any method you choose, while still letting you use the VCL data controls to build your user interface. For more information about creating custom components, see Overview of component creation. (see page 1313)

Although each *TDataSet* descendant has its own unique properties and methods, some of the properties and methods introduced by descendant classes are the same as those introduced by other descendant classes that use another data access mechanism. For example, there are similarities between the "table" components (*TTable*, *TADOTable*, *TSQLTable*, and *TIBTable*). For information about the commonalities introduced by *TDataSet* descendants, see Types of datasets (see page 1635).

3.2.3.6.49 Using Table Type Datasets

To use a table type dataset

1. Place the appropriate dataset component in a data module or on a form, and set its Name property to a unique value appropriate to your application.
2. Identify the database server that contains the table you want to use. Each table type dataset does this differently, but typically you specify a database connection component:

- For *TTable*, specify a *TDatabase* component or a BDE alias using the DatabaseName property.
- For *TADOTable*, specify a *TADOConnection* component using the Connection property.
- For *TSQLTable*, specify a *TSQLConnection* component using the SQLConnection property.
- For *TIBTable*, specify a *TIBConnection* component using the Database property. For information about using database connection components, see Connecting to databases (see page 1506)

3. Set the *TableName* property to the name of the table in the database. You can select tables from a drop-down list if you have already identified a database connection component.
4. Place a data source component in the data module or on the form, and set its *DataSet* property to the name of the dataset. The data source component is used to pass a result set from the dataset to data-aware components for display.

Advantages of using table type datasets

The main advantage of using table type datasets is the availability of indexes. Indexes enable your application to

- Sort the Records in the Dataset (see page 1609).
- Locate Records Quickly (see page 1615).
- Limit the Records That are Visible (see page 1597).
- Establish Master/Detail Relationships (see page 1590).

In addition, the one-to-one relationship between table type datasets and database tables enables many of them to be used for

- Controlling Read/Write Access To Tables (see page 1587)
- Creating and Deleting Tables (see page 1587)
- Emptying Tables (see page 1592)
- Synchronizing Tables (see page 1614)

Using Query-type Datasets (see page 1618)

Using Stored Procedure-type Datasets (see page 1618)

3.2.3.6.50 Using the Eof and Bof Properties

Two read-only, runtime properties, *Eof* (End-of-file) and *Bof(Beginning-of-file), are useful when you want to iterate through all records in a dataset.*

Eof

When EOF is *True*, it indicates that the cursor is unequivocally at the last row in a dataset. *Eof* is set to *True* when an application

- Opens an empty dataset.
- Calls a dataset's *Last* method.
- Calls a dataset's *Next* method, and the method fails (because the cursor is currently at the last row in the dataset.
- Calls *SetRange* on an empty range or dataset.

Eof is set to *False* in all other cases; you should assume *Eof* is *False* unless one of the conditions above is met *and* you test the property directly.

Eof is commonly tested in a loop condition to control iterative processing of all records in a dataset. If you open a dataset containing records (or you call First) *Eof* is *False*. To iterate through the dataset a record at a time, create a loop that steps through each record by calling Next, and terminates when *Eof* is *True*. *Eof* remains *False* until you call *Next* when the cursor is already on the last record.

The following code illustrates one way you might code a record-processing loop for a dataset called *CustTable*:

```
CustTable.DisableControls;
try
  CustTable.First; { Go to first record, which sets Eof False }
  while not CustTable.Eof do { Cycle until Eof is True }
  begin
    { Process each record here }
    .
    .
    .
    CustTable.Next; { Eof False on success; Eof True when Next fails on last record }
  end;
finally
  CustTable.EnableControls;
end;
CustTable->DisableControls(); // Speed up processing; prevent screen flicker
try
{
  while (!CustTable->Bof) // Cycle until Bof is true
  (
```

```
    // Process each record here
    .
    .
    .
    CustTable->Prior();
    // Bof false on success; Bof true when Prior fails on first record
  }
}
__finally
{
  CustTable->EnableControls();
}
CustTable->DisableControls();
try
{
  for (CustTable->First(); !CustTable->Eof; CustTable->Next())
  (
    // Process each record here
    .
    .
    .
  }
}
__finally
{
  CustTable->EnableControls();
}
```

Tip: This example also shows how to disable and enable data-aware visual controls tied to a dataset. If you disable visual controls during dataset iteration, it speeds processing because your application does not need to update the contents of the controls as the current record changes. After iteration is complete, controls should be enabled again to update them with values for the new current row. Note that enabling of the visual controls takes place in the **finally** clause of a **try...finally** statement. This guarantees that even if an exception terminates loop processing prematurely, controls are not left disabled.

Bof

When BOF is *True*, it indicates that the cursor is unequivocally at the first row in a dataset. *Bof* is set to *True* when an application

- Opens a dataset.
- Calls a dataset's First method.
- Calls a dataset's Prior method, and the method fails (because the cursor is currently at the first row in the dataset.
- Calls *SetRange* on an empty range or dataset.

Bof is set to *False* in all other cases; you should assume *Bof* is *False* unless one of the conditions above is met *and* you test the property directly.

Like EOF, *Bof* can be in a loop condition to control iterative processing of records in a dataset. The following code illustrates one way you might code a record-processing loop for a dataset called *CustTable*:

```
CustTable.DisableControls; { Speed up processing; prevent screen flicker }
try
  while not CustTable.Bof do { Cycle until Bof is True }
  begin
    { Process each record here }
    .
    .
    .
    CustTable.Prior; { Bof False on success; Bof True when Prior fails on first record }
  end;
finally
  CustTable.EnableControls; { Display new current row in controls }
end;
```

See Also

Using the First and Last Methods (see page 1623)

Using the Next and Prior Methods (see page 1624)

Using the MoveBy Method (see page 1623)

Marking and Returning to Records (see page 1599)

3.2.3.6.51 Using the First and Last Methods

The First method moves the cursor to the first row in a dataset and sets the BOF property to *True*. If the cursor is already at the first row in the dataset, *First* does nothing.

For example, the following code moves to the first record in *CustTable*:

```
CustTable.First;
CustTable->First();
```

The Last method moves the cursor to the last row in a dataset and sets the EOF property to *True*. If the cursor is already at the last row in the dataset, *Last* does nothing.

The following code moves to the last record in *CustTable*:

```
CustTable.Last;
CustTable->Last();
```

Note: The *Last* method raises an exception in unidirectional datasets.

Tip: While there may be programmatic reasons to move to the first or last rows in a dataset without user intervention, you can also enable your users to navigate from record to record using the TDBNavigator component. The navigator component contains buttons that, when active and visible, enable a user to move to the first and last rows of an active dataset. The OnClick events for these buttons call the *First* and *Last* methods of the dataset. For more information about making effective use of the navigator component, see Navigating and manipulating records (see page 1767).

See Also

Using the Next and Prior Methods (see page 1624)

Using the MoveBy Method (see page 1623)

Using the Eof and Bof Properties (see page 1621)

Marking and Returning to Records (see page 1599)

3.2.3.6.52 Using the MoveBy Method

MoveBy lets you specify how many rows forward or back to move the cursor in a dataset. Movement is relative to the current record at the time that *MoveBy* is called. *MoveBy* also sets the BOF and EOF properties for the dataset as appropriate.

This function takes an integer parameter, the number of records to move. Positive integers indicate a forward move and negative integers indicate a backward move.

Note: *MoveBy* raises an exception in unidirectional datasets if you use a negative argument.

MoveBy returns the number of rows it moves. If you attempt to move past the beginning or end of the dataset, the number of rows returned by *MoveBy* differs from the number of rows you requested to move. This is because *MoveBy* stops when it reaches the first or last record in the dataset.

The following code moves two records backward in *CustTable*:

```
CustTable.MoveBy(-2);
CustTable->MoveBy(-2);
```

Note: If your application uses *MoveBy* in a multi-user database environment, keep in mind that datasets are fluid. A record that was five records back a moment ago may now be four, six, or even an unknown number of records back if several users are simultaneously accessing the database and changing its data.

Marking and Returning to Records (see page 1599)

3.2.3.6.53 Using the Next and Prior Methods

The Next method moves the cursor forward one row in the dataset and sets the BOF property to *False* if the dataset is not empty. If the cursor is already at the last row in the dataset when you call *Next*, nothing happens.

For example, the following code moves to the next record in *CustTable*:

```
CustTable.Next;
CustTable->Next();
```

The Prior method moves the cursor back one row in the dataset, and sets*EOF to False if the dataset is not empty. If the cursor is already at the first row in the dataset when you call Prior, Prior does nothing.*

For example, the following code moves to the previous record in CustTable:

```
CustTable.Prior;
CustTable->Prior();
```

Note: The *Prior* method raises an exception in unidirectional datasets.

Marking and Returning to Records (see page 1599)

3.2.3.6.54 Using Unidirectional Result Sets

When a query-type dataset returns a result set, it also receives a cursor, or pointer to the first record in that result set. The record pointed to by the cursor is the currently active record. The current record is the one whose field values are displayed in data-aware components associated with the result set's data source. Unless you are using dbExpress, this cursor is bi-directional by default. A bi-directional cursor can navigate both forward and backward through its records. Bi-directional cursor support requires some additional processing overhead, and can slow some queries.

If you do not need to be able to navigate backward through a result set, *TQuery* and *TIBQuery* let you improve query performance by requesting a unidirectional cursor instead. To request a unidirectional cursor, set the *UniDirectional* property to True.

Set *UniDirectional* before preparing and executing a query. The following code illustrates setting *UniDirectional* prior to preparing

and executing a query:

```
if not (CustomerQuery.Prepared) then
begin
  CustomerQuery.UniDirectional := True;
  CustomerQuery.Prepared := True;
end;
CustomerQuery.Open;  { returns a result set with a one-way cursor }
```

```
if (!CustomerQuery->Prepared)
{
  CustomerQuery->UniDirectional = true;
CustomerQuery->Prepared = true;
}
CustomerQuery->Open(); // Returns a result set with a one-way cursor
```

Note: Do not confuse the *UniDirectional* property with a unidirectional dataset. Unidirectional datasets (*TSQLDataSet*, *TSQLTable*, *TSQLQuery*, and *TSQLStoredProc*) use dbExpress, which only returns unidirectional cursors. In addition to restricting the ability to navigate backwards, unidirectional datasets do not buffer records, and so have additional limitations (such as the inability to use filters).

3.2.3.6.55 Working with Stored Procedure Parameters

There are four types of parameters that can be associated with stored procedures:

- *Input p*arameters, used to pass values to a stored procedure for processing.
- *Output* parameters, used by a stored procedure to pass return values to an application.
- *Input/output parameters*, used to pass values to a stored procedure for processing, and used by the stored procedure to pass return values to the application.
- *A result parameter*, used by some stored procedures to return an error or status value to an application. A stored procedure can only return one result parameter.

Whether a stored procedure uses a particular type of parameter depends both on the general language implementation of stored procedures on your database server and on a specific instance of a stored procedure. For any server, individual stored procedures may or may not use input parameters. On the other hand, some uses of parameters are server-specific. For example, on MS-SQL Server and Sybase stored procedures always return a result parameter, but the InterBase implementation of a stored procedure never returns a result parameter.

Access to stored procedure parameters is provided by the *Params* property (in *TStoredProc*, *TSQLStoredProc*, *TIBStoredProc*) or the *Parameters* property (in *TADOStoredProc*). When you assign a value to the *StoredProcName* (or *ProcedureName*) property, the dataset automatically generates objects for each parameter of the stored procedure. For some datasets, if the stored procedure name is not specified until runtime, objects for each parameter must be programmatically created at that time. Not specifying the stored procedure and manually creating the *TParam* or *TParameter* objects allows a single dataset to be used with any number of available stored procedures.

Note: Some stored procedures return a dataset in addition to output and result parameters. Applications can display dataset records in data-aware controls, but must separately process output and result parameters.

Setting up parameters at design time

You can specify stored procedure parameter values at design time using the parameter collection editor. To display the parameter collection editor, click on the ellipsis button for the *Params* or *Parameters* property in the **Object Inspector**.

Warning: You can assign values to input parameters by selecting them in the parameter collection editor and using the Object Inspector

to set the *Value* property. However, do not change the names or data types for input parameters reported by the server. Otherwise, when you execute the stored procedure an exception is raised. Some servers do not report parameter names or data types. In these cases, you must set up the parameters manually using the parameter collection editor. Right click and choose Add to add parameters. For each parameter you add, you must fully describe the parameter. Even if you do not need to add any parameters, you should check the properties of individual parameter objects to ensure that they are correct.

If the dataset has a *Params* property (*TParam* objects), the following properties must be correctly specified:

- The Name property indicates the name of the parameter as it is defined by the stored procedure.
- The DataType property gives the data type for the parameter's value. When using *TSQLStoredProc*, some data types require additional information:
- The NumericScale property indicates the number of decimal places for numeric parameters.
- The Precision property indicates the total number of digits for numeric parameters.
- The Size property indicates the number of characters in string parameters.
- The ParamType property indicates the type of the selected parameter. This can be *ptInput* (for input parameters), *ptOutput* (for output parameters), *ptInputOutput* (for input/output parameters) or *ptResult* (for result parameters).
- The Value property specifies a value for the selected parameter. You can never set values for output and result parameters. These types of parameters have values set by the execution of the stored procedure. For input and input/output parameters, you can leave *Value* blank if your application supplies parameter values at runtime.

If the dataset uses a *Parameters* property (*TParameter* objects), the following properties must be correctly specified:

- The Name property indicates the name of the parameter as it is defined by the stored procedure.
- The DataType property gives the data type for the parameter's value. For some data types, you must provide additional information:
- The NumericScale property indicates the number of decimal places for numeric parameters.
- The Precision property indicates the total number of digits for numeric parameters.
- The Size property indicates the number of characters in string parameters.
- The Direction property gives the type of the selected parameter. This can be *pdInput* (for input parameters), *pdOutput* (for output parameters), *pdInputOutput* (for input/output parameters) or *pdReturnValue* (for result parameters).
- The Attributes property controls the type of values the parameter will accept. *Attributes* may be set to a combination of *psSigned*, *psNullable*, and *psLong*.
- The Value property specifies a value for the selected parameter. Do not set values for output and result parameters. For input and input/output parameters, you can leave *Value* blank if your application supplies parameter values at runtime.

Using parameters at runtime

With some datasets, if the name of the stored procedure is not specified until runtime, no *TParam* objects are automatically created for parameters and they must be created programmatically. This can be done using the *TParam.Create* method or the *TParams.AddParam* method:

```
var
  P1, P2: TParam;
begin
  ...
  with StoredProc1 do begin
    StoredProcName := 'GET_EMP_PROJ';
    Params.Clear;
    P1 := TParam.Create(Params, ptInput);
    P2 := TParam.Create(Params, ptOutput);
    try
      Params[0].Name := 'EMP_NO';
      Params[1].Name := 'PROJ_ID';
```

```
      ParamByname('EMP_NO').AsSmallInt := 52;
      ExecProc;
      Edit1.Text := ParamByname('PROJ_ID').AsString;
    finally
      P1.Free;
      P2.Free;
    end;
  end;
  ...
end;
TParam *P1, *P2;
StoredProc1->StoredProcName = "GET_EMP_PROJ";
StoredProc1->Params->Clear();
P1 = new TParam(StoredProc1->Params, ptInput);
P2 = new TParam(StoredProc1->Params, ptOutput);
try
{
  StoredProc1->Params->Items[0]->Name = "EMP_NO";
  StoredProc1->Params->Items[1]->Name = "PROJ_ID";
  StoredProc1->ParamByName("EMP_NO")->AsSmallInt = 52;
  StoredProc1->ExecProc();
  Edit1->Text = StoredProc1->ParamByName("PROJ_ID")->AsString;
}
__finally
{
  delete P1;
  delete P2;
}
```

Even if you do not need to add the individual parameter objects at runtime, you may want to access individual parameter objects to assign values to input parameters and to retrieve values from output parameters. You can use the dataset's *ParamByName* method to access individual parameters based on their names. For example, the following code sets the value of an input/output parameter, executes the stored procedure, and retrieves the returned value:

```
with SQLStoredProc1 do
begin
  ParamByName('IN_OUTVAR').AsInteger := 103;
  ExecProc;
  IntegerVar := ParamByName('IN_OUTVAR').AsInteger;
end;
SQLDataSet1->ParamByName("IN_OUTVAR")->AsInteger = 103;
SQLDataSet1->ExecSQL();
int Result = SQLDataSet1->ParamByName("IN_OUTVAR")->AsInteger;
```

3.2.3.6.56 Using Locate

Locate moves the cursor to the first row matching a specified set of search criteria. In its simplest form, you pass *Locate* the name of a column to search, a field value to match, and an options flag specifying whether the search is case-insensitive or if it can use partial-key matching. (Partial-key matching is when the criterion string need only be a prefix of the field value.) For example, the following code moves the cursor to the first row in the *CustTable* where the value in the *Company* column is "Professional Divers, Ltd.":

```
var
  LocateSuccess: Boolean;
  SearchOptions: TLocateOptions;
begin
```

```
  SearchOptions := [loPartialKey];
  LocateSuccess := CustTable.Locate('Company', 'Professional Divers, Ltd.', SearchOptions);
end;
TLocateOptions SearchOptions;
SearchOptions.Clear();
SearchOptions << loPartialKey;
bool LocateSuccess = CustTable->Locate("Company", "Professional Divers, Ltd.",
```

If *Locate* finds a match, the first record containing the match becomes the current record. *Locate* returns *True* if it finds a matching record, *False* if it does not. If a search fails, the current record does not change.

The real power of *Locate* comes into play when you want to search on multiple columns and specify multiple values to search for. Search values are Variants, which means you can specify different data types in your search criteria. To specify multiple columns in a search string, separate individual items in the string with semicolons.

Because search values are Variants, if you pass multiple values, you must either pass a Variant array as an argument (for example, the return values from the Lookup method), or you must construct the Variant array in code using the *VarArrayOf* function. The following code illustrates a search on multiple columns using multiple search values and partial-key matching:

```
with CustTable do
  Locate('Company;Contact;Phone', VarArrayOf(['Sight Diver','P']), loPartialKey);
TLocateOptions Opts;
Opts.Clear();
Opts << loPartialKey;
Variant locvalues[2];
locvalues[0] = Variant("Sight Diver");
locvalues[1] = Variant("P");
CustTable->Locate("Company;Contact", VarArrayOf(locvalues, 1), Opts);
```

Locate uses the fastest possible method to locate matching records. If the columns to search are indexed and the index is compatible with the search options you specify, *Locate* uses the index.

See Also

Using Lookup (see page 1628)

3.2.3.6.57 Using Lookup

Lookup searches for the first row that matches specified search criteria. If it finds a matching row, it forces the recalculation of any calculated fields and lookup fields associated with the dataset, then returns one or more fields from the matching row. *Lookup* does not move the cursor to the matching row; it only returns values from it.

In its simplest form, you pass *Lookup* the name of field to search, the field value to match, and the field or fields to return. For example, the following code looks for the first record in the *CustTable* where the value of the *Company* field is "Professional Divers, Ltd.", and returns the company name, a contact person, and a phone number for the company:

```
var
  LookupResults: Variant;
begin
  LookupResults := CustTable.Lookup('Company', 'Professional Divers, Ltd.',
'Company;Contact; Phone');
end;
Variant LookupResults = CustTable->Lookup("Company", "Professional Divers, Ltd",
    "Company;Contact;Phone");
```

Lookup returns values for the specified fields from the first matching record it finds. Values are returned as Variants. If more than one return value is requested, *Lookup* returns a Variant array. If there are no matching records, *Lookup* returns a Null Variant.

The real power of *Lookup* comes into play when you want to search on multiple columns and specify multiple values to search for. To specify strings containing multiple columns or result fields, separate individual fields in the string items with semicolons.

Because search values are Variants, if you pass multiple values, you must either pass a Variant array as an argument (for example, the return values from the *Lookup* method), or you must construct the Variant array in code using the *VarArrayOf*

function. The following code illustrates a lookup search on multiple columns:

```
var
  LookupResults: Variant;
begin
with CustTable do
  LookupResults := Lookup('Company; City', VarArrayOf(['Sight Diver', 'Christiansted']),
'Company; Addr1; Addr2; State; Zip');
end;
Variant LookupResults;
Variant locvalues[2];
Variant v;
locvalues[0] = Variant("Sight Diver");
locvalues[1] = Variant("Kato Paphos");
LookupResults = CustTable->Lookup("Company;City", VarArrayOf(locvalues, 1),
                  "Company;Addr1;Addr2;State;Zip");
// now put the results in a global stringlist (created elsewhere)
pFieldValues->Clear();
for (int i = 0; i < 5; i++) // Lookup call requested 5 fields
{
v = LookupResults.GetElement(i);
if (v.IsNull())
pFieldValues->Add("");
else
pFieldValues->Add(v);
}
```

Like *Locate*, *Lookup* uses the fastest possible method to locate matching records. If the columns to search are indexed, *Lookup* uses the index.

Using Locate (see page 1627)

3.2.3.6.58 Modifying Data

You can use the following dataset methods to insert, update, and delete data if the read-only *CanModify* property is *True*. *CanModify* is *True* unless the dataset is unidirectional, the database underlying the dataset does not permit read and write privileges, or some other factor intervenes. (Intervening factors include the *ReadOnly* property on some datasets or the *RequestLive* property on *TQuery* components.)

Dataset methods for inserting, updating, and deleting data

Method	Description
Edit	Puts the dataset into *dsEdit* state if it is not already in *dsEdit* or *dsInsert* states.
Append	Posts any pending data, moves current record to the end of the dataset, and puts the dataset in *dsInsert* state.
Insert	Posts any pending data, and puts the dataset in *dsInsert* state.
Post	Attempts to post the new or altered record to the database. If successful, the dataset is put in *dsBrowse* state; if unsuccessful, the dataset remains in its current state.
Cancel	Cancels the current operation and puts the dataset in *dsBrowse* state.
Delete	Deletes the current record and puts the dataset in *dsBrowse* state.

The following topics discuss these methods in greater detail:

- Editing Records (see page 1591)
- Adding New Records (see page 1583)
- Deleting Records (see page 1591)

- Posting Data (see page 1606)
- Canceling Changes (see page 1586)
- Modifying Entire Records (see page 1601)

3.2.3.6.59 Searching Datasets

If a dataset is not unidirectional, you can search against it using the *Locate* and *Lookup* methods. These methods enable you to search on any type of columns in any dataset.

The following topics discuss Locate and Lookup in greater detail:

- Using Locate (see page 1627)
- Using Lookup (see page 1628)

Note: Some *TDataSet* descendants introduce an additional family of methods for searching based on an index. For information about these additional methods, see Using Indexes to Search for Records (see page 1615).

3.2.3.6.60 Specifying an Index with IndexName

Use the *IndexName* property to cause an index to be active. Once active, an index determines the order of records in the dataset. (It can also be used as the basis for a master-detail link, an index-based search, or index-based filtering.)

To activate an index, set the *IndexName* property to the name of the index. In some database systems, primary indexes do not have names. To activate one of these indexes, set *IndexName* to a blank string.

At design-time, you can select an index from a list of available indexes by clicking the property's ellipsis button in the **Object**

Inspector. At runtime set *IndexName* using a *String* literal or variable. You can obtain a list of available indexes by calling the *GetIndexNames* method.

The following code sets the index for *CustomersTable* to *CustDescending*:

```
CustomersTable.IndexName := 'CustDescending';
CustomersTable->IndexName = "CustDescending";
```

For information on specifying dBASE non-production index files and dBASE III PLUS-style .NDX files, see Specifying a dBASE index file (see page 1672)

See Also

Obtaining Information About Indexes (see page 1603)

Creating an Index with IndexFieldNames (see page 1581)

3.2.3.6.61 Displaying and Editing a Subset of Data Using Filters

An application is frequently interested in only a subset of records from a dataset. For example, you may be interested in retrieving or viewing only those records for companies based in California in your customer database, or you may want to find a record that contains a particular set of field values. In each case, you can use filters to restrict an application's access to a subset of all records in the dataset.

With unidirectional datasets, you can only limit the records in the dataset by using a query that restricts the records in the dataset. With other *TDataSet* descendants, however, you can define a subset of the data that has already been fetched. To restrict an application's access to a subset of all records in the dataset, you can use filters.

A filter specifies conditions a record must meet to be displayed. Filter conditions can be stipulated in a dataset's Filter property or coded into its OnFilterRecord event handler. Filter conditions are based on the values in any specified number of fields in a dataset, regardless of whether those fields are indexed. For example, to view only those records for companies based in California, a simple filter might require that records contain a value in the State field of "CA".

Note: Filters are applied to every record retrieved in a dataset. When you want to filter large volumes of data, it may be more efficient to use a query to restrict record retrieval, or to set a range on an indexed table rather than using filters.

The following topics describe how to work with filters:

- Enabling and Disabling Filtering (see page 1593)
- Navigating Records in a Filtered Dataset (see page 1603)

3.2.3.6.62 Understanding Datasets: Overview

The fundamental unit for accessing data is the dataset family of objects. Your application uses datasets for all database access. A dataset object represents a set of records from a database organized into a logical table. These records may be the records from a single database table, or they may represent the results of executing a query or stored procedure.

All dataset objects that you use in your database applications descend from TDataSet, and they inherit data fields, properties, events, and methods from this class.

TDataSet is a virtualized dataset, meaning that many of its properties and methods are **virtual** or **abstract**. A *virtual method* is a function or procedure declaration where the implementation of that method can be (and usually is) overridden in descendant objects. An abstract *method* is a function or procedure declaration without an actual implementation. The declaration is a prototype that describes the method (and its parameters and return type, if any) that must be implemented in all descendant dataset objects, but that might be implemented differently by each of them.

Because *TDataSet* contains **abstract** methods, you cannot use it directly in an application without generating a runtime error. Instead, you either create instances of the built-in *TDataSet* descendants and use them in your application, or you derive your own dataset object from *TDataSet* or its descendants and write implementations for all its abstract methods.

TDataSet defines much that is common to all dataset objects. For example, *TDataSet* defines the basic structure of all datasets: an array of TField components that correspond to actual columns in one or more database tables, lookup fields provided by your application, or calculated fields provided by your application. For information about *TField* components, see "Working with field components." (see page 1877)

The following topics describe how to use the common database functionality introduced by *TDataSet*. Bear in mind, however, that although *TDataSet* introduces the methods for this functionality, not all *TDataSet* dependants implement them. In particular, unidirectional datasets implement only a limited subset.

- Using TDataSet Descendants (see page 1619)
- Determining Dataset States (see page 1633)

3.2.3.6.63 Determining Dataset States

The *state*—or *mode*—of a dataset determines what can be done to its data. For example, when a dataset is closed, its state is *dsInactive*, meaning that nothing can be done to its data. At runtime, you can examine a dataset's read-only State property to determine its current state. The following table summarizes possible values for the *State* property and what they mean:

Values for the dataset State property

Value	State	Meaning
dsInactive	Inactive	DataSet closed. Its data is unavailable.
dsBrowse	Browse	DataSet open. Its data can be viewed, but not changed. This is the default state of an open dataset.
dsEdit	Edit	DataSet open. The current row can be modified. (not supported on unidirectional datasets)
dsInsert	Insert	DataSet open. A new row is inserted or appended. (not supported on unidirectional datasets)
dsSetKey	SetKey	DataSet open. Enables setting of ranges and key values used for ranges and *GotoKey* operations. (not supported by all datasets)
dsCalcFields	CalcFields	DataSet open. Indicates that an *OnCalcFields* event is under way. Prevents changes to fields that are not calculated.
dsCurValue	CurValue	DataSet open. Indicates that the CurValue property of fields is being fetched for an event handler that responds to errors in applying cached updates.
dsNewValue	NewValue	DataSet open. Indicates that the NewValue property of fields is being fetched for an event handler that responds to errors in applying cached updates.
dsOldValue	OldValue	DataSet open. Indicates that the OldValue property of fields is being fetched for an event handler that responds to errors in applying cached updates.
dsFilter	Filter	DataSet open. Indicates that a filter operation is under way. A restricted set of data can be viewed, and no data can be changed. (not supported on unidirectional datasets)
dsBlockRead	Block Read	DataSet open. Data-aware controls are not updated and events are not triggered when the current record changes.
dsInternalCalc	Internal Calc	DataSet open. An *OnCalcFields* event is underway for calculated values that are stored with the record. (client datasets only)
dsOpening	Opening	DataSet is in the process of opening but has not finished. This state occurs when the dataset is opened for asynchronous fetching.

Typically, an application checks the dataset state to determine when to perform certain tasks. For example, you might check for the *dsEdit* or *dsInsert* state to ascertain whether you need to post updates.

Note: Whenever a dataset's state changes, the *OnStateChange* event is called for any data source components associated with the dataset. For more information about data source components and *OnStateChange*, see Responding to Changes Mediated by the Data Source (see page 1776).

3.2.3.6.64 Navigating Datasets

Each active dataset has a *cursor*, or pointer, to the current row in the dataset. The *current row* in a dataset is the one whose field values currently show in single-field, data-aware controls on a form, such as TDBEdit, *TDBLabel*, and TDBMemo. If the dataset supports editing, the current record contains the values that can be manipulated by edit, insert, and delete methods.

You can change the current row by moving the cursor to point at a different row. The following table lists methods you can use in application code to move to different records:

Navigational methods of datasets

Method	Moves the Cursor to
First	The first row in a dataset.
Last	The last row in a dataset. (not available for unidirectional datasets)
Next	The next row in a dataset.
Prior	The previous row in a dataset. (not available for unidirectional datasets)
MoveBy	A specified number of rows forward or back in a dataset.

The data-aware, visual component TDBNavigator encapsulates these methods as buttons that users can click to move among records at runtime. For information about the navigator component, see Navigating and manipulating records (see page 1767).

Whenever you change the current record using one of these methods (or by other methods that navigate based on a search criterion), the dataset receives two events: BeforeScroll (before leaving the current record) and AfterScroll (after arriving at the new record). You can use these events to update your user interface (for example, to update a status bar that indicates information about the current record).

TDataSet also defines two boolean properties that provide useful information when iterating through the records in a dataset.

Navigational properties of datasets

Property	Description
BOF (Beginning-of-file)	*True*: the cursor is at the first row in the dataset. *False*: the cursor is not known to be at the first row in the dataset
EOF (End-of-file)	*True*: the cursor is at the last row in the dataset. *False*: the cursor is not known to be at the first row in the dataset

The following topics discuss these properties and methods in more detail:

- Using the First and Last methods (see page 1623)
- Using the Next and Prior methods (see page 1624)
- Using the MoveBy method (see page 1623)
- Using the Eof and Bof Properties (see page 1621)

- Marking and Returning to Records (see page 1599)

3.2.3.6.65 Writing an OnFilterRecord Event Handler

You can write code to filter records using the OnFilterRecord events generated by the dataset for each record it retrieves. This event handler implements a test that determines if a record should be included in those that are visible to the application.

To indicate whether a record passes the filter condition, your *OnFilterRecord* handler sets its *Accept* parameter to *True* to include a record, or *False* to exclude it. For example, the following filter displays only those records with the State field set to "CA":

```
procedure TForm1.Table1FilterRecord(DataSet: TDataSet; var Accept: Boolean);
begin
  Accept := DataSet['State'].AsString = 'CA';
end;
void __fastcall TForm1::Table1FilterRecord(TDataSet *DataSet; bool &Accept)
{
  Accept = DataSet->FieldByName["State"]->AsString == "CA";
}
```

When filtering is enabled, an *OnFilterRecord* event is generated for each record retrieved. The event handler tests each record, and only those that meet the filter's conditions are displayed. Because the *OnFilterRecord* event is generated for every record in a dataset, you should keep the event handler as tightly coded as possible to avoid adversely affecting the performance.

You can code any number of *OnFilterRecord* event handlers and switch among them at runtime. For example, the following statements switch to an *OnFilterRecord* event handler called *NewYorkFilter*:

```
DataSet1.OnFilterRecord := NewYorkFilter;
Refresh;
DataSet1->OnFilterRecord = NewYorkFilter;
()
```

Setting the Filter Property (see page 1608)

3.2.3.6.66 Types of Datasets

Using TDataSet descendants (see page 1619) classifies *TDataSet* descendants by the method they use to access their data. Another useful way to classify *TDataSet* descendants is to consider the type of server data they represent. Viewed this way, there are three basic classes of datasets:

Table type datasets (see page 1620): Table type datasets represent a single table from the database server, including all of its rows and columns. Table type datasets include TTable, TADOTable, TSQLTable, and TIBTable.

Table type datasets let you take advantage of indexes defined on the server. Because there is a one-to-one correspondence between database table and dataset, you can use server indexes that are defined for the database table. Indexes allow your application to sort the records in the table, speed searches and lookups, and can form the basis of a master/detail relationship. Some table type datasets also take advantage of the one-to-one relationship between dataset and database table to let you perform table-level operations such as creating and deleting database tables.

Query-type datasets (see page 1618): Query-type datasets represent a single SQL command, or query. Queries can represent the result set from executing a command (typically a SELECT statement), or they can execute a command that does not return any records (for example, an UPDATE statement). Query-type datasets include TQuery, TADOQuery, TSQLQuery, and TIBQuery.

To use a query-type dataset effectively, you must be familiar with SQL and your server's SQL implementation, including limitations and extensions to the SQL-92 standard. If you are new to SQL, you may want to purchase a third party book that covers SQL in-depth. One of the best is *Understanding the New SQL: A Complete Guide*, by Jim Melton and Alan R. Simpson, Morgan Kaufmann Publishers.

Stored procedure-type datasets (see page 1618): Stored procedure-type datasets represent a stored procedure on the database server. Stored procedure-type datasets include TStoredProc, TADOStoredProc, TSQLStoredProc, and TIBStoredProc.

A stored procedure is a self-contained program written in the procedure and trigger language specific to the database system used. They typically handle frequently repeated database-related tasks, and are especially useful for operations that act on large numbers of records or that use aggregate or mathematical functions. Using stored procedures typically improves the performance of a database application by:

- Taking advantage of the server's usually greater processing power and speed.
- Reducing network traffic by moving processing to the server.

Stored procedures may or may not return data. Those that return data may return it as a cursor (similar to the results of a SELECT query), as multiple cursors (effectively returning multiple datasets), or they may return data in output parameters. These differences depend in part on the server: Some servers do not allow stored procedures to return data, or only allow output parameters. Some servers do not support stored procedures at all. See your server documentation to determine what is available.

Note: You can usually use a query-type dataset to execute stored procedures because most servers provide extensions to SQL for working with stored procedures. Each server, however, uses its own syntax for this. If you choose to use a query-type dataset instead of a stored procedure-type dataset, see your server documentation for the necessary syntax.

In addition to the datasets that fall neatly into these three categories, *TDataSet* has some descendants that fit into more than one category:

- TADODataSet and TSQLDataSet*have a CommandType property that lets you specify whether they represent a table, query, or stored procedure. Property and method names are most similar to query-type datasets, although TADODataSet lets you specify an index like a table type dataset.*
- TClientDataSet represents the data from another dataset. As such, it can represent a table, query, or stored procedure. *TClientDataSet* behaves most like a table type dataset, because of its index support. However, it also has some of the features of queries and stored procedures: the management of parameters and the ability to execute without retrieving a result set.
- Some other client datasets (like TBDEClientDataSet) have a *CommandType* property that lets you specify whether they represent a table, query, or stored procedure. Property and method names are like *TClientDataSet*, including parameter support, indexes, and the ability to execute without retrieving a result set.
- TIBDataSet can represent both queries and stored procedures. In fact, it can represent multiple queries and stored procedures simultaneously, with separate properties for each.

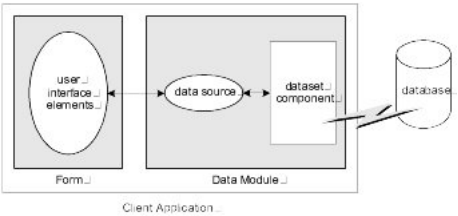
Connecting to databases with TDatabase (see page 1644)	The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

Managing database sessions (see page 1649)	The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.
Using BDE-enabled datasets (see page 1666)	The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.
Using TBatchMove (see page 1678)	The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.
Using the BDE to cache updates (see page 1685)	The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.
Using transactions with the BDE (see page 1698)	The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.



3.2.3.7.1 BDE-based Architecture

Warning: The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

When using the BDE, your application uses a variation of the general database architecture described in Database Architecture (see page 1562). In addition to the user interface elements, datasource, and datasets common to all Delphi database applications, A BDE-based application can include

- One or more database components to control transactions and to manage database connections.
- One or more session components to isolate data access operations such as database connections, and to manage groups of databases.

The relationships between the components in a BDE-based application are illustrated in the following figure:

The following topics provide additional information about these components:

- Using BDE-enabled Datasets (see page 1675)
- Connecting to Databases with TDatabase (see page 1646)
- Managing Database Sessions (see page 1664)

3.2.3.7.2 Executing an Update Statement

The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

The *ExecSQL* method for an update component manually applies updates for the current record. Unlike the *Apply* method, *ExecSQL* does not bind parameters in the SQL statement before executing it. The *ExecSQL* method is most often called from within a handler for the *OnUpdateRecord* event (when using the BDE) or the *BeforeUpdateRecord* event (when using a client dataset).

Because *ExecSQL* does not bind parameter values, it is used primarily when the update object's SQL statements do not include parameters. You can use *Apply* instead, even when there are no parameters, but *ExecSQL* is more efficient because it does not check for parameters.

If the SQL statements include parameters, you can still call *ExecSQL,* but only after explicitly binding parameters. If you are using the BDE to cache updates, you can explicitly bind parameters by setting the update object's *DataSet* property and then calling its *SetParams* method. When using a client dataset to cache updates, you must supply parameters to the underlying query object maintained by *TUpdateSQL*. For information on how to do this, see Using an update component's Query property (see page 1640).

Warning: If you use the dataset's *UpdateObject* property to associate dataset and update object, *ExecSQL* is called automatically. In that case, do not call *ExecSQL* in an *OnUpdateRecord* or *BeforeUpdateRecord* event handler as this will result in a second attempt to apply the current record's update.

OnUpdateRecord and *BeforeUpdateRecord* event handlers indicate the type of update that needs to be applied with an *UpdateKind* parameter of type *TUpdateKind*. You must pass this parameter to the *ExecSQL* method to indicate which update SQL statement to use. The following code illustrates this using a *BeforeUpdateRecord* event handler:

```
procedure TForm1.BDEClientDataSet1BeforeUpdateRecord(Sender: TObject; SourceDS: TDataSet;
          DeltaDS: TCustomClientDataSet; UpdateKind: TUpdateKind; var Applied: Boolean);
begin
  with UpdateSQL1 do
  begin
    DatabaseName := (SourceDS as TDBDataSet).DatabaseName;
    SessionName := (SourceDS as TDBDataSet).SessionName;
    ExecSQL(UpdateKind);
    Applied := True;
  end;
end;
void __fastcall TForm1::BDEClientDataSet1BeforeUpdateRecord(TObject *Sender,
   TDataSet *SourceDS, TCustomClientDataSet *DeltaDS, TUpdateKind UpdateKind, bool &Applied)
{
  TDBDataSet *pSrcDS = dynamic_cast<TDBDataSet *>(SourceDS);
  UpdateSQL1->DatabaseName = pSrcDS->DatabaseName;
  UpdateSQL1->SessionName = pSrcDS->SessionName;
  UpdateSQL1->ExecSQL(UpdateKind);
  Applied = true;
}
```

If an exception is raised during the execution of the update program, execution continues in the *OnUpdateError* event, if it is defined.

Topics

Name	Description
Using an Update Component's Query Property (see page 1640)	The *Query* property of an update component provides access to the query components that implement its *DeleteSQL*, *InsertSQL*, and *ModifySQL* statements. In most applications, there is no need to access these query components directly: you can use the *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties to specify the statements these queries execute, and execute them by calling the update object's *Apply* or *ExecSQL* method. There are times, however, when you may need to directly manipulate the query component. In particular, the *Query* property is useful when you want to supply your own values for parameters in the SQL... more (see page 1640)

See Also

Calling the Apply Method (see page 1642)

3.2.3.7.2.1 Using an Update Component's Query Property

The *Query* property of an update component provides access to the query components that implement its *DeleteSQL*, *InsertSQL*, and *ModifySQL* statements. In most applications, there is no need to access these query components directly: you can use the *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties to specify the statements these queries execute, and execute them by calling the update object's *Apply* or *ExecSQL* method. There are times, however, when you may need to directly manipulate the query component. In particular, the *Query* property is useful when you want to supply your own values for parameters in the SQL statements rather than relying on the update object's automatic parameter binding to old and new field values.

Note: The *Query* property is only accessible at runtime.

The *Query* property is indexed on a *TUpdateKind* value:

- Using an index of *ukModify* accesses the query that updates existing records.
- Using an index of *ukInsert* accesses the query that inserts new records.
- Using an index of *ukDelete* accesses the query that deletes records.

The following shows how to use the *Query* property to supply parameter values that can't be bound automatically:

```
procedure TForm1.BDEClientDataSet1BeforeUpdateRecord(Sender: TObject; SourceDS: TDataSet;
          DeltaDS: TCustomClientDataSet; UpdateKind: TUpdateKind; var Applied: Boolean);
begin
  UpdateSQL1.DataSet := DeltaDS; { required for the automatic parameter substitution }
  with UpdateSQL1.Query[UpdateKind] do
  begin
    { Make sure the query has the correct DatabaseName and SessionName }
    DatabaseName := (SourceDS as TDBDataSet).DatabaseName;
    SessionName := (SourceDS as TDBDataSet).SessionName;
    ParamByName('TimeOfUpdate').Value = Now;
  end;
  UpdateSQL1.Apply(UpdateKind); { now perform automatic substitutions and execute }
  Applied := True;
end;
void __fastcall TForm1::BDEClientDataSet1BeforeUpdateRecord(TObject *Sender,
   TDataSet *SourceDS, TCustomClientDataSet *DeltaDS, TUpdateKind UpdateKind, bool &Applied)
{
  UpdateSQL1->DataSet = DeltaDS; // required for the automatic parameter substitution
  TQuery *pQuery = UpdateSQL1->Query[UpdateKind]; // access the query
  // make sure the query has the correct DatabaseName and SessionName
  TDBDataSet *pSrcDS = dynamic_cast<TDBDataSet *>(SourceDS);
  pQuery->DatabaseName = pSrcDS->DatabaseName;
  pQuery->SessionName = pSrcDS->SessionName;
  // now substitute values for custom parameters
  pQuery->ParamByName("TimeOfLastUpdate")->Value = Now();
  UpdateSQL1->Apply(UpdateKind); // now do automatic substitution and execute
  Applied = true;
```

```
}
```

See Also

Calling the Apply Method (see page 1642)

3.2.3.7.3 Using Multiple Update Objects

The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

When more than one base table referenced in the update dataset needs to be updated, you need to use multiple update objects: one for each base table updated. Because the dataset component's *UpdateObject* only allows one update object to be associated with the dataset, you must associate each update object with a dataset by setting its DataSet property to the name of the dataset.

Tip: When using multiple update objects, you can use *TBDEClientDataSet* instead of *TClientDataSet* with an external provider. This is because you do not need to set the source dataset's *UpdateObject* property.

The *DataSet* property for update objects is not available at design time in the **Object Inspector**. You can only set this property at runtime.

```
UpdateSQL1.DataSet := Query1;
UpdateSQL1->DataSet = Query1;
```

The update object uses this dataset to obtain original and updated field values for parameter substitution and, if it is a BDE-enabled dataset, to identify the session and database to use when applying the updates. So that parameter substitution will work correctly, the update object's *DataSet* property must be the dataset that contains the updated field values. When using the BDE-enabled dataset to cache updates, this is the BDE-enabled dataset itself. When using a client dataset, this is a client dataset that is provided as a parameter to the *BeforeUpdateRecord* event handler.

When the update object has not been assigned to the dataset's *UpdateObject* property, its SQL statements are not automatically executed when you call *ApplyUpdates*. To update records, you must manually call the update object from an OnUpdateRecord event handler (when using the BDE to cache updates) or a BeforeUpdateRecord event handler (when using a client dataset). In the event handler, the minimum actions you need to take are

- If you are using a client dataset to cache updates, you must be sure that the updates object's DatabaseName and SessionName properties are set to the DatabaseName and SessionName properties of the source dataset.
- The event handler must call the update object's ExecSQL or Apply method. This invokes the update object for each record that requires updating. For more information about executing update statements, see Executing the SQL statements (see page 1643).
- Set the event handler's *UpdateAction* parameter to *uaApplied* (*OnUpdateRecord*) or the *Applied* parameter to *True* (*BeforeUpdateRecord*).

You may optionally perform data validation, data modification, or other operations that depend on each record's update.

Warning: If you call an update object's *ExecSQL* or *Apply* method in an *OnUpdateRecord* event handler, be sure that you do not set the dataset's *UpdateObject* property to that update object. Otherwise, this will result in a second attempt to apply each record's update.

Topics

Name	Description
Calling the Apply Method (see page 1642)	The *Apply* method for an update component manually applies updates for the current record. There are two steps involved in this process: 1. Initial and edited field values for the record are bound to parameters in the appropriate SQL statement. 2. The SQL statement is executed. Call the *Apply* method to apply the update for the current record in the update cache. The *Apply* method is most often called from within a handler for the dataset's *OnUpdateRecord* event or from a provider's *BeforeUpdateRecord* event handler. **Warning:** If you use the dataset's *UpdateObject* property to associate dataset and update object, *Apply* is called... more (see page 1642)
Executing the SQL Statements (see page 1643)	When you use multiple update objects, you do not associate the update objects with a dataset by setting its *UpdateObject* property. As a result, the appropriate statements are not automatically executed when you apply updates. Instead, you must explicitly invoke the update object in code. There are two ways to invoke the update object. Which way you choose depends on whether the SQL statement uses parameters to represent field values (see page 1689): • If the SQL statement to execute uses parameters, call the Apply method (see page 1642). • If the SQL statement to execute does not use parameters, it is more efficient to call... more (see page 1643)

See Also

Creating SQL Statements for Update Components (see page 1696)

3.2.3.7.3.1 Calling the Apply Method

The *Apply* method for an update component manually applies updates for the current record. There are two steps involved in this process:

1. Initial and edited field values for the record are bound to parameters in the appropriate SQL statement.
2. The SQL statement is executed.

Call the *Apply* method to apply the update for the current record in the update cache. The *Apply* method is most often called from within a handler for the dataset's *OnUpdateRecord* event or from a provider's *BeforeUpdateRecord* event handler.

Warning: If you use the dataset's *UpdateObject* property to associate dataset and update object, *Apply* is called automatically. In that case, do not call *Apply* in an *OnUpdateRecord* event handler as this will result in a second attempt to apply the current record's update.

OnUpdateRecord event handlers indicate the type of update that needs to be applied with an *UpdateKind* parameter of type *TUpdateKind*. You must pass this parameter to the *Apply* method to indicate which update SQL statement to use. The following code illustrates this using a *BeforeUpdateRecord* event handler:

```
procedure TForm1.BDEClientDataSet1BeforeUpdateRecord(Sender: TObject; SourceDS: TDataSet;
          DeltaDS: TCustomClientDataSet; UpdateKind: TUpdateKind; var Applied: Boolean);
begin
  with UpdateSQL1 do
  begin
    DataSet := DeltaDS;
    DatabaseName := (SourceDS as TDBDataSet).DatabaseName;
    SessionName := (SourceDS as TDBDataSet).SessionName;
    Apply(UpdateKind);
```

```
    Applied := True;
  end;
end;
void __fastcall TForm1::BDEClientDataSet1BeforeUpdateRecord(TObject *Sender,
   TDataSet *SourceDS, TCustomClientDataSet *DeltaDS, TUpdateKind UpdateKind, bool &Applied)
{
  UpdateSQL1->DataSet = DeltaDS;
  TDBDataSet *pSrcDS = dynamic_cast<TDBDataSet *>(SourceDS);
  UpdateSQL1->DatabaseName = pSrcDS->DatabaseName;
  UpdateSQL1->SessionName = pSrcDS->SessionName;
  UpdateSQL1->Apply(UpdateKind);
  Applied = true;
}
```

See Also

Executing an Update Statement (see page 1639)

3.2.3.7.3.2 Executing the SQL Statements

When you use multiple update objects, you do not associate the update objects with a dataset by setting its *UpdateObject* property. As a result, the appropriate statements are not automatically executed when you apply updates. Instead, you must explicitly invoke the update object in code.

There are two ways to invoke the update object. Which way you choose depends on whether the SQL statement uses parameters to represent field values (see page 1689):

- If the SQL statement to execute uses parameters, call the Apply method (see page 1642).
- If the SQL statement to execute does not use parameters, it is more efficient to call the ExecSQL method.

  Note: If the SQL statement uses parameters other than the built-in types (for the original and updated field values), you must manually supply parameter values instead of relying on the parameter substitution provided by the *Apply* method. See Using an update component's Query property (see page 1640) for information on manually providing parameter values.

See Also

Creating SQL Statements for Update Components (see page 1696)

3.2.3.7.4 Using the Borland Database Engine

The Borland Database Engine (BDE) is a data-access mechanism that can be shared by several applications. The BDE defines a powerful library of API calls that can create, restructure, fetch data from, update, and otherwise manipulate local and remote database servers. The BDE provides a uniform interface to access a wide variety of database servers, using drivers to connect to different databases. Depending on your edition of Delphi, you can use the drivers for local databases (Paradox, dBASE, FoxPro, and Access) and an ODBC adapter that lets you supply your own ODBC drivers.

When deploying BDE-based applications, you must include the BDE with your application. While this increases the size of the application and the complexity of deployment, the BDE can be shared with other BDE-based applications and provides a broad range of support for database manipulation. Although you can use the BDE's API directly in your application, the components on the BDE category of the **Tool palette** wrap most of this functionality for you.

3.2.3.7.5 Connecting to databases with TDatabase

The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

Topics

Name	Description
Associating a Database Component with a Session (see page 1645)	All database components must be associated with a BDE session. Use the SessionName, establish this association. When you first create a database component at design time, *SessionName* is set to "Default", meaning that it is associated with the default session component that is referenced by the global Session variable. Multi-threaded or reentrant BDE applications may require more than one session. If you need to use multiple sessions, add TSession components for each session. Then, associate your dataset with a session component by setting the SessionName property to a session component's SessionName property. At runtime, you can access the session component... more (see page 1645)
Using TDatabase to Connect to Databases (see page 1646)	When a Delphi application uses the Borland Database Engine (BDE) to connect to a database, that connection is encapsulated by a TDatabase component. A database component represents the connection to a single database in the context of a BDE session. *TDatabase* performs many of the same tasks as and shares many common properties, methods, and events with other database connection components. These commonalities are described in Connecting to databases (see page 1506). In addition to the common properties, methods, and events, *TDatabase* introduces many BDE-specific features. These features are described in the following topics: • Associating a Database Component with a Session (see page 1645)... more (see page 1646)
Opening a Connection Using TDataBase (see page 1646)	As with all database connection components, to connect to a database using *TDatabase*, you set the *Connected* property to *True* or call the *Open* method. This process is described in Connecting to a database server (see page 1509). Once a database connection is established the connection is maintained as long as there is at least one active dataset. When there are no more active datasets, the connection is dropped unless the database component's KeepConnection property is *True*. When you connect to a remote database server from an application, the application uses the BDE and the CodeGear SQL Links driver to... more (see page 1646)
Understanding Database and Session Component Interactions (see page 1647)	In general, session component properties provide global, default behaviors that apply to all implicit database components created at runtime. For example, the controlling session's KeepConnections property determines whether a database connection is maintained even if its associated datasets are closed (the default), or if the connections are dropped when all its datasets are closed. Similarly, the default *OnPasswordevent for a session guarantees that when an application attempts to attach to a database on a server that requires a password, it displays a standard password prompt dialog box.* *Session methods apply somewhat differently. TSession methods affect all database components, regardless... more (see page 1647)*

Using Database Components in Data Modules (see page 1647)	You can safely place database components in data modules. If you put a data module that contains a database component into the Object Repository, however, and you want other users to be able to inherit from it, you must set the HandleShared property of the database component to *True* to prevent global name space conflicts.
Setting BDE Alias Parameters (see page 1648)	At design time you can create or edit connection parameters in three ways: • Use the Database Explorer to create or modify BDE aliases, including parameters. For more information about these utilities, see their online Help files. • Double-click the *Params* property in the **Object Inspector** to invoke the String List editor (see page 2140). • Double-click a database component in a data module or form to invoke the Database Properties editor. All of these methods edit the Params property for the database component. *Params* is a string list containing the database connection parameters for the BDE alias associated with a database component. Some typical... more (see page 1648)
Identifying the Database (see page 1648)	*AliasName* and *DriverName* are mutually exclusive properties that identify the database server to which the *TDatabase* component connects. AliasName specifies the name of an existing BDE alias to use for the database component. The alias appears in subsequent drop-down lists for dataset components so that you can link them to a particular database component. If you specify *AliasName* for a database component, any value already assigned to *DriverName* is cleared because a driver name is always part of a BDE alias. You create and edit BDE aliases using the Database Explorer . For more information about creating and maintaining BDE... more (see page 1648)

3.2.3.7.5.1 Associating a Database Component with a Session

All database components must be associated with a BDE session. Use the SessionName, establish this association. When you first create a database component at design time, *SessionName* is set to "Default", meaning that it is associated with the default session component that is referenced by the global Session variable.

Multi-threaded or reentrant BDE applications may require more than one session. If you need to use multiple sessions, add TSession components for each session. Then, associate your dataset with a session component by setting the SessionName property to a session component's SessionName property.

At runtime, you can access the session component with which the database is associated by reading the Session property. If *SessionName* is blank or "Default", then the *Session* property references the same *TSession* instance referenced by the global *Session* variable. *Session* enables applications to access the properties, methods, and events of a database component's parent session component without knowing the session's actual name.

For more information about BDE sessions, see Managing database sessions (see page 1664).

If you are using an implicit database component (see page 1505), the session for that database component is the one specified by the dataset's SessionName property.

Opening a Connection Using TDataBase (see page 1646)

Using Database Components in Data Modules (see page 1647)

Applying Cached Updates with a Database Component Method (see page 1695)

3.2.3.7.5.2 Using TDatabase to Connect to Databases

When a Delphi application uses the Borland Database Engine (BDE) to connect to a database, that connection is encapsulated by a TDatabase component. A database component represents the connection to a single database in the context of a BDE session.

TDatabase performs many of the same tasks as and shares many common properties, methods, and events with other database connection components. These commonalities are described in Connecting to databases (see page 1506).

In addition to the common properties, methods, and events, *TDatabase* introduces many BDE-specific features. These features are described in the following topics:

- Associating a Database Component with a Session (see page 1645)
- Understanding Database and Session Component Interactions (see page 1647)
- Identifying the Database (see page 1648)
- Opening a Connection Using TDatabase (see page 1646)
- Using Database Components in Data Modules (see page 1647)
- Applying Cached Updates Using a Database (see page 1687).

See Also

Using BDE Enabled Datasets (see page 1675)

Managing Database Sessions Using TSession (see page 1664)

3.2.3.7.5.3 Opening a Connection Using TDataBase

As with all database connection components, to connect to a database using *TDatabase*, you set the *Connected* property to *True* or call the *Open* method. This process is described in Connecting to a database server (see page 1509). Once a database connection is established the connection is maintained as long as there is at least one active dataset. When there are no more active datasets, the connection is dropped unless the database component's KeepConnection property is *True*.

When you connect to a remote database server from an application, the application uses the BDE and the CodeGear SQL Links driver to establish the connection. (The BDE can also communicate with an ODBC driver that you supply.) You need to configure the SQL Links or ODBC driver for your application prior to making the connection. SQL Links and ODBC parameters are stored in the Params property of a database component. For information about SQL Links parameters, see the online *SQL Links* User's Guide. To edit the *Params* property, see Setting BDE alias parameters (see page 1648)

Working with network protocols

As part of configuring the appropriate SQL Links or ODBC driver, you may need to specify the network protocol used by the server, such as SPX/IPX or TCP/IP, depending on the driver's configuration options. In most cases, network protocol configuration is handled using a server's client setup software. For ODBC it may also be necessary to check the driver setup using the ODBC driver manager.

Establishing an initial connection between client and server can be problematic. The following troubleshooting checklist should be helpful if you encounter difficulties:

- Is your server's client-side connection properly configured?
- Are the DLLs for your connection and database drivers in the search path?
- If you are using TCP/IP:
- Is your TCP/IP communications software installed? Is the proper WINSOCK.DLL installed?
- Is the server's IP address registered in the client's HOSTS file?
- Is the Domain Name Services (DNS) properly configured?

- Can you ping the server?

For more troubleshooting information, see the online *SQL Links User's Guide* and your server documentation.

Using ODBC

An application can use ODBC data sources (for example, Btrieve). An ODBC driver connection requires

- A vendor-supplied ODBC driver.
- The Microsoft ODBC Driver Manager.

3.2.3.7.5.4 Understanding Database and Session Component Interactions

In general, session component properties provide global, default behaviors that apply to all implicit database components created at runtime. For example, the controlling session's KeepConnections property determines whether a database connection is maintained even if its associated datasets are closed (the default), or if the connections are dropped when all its datasets are closed. Similarly, the default *OnPasswordevent for a session guarantees that when an application attempts to attach to a database on a server that requires a password, it displays a standard password prompt dialog box.*

Session methods apply somewhat differently. TSession methods affect all database components, regardless of whether they are explicitly created or instantiated implicitly by a dataset. For example, the session method DropConnectionscloses all datasets belonging to a session's database components, and then drops all database connections, even if the KeepConnection property for individual database components is True.

Database component methods apply only to the datasets associated with a given database component. For example, suppose the database component Database1 is associated with the default session. Database1.CloseDataSets() closes only those datasets associated with Database1. Open datasets belonging to other database components within the default session remain open.

Applying Cached Updates with a Database Component Method (see page 1695)

3.2.3.7.5.5 Using Database Components in Data Modules

You can safely place database components in data modules. If you put a data module that contains a database component into the Object Repository, however, and you want other users to be able to inherit from it, you must set the HandleShared property of the database component to *True* to prevent global name space conflicts.

Opening a Connection Using TDataBase (see page 1646)

Applying Cached Updates with a Database Component Method (see page 1695)

3.2.3.7.5.6 Setting BDE Alias Parameters

At design time you can create or edit connection parameters in three ways:

- Use the Database Explorer to create or modify BDE aliases, including parameters. For more information about these utilities, see their online Help files.
- Double-click the *Params* property in the **Object Inspector** to invoke the String List editor (see page 2140).
- Double-click a database component in a data module or form to invoke the Database Properties editor.

All of these methods edit the Params property for the database component. *Params* is a string list containing the database connection parameters for the BDE alias associated with a database component. Some typical connection parameters include path statement, server name, schema caching size, language driver, and SQL query mode.

When you first invoke the Database Properties editor, the parameters for the BDE alias are not visible. To see the current settings, click Defaults. The current parameters are displayed in the Parameter overrides memo box. You can edit existing entries or add new ones. To clear existing parameters, click Clear. Changes you make take effect only when you click OK.

At runtime, an application can set alias parameters only by editing the *Params* property directly.

3.2.3.7.5.7 Identifying the Database

AliasName and *DriverName* are mutually exclusive properties that identify the database server to which the *TDatabase* component connects.

AliasName specifies the name of an existing BDE alias to use for the database component. The alias appears in subsequent drop-down lists for dataset components so that you can link them to a particular database component. If you specify *AliasName* for a database component, any value already assigned to *DriverName* is cleared because a driver name is always part of a BDE alias.

You create and edit BDE aliases using the Database Explorer . For more information about creating and maintaining BDE aliases, see the online documentation for these utilities.

DriverName*is the name of a BDE driver. A driver name is one parameter in a BDE alias, but you may specify a driver name instead of an alias when you create a local BDE alias for a database component using the DatabaseName property. If you specify DriverName, any value already assigned to AliasName is cleared to avoid potential conflicts between the driver name you specify and the driver name that is part of the BDE alias identified in AliasName.*

DatabaseName lets you provide your own name for a database connection. The name you supply is in addition to AliasName or DriverName, and is local to your application. DatabaseName can be a BDE alias, or, for Paradox and dBASE files, a fully-qualified path name. Like AliasName, DatabaseName appears in subsequent drop-down lists for dataset components to let you link them to database components.

At design time, to specify a BDE alias, assign a BDE driver, or create a local BDE alias, double-click a database component to invoke the Database Properties editor.

You can enter a DatabaseName in the Name edit box in the properties editor. You can enter an existing BDE alias name in the Alias name combo box for the Alias property, or you can choose from existing aliases in the drop-down list. The Driver name combo box enables you to enter the name of an existing BDE driver for the DriverName property, or you can choose from existing driver names in the drop-down list.

Note: *The Database Properties editor also lets you view and set BDE connection parameters, and set the states of the*

LoginPrompt and KeepConnection properties. For information on connection parameters, see Setting BDE Alias Parameters (see page 1648). For information on LoginPrompt, see Controlling Server Login (see page 1507). For information on KeepConnection see Opening a Connection Using TDatabase (see page 1646).

3.2.3.7.6 Managing database sessions

The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

Topics

Name	Description
Activating a Session (see page 1651)	Active is a Boolean property that determines if database and dataset components associated with a session are open. You can use this property to read the current state of a session's database and dataset connections, or to change it. If *Active* is *False* (the default), all databases and datasets associated with the session are closed. If *True*, databases and datasets are open. A session is activated when it is first created, and subsequently, whenever its *Active* property is changed to *True* from *False* (for example, when a database or dataset is associated with a session is opened and there... more (see page 1651)
Creating Additional Sessions (see page 1652)	You can create sessions to supplement the default session. At design time, you can place additional sessions on a data module (or form), set their properties in the **Object Inspector**, write event handlers for them, and write code that calls their methods. You can also create sessions, set their properties, and call their methods at runtime. **Note:** Creating additional sessions is optional unless an application runs concurrent queries against a database or the application is multi-threaded.
Iterating Through a Session's Database Components (see page 1652)	You can use two session component properties, *Databases* and *DatabaseCount*, to cycle through all the active database components associated with a session. *Databases* is an array of all currently active database components associated with a session. *DatabaseCount* is the number of databases in that array. As connections are opened or closed during a session's life-span, the values of *Databases* and *DatabaseCount* change. For example, if a session's *KeepConnections* property is *False* and all database components are created as needed at runtime, each time a unique database is opened, *DatabaseCount* increases by one. Each time a unique database is closed,... more (see page 1652)
Opening Database Connections (see page 1653)	To open a database connection within a session, call the OpenDatabase method. *OpenDatabase* takes one parameter, the name of the database to open. This name is a BDE alias or the name of a database component. For Paradox or dBASE, the name can also be a fully qualified path name. For example, the following statement uses the default session and attempts to open a database connection for the database pointed to by the DBDEMOS alias:
Searching for a Database Connection (see page 1654)	Use a session's FindDatabase method to determine whether a specified database component is already associated with a session. *FindDatabase* takes one parameter, the name of the database to search for. This name is a BDE alias or database component name. For Paradox or dBASE, it can also be a fully-qualified path name. *FindDatabase* returns the database component if it finds a match. Otherwise it returns **nil**. The following code searches the default session for a database component using the DBDEMOS alias, and if it is not found, creates one and opens it:

Specifying Paradox Directory Locations (see page 1654)	Two session component properties, *NetFileDir* and *PrivateDir*, are specific to applications that work with Paradox tables. *NetFileDir* specifies the directory that contains the Paradox network control file, PDOXUSRS.NET. This file governs sharing of Paradox tables on network drives. All applications that need to share Paradox tables must specify the same directory for the network control file (typically a directory on a network file server). Delphi derives a value for *NetFileDir* from the Borland Database Engine (BDE) configuration file for a given database alias. If you set *NetFileDir* yourself, the value you supply overrides the BDE configuration setting, so... more (see page 1654)
Retrieving Information About a Session (see page 1655)	You can retrieve information about a session and its database components by using a session's informational methods. For example, one method retrieves the names of all aliases known to the session, and another method retrieves the names of tables associated with a specific database component used by the session. The following table summarizes the informational methods to a session component: ***Database-related informational methods for session components***
Closing Database Connections (see page 1656)	To close an individual database connection, call the CloseDatabase method. When you call *CloseDatabase*, the reference count for the database, which is incremented when you call *OpenDatabase*, is decremented by 1. When the reference count for a database is 0, the database is closed. *CloseDatabase* takes one parameter, the database to close. If you opened the database using the *OpenDatabase* method, this parameter can be set to the return value of *OpenDatabase*.
Working with BDE Aliases (see page 1657)	Each database component associated with a session has a BDE alias (although optionally a fully-qualified path name may be substituted for an alias when accessing Paradox and dBASE tables). A session can create, modify, and delete aliases during its lifetime. The AddAlias method creates a new BDE alias for an SQL database server. *AddAlias* takes three parameters: a string containing a name for the alias, a string that specifies the SQL Links driver to use, and a string list populated with parameters for the alias. For example, the following statements use *AddAlias* to add a new alias for accessing an... more (see page 1657)
Naming a Session (see page 1659)	A session's *SessionName* property is used to name the session so that you can associate databases and datasets with it. For the default session, *SessionName* is "Default," For each additional session component you create, you must set its *SessionName* property to a unique value. Database and dataset components have *SessionName* properties that correspond to the *SessionName* property of a session component. If you leave the *SessionName* property blank for a database or dataset component it is automatically associated with the default session. You can also set *SessionName* for a database or dataset component to a name that corresponds to the... more (see page 1659)
Managing Multiple Sessions (see page 1659)	If you create a single application that uses multiple threads to perform database operations, you must create one additional session for each thread. The BDE category on the **Tool palette** contains a session component that you can place in a data module or on a form at design time. **Warning:** When you place a session component, you must also set its *SessionName* property to a unique value so that it does not conflict with the default session's *SessionName* property. Placing a session component at design time presupposes that the number of threads (and therefore sessions) required by the application at... more (see page 1659)
Specifying Default Database Connection Behavior (see page 1661)	KeepConnections provides the default value for the *KeepConnection* property of implicit database components created at runtime. *KeepConnection* specifies what happens to a database connection established for a database component when all its datasets are closed. If *True* (the default), a constant, or *persistent*, database connection is maintained even if no dataset is active. If *False*, a database connection is dropped as soon as all its datasets are closed. **Note:** Connection persistence for a database component you explicitly place in a data module or form is controlled by that database component's *KeepConnection* property. If set differently, *KeepConnection* for a... more (see page 1661)
Dropping Inactive Database Connections (see page 1661)	If the *KeepConnections* property for a session is *True* (the default), then database connections for temporary database components are maintained even if all the datasets used by the component are closed. You can eliminate these connections and free all inactive temporary database components for a session by calling the DropConnections method. For example, the following code frees all inactive, temporary database components for the default session:

Working with Password-protected Paradox and dBASE Tables (see page 1662)	A session component can store passwords for password-protected Paradox and dBASE tables. Once you add a password to the session, your application can open tables protected by that password. Once you remove the password from the session, your application can't open tables that use the password until you add it again.
Managing Database Sessions (see page 1664)	An BDE-based application's database connections, drivers, cursors, queries, and so on are maintained within the context of one or more BDE sessions. Sessions isolate a set of database access operations, such as database connections, without the need to start another instance of the application. All BDE-based database applications automatically include a default session component, named Session, that encapsulates the default BDE session. When database components are added to the application, they are automatically associated with the default session (note that its *SessionName* is "Default"). The default session provides global control over all database components not associated with another session, whether... more (see page 1664)
Managing Database Connections (see page 1665)	You can use a session component to manage the database connections within it. The session component includes properties and methods you can use to • Open database connections (see page 1653). • Close database connections (see page 1656). • Close and free all inactive temporary database connections (see page 1661). • Locate specific database connections (see page 1654). • Iterate through all open database connections (see page 1652).

3.2.3.7.6.1 Activating a Session

Active is a Boolean property that determines if database and dataset components associated with a session are open. You can use this property to read the current state of a session's database and dataset connections, or to change it. If *Active* is *False* (the default), all databases and datasets associated with the session are closed. If *True*, databases and datasets are open.

A session is activated when it is first created, and subsequently, whenever its *Active* property is changed to *True* from *False* (for example, when a database or dataset is associated with a session is opened and there are currently no other open databases or datasets). Setting *Active* to *True* triggers a session's OnStartup event, registers the paradox directory locations. (see page 1654) with the BDE, and registers the *ConfigMode* property, which determines what BDE aliases (see page 1657) are available within the session. You can write an *OnStartup* event handler to initialize the *NetFileDir*, *PrivateDir*, and *ConfigMode* properties before they are registered with the BDE, or to perform other specific session start-up activities.

Once a session is active, you can open its database connections by calling the OpenDatabase method.

For session components you place in a data module or form, setting *Active* to *False* when there are open databases or datasets closes them. At runtime, closing databases and datasets may trigger events associated with them.

Note: You cannot set *Active* to *False* for the default session at design time. While you can close the default session at runtime, it is not recommended.

You can also use a session's *Open* and *Close* methods to activate or deactivate sessions other than the default session at runtime. For example, the following single line of code closes all open databases and datasets for a session:

```
Session1.Close;
Session1->Close();
```

This code sets Session1's *Active* property to *False*. When a session's *Active* property is *False*, any subsequent attempt by the application to open a database or dataset resets *Active* to *True* and calls the session's *OnStartup* event handler if it exists. You can also explicitly code session reactivation at runtime. The following code reactivates *Session1*:

```
Session1.Open;
Session1->Open();
```

Note: If a session is active you can also open and close individual database connections. For more information, see Closing

database connections. (see page 1656)

Working with Password Protected Paradox Tables (see page 1662)

Managing Multiple Sessions (see page 1659)

3.2.3.7.6.2 Creating Additional Sessions

You can create sessions to supplement the default session. At design time, you can place additional sessions on a data module (or form), set their properties in the **Object Inspector**, write event handlers for them, and write code that calls their methods. You can also create sessions, set their properties, and call their methods at runtime.

Note: Creating additional sessions is optional unless an application runs concurrent queries against a database or the application is multi-threaded.

To enable dynamic creation of a session component at runtime

1. Declare a *TSession* variable.
2. Instantiate a new session by calling the *Create* method. The constructor sets up an empty list of database components for the session, sets the *KeepConnections* property to *True*, and adds the session to the list of sessions maintained by the application's session list component.
3. Set the *SessionName* property for the new session to a unique name. This property is used to associate database components with the session. For more information about the *SessionName* property, see Naming a session. (see page 1659)
4. Activate the session and optionally adjust its properties.

You can also create and open sessions using the *OpenSession* method of *TSessionList*. Using *OpenSession* is safer than calling *Create*, because *OpenSession* only creates a session if it does not already exist. For information about *OpenSession*, see Managing multiple sessions. (see page 1659).

Specifying Paradox Directory Locations (see page 1654)

Managing Database Connections (see page 1665)

Managing Multiple Sessions (see page 1659)

Working with Password Protected Paradox Tables (see page 1662)

3.2.3.7.6.3 Iterating Through a Session's Database Components

You can use two session component properties, *Databases* and *DatabaseCount*, to cycle through all the active database components associated with a session.

Databases is an array of all currently active database components associated with a session. *DatabaseCount* is the number of databases in that array. As connections are opened or closed during a session's life-span, the values of *Databases* and *DatabaseCount* change. For example, if a session's *KeepConnections* property is *False* and all database components are created as needed at runtime, each time a unique database is opened, *DatabaseCount* increases by one. Each time a unique database is closed, *DatabaseCount* decreases by one. If *DatabaseCount* is zero, there are no currently active database components for the session.

The following example code sets the *KeepConnection* property of each active database in the default session to *True*:

```
var
  MaxDbCount: Integer;
begin
  with Session do
    if (DatabaseCount > 0) then
      for MaxDbCount := 0 to (DatabaseCount - 1) do
        Databases[MaxDbCount].KeepConnection := True;
end;
if (Session->DatabaseCount > 0)
  for (int MaxDbCount = 0; MaxDbCount < Session->DatabaseCount; MaxDbCount++)
    Session->Databases[MaxDbCount]->KeepConnection = true;
```

See Also

Opening Database Connections (see page 1653)

Closing Database Connections (see page 1656)

Searching for a Database Connection (see page 1654)

Dropping Inactive Database Connections (see page 1661)

3.2.3.7.6.4 Opening Database Connections

To open a database connection within a session, call the OpenDatabase method. *OpenDatabase* takes one parameter, the name of the database to open. This name is a BDE alias or the name of a database component. For Paradox or dBASE, the name can also be a fully qualified path name. For example, the following statement uses the default session and attempts to open a database connection for the database pointed to by the DBDEMOS alias:

```
var
  DBDemosDatabase: TDatabase;
begin
  DBDemosDatabase := Session.OpenDatabase('DBDEMOS');
  ...
TDatabase *BCDemosDatabase = Session->OpenDatabase("BCDEMOS");
```

OpenDatabase actives the session if it is not already active, and then checks if the specified database name matches the *DatabaseName* property of any database components for the session. If the name does not match an existing database component, *OpenDatabase* creates a temporary database component using the specified name. Finally, *OpenDatabase* calls the *Open* method of the database component to connect to the server. Each call to *OpenDatabase* increments a reference count for the database by 1. As long as this reference count remains greater than 0, the database is open.

See Also

Closing Database Connections (see page 1656)

Dropping Temporary Database Connections (see page 1661)

Iterating Through a Session's Database Components (see page 1652)

Searching for a Database Connection (see page 1654)

3.2.3.7.6.5 Searching for a Database Connection

Use a session's FindDatabase method to determine whether a specified database component is already associated with a session. *FindDatabase* takes one parameter, the name of the database to search for. This name is a BDE alias or database component name. For Paradox or dBASE, it can also be a fully-qualified path name.

FindDatabase returns the database component if it finds a match. Otherwise it returns **nil**.

The following code searches the default session for a database component using the DBDEMOS alias, and if it is not found, creates one and opens it:

```
var
  DB: TDatabase;
begin
  DB := Session.FindDatabase('DBDEMOS');
  if (DB = nil) then                          { database doesn't exist for session so,}
    DB := Session.OpenDatabase('DBDEMOS');    { create and open it}
  if Assigned(DB) and DB.Connected then begin
    DB.StartTransaction;
    ...
  end;
end;
```

```
TDatabase *DB = Session->FindDatabase("BCDEMOS");
if ( !DB )                                  // Database does not exist for session so
  DB = Session->OpenDatabase("BCDEMOS"); // create and open it
if (DB && DB->Connected)
{
  if (!DB->InTransaction)
  {
    DB->StartTransaction();
    .
    .
    .
  }
}
```

Dropping Inactive Database Connections (see page 1661)

3.2.3.7.6.6 Specifying Paradox Directory Locations

Two session component properties, *NetFileDir* and *PrivateDir*, are specific to applications that work with Paradox tables.

NetFileDir specifies the directory that contains the Paradox network control file, PDOXUSRS.NET. This file governs sharing of Paradox tables on network drives. All applications that need to share Paradox tables must specify the same directory for the network control file (typically a directory on a network file server). Delphi derives a value for *NetFileDir* from the Borland Database Engine (BDE) configuration file for a given database alias. If you set *NetFileDir* yourself, the value you supply overrides the BDE configuration setting, so be sure to validate the new value.

At design time, you can specify a value for *NetFileDir* in the **Object Inspector**. You can also set or change *NetFileDir* in code at runtime. The following code sets *NetFileDir* for the default session to the location of the directory from which your application runs:

```
Session.NetFileDir := ExtractFilePath(Application.EXEName);
```

```
Session->NetFileDir = ExtractFilePath(ParamStr(0));
```

Note: *NetFileDir* can only be changed when an application does not have any open Paradox files. If you change *NetFileDir* at runtime, verify that it points to a valid network directory that is shared by your network users.

PrivateDir specifies the directory for storing temporary table processing files, such as those generated by the BDE to handle local SQL statements. If no value is specified for the *PrivateDir* property, the BDE automatically uses the current directory at the time it is initialized. If your application runs directly from a network file server, you can improve application performance at runtime by setting *PrivateDir* to a user's local hard drive before opening the database.

Note: Do not set *PrivateDir* at design time and then open the session in the IDE. Doing so generates a Directory is busy error when running your application from the IDE.

The following code changes the setting of the default session's *PrivateDir* property to a user's C:\TEMP directory:

```
Session.PrivateDir := "C:\TEMP";
Session->PrivateDir = "C:\\TEMP";
```

Warning: Do not set *PrivateDir* to a root directory on a drive. Always specify a subdirectory.

3.2.3.7.6.7 Retrieving Information About a Session

You can retrieve information about a session and its database components by using a session's informational methods. For example, one method retrieves the names of all aliases known to the session, and another method retrieves the names of tables associated with a specific database component used by the session. The following table summarizes the informational methods to a session component:

Database-related informational methods for session components

Method	Purpose
GetAliasDriverName	Retrieves the BDE driver for a specified alias of a database.
GetAliasNames	Retrieves the list of BDE aliases for a database.
GetAliasParams	Retrieves the list of parameters for a specified BDE alias of a database.
GetConfigParams	Retrieves configuration information from the BDE configuration file.
GetDatabaseNames	Retrieves the list of BDE aliases and the names of any *TDatabase* components currently in use.
GetDriverNames	Retrieves the names of all currently installed BDE drivers.
GetDriverParams	Retrieves the list of parameters for a specified BDE driver.
GetStoredProcNames	Retrieves the names of all stored procedures for a specified database.
GetTableNames	Retrieves the names of all tables matching a specified pattern for a specified database.
GetFieldNames	Retrieves the names of all fields in a specified table in a specified database.

Except for *GetAliasDriverName*, these methods return a set of values into a string list declared and maintained by your

application. (*GetAliasDriverName* returns a single string, the name of the current BDE driver for a particular database component used by the session.)

For example, the following code retrieves the names of all database components and aliases known to the default session:

```
var
  List: TStringList;
begin
  List := TStringList.Create;
  try
    Session.GetDatabaseNames(List);
    ...
  finally
    List.Free;
  end;
end;
```

```
TStringList *List = new TStringList();
try
{
  Session->GetDatabaseNames(List);
  .
  .
  .
}
catch (...)
{
delete List;
throw;
}
delete List;
```

Managing Database Connections (see page 1665)

3.2.3.7.6.8 Closing Database Connections

To close an individual database connection, call the CloseDatabase method. When you call *CloseDatabase*, the reference count for the database, which is incremented when you call *OpenDatabase*, is decremented by 1. When the reference count for a database is 0, the database is closed. *CloseDatabase* takes one parameter, the database to close. If you opened the database using the *OpenDatabase* method, this parameter can be set to the return value of *OpenDatabase*.

```
Session.CloseDatabase(DBDemosDatabase);
Session->CloseDatabase(BCDemosDatabase);
```

If the specified database name is associated with a temporary (implicit) database component, and the session's *KeepConnections* property is *False*, the database component is freed, effectively closing the connection.

Note: If *KeepConnections* is *False* temporary database components are closed and freed automatically when the last dataset associated with the database component is closed. An application can always call *CloseDatabase* prior to that time to force closure. To free temporary database components when *KeepConnections* is *True*, call the database component's *Close* method, and then call the session's *DropConnections* method.

Note: Calling *CloseDatabase* for a persistent database component does not actually close the connection. To close the connection, call the database component's *Close* method directly.

There are two ways to close all database connections within the session:

- Set the *Active* property for the session to *False*.

- Call the *Close* method for the session.

When you set *Active* to *False*, Delphi automatically calls the *Close* method. *Close* disconnects from all active databases by freeing temporary database components and calling each persistent database component's *Close* method. Finally, *Close* sets the session's BDE handle to **nil**.

3.2.3.7.6.9 Working with BDE Aliases

Each database component associated with a session has a BDE alias (although optionally a fully-qualified path name may be substituted for an alias when accessing Paradox and dBASE tables). A session can create, modify, and delete aliases during its lifetime.

The AddAlias method creates a new BDE alias for an SQL database server. *AddAlias* takes three parameters: a string containing a name for the alias, a string that specifies the SQL Links driver to use, and a string list populated with parameters for the alias. For example, the following statements use *AddAlias* to add a new alias for accessing an InterBase server to the default session:

```
var
  AliasParams: TStringList;
begin
  AliasParams := TStringList.Create;
  try
    with AliasParams do begin
      Add('OPEN MODE=READ');
      Add('USER NAME=TOMSTOPPARD');
      Add('SERVER NAME=ANIMALS:/CATS/PEDIGREE.GDB');
    end;
    Session.AddAlias('CATS', 'INTRBASE', AliasParams);
    ...
  finally
    AliasParams.Free;
  end;
end;
```

```
TStringList *AliasParams = new TStringList();
try
{
  AliasParams->Add("OPEN MODE=READ");
  AliasParams->Add("USER NAME=TOMSTOPPARD");
  AliasParams->Add("SERVER NAME=ANIMALS:/CATS/PEDIGREE.GDB");
  Session->AddAlias("CATS", "INTRBASE", AliasParams);
  .
  .
  .
}
catch (...)
{
  delete AliasParams;
  throw;
}
delete AliasParams;
```

AddStandardAlias creates a new BDE alias for Paradox, dBASE, or ASCII tables. *AddStandardAlias* takes three string parameters: the name for the alias, the fully-qualified path to the Paradox or dBASE table to access, and the name of the default driver to use when attempting to open a table that does not have an extension. For example, the following statement uses

AddStandardAlias to create a new alias for accessing a Paradox table:

```
AddStandardAlias('MYDBDEMOS', 'C:\TESTING\DEMOS\', 'Paradox');
Session->AddStandardAlias("MYBCDEMOS", "C:\\TESTING\\DEMOS\\", "Paradox");
```

When you add an alias to a session, the BDE stores a copy of the alias in memory, where it is only available to this session and any other sessions with *cfmPersistent* included in the *ConfigMode* property. *ConfigMode* is a set that describes which types of aliases can be used by the databases in the session. The default setting is *cmAll*, which translates into the set [*cfmVirtual*, *cfmPersistent, cfmSession*]. If *ConfigMode* is *cmAll*, a session can see all aliases created within the session (*cfmSession*), all aliases in the BDE configuration file on a user's system (*cfmPersistent*), and all aliases that the BDE maintains in memory (*cfmVirtual*). You can change *ConfigMode* to restrict what BDE aliases the databases in a session can use. For example, setting *ConfigMode* to *cfmSession* restricts a session's view of aliases to those created within the session. All other aliases in the BDE configuration file and in memory are not available.

To make a newly created alias available to all sessions and to other applications, use the session's SaveConfigFile method. *SaveConfigFile* writes aliases in memory to the BDE configuration file where they can be read and used by other BDE-enabled applications.

After you create an alias, you can make changes to its parameters by calling ModifyAlias. *ModifyAlias* takes two parameters: the name of the alias to modify and a string list containing the parameters to change and their values. For example, the following statements use *ModifyAlias* to change the OPEN MODE parameter for the CATS alias to READ/WRITE in the default session:

```
var
  List: TStringList;
begin
  List := TStringList.Create;
  with List do begin
    Clear;
    Add('OPEN MODE=READ/WRITE');
  end;
  Session.ModifyAlias('CATS', List);
  List.Free;
  ...
TStringList *List = new TStringList();
List->Clear();
List->Add("OPEN MODE=READ/WRITE");
Session->ModifyAlias("CATS", List);
delete List;
```

To delete an alias previously created in a session, call the DeleteAlias method. *DeleteAlias* takes one parameter, the name of the alias to delete. *DeleteAlias* makes an alias unavailable to the session.

Note: *DeleteAlias* does not remove an alias from the BDE configuration file if the alias was written to the file by a previous call to *SaveConfigFile*. To remove the alias from the configuration file after calling *DeleteAlias*, call *SaveConfigFile* again.

Session components provide five methods for retrieving information about a BDE aliases, including parameter information and driver information. They are:

- GetAliasNames, to list the aliases to which a session has access.
- GetAliasParams, to list the parameters for a specified alias.
- GetAliasDriverName, to return the name of the BDE driver used by the alias.
- GetDriverNames, to return a list of all BDE drivers available to the session.
- GetDriverParams, to return driver parameters for a specified driver.

For more information about using a session's informational methods, see Using transactions with the BDE. (see page 1655).
For more information about BDE aliases see the BDE online help, BDE32.HLP.

3.2.3.7.6.10 Naming a Session

A session's *SessionName* property is used to name the session so that you can associate databases and datasets with it. For the default session, *SessionName* is "Default," For each additional session component you create, you must set its *SessionName* property to a unique value.

Database and dataset components have *SessionName* properties that correspond to the *SessionName* property of a session component. If you leave the *SessionName* property blank for a database or dataset component it is automatically associated with the default session. You can also set *SessionName* for a database or dataset component to a name that corresponds to the *SessionName* of a session component you create.

The following code uses the *OpenSession* method of the default *TSessionList* component, *Sessions*, to open a new session component, sets its *SessionName* to "InterBaseSession," activate the session, and associate an existing database component *Database1* with that session:

```
var
  IBSession: TSession;
  ...
begin
  IBSession := Sessions.OpenSession('InterBaseSession');
  Database1.SessionName := 'InterBaseSession';
end;
```

```
TSession *IBSession = Sessions->OpenSession("InterBaseSession");
Database1->SessionName = "InterBaseSession";
```

For more information about using *Sessions*, see Managing Multiple Sessions. (see page 1659).

Creating Additional Sessions (see page 1652)

3.2.3.7.6.11 Managing Multiple Sessions

If you create a single application that uses multiple threads to perform database operations, you must create one additional session for each thread. The BDE category on the **Tool palette** contains a session component that you can place in a data module or on a form at design time.

Warning: When you place a session component, you must also set its *SessionName* property to a unique value so that it does not conflict with the default session's *SessionName* property.

Placing a session component at design time presupposes that the number of threads (and therefore sessions) required by the application at runtime is static. More likely, however, is that an application needs to create sessions dynamically. To create sessions dynamically, call the OpenSession method of the global Sessions object at runtime.

OpenSession requires a single parameter, a name for the session that is unique across all session names for the application. The following code dynamically creates and activates a new session with a uniquely generated name:

```
Sessions.OpenSession('RunTimeSession' + IntToStr(Sessions.Count + 1));
```

```
Sessions->OpenSession("RunTimeSession" + IntToStr(Sessions->Count + 1));
```

This statement generates a unique name for a new session by retrieving the current number of sessions, and adding one to that value. Note that if you dynamically create and destroy sessions at runtime, this example code will not work as expected. Nevertheless, this example illustrates how to use the properties and methods of *Sessions* to manage multiple sessions.

Sessions is a variable of type *TSessionList* that is automatically instantiated for BDE-based database applications. You use the properties and methods of *Sessions* to keep track of multiple sessions in a multi-threaded database application. The following table summarizes the properties and methods of the *TSessionList* component:

TSessionList properties and methods

Property or Method	Purpose
Count	Returns the number of sessions, both active and inactive, in the session list.
FindSession	Searches for a session with a specified name and returns a pointer to it, or **nil** if there is no session with the specified name. If passed a blank session name, *FindSession* returns a pointer to the default session, *Session*.
GetSessionNames	Populates a string list with the names of all currently instantiated session components. This procedure always adds at least one string, "Default" for the default session.
List	Returns the session component for a specified session name. If there is no session with the specified name, an exception is raised.
OpenSession	Creates and activates a new session or reactivates an existing session for a specified session name.
Sessions	Accesses the session list by ordinal value.

As an example of using *Sessions* properties and methods in a multi-threaded application, consider what happens when you want to open a database connection. To determine if a connection already exists, use the *Sessions* property to walk through each session in the sessions list, starting with the default session. For each session component, examine its *Databases* property to see if the database in question is open. If you discover that another thread is already using the desired database, examine the next session in the list.

If an existing thread is not using the database, then you can open the connection within that session.

If, on the other hand, all existing threads are using the database, you must open a new session in which to open another database connection.

If you are replicating a data module that contains a session in a multi-threaded application, where each thread contains its own copy of the data module, you can use the AutoSessionName property to make sure that all datasets in the data module use the correct session. Setting *AutoSessionName* to *True* causes the session to generate its own unique name dynamically when it is created at runtime. It then assigns this name to every dataset in the data module, overriding any explicitly set session names. This ensures that each thread has its own session, and each dataset uses the session in its own data module.

3.2.3.7.6.12 Specifying Default Database Connection Behavior

KeepConnections provides the default value for the *KeepConnection* property of implicit database components created at runtime. *KeepConnection* specifies what happens to a database connection established for a database component when all its datasets are closed. If *True* (the default), a constant, or *persistent*, database connection is maintained even if no dataset is active. If *False*, a database connection is dropped as soon as all its datasets are closed.

Note: Connection persistence for a database component you explicitly place in a data module or form is controlled by that database component's *KeepConnection* property. If set differently, *KeepConnection* for a database component always overrides the *KeepConnections* property of the session. For more information about controlling individual database connections within a session, see Managing database connections. (see page 1665)

KeepConnections should be set to *True* for applications that frequently open and close all datasets associated with a database on a remote server. This setting reduces network traffic and speeds data access because it means that a connection need only be opened and closed once during the lifetime of the session. Otherwise, every time the application closes or reestablishes a connection, it incurs the overhead of attaching and detaching the database.

Note: Even when *KeepConnections* is *True* for a session, you can close and free inactive database connections for all implicit database components by calling the DropConnections method. For more information about *DropConnections*, see Dropping inactive database connections (see page 1661).

Managing Multiple Sessions (see page 1659)

3.2.3.7.6.13 Dropping Inactive Database Connections

If the *KeepConnections* property for a session is *True* (the default), then database connections for temporary database components are maintained even if all the datasets used by the component are closed. You can eliminate these connections and free all inactive temporary database components for a session by calling the DropConnections method. For example, the following code frees all inactive, temporary database components for the default session:

```
Session.DropConnections;
Session->DropConnections();
```

Temporary database components for which one or more datasets are active are not dropped or freed by this call. To free these components, call Close.

Opening Database Connections (see page 1653)

Closing Database Connections (see page 1656)

Iterating Through a Session's Database Components (see page 1652)

Searching for a Database Connection (see page 1654)

3.2.3.7.6.14 Working with Password-protected Paradox and dBASE Tables

A session component can store passwords for password-protected Paradox and dBASE tables. Once you add a password to the session, your application can open tables protected by that password. Once you remove the password from the session, your application can't open tables that use the password until you add it again.

Using the AddPassword method

The AddPassword method provides an optional way for an application to provide a password for a session prior to opening an encrypted Paradox or dBASE table that requires a password for access. If you do not add the password to the session, when your application attempts to open a password-protected table, a dialog box prompts the user for a password.

AddPassword takes one parameter, a string containing the password to use. You can call *AddPassword* as many times as necessary to add passwords (one at a time) to access tables protected with different passwords.

```
var
  Passwrd: String;
begin
  Passwrd := InputBox('Enter password', 'Password:', '');
  Session.AddPassword(Passwrd);
  try
    Table1.Open;
  except
    ShowMessage('Could not open table!');
    Application.Terminate;
  end;
end;
```

```
AnsiString PassWrd;
PassWrd = InputBox("Enter password", "Password:", "");
Session->AddPassword(PassWrd);
try
{
  Table1->Open();
}
catch(...)
{
  ShowMessage("Could not open table!");
  Application->Terminate();
}
```

Note: Use of the *InputBox* function, above, is for demonstration purposes. In a real-world application, use password entry facilities that mask the password as it is entered, such as the *PasswordDialog* function or a custom form.

The Add button of the PasswordDialog function dialog has the same effect as the *AddPassword* method.

```
if PasswordDialog(Session) then
  Table1.Open
else
  ShowMessage('No password given, could not open table!');
end;
```

```
if (PasswordDlg(Session))
  Table1->Open();
else
  ShowMessage("No password given, could not open table!");
```

Using the RemovePassword and RemoveAllPasswords methods

RemovePassword deletes a previously added password from memory. *RemovePassword* takes one parameter, a string containing the password to delete.

```
Session.RemovePassword('secret');
```

```
Session->RemovePassword("secret");
```

RemoveAllPasswords deletes all previously added passwords from memory.

```
Session.RemoveAllPasswords;
Session->RemoveAllPasswords();
```

Using the GetPassword method and OnPassword event

The OnPassword event allows you to control how your application supplies passwords for Paradox and dBASE tables when they are required. Provide a handler for the OnPassword event if you want to override the default password handling behavior. If you do not provide a handler, Delphi presents a default dialog for entering a password and no special behavior is provided—the table open attempt either succeeds or an exception is raised.

If you provide a handler for the OnPassword event, do two things in the event handler: call the AddPassword method and set the event handler's Continue parameter to True. The AddPassword method passes a string to the session to be used as a password for the table. The Continue parameter indicates to Delphi that no further password prompting need be done for this table open attempt. The default value for Continue is False, and so requires explicitly setting it to True. If Continue is False after the event handler has finished executing, an OnPassword event fires again—even if a valid password has been passed using AddPassword. If Continue is True after execution of the event handler and the string passed with AddPassword is not the valid password, the table open attempt fails and an exception is raised.

OnPassword can be triggered by two circumstances. The first is an attempt to open a password-protected table (dBASE or Paradox) when a valid password has not already been supplied to the session. (If a valid password for that table has already been supplied, the OnPassword event does not occur.)

The other circumstance is a call to the GetPassword method. GetPassword either generates an OnPassword event, or, if the session does not have an OnPassword event handler, displays a default password dialog. It returns True if the OnPassword event handler or default dialog added a password to the session, and False if no entry at all was made.

In the following example, the Password method is designated as the OnPassword event handler for the default sessionby assigning it to the global Session object's OnPassword property.

```
procedure TForm1.FormCreate(Sender: TObject);
begin
  Session.OnPassword := Password;
end;
void __fastcall TForm1::FormCreate(TObject *Sender)
{
  Session->OnPassword = Password;
}
```

In the *Password* method, the *InputBox* function prompts the user for a password. The *AddPassword* method then programmatically supplies the password entered in the dialog to the session.

```
procedure TForm1.Password(Sender: TObject; var Continue: Boolean);
var
  Passwrd: String;
begin
  Passwrd := InputBox('Enter password', 'Password:', '');
  Continue := (Passwrd > '');
  Session.AddPassword(Passwrd);
end;
void __fastcall TForm1::Password(TObject *Sender, bool &Continue)
{
  AnsiString PassWrd = InputBox("Enter password", "Password:", "");
  Session->AddPassword(PassWrd);
  Continue = (PassWrd > "");
}
```

The *OnPassword* event (and thus the *Password* event handler) is triggered by an attempt to open a password-protected table, as demonstrated below. Even though the user is prompted for a password in the handler for the *OnPassword* event, the table open attempt can still fail if they enter an invalid password or something else goes wrong.

```
procedure TForm1.OpenTableBtnClick(Sender: TObject);
const
CRLF = #13 + #10;
```

```
begin
  try
    Table1.Open;                                { this line triggers the OnPassword event }
  except
    on E:Exception do begin                             { exception if cannot open table }
      ShowMessage('Error!' + CRLF +              { display error explaining what happened }
        E.Message + CRLF +
        'Terminating application...');
      Application.Terminate;                                      { end the application }
    end;
  end;
end;
void __fastcall TForm1::OpenTableBtnClick(TObject *Sender)
{
  try
  {
    // this line triggers the OnPassword event
    Table1->Open();
  }
  // exception if cannot open table
  catch(...)
  {
    ShowMessage("Could not open table!");
    Application->Terminate();
  }
}
```

3.2.3.7.6.15 Managing Database Sessions

An BDE-based application's database connections, drivers, cursors, queries, and so on are maintained within the context of one or more BDE sessions. Sessions isolate a set of database access operations, such as database connections, without the need to start another instance of the application.

All BDE-based database applications automatically include a default session component, named Session, that encapsulates the default BDE session. When database components are added to the application, they are automatically associated with the default session (note that its *SessionName* is "Default"). The default session provides global control over all database components not associated with another session, whether they are implicit (created by the session at runtime when you open a dataset that is not associated with a database component you create) or persistent (explicitly created by your application). The default session is not visible in your data module or form at design time, but you can access its properties and methods in your code at runtime.

To use the default session, you need write no code unless your application must

- Explicitly activate or deactivate a session (see page 1651), enabling or disabling the session's databases' ability to open.
- Modify the properties of the session, such as specifying default properties for implicitly generated database components (see page 1661).
- Execute a session's methods, such as managing database connections (see page 1665) (for example opening and closing

database connections in response to user actions).

- Respond to session events, such as when the application attempts to access a password-protected Paradox or dBASE table (see page 1662).
- Set Paradox directory locations (see page 1654) such as the *NetFileDir* property to access Paradox tables on a network and the *PrivateDir* property to a local hard drive to speed performance.
- Manage the BDE aliases (see page 1657) that describe possible database connection configurations for databases and datasets that use the session.

Whether you add database components to an application at design time or create them dynamically at runtime, they are automatically associated with the default session unless you specifically assign them to a different session (see page 1645). If you open a dataset that is not associated with a database component, Delphi automatically

- Creates a database component for it at runtime.
- Associates the database component with the default session.
- Initializes some of the database component's key properties based on the default session's properties. Among the most important of these properties is *KeepConnections*, which determines when database connections are maintained or dropped by an application.

The default session provides a widely applicable set of defaults that can be used as is by most applications. You need only associate a database component with an explicitly named session if the component performs a simultaneous query against a database already opened by the default session. In this case, each concurrent query must run under its own session. Multi-threaded database applications also require multiple sessions, where each thread has its own session.

Applications can create additional session components (see page 1652) as needed. BDE-based database applications automatically include a session list component, named Sessions, that you can use to manage all of your session components. For more information about managing multiple sessions see, Managing multiple sessions. (see page 1659)

You can safely place session components in data modules. If you put a data module that contains one or more session components into the Object Repository, however, make sure to set the *AutoSessionName* property to *True* to avoid namespace conflicts when users inherit from it.

3.2.3.7.6.16 Managing Database Connections

You can use a session component to manage the database connections within it. The session component includes properties and methods you can use to

- Open database connections (see page 1653).
- Close database connections (see page 1656).
- Close and free all inactive temporary database connections (see page 1661).
- Locate specific database connections (see page 1654).
- Iterate through all open database connections (see page 1652).

3.2.3.7.7 Using BDE-enabled datasets

The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

Topics

Name	Description
Associating a Dataset with Database and Session Connections (see page 1668)	In order for a BDE-enabled dataset to fetch data from a database server it needs to use both a database and a session. Databases (see page 1646) represent connections to specific database servers. The database identifies a BDE driver, a particular database server that uses that driver, and a set of connection parameters for connecting to that database server. Each database is represented by a TDatabase component. You can either associate your datasets with a *TDatabase* component you add to a form or data module, or you can simply identify the database server by name and let Delphi generate an implicit database component... more (see page 1668)
Binding Parameters (see page 1669)	When you prepare and execute a stored procedure, its input parameters are automatically bound to parameters on the server. *TStoredProc* lets you use the ParamBindMode property to specify how parameters should be bound to the parameters on the server. By default *ParamBindMode* is set to *pbByName*, meaning that parameters from the stored procedure component are matched to those on the server by name. This is the easiest method of binding parameters. Some servers also support binding parameters by ordinal value, the order in which the parameters appear in the stored procedure. In this case the order in which you... more (see page 1669)
Caching BLOBs (see page 1670)	BDE-enabled datasets all have a CacheBlobs property that controls whether BLOB fields are cached locally by the BDE when an application reads BLOB records. By default, *CacheBlobs* is *True*, meaning that the BDE caches a local copy of BLOB fields. Caching BLOBs improves application performance by enabling the BDE to store local copies of BLOBs instead of fetching them repeatedly from the database server as a user scrolls through records. In applications and environments where BLOBs are frequently updated or replaced, and a fresh view of BLOB data is more important than application performance, you can set *CacheBlobs* to... more (see page 1670)
Controlling Read/Write Access to Local Tables (see page 1670)	Like any table type dataset, *TTable* lets you control read and write access (see page 1587) by your application using the ReadOnly property. In addition, for Paradox, dBASE, and FoxPro tables, *TTable* can let you control read and write access to tables by other applications. The Exclusive property controls whether your application gains sole read/write access to a Paradox, dBASE, or FoxPro table. To gain sole read/write access for these table types, set the table component's *Exclusive* property to *True* before opening the table. If you succeed in opening a table for exclusive access, other applications cannot read data from or write data... more (see page 1670)
Importing Data from Another Table (see page 1670)	You can use a table component's BatchMove*method to import data from another table. BatchMove can* • Copy records from another table into this table. • Update records in this table that occur in another table. • Append records from another table to the end of this table. • Delete records in this table that occur in another table. *BatchMove* takes two parameters: the name of the table from which to import data, and a mode specification that determines which import operation to perform. The following table describes the possible settings for the mode specification: ***BatchMove import modes***

Working with BDE Handle Properties (see page 1671)	You can use BDE-enabled datasets without ever needing to make direct API calls to the Borland Database Engine. The BDE-enabled datasets, in combination with database and session components, encapsulate much of the BDE functionality. However, if you need to make direct API calls to the BDE, you may need BDE handles for resources managed by the BDE. Many BDE APIs require these handles as parameters. All BDE-enabled datasets include three read-only properties for accessing BDE handles at runtime: • Handle is a handle to the BDE cursor that accesses the records in the dataset. • DBHandle is a handle to the... more (see page 1671)
Renaming a Table (see page 1671)	To rename a Paradox or dBASE table at runtime, call the table's RenameTable method. For example, the following statement renames the Customer table to CustInfo:
Specifying a dBASE Index File (see page 1672)	For most servers, you use the methods common to all table type datasets to specify an index. These methods are described in Sorting records with indexes (see page 1609). For dBASE tables that use non-production index files or dBASE III PLUS-style indexes (*.NDX), however, you must use the *IndexFiles and IndexNameproperties instead. Set the IndexFiles property to the name of the non-production index file or list the .NDX files. Then, specify one index in the IndexName property to have it actively sorting the dataset.* *At design time, click the ellipsis button in the IndexFiles property value in the **Object Inspector** to... more (see page 1672)*
Specifying the Table Type for Local Tables (see page 1673)	If an application accesses Paradox, dBASE, FoxPro, or comma-delimited ASCII text tables, then the BDE uses the TableType property to determine the table's type (its expected structure). *TableType* is not used when *TTable* represents an SQL-based table on a database server. By default *TableType* is set to *ttDefault*. When *TableType* is *ttDefault*, the BDE determines a table's type from its filename extension. The following table summarizes the file extensions recognized by the BDE and the assumptions it makes about a table's type: ***Table types recognized by the BDE based on file extension***
Using TQuery (see page 1674)	*TQuery* represents a single Data Definition Language (DDL) or Data Manipulation Language (DML) statement (For example, a SELECT, INSERT, DELETE, UPDATE, CREATE INDEX, or ALTER TABLE command). The language used in commands is server-specific, but usually compliant with the SQL-92 standard for the SQL language. *TQuery* implements all of the basic functionality introduced by TDataSet (see page 1632), as well as all of the special features typical of query-type datasets (see page 1618). Because *TQuery* is a BDE-enabled dataset, it must usually be associated with a database and a session (see page 1668). (The one exception is when you use the *TQuery* for a heterogeneous query.)... more (see page 1674)
Using TStoredProc (see page 1674)	*TStoredProc* represents a stored procedure. It implements all of the basic functionality introduced by TDataSet (see page 1632), as well as most of the special features typical of stored procedure-type datasets (see page 1618). Because *TStoredProc* is a BDE-enabled dataset, it must be associated with a database and a session (see page 1668). Once the dataset is associated with a database and session, you can bind it to a particular stored procedure by setting the StoredProcName property. *TStoredProc* differs from other stored procedure-type datasets in the following ways: • It gives you greater control over how to bind parameters (see page 1669). • It provides support for Oracle overloaded stored (see page 1677)... more (see page 1674)
Using TTable (see page 1674)	*TTable* encapsulates the full structure of and data in an underlying database table. It implements all of the basic functionality introduced by TDataSet (see page 1632), as well as all of the special features typical of table type datasets (see page 1620). Because *TTable* is a BDE-enabled dataset, it must be associated with a database and a session (see page 1668). Once the dataset is associated with a database and session, you can bind it to a particular database table by setting the TableName property and, if you are using a Paradox, dBASE, FoxPro, or comma-delimited ASCII text table, the TableType property. **Note:** The table must... more (see page 1674)

Using BDE-enabled Datasets (see page 1675)	BDE-enabled datasets use the Borland Database Engine (BDE) to access data. They inherit the common dataset capabilities described in Understanding datasets (see page 1632), using the BDE to provide the implementation. In addition, all BDE datasets add properties, events, and methods for • Associating a dataset with database and session connections (see page 1668). • Caching BLOBs (see page 1670). • Obtaining a BDE handle (see page 1671). There are three BDE-enabled datasets: • *TTable*, a table type dataset (see page 1620) that represents all of the rows and columns of a single database table. See Using TTable (see page 1674) for a description of features unique to *TTable*. • *TQuery*, a query-type dataset (see page 1618) that... more (see page 1675)
Creating Heterogenous Queries (see page 1676)	*TQuery* supports heterogeneous queries against more than one server or table type (for example, data from an Oracle table and a Paradox table. When you execute a heterogeneous query, the BDE parses and processes the query using Local SQL. Because BDE uses Local SQL, extended, server-specific SQL syntax is not supported.
Obtaining an Editable Result Set (see page 1676)	To request a result set that users can edit in data-aware controls, set a query component's RequestLive property to True. Setting *RequestLive* to True does not guarantee a live result set, but the BDE attempts to honor the request whenever possible. There are some restrictions on live result set requests, depending on whether the query uses the local SQL parser or a server's SQL parser. • Queries where table names are preceded by a BDE database alias (as in heterogeneous queries) and queries executed against Paradox or dBASE are parsed by the BDE using Local SQL. When queries use the local... more (see page 1676)
Updating a Read-only Result Set (see page 1677)	Applications can update data returned in a read-only result set if they are using cached updates. If you are using a client dataset to cache updates (see page 1731), the client dataset or its associated provider can automatically generate the SQL for applying updates unless the query represents multiple tables. If the query represents multiple tables, you must indicate how to apply the updates: If all updates are applied to a single database table, you can indicate the underlying table to update in an OnGetTableName event handler. If you need more control over applying updates, you can associate the query with an... more (see page 1677)
Working with Oracle Overloaded Stored Procedures (see page 1677)	Oracle servers allow overloading of stored procedures; overloaded procedures are different procedures with the same name. The stored procedure component's Overload property enables an application to specify the procedure to execute. If *Overload* is zero (the default), there is assumed to be no overloading. If *Overload* is one (1), then the stored procedure component executes the first stored procedure it finds on the Oracle server that has the overloaded name; if it is two (2), it executes the second, and so on. **Note:** Overloaded stored procedures may take different input and output parameters. See your Oracle server documentation for more... more (see page 1677)

3.2.3.7.7.1 Associating a Dataset with Database and Session Connections

In order for a BDE-enabled dataset to fetch data from a database server it needs to use both a database and a session.

Databases (see page 1646) represent connections to specific database servers. The database identifies a BDE driver, a particular database server that uses that driver, and a set of connection parameters for connecting to that database server. Each database is represented by a TDatabase component. You can either associate your datasets with a *TDatabase* component you add to a form or data module, or you can simply identify the database server by name and let Delphi generate an implicit database component for you. Using an explicitly-created *TDatabase* component is recommended for most applications, because

the database component gives you greater control over how the connection is established, including the login process, and lets you create and use transactions.

To associate a BDE-enabled dataset with a database, use the *DatabaseName property. DatabaseName is a string that contains different information, depending on whether you are using an explicit database component and, if not, the type of database you are using:*

- If you are using an explicit *TDatabase* component, *DatabaseName* is the value of the *DatabaseName* property of the database component.
- If you want to use an implicit database component and the database has a BDE alias, you can specify a BDE alias as the value of *DatabaseName*. A BDE alias represents a database plus configuration information for that database. The configuration information associated with an alias differs by database type (Oracle, Sybase, InterBase, Paradox, dBASE, and so on).
- If you want to use an implicit database component for a Paradox or dBASE database, you can also use *DatabaseName* to simply specify the directory where the database tables are located.

A session (see page 1664) provides global management for a group of database connections in an application. When you add BDE-enabled datasets to your application, your application automatically contains a session component, named *Session. As you add database and dataset components to the application, they are automatically associated with this default session. It also controls access to password protected Paradox files, and it specifies directory locations for sharing Paradox files over a network. You can control database connections and access to Paradox files using the properties, events, and methods of the session.*

You can use the default session to control all database connections in your application. Alternatively, you can add additional session components at design time or create them dynamically at runtime to control a subset of database connections in an application. To associate your dataset with an explicitly created session component, use the SessionName property. If you do not use explicit session components in your application, you do not have to provide a value for this property. Whether you use the default session or explicitly specify a session using the SessionName property, you can access the session associated with a dataset by reading the DBSession property.

***Note:** If you use a session component, the SessionName property of a dataset must match the SessionName property for the database component with which the dataset is associated.*

Caching BLOBs (see page 1670)

Working with BDE Handle Properties (see page 1671)

3.2.3.7.7.2 Binding Parameters

When you prepare and execute a stored procedure, its input parameters are automatically bound to parameters on the server.

TStoredProc lets you use the ParamBindMode property to specify how parameters should be bound to the parameters on the server. By default *ParamBindMode* is set to *pbByName*, meaning that parameters from the stored procedure component are matched to those on the server by name. This is the easiest method of binding parameters.

Some servers also support binding parameters by ordinal value, the order in which the parameters appear in the stored procedure. In this case the order in which you specify parameters in the parameter collection editor is significant. The first parameter you specify is matched to the first input parameter on the server, the second parameter is matched to the second input parameter on the server, and so on. If your server supports parameter binding by ordinal value, you can set *ParamBindMode* to *pbByNumber*.

Tip: If you want to set *ParamBindMode* to *pbByNumber*, you need to specify the correct parameter types in the correct order.

See Also

Working with Oracle Overloaded Stored Procedures (see page 1677)

3.2.3.7.7.3 Caching BLOBs

BDE-enabled datasets all have a CacheBlobs property that controls whether BLOB fields are cached locally by the BDE when an application reads BLOB records. By default, *CacheBlobs* is *True*, meaning that the BDE caches a local copy of BLOB fields. Caching BLOBs improves application performance by enabling the BDE to store local copies of BLOBs instead of fetching them repeatedly from the database server as a user scrolls through records.

In applications and environments where BLOBs are frequently updated or replaced, and a fresh view of BLOB data is more important than application performance, you can set *CacheBlobs* to *False* to ensure that your application always sees the latest version of a BLOB field.

Associating a Dataset with Database and Session Connections (see page 1668)

Working with BDE Handle Properties (see page 1671)

3.2.3.7.7.4 Controlling Read/Write Access to Local Tables

Like any table type dataset, *TTable* lets you control read and write access (see page 1587) by your application using the ReadOnly property.

In addition, for Paradox, dBASE, and FoxPro tables, *TTable* can let you control read and write access to tables by other applications. The Exclusive property controls whether your application gains sole read/write access to a Paradox, dBASE, or FoxPro table. To gain sole read/write access for these table types, set the table component's *Exclusive* property to *True* before opening the table. If you succeed in opening a table for exclusive access, other applications cannot read data from or write data to the table. Your request for exclusive access is not honored if the table is already in use when you attempt to open it.

The following statements open a table for exclusive access:

```
CustomersTable.Exclusive := True; {Set request for exclusive lock}
CustomersTable.Active := True; {Now open the table}
CustomersTable->Exclusive = true; // Set request for exclusive lock
CustomersTable->Active = true; // Now open the table
```

Note: You can attempt to set *Exclusive* on SQL tables, but some servers do not support exclusive table-level locking. Others may grant an exclusive lock, but permit other applications to read data from the table. For more information about exclusive locking of database tables on your server, see your server documentation.

Specifying a dBASE Index File (see page 1672)

Renaming Local Tables (see page 1671)

Specifying the Table Type for Local Tables (see page 1673)

3.2.3.7.7.5 Importing Data from Another Table

You can use a table component's BatchMove*method to import data from another table. BatchMove can*

- Copy records from another table into this table.
- Update records in this table that occur in another table.
- Append records from another table to the end of this table.
- Delete records in this table that occur in another table.

BatchMove takes two parameters: the name of the table from which to import data, and a mode specification that determines which import operation to perform. The following table describes the possible settings for the mode specification:

BatchMove import modes

Value	Meaning
batAppend	Append all records from the source table to the end of this table.
batAppendUpdate	Append all records from the source table to the end of this table and update existing records in this table with matching records from the source table.
batCopy	Copy all records from the source table into this table.
batDelete	Delete all records in this table that also appear in the source table.
batUpdate	Update existing records in this table with matching records from the source table.

For example, the following code updates all records in the current table with records from the *Customer* table that have the same values for fields in the current index:

```
Table1.BatchMove('CUSTOMER.DB', batUpdate);
Table1->BatchMove("CUSTOMER.DB", batUpdate);
```

BatchMove returns the number of records it imports successfully.

Warning: Importing records using the *batCopy* mode overwrites existing records. To preserve existing records use *batAppend* instead.

BatchMove performs only some of the batch operations supported by the BDE. Additional functions are available using the *TBatchMove* component. If you need to move a large amount of data between or among tables, use *TBatchMove* instead of calling a table's *BatchMove* method. For information about using *TBatchMove*, see Using TBatchMove (see page 1683)

Renaming Local Tables (see page 1671)

3.2.3.7.7.6 Working with BDE Handle Properties

You can use BDE-enabled datasets without ever needing to make direct API calls to the Borland Database Engine. The BDE-enabled datasets, in combination with database and session components, encapsulate much of the BDE functionality. However, if you need to make direct API calls to the BDE, you may need BDE handles for resources managed by the BDE. Many BDE APIs require these handles as parameters.

All BDE-enabled datasets include three read-only properties for accessing BDE handles at runtime:

- Handle is a handle to the BDE cursor that accesses the records in the dataset.
- DBHandle is a handle to the database that contains the underlying tables or stored procedure.
- DBLocale is a handle to the BDE language driver for the dataset. The locale controls the sort order and character set used for string data.

These properties are automatically assigned to a dataset when it is connected to a database server through the BDE.

See Also

Associating a Dataset with Database and Session Connections (see page 1668)

Caching BLOBs (see page 1670)

3.2.3.7.7.7 Renaming a Table

To rename a Paradox or dBASE table at runtime, call the table's RenameTable method. For example, the following statement renames the Customer table to CustInfo:

```
Customer.RenameTable('CustInfo');
Customer->RenameTable("CustInfo");
```

See Also

Controlling Read/Write Access to Local Tables (see page 1670)

Specifying a dBASE Index File (see page 1672)

Specifying the Table Type for Local Tables (see page 1673)

3.2.3.7.7.8 Specifying a dBASE Index File

For most servers, you use the methods common to all table type datasets to specify an index. These methods are described in Sorting records with indexes (see page 1609).

For dBASE tables that use non-production index files or dBASE III PLUS-style indexes (*.NDX), however, you must use the *IndexFiles and IndexNameproperties instead. Set the IndexFiles property to the name of the non-production index file or list the .NDX files. Then, specify one index in the IndexName property to have it actively sorting the dataset.*

*At design time, click the ellipsis button in the IndexFiles property value in the **Object Inspector** to invoke the Index Files editor. To add one non-production index file or .NDX file: click the Add button in the Index Files dialog and select the file from the Open dialog. Repeat this process once for each non-production index file or .NDX file. Click the OK button in the Index Files dialog after adding all desired indexes.*

This same operation can be performed programmatically at runtime. To do this, access the IndexFiles property using properties and methods of string lists. When adding a new set of indexes, first call the Clear method of the table's IndexFiles property to remove any existing entries. Call the Add method to add each non-production index file or .NDX file:

```
with Table2.IndexFiles do begin
  Clear;
  Add('Bystate.ndx');
  Add('Byzip.ndx');
  Add('Fullname.ndx');
  Add('St_name.ndx');
end;
Table2->IndexFiles->Clear();
Table2->IndexFiles->Add("Bystate.ndx");
Table2->IndexFiles->Add("Byzip.ndx");
Table2->IndexFiles->Add("Fullname.ndx");
Table2->IndexFiles->Add("St_name.ndx");
```

After adding any desired non-production or .NDX index files, the names of individual indexes in the index file are available, and can be assigned to the *IndexName* property. The index tags are also listed when using the *GetIndexNames* method and when inspecting index definitions through the *TIndexDef* objects in the *IndexDefs* property. Properly listed .NDX files are automatically updated as data is added, changed, or deleted in the table (regardless of whether a given index is used in the IndexName property).

In the example below, the *IndexFiles* for the *AnimalsTable* table component is set to the non-production index file ANIMALS.MDX, and then its *IndexName* property is set to the index tag called "NAME":

```
AnimalsTable.IndexFiles.Add('ANIMALS.MDX');
AnimalsTable.IndexName := 'NAME';
AnimalsTable->IndexFiles->Add("ANIMALS.MDX");
AnimalsTable->IndexName = "NAME";
```

Once you have specified the index file, using non-production or .NDX indexes works the same as any other index. Specifying an index name sorts the data in the table and makes it available for indexed-based searches, ranges, and (for non-production indexes) master-detail linking. See Using table type datasets (see page 1620) for details on these uses of indexes.

There are two special considerations when using dBASE III PLUS-style .NDX indexes with *TTable* components. The first is that .NDX files cannot be used as the basis for master-detail links. The second is that when activating a .NDX index with the *IndexName* property, you must include the .NDX extension in the property value as part of the index name:

```
with Table1 do begin
  IndexName := 'ByState.NDX';
  FindKey(['CA']);
end;
Table1->IndexName = "ByState.NDX";
TVarRec vr = ("NE");
Table1->FindKey(&vr, 0);
```

Controlling Read/Write Access to Local Tables (see page 1670)

Renaming Local Tables (see page 1671)

Specifying the Table Type for Local Tables (see page 1673)

3.2.3.7.7.9 Specifying the Table Type for Local Tables

If an application accesses Paradox, dBASE, FoxPro, or comma-delimited ASCII text tables, then the BDE uses the TableType property to determine the table's type (its expected structure). *TableType* is not used when *TTable* represents an SQL-based table on a database server.

By default *TableType* is set to *ttDefault*. When *TableType* is *ttDefault*, the BDE determines a table's type from its filename extension. The following table summarizes the file extensions recognized by the BDE and the assumptions it makes about a table's type:

Table types recognized by the BDE based on file extension

Extension	Table Type
No file extension	Paradox
.DB	Paradox
.DBF	dBASE
.TXT	ASCII text

If your local Paradox, dBASE, and ASCII text tables use the file extensions as described in the previous table, then you can leave *TableType* set to *ttDefault*. Otherwise, your application must set *TableType* to indicate the correct table type. The following table indicates the values you can assign to *TableType*:

TableType values

Value	Table Type
ttDefault	Table type determined automatically by the BDE
ttParadox	Paradox
ttDBase	dBASE
ttFoxPro	FoxPro
ttASCII	Comma-delimited ASCII text

3.2.3.7.7.10 Using TQuery

TQuery represents a single Data Definition Language (DDL) or Data Manipulation Language (DML) statement (For example, a SELECT, INSERT, DELETE, UPDATE, CREATE INDEX, or ALTER TABLE command). The language used in commands is server-specific, but usually compliant with the SQL-92 standard for the SQL language. *TQuery* implements all of the basic functionality introduced by TDataSet (see page 1632), as well as all of the special features typical of query-type datasets (see page 1618).

Because *TQuery* is a BDE-enabled dataset, it must usually be associated with a database and a session (see page 1668). (The one exception is when you use the *TQuery* for a heterogeneous query.) You specify the SQL statement for the query by setting the SQL property.

A TQuery component can access data in:

- Paradox or dBASE tables, using Local SQL, which is part of the BDE. Local SQL is a subset of the SQL-92 specification. Most DML is supported and enough DDL syntax to work with these types of tables. See the local SQL help, LOCALSQL.HLP, for details on supported SQL syntax.
- Local InterBase Server databases, using the InterBase engine. For information on InterBase's SQL-92 standard SQL syntax support and extended syntax support, see the InterBase *Language Reference.*
- Databases on remote database servers such as Oracle, Sybase, MS-SQL Server, Informix, DB2, and InterBase. You must install the appropriate SQL Link driver and client software (vendor-supplied) specific to the database server to access a remote server. Any standard SQL syntax supported by these servers is allowed. For information on SQL syntax, limitations, and extensions, see the documentation for your particular server.

The following topics discuss features that are unique to *TQuery* components (as opposed to other query-type datasets):

- Creating Heterogeneous Queries. (see page 1676)
- Obtaining an Editable Result Set (see page 1676)
- Updating Read-only Result Sets (see page 1677)

See Also

Using TTable (see page 70)

Using TStoredProc (see page 69)

3.2.3.7.7.11 Using TStoredProc

TStoredProc represents a stored procedure. It implements all of the basic functionality introduced by TDataSet (see page 1632), as well as most of the special features typical of stored procedure-type datasets (see page 1618).

Because *TStoredProc* is a BDE-enabled dataset, it must be associated with a database and a session (see page 1668). Once the dataset is associated with a database and session, you can bind it to a particular stored procedure by setting the StoredProcName property.

TStoredProc differs from other stored procedure-type datasets in the following ways:

- It gives you greater control over how to bind parameters (see page 1669).
- It provides support for Oracle overloaded stored procedures (see page 1677).

See Also

Using TTable (see page 70)

Using TQuery (see page 63)

3.2.3.7.7.12 Using TTable

TTable encapsulates the full structure of and data in an underlying database table. It implements all of the basic functionality

introduced by TDataSet (see page 1632), as well as all of the special features typical of table type datasets (see page 1620).

Because *TTable* is a BDE-enabled dataset, it must be associated with a database and a session (see page 1668). Once the dataset is associated with a database and session, you can bind it to a particular database table by setting the TableName property and, if you are using a Paradox, dBASE, FoxPro, or comma-delimited ASCII text table, the TableType property.

Note: The table must be closed when you change its association to a database, session, or database table, or when you set the *TableType* property. However, before you close the table to change these properties, first post or discard any pending changes. If cached updates are enabled, call the ApplyUpdates method to write the posted changes to the database.

TTable components are unique in the support they offer for local database tables (Paradox, dBASE, FoxPro, and comma-delimited ASCII text tables). The following topics describe the special properties and methods that implement this support:

- Specifying the Table Type for Local Tables (see page 1673)
- Controlling Read/Write Access to Local Tables (see page 1670)
- Specifying a dBASE Index File (see page 1672)
- Renaming Local Tables (see page 1671)

In addition, *TTable* components can take advantage of the BDE's support for batch operations (table level operations to append, update, delete, or copy entire groups of records). This support is described in Importing data from another table (see page 1670).

Using TQuery (see page 63)

Using TStoredProc (see page 69)

3.2.3.7.7.13 Using BDE-enabled Datasets

BDE-enabled datasets use the Borland Database Engine (BDE) to access data. They inherit the common dataset capabilities described in Understanding datasets (see page 1632), using the BDE to provide the implementation. In addition, all BDE datasets add properties, events, and methods for

- Associating a dataset with database and session connections (see page 1668).
- Caching BLOBs (see page 1670).
- Obtaining a BDE handle (see page 1671).

There are three BDE-enabled datasets:

- *TTable*, a table type dataset (see page 1620) that represents all of the rows and columns of a single database table. See Using TTable (see page 1674) for a description of features unique to *TTable*.
- *TQuery*, a query-type dataset (see page 1618) that encapsulates an SQL statement and enables applications to access the resulting records, if any. See Using TQuery (see page 1674) for a description of features unique to *TQuery*.
- *TStoredProc*, a stored procedure-type dataset (see page 1618) that executes a stored procedure that is defined on a database server. See Using TStoredProc (see page 1674) for a description of features unique to *TStoredProc*.

  Note: In addition to the three types of BDE-enabled datasets, there is a BDE-based client dataset (*TBDEClientDataSet*) that can be used for caching updates (see page 1731).

See Also

Connecting to Databases with TDatabase (see page 1646)

Managing Database Sessions Using TSession (see page 1664)

3.2.3.7.7.14 Creating Heterogenous Queries

TQuery supports heterogeneous queries against more than one server or table type (for example, data from an Oracle table and a Paradox table. When you execute a heterogeneous query, the BDE parses and processes the query using Local SQL. Because BDE uses Local SQL, extended, server-specific SQL syntax is not supported.

To perform a heterogeneous query

1. Define separate BDE aliases for each database accessed in the query using the BDE Administration tool or the SQL explorer.
2. Leave the *DatabaseName* property of the *TQuery* blank; the names of the databases used will be specified in the SQL statement.
3. In the SQL property, specify the SQL statement to execute. Precede each table name in the statement with the BDE alias for the table's database, enclosed in colons. This whole reference is then enclosed in quotation marks.
4. Set any parameters for the query in the *Params* property.
5. Call *Prepare* to prepare the query for execution prior to executing it for the first time.
6. Call *Open* or *ExecSQL* depending on the type of query you are executing.

For example, suppose you define an alias called Oracle1 for an Oracle database that has a CUSTOMER table, and Sybase1 for a Sybase database that has an ORDERS table. A simple query against these two tables would be:

```
SELECT Customer.CustNo, Orders.OrderNo
FROM ":Oracle1:CUSTOMER"
  JOIN ":Sybase1:ORDERS"
    ON (Customer.CustNo = Orders.CustNo)
WHERE (Customer.CustNo = 1503)
```

As an alternative to using a BDE alias to specify the database in a heterogeneous query, you can use a *TDatabase* component. Configure the *TDatabase* as normal to point to the database, set the *TDatabase.DatabaseName* to an arbitrary but unique value, and then use that value in the SQL statement instead of a BDE alias name.

Obtaining an Editable Result Set (see page 1676)

Updating Read-only Result Sets (see page 1677)

3.2.3.7.7.15 Obtaining an Editable Result Set

To request a result set that users can edit in data-aware controls, set a query component's RequestLive property to True. Setting *RequestLive* to True does not guarantee a live result set, but the BDE attempts to honor the request whenever possible. There are some restrictions on live result set requests, depending on whether the query uses the local SQL parser or a server's SQL parser.

- Queries where table names are preceded by a BDE database alias (as in heterogeneous queries) and queries executed against Paradox or dBASE are parsed by the BDE using Local SQL. When queries use the local SQL parser, the BDE offers expanded support for updatable, live result sets in both single table and multi-table queries. When using Local SQL, a live result set for a query against a single table or view is returned if the query does not contain any of the following:
- DISTINCT in the SELECT clause
- Joins (inner, outer, or UNION)
- Aggregate functions with or without GROUP BY or HAVING clauses
- Base tables or views that are not updatable
- Subqueries
- ORDER BY clauses not based on an index
- Queries against a remote database server are parsed by the server. If the *RequestLive* property is set to True, the SQL

statement must abide by Local SQL standards in addition to any server-imposed restrictions because the BDE needs to use it for conveying data changes to the table. A live result set for a query against a single table or view is returned if the query does not contain any of the following:

- A DISTINCT clause in the SELECT statement
- Aggregate functions, with or without GROUP BY or HAVING clauses
- References to more than one base table or updatable views (joins)
- Subqueries that reference the table in the FROM clause or other tables

If an application requests and receives a live result set, the *CanModify* property of the query component is set to *True*. Even if the query returns a live result set, you may not be able to update the result set directly if it contains linked fields or you switch indexes before attempting an update. If these conditions exist, you should treat the result set as a read-only result set, and update it accordingly (see page 1677).

If an application requests a live result set, but the SELECT statement syntax does not allow it, the BDE returns either

- A read-only result set for queries made against Paradox or dBASE.
- An error code for SQL queries made against a remote server.

See Also

Updating Read-only Result Sets (see page 1677)

3.2.3.7.7.16 Updating a Read-only Result Set

Applications can update data returned in a read-only result set if they are using cached updates.

If you are using a client dataset to cache updates (see page 1731), the client dataset or its associated provider can automatically generate the SQL for applying updates unless the query represents multiple tables. If the query represents multiple tables, you must indicate how to apply the updates:

If all updates are applied to a single database table, you can indicate the underlying table to update in an OnGetTableName event handler.

If you need more control over applying updates, you can associate the query with an update object (TUpdateSQL). A provider automatically uses this update object to apply updates:

- Associate the update object with the query by setting the query's UpdateObject property to the *TUpdateSQL* object you are using.
- Set the update object's ModifySQL, InsertSQL, and DeleteSQL properties to SQL statements that perform the appropriate updates for your query's data.

You must use an update object if you are using the BDE to cache updates (see page 1689).

Note: For more information on using update objects, see Using update objects to update a dataset (see page 1692).

3.2.3.7.7.17 Working with Oracle Overloaded Stored Procedures

Oracle servers allow overloading of stored procedures; overloaded procedures are different procedures with the same name. The stored procedure component's Overload property enables an application to specify the procedure to execute.

If *Overload* is zero (the default), there is assumed to be no overloading. If *Overload* is one (1), then the stored procedure component executes the first stored procedure it finds on the Oracle server that has the overloaded name; if it is two (2), it executes the second, and so on.

Note: Overloaded stored procedures may take different input and output parameters. See your Oracle server documentation for more information.

3.2.3.7.8 Using TBatchMove

The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

Topics

Name	Description
Creating a Batch Move Component (see page 1679)	
Executing a Batch Move (see page 1680)	Use the Execute method to execute a previously prepared batch operation at runtime. For example, if *BatchMoveAdd* is the name of a batch move component, the following statement executes it:
The Data Dictionary (see page 1680)	When you use the BDE to access your data, your application has access to the Data Dictionary. The Data Dictionary provides a customizable storage area, independent of your applications, where you can create extended field attribute sets that describe the content and appearance of data. For example, if you frequently develop financial applications, you may create a number of specialized field attribute sets describing different display formats for currency. When you create datasets for your application at design time, rather than using the **Object Inspector** to set the currency fields in each dataset by hand, you can associate those fields... more (see page 1680)
Tools for Working with the BDE (see page 1681)	One advantage of using the BDE as a data access mechanism is the wealth of supporting utilities that ship with Delphi. These utilities include: • **SQL Explorer** and **Database Explorer**: Delphi ships with one of these two applications, depending on which version you have purchased. Both Explorers enable you to • Examine existing database tables and structures. The SQL Explorer lets you examine and query remote SQL databases. • Populate tables with data • Create extended field attribute sets in the Data Dictionary (see page 1680) or associate them with fields in your application. • Create and manage BDE aliases. SQL Explorer lets you do the following... more (see page 1681)
Specifying a Batch Move Mode (see page 1682)	The Mode property specifies the operation a batch move component performs: ***Batch move modes***

Using TBatchMove (see page 1683)	TBatchMove encapsulates Borland Database Engine (BDE) features that let you to duplicate a dataset, append records from one dataset to another, update records in one dataset with records from another dataset, and delete records from one dataset that match records in another dataset. *TBatchMove* is most often used to: • Download data from a server to a local data source for analysis or other operations. • Move a desktop database into tables on a remote server as part of an upsizing operation. A batch move component can create tables on the destination that correspond to the source tables, automatically mapping the... more (see page 1683)
Handling Batch Move Errors (see page 1684)	There are two types of errors that can occur in a batch move operation: data type conversion errors and integrity violations. TBatchMove has a number of properties that report on and control error handling. The AbortOnProblem property specifies whether to abort the operation when a data type conversion error occurs. If *AbortOnProblem* is *True*, the batch move operation is canceled when an error occurs. If *False*, the operation continues. You can examine the table you specify in the *ProblemTableName* to determine which records caused problems. The AbortOnKeyViol property indicates whether to abort the operation when a Paradox key... more (see page 1684)
Mapping Data Types (see page 1684)	In *batAppend* mode, a batch move component creates the destination table based on the column data types of the source table. Columns and types are matched based on their position in the source and destination tables. That is, the first column in the source is matched with the first column in the destination, and so on. To override the default column mappings, use the Mappings property. *Mappings* is a list of column mappings (one per line). This listing can take one of two forms. To map a column in the source table to a column of the same name in... more (see page 1684)

3.2.3.7.8.1 Creating a Batch Move Component

To create a batch move component

1. Place a table or query component for the dataset from which you want to import records (called the *Source* dataset) on a form or in a data module.
2. Place the dataset to which to move records (called the *Destination* dataset) on the form or data module.
3. Place a*TBatchMove component from the BDE category of the **Tool palette** in the data module or form, and set its Nameproperty to a unique value appropriate to your application.*
4. Set the Source property of the batch move component to the name of the table from which to copy, append, or update records. You can select tables from the drop-down list of available dataset components.
5. Set the Destination property to the dataset to create, append to, or update. You can select a destination table from the drop-down list of available dataset components.

- If you are appending, updating, or deleting, *Destination* must represent an existing database table.
- If you are copying a table and *Destination* represents an existing table, executing the batch move overwrites all of the current data in the destination table.
- If you are creating an entirely new table by copying an existing table, the resulting table has the name specified in the *Name* property of the table component to which you are copying. The resulting table type will be of a structure appropriate to the server specified by the *DatabaseName* property.

6. Set the Mode property to indicate the type of operation to perform. Valid operations are *batAppend* (the default), *batUpdate*, *batAppendUpdate*, *batCopy*, and *batDelete*. For information about these modes, see Specifying a batch move mode (see page 1682).
7. Optionally set the *Transliterate property. If Transliterate is True (the default), character data is translated from the Source dataset's character set to the Destination dataset's character set as necessary.*

8. Optionally set column mappings using the Mappings property. You need not set this property if you want batch move to match columns based on their position in the source and destination tables. For more information about mapping columns, see Mapping data types (see page 1684).
9. Optionally specify the ChangedTableName, KeyViolTableName, and ProblemTableName properties. Batch move stores problem records it encounters during the batch operation in the table specified by *ProblemTableName*. If you are updating a Paradox table through a batch move, key violations can be reported in the table you specify in *KeyViolTableName*. *ChangedTableName* lists all records that changed in the destination table as a result of the batch move operation. If you do not specify these properties, these error tables are not created or used. For more information about handling batch move errors, see Handling batch move errors (see page 1684).

See Also

Executing a Batch Move (see page 1680)

3.2.3.7.8.2 Executing a Batch Move

Use the Execute method to execute a previously prepared batch operation at runtime. For example, if *BatchMoveAdd* is the name of a batch move component, the following statement executes it:

```
BatchMoveAdd.Execute;
BatchMoveAdd->Execute();
```

You can also execute a batch move at design time by right clicking the mouse on a batch move component and choosing Execute from the context menu.

The MovedCount property keeps track of the number of records that are moved when a batch move executes.

The RecordCount property specifies the maximum number of records to move. If *RecordCount* is zero, all records are moved, beginning with the first record in the source dataset. If *RecordCount* is a positive number, a maximum of *RecordCount* records are moved, beginning with the current record in the source dataset. If *RecordCount* is greater than the number of records between the current record in the source dataset and its last record, the batch move terminates when the end of the source dataset is reached. You can examine *MoveCount* to determine how many records were actually transferred.

Handling Batch Move Errors (see page 1684)

3.2.3.7.8.3 The Data Dictionary

When you use the BDE to access your data, your application has access to the Data Dictionary. The Data Dictionary provides a customizable storage area, independent of your applications, where you can create extended field attribute sets that describe the content and appearance of data.

For example, if you frequently develop financial applications, you may create a number of specialized field attribute sets describing different display formats for currency. When you create datasets for your application at design time, rather than using the **Object Inspector** to set the currency fields in each dataset by hand, you can associate those fields with an extended field attribute set in the data dictionary. Using the data dictionary ensures a consistent data appearance within and across the applications you create.

In a client/server environment, the Data Dictionary can reside on a remote server for additional sharing of information.

To learn how to create extended field attribute sets from the Fields editor at design time, and how to associate them with fields throughout the datasets in your application, see Creating attribute sets for field components (see page 1870). To learn more about creating a data dictionary and extended field attributes with the SQL and Database Explorers, see their respective online

help files.

Note: A programming interface to the Data Dictionary is available in the drintf unit (located in the lib directory). This interface supplies the following methods:

Data Dictionary interface

Routine	Use
DictionaryActive	Indicates if the data dictionary is active.
DictionaryDeactivate	Deactivates the data dictionary.
IsNullID	Indicates whether a given ID is a null ID
FindDatabaseID	Returns the ID for a database given its alias.
FindTableID	Returns the ID for a table in a specified database.
FindFieldID	Returns the ID for a field in a specified table.
FindAttrID	Returns the ID for a named attribute set.
GetAttrName	Returns the name an attribute set given its ID.
GetAttrNames	Executes a callback for each attribute set in the dictionary.
GetAttrID	Returns the ID of the attribute set for a specified field.
NewAttr	Creates a new attribute set from a field component.
UpdateAttr	Updates an attribute set to match the properties of a field.
CreateField	Creates a field component based on stored attributes.
UpdateField	Changes the properties of a field to match a specified attribute set.
AssociateAttr	Associates an attribute set with a given field ID.
UnassociateAttr	Removes an attribute set association for a field ID.
GetControlClass	Returns the control class for a specified attribute ID.
QualifyTableName	Returns a fully qualified table name (qualified by user name).
QualifyTableNameByName	Returns a fully qualified table name (qualified by user name).
HasConstraints	Indicates whether the dataset has constraints in the dictionary.
UpdateConstraints	Updates the imported constraints of a dataset.
UpdateDataset	Updates a dataset to the current settings and constraints in the dictionary.

3.2.3.7.8.4 Tools for Working with the BDE

One advantage of using the BDE as a data access mechanism is the wealth of supporting utilities that ship with Delphi. These utilities include:

- **SQL Explorer** and **Database Explorer**: Delphi ships with one of these two applications, depending on which version you have purchased. Both Explorers enable you to

- Examine existing database tables and structures. The SQL Explorer lets you examine and query remote SQL databases.
- Populate tables with data
- Create extended field attribute sets in the Data Dictionary (see page 1680) or associate them with fields in your application.
- Create and manage BDE aliases.

SQL Explorer lets you do the following as well:

- Create SQL objects such as stored procedures on remote database servers.
- View the reconstructed text of SQL objects on remote database servers.
- Run SQL scripts.
- **SQL Monitor**: SQL Monitor lets you watch all of the communication that passes between the remote database server and the BDE. You can filter the messages you want to watch, limiting them to only the categories of interest. SQL Monitor is most useful when debugging your application.
- **Database Desktop**: If you are using Paradox or dBASE tables, Database Desktop lets you view and edit their data, create new tables, and restructure existing tables. Using Database Desktop affords you more control than using the methods of a *TTable* component (for example, it allows you to specify validity checks and language drivers). It provides the only mechanism for restructuring Paradox and dBASE tables other than making direct calls the BDE's API.

Using Transactions with the BDE (see page 1699)

3.2.3.7.8.5 Specifying a Batch Move Mode

The Mode property specifies the operation a batch move component performs:

Batch move modes

Property	Purpose
batAppend	Append records to the destination table.
batUpdate	Update records in the destination table with matching records from the source table. Updating is based on the current index of the destination table.
batAppendUpdate	If a matching record exists in the destination table, update it. Otherwise, append records to the destination table.
batCopy	Create the destination table based on the structure of the source table. If the destination table already exists, it is dropped and recreated.
batDelete	Delete records in the destination table that match records in the source table.

Appending records

To append data, the destination dataset must represent an existing table. During the append operation, the BDE converts data to appropriate data types and sizes for the destination dataset if necessary. If a conversion is not possible, an exception is thrown and the data is not appended.

Updating records

To update data, the destination dataset must represent an existing table and must have an index defined that enables records to be matched. If the primary index fields are used for matching, records with index fields in the destination dataset that match index fields records in the source dataset are overwritten with the source data. During the update operation, the BDE converts data to appropriate data types and sizes for the destination dataset if necessary.

Appending and updating records

To append and update data the destination dataset must represent an existing table and must have an index defined that enables records to be matched. If the primary index fields are used for matching, records with index fields in the destination dataset that match index fields records in the source dataset are overwritten with the source data. Otherwise, data from the source dataset is appended to the destination dataset. During append and update operations, the BDE converts data to appropriate data types and sizes for the destination dataset, if necessary.

Copying datasets

To copy a source dataset, the destination dataset should not represent an exist table. If it does, the batch move operation overwrites the existing table with a copy of the source dataset.

If the source and destination datasets are maintained by different types of database engines, for example, Paradox and InterBase, the BDE creates a destination dataset with a structure as close as possible to that of the source dataset and automatically performs data type and size conversions as necessary.

Note: *TBatchMove* does not copy metadata structures such as indexes, constraints, and stored procedures. You must recreate these metadata objects on your database server as appropriate.

Deleting records

To delete data in the destination dataset, it must represent an existing table and must have an index defined that enables records to be matched. If the primary index fields are used for matching, records with index fields in the destination dataset that match index fields records in the source dataset are deleted in the destination table.

Handling Batch Move Errors (see page 1684)

3.2.3.7.8.6 Using TBatchMove

TBatchMove encapsulates Borland Database Engine (BDE) features that let you to duplicate a dataset, append records from one dataset to another, update records in one dataset with records from another dataset, and delete records from one dataset that match records in another dataset. *TBatchMove* is most often used to:

- Download data from a server to a local data source for analysis or other operations.
- Move a desktop database into tables on a remote server as part of an upsizing operation.

A batch move component can create tables on the destination that correspond to the source tables, automatically mapping the column names and data types as appropriate.

The following topics describe how to work with a TBatchMove component:

- Creating a Batch Move Component (see page 1679)
- Specifying a Batch Move Mode (see page 1682)
- Mapping Data Types (see page 1684)
- Executing a Batch Move (see page 1680)
- Handling Batch Move Errors (see page 1684)

See Also

BDE-based Architecture (see page 1638)

Tools for Working with the BDE (see page 1681)

Using Transactions with the BDE (see page 1699)

The Data Dictionary (see page 1680)

3.2.3.7.8.7 Handling Batch Move Errors

There are two types of errors that can occur in a batch move operation: data type conversion errors and integrity violations. TBatchMove has a number of properties that report on and control error handling.

The AbortOnProblem property specifies whether to abort the operation when a data type conversion error occurs. If *AbortOnProblem* is *True*, the batch move operation is canceled when an error occurs. If *False*, the operation continues. You can examine the table you specify in the *ProblemTableName* to determine which records caused problems.

The AbortOnKeyViol property indicates whether to abort the operation when a Paradox key violation occurs.

The *ProblemCount property indicates the number of records that could not be handled in the destination table without a loss of data. If AbortOnProblem is True, this number is one, since the operation is aborted when an error occurs.*

The following properties enable a batch move component to create additional tables that document the batch move operation:

- ChangedTableName, if specified, creates a local Paradox table containing all records in the destination table that changed as a result of an update or delete operation.
- KeyViolTableName, if specified, creates a local Paradox table containing all records from the source table that caused a key violation when working with a Paradox table. If *AbortOnKeyViol* is *True*, this table will contain at most one entry since the operation is aborted on the first problem encountered.
- ProblemTableName, if specified, creates a local Paradox table containing all records that could not be posted in the destination table due to data type conversion errors. For example, the table could contain records from the source table whose data had to be trimmed to fit in the destination table. If *AbortOnProblem* is *True*, there is at most one record in this table since the operation is aborted on the first problem encountered.

  Note: If *ProblemTableName* is not specified, the data in the record is trimmed and placed in the destination table.

See Also

Creating a Batch Move Component (see page 1679)

Specifying a Batch Move Mode (see page 1682)

Mapping Data Types (see page 1684)

Executing a Batch Move (see page 1680)

3.2.3.7.8.8 Mapping Data Types

In *batAppend* mode, a batch move component creates the destination table based on the column data types of the source table. Columns and types are matched based on their position in the source and destination tables. That is, the first column in the source is matched with the first column in the destination, and so on.

To override the default column mappings, use the Mappings property. *Mappings* is a list of column mappings (one per line). This listing can take one of two forms. To map a column in the source table to a column of the same name in the destination table, you can use a simple listing that specifies the column name to match. For example, the following mapping specifies that a column named *ColName* in the source table should be mapped to a column of the same name in the destination table:

```
ColName
```

To map a column named *SourceColName* in the source table to a column named *DestColName* in the destination table, the syntax is as follows:

```
DestColName = SourceColName
```

If source and destination column data types are not the same, a batch move operation attempts a "best fit". It trims character

data types, if necessary, and attempts to perform a limited amount of conversion, if possible. For example, mapping a CHAR(10) column to a CHAR(5) column will result in trimming the last five characters from the source column.

As an example of conversion, if a source column of character data type is mapped to a destination of integer type, the batch move operation converts a character value of '5' to the corresponding integer value. Values that cannot be converted generate errors. For more information about errors, see Handling batch move errors (see page 1684).

When moving data between different table types, a batch move component translates data types as appropriate based on the dataset's server types. See the BDE online help file for the latest tables of mappings among server types.

Note: To batch move data to an SQL server database, you must have that database server and a version of Delphi with the appropriate SQL Link installed, or you can use ODBC if you have the proper third party ODBC drivers installed.

3.2.3.7.9 Using the BDE to cache updates

The Borland Database Engine (BDE) has been deprecated, so it will not be enhanced. For instance, BDE will never have Unicode support. You should not undertake new development with BDE. Consider migrating your existing database applications from BDE to dbExpress.

Topics

Name	Description
Applying Cached Updates Using a Database (see page 1687)	To apply cached updates to one or more datasets in the context of a database connection, call the database component's ApplyUpdates method. The following code applies updates to the *CustomersQuery* dataset in response to a button click event:
Composing Update SQL Statements (see page 1687)	At design time, you can use the Update SQL editor to write the SQL statements for the *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties. If you do not use the Update SQL editor, or if you want to modify the generated statements, you should keep in mind the following guidelines when writing statements to delete, insert, and modify records in the base table. The *DeleteSQL* property should contain only an SQL statement with the DELETE command. The base table to be updated must be named in the FROM clause. So that the SQL statement only deletes the record in the... more (see page 1687)
Enabling BDE-based Cached Updates (see page 1688)	To use the BDE for cached updates, the BDE-enabled dataset must indicate that it should cache updates. This is specified by setting the CachedUpdates property to *True*. When you enable cached updates, a copy of all records is cached in local memory. Users view and edit this local copy of data. Changes, insertions, and deletions are also cached in memory. They accumulate in memory until the application applies those changes to the database server. If changed records are successfully applied to the database, the record of those changes are freed in the cache. The dataset caches all updates until... more (see page 1688)
Understanding Parameter Substitution in Update SQL Statements (see page 1689)	Update SQL statements use a special form of parameter substitution that enables you to substitute old or new field values in record updates. When the Update SQL editor generates its statements, it determines which field values to use. When you write the update SQL, you specify the field values to use. When the parameter name matches a column name in the table, the new value in the field in the cached update for the record is automatically used as the value for the parameter. When the parameter name matches a column name prefixed by the string "OLD_", then the old... more (see page 1689)

Using the BDE to Cache Updates (see page 1689)	The recommended approach for caching updates is to use a client dataset (*TBDEClientDataSet*) or to connect the BDE-dataset to a client dataset using a dataset provider. The advantages of using a client dataset are discussed in Using a client dataset to cache updates (see page 1731). For simple cases, however, you may choose to use the BDE to cache updates instead. BDE-enabled datasets and *TDatabase* components provide built-in properties, methods, and events for handling cached updates. Most of these correspond directly to the properties, methods, and events that you use with client datasets and dataset providers when using a client... more (see page 1689)
Using the Update SQL Editor (see page 1691)	
Applying BDE-based Cached Updates (see page 1691)	Applying updates is a two-phase process that should occur in the context of a database component's transaction so that your application can recover gracefully from errors. For information about transaction handling with database components, see Managing Transactions (see page 1498). When applying updates under database transaction control, the following events take place: 1. A database transaction starts. 2. Cached updates are written to the database (phase 1). If you provide it, an *OnUpdateRecord* event is triggered once for each record written to the database. If an error occurs when a record is applied to the database, the *OnUpdateError* event is triggered if you provide... more (see page 1691)
Using Update Objects to Update a Dataset (see page 1692)	When the BDE-enabled dataset represents a stored procedure or a query that is not "live", it is not possible to apply updates directly from the dataset. Such datasets may also cause a problem when you use a client dataset to cache updates. Whether you are using the BDE or a client dataset to cache updates, you can handle these problem datasets by using an update object.
Creating an OnUpdateRecord Event Handler (see page 1693)	When a BDE-enabled dataset applies its cached updates, it iterates through the changes recorded in its cache, attempting to apply them to the corresponding records in the base table. As the update for each changed, deleted, or newly inserted record is about to be applied, the dataset component's *OnUpdateRecord* event fires. Providing a handler for the *OnUpdateRecord* event allows you to perform actions just before the current record's update is actually applied. Such actions can include special data validation, updating other tables, special parameter substitution, or executing multiple update objects (see page 1692). A handler for the *OnUpdateRecord* event affords you greater... more (see page 1693)
Applying Cached Updates with Dataset Component Methods (see page 1695)	You can apply updates for individual BDE-enabled datasets directly using the dataset's ApplyUpdates and CommitUpdates methods. Each of these methods encapsulate one phase of the update process: 1. *ApplyUpdates* writes cached changes to a database (phase 1). 2. *CommitUpdates* clears the internal cache when the database write is successful (phase 2). The following code illustrates how you apply updates within a transaction for the *CustomerQuery* dataset:
Creating SQL Statements for Update Components (see page 1696)	To update a record in an associated dataset, an update object uses one of three SQL statements. Each update object can only update a single table, so the object's update statements must each reference the same base table. The three SQL statements delete, insert, and modify records cached for update. You must provide these statements as update object's *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties. You can provide these values at design time or at runtime. For example, the following code specifies a value for the *DeleteSQL* property at runtime:
Handling Cached Update Errors (see page 1696)	The Borland Database Engine (BDE) specifically checks for user update conflicts and other conditions when attempting to apply updates, and reports any errors. The dataset component's OnUpdateError event enables you to catch and respond to errors. You should create a handler for this event if you use cached updates. If you do not, and an error occurs, the entire update operation fails. Here is the skeleton code for an *OnUpdateError* event handler:

3.2.3.7.9.1 Applying Cached Updates Using a Database

To apply cached updates to one or more datasets in the context of a database connection, call the database component's ApplyUpdates method. The following code applies updates to the *CustomersQuery* dataset in response to a button click event:

```
procedure TForm1.ApplyButtonClick(Sender: TObject);
begin
  // for local databases such as Paradox, dBASE, and FoxPro
  // set TransIsolation to DirtyRead
  if not (Database1.IsSQLBased) and not (Database1.TransIsolation = tiDirtyRead) then
    Database1.TransIsolation := tiDirtyRead;
  Database1.ApplyUpdates([CustomersQuery]);
end;
void __fastcall TForm1::ApplyButtonClick(TObject *Sender)
{
  // for local databases such as Paradox, dBASE, and FoxPro
  // set TransIsolation to DirtyRead
  if (!Database1->IsSQLBased && Database1->TransIsolation != tiDirtyRead)
    Database1->TransIsolation = tiDirtyRead;
  Database1->ApplyUpdates(&CustomersQuery,0);
}
```

The above sequence writes cached updates to the database in the context of an automatically-generated transaction. If successful, it commits the transaction and then commits the cached updates. If unsuccessful, it rolls back the transaction and leaves the update cache unchanged. In this latter case, you should handle cached update errors through a dataset's *OnUpdateError* event. For more information about handling update errors, see Handling cached update errors. (see page 1696)

The main advantage to calling a database component's *ApplyUpdates* method is that you can update any number of dataset components that are associated with the database. The parameter for the *ApplyUpdates* method for a database is an array of *TDBDataSet*. For example, the following code applies updates for two queries:

```
if not (Database1.IsSQLBased) and not (Database1.TransIsolation = tiDirtyRead) then
  Database1.TransIsolation := tiDirtyRead;
Database1.ApplyUpdates([CustomerQuery, OrdersQuery]);
TDBDataSet* ds[] = {CustomerQuery, OrdersQuery};
if (!Database1->IsSQLBased && Database1->TransIsolation != tiDirtyRead)
  Database1->TransIsolation = tiDirtyRead;
Database1->ApplyUpdates(ds,1);
```

3.2.3.7.9.2 Composing Update SQL Statements

At design time, you can use the Update SQL editor to write the SQL statements for the *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties. If you do not use the Update SQL editor, or if you want to modify the generated statements, you should keep in mind the following guidelines when writing statements to delete, insert, and modify records in the base table.

The *DeleteSQL* property should contain only an SQL statement with the DELETE command. The base table to be updated must be named in the FROM clause. So that the SQL statement only deletes the record in the base table that corresponds to the record deleted in the update cache, use a WHERE clause. In the WHERE clause, use a parameter for one or more fields to uniquely identify the record in the base table that corresponds to the cached update record. If the parameters are named the same as the field and prefixed with "OLD_", the parameters are automatically given the values from the corresponding field from the cached update record. If the parameter are named in any other manner, you must supply the parameter values.

```
DELETE FROM Inventory I
WHERE (I.ItemNo = :OLD_ItemNo)
```

Some table types might not be able to find the record in the base table when fields used to identify the record contain NULL values. In these cases, the delete update fails for those records. To accommodate this, add a condition for those fields that might contain NULLs using the IS NULL predicate (in addition to a condition for a non-NULL value). For example, when a FirstName field may contain a NULL value:

```
DELETE FROM Names
WHERE (LastName = :OLD_LastName) AND
  ((FirstName = :OLD_FirstName) OR (FirstName IS NULL))
```

The *InsertSQL* statement should contain only an SQL statement with the INSERT command. The base table to be updated must be named in the INTO clause. In the VALUES clause, supply a comma-separated list of parameters. If the parameters are named the same as the field, the parameters are automatically given the value from the cached update record. If the parameter are named in any other manner, you must supply the parameter values. The list of parameters supplies the values for fields in the newly inserted record. There must be as many value parameters as there are fields listed in the statement.

```
INSERT INTO Inventory
(ItemNo, Amount)
VALUES (:ItemNo, 0)
```

The *ModifySQL* statement should contain only an SQL statement with the UPDATE command. The base table to be updated must be named in the FROM clause. Include one or more value assignments in the SET clause. If values in the SET clause assignments are parameters named the same as fields, the parameters are automatically given values from the fields of the same name in the updated record in the cache. You can assign additional field values using other parameters, as long as the parameters are not named the same as any fields and you manually supply the values. As with the *DeleteSQL* statement, supply a WHERE clause to uniquely identify the record in the base table to be updated using parameters named the same as the fields and prefixed with "OLD_". In the update statement below, the parameter :ItemNo is automatically given a value and :Price is not.

```
UPDATE Inventory I
SET I.ItemNo = :ItemNo, Amount = :Price
WHERE (I.ItemNo = :OLD_ItemNo)
```

Considering the above update SQL, take an example case where the application end-user modifies an existing record. The original value for the ItemNo field is 999. In a grid connected to the cached dataset, the end-user changes the ItemNo field value to 123 and Amount to 20. When the ApplyUpdates method is invoked, this SQL statement affects all records in the base table where the ItemNo field is 999, using the old field value in the parameter :OLD_ItemNo. In those records, it changes the ItemNo field value to 123 (using the parameter :ItemNo, the value coming from the grid) and Amount to 20.

3.2.3.7.9.3 Enabling BDE-based Cached Updates

To use the BDE for cached updates, the BDE-enabled dataset must indicate that it should cache updates. This is specified by setting the CachedUpdates property to *True*. When you enable cached updates, a copy of all records is cached in local memory. Users view and edit this local copy of data. Changes, insertions, and deletions are also cached in memory. They accumulate in memory until the application applies those changes to the database server. If changed records are successfully applied to the database, the record of those changes are freed in the cache.

The dataset caches all updates until you set *CachedUpdates* to *False*. Applying cached updates does not disable further cached updates; it only writes the current set of changes to the database and clears them from memory. Canceling the updates by calling CancelUpdates removes all the changes currently in the cache, but does not stop the dataset from caching any subsequent changes.

Note: If you disable cached updates by setting *CachedUpdates* to *False*, any pending changes that you have not yet applied are discarded without notification. To prevent losing changes, test the UpdatesPending property before disabling cached updates.

Applying BDE Based Cached Updates (see page 1691)

3.2.3.7.9.4 Understanding Parameter Substitution in Update SQL Statements

Update SQL statements use a special form of parameter substitution that enables you to substitute old or new field values in record updates. When the Update SQL editor generates its statements, it determines which field values to use. When you write the update SQL, you specify the field values to use.

When the parameter name matches a column name in the table, the new value in the field in the cached update for the record is automatically used as the value for the parameter. When the parameter name matches a column name prefixed by the string "OLD_", then the old value for the field will be used. For example, in the update SQL statement below, the parameter :LastName is automatically filled with the new field value in the cached update for the inserted record.

```
INSERT INTO Names
(LastName, FirstName, Address, City, State, Zip)
VALUES (:LastName, :FirstName, :Address, :City, :State, :Zip)
```

New field values are typically used in the *InsertSQL* and *ModifySQL* statements. In an update for a modified record, the new field value from the update cache is used by the UPDATE statement to replace the old field value in the base table updated.

In the case of a deleted record, there are no new values, so the *DeleteSQL* property uses the ":OLD_FieldName" syntax. Old field values are also normally used in the WHERE clause of the SQL statement for a modified or deletion update to determine which record to update or delete.

In the WHERE clause of an UPDATE or DELETE update SQL statement, supply at least the minimal number of parameters to uniquely identify the record in the base table that is updated with the cached data. For instance, in a list of customers, using just a customer's last name may not be sufficient to uniquely identify the correct record in the base table; there may be a number of records with "Smith" as the last name. But by using parameters for last name, first name, and phone number could be a distinctive enough combination. Even better would be a unique field value like a customer number.

Note: If you create SQL statements that contain parameters that do not refer the edited or original field values, the update object does not know how to bind their values. You can, however, do this manually, using the update object's Query property (see page 1640).

Creating SQL Statements at Design Time (see page 1691)

3.2.3.7.9.5 Using the BDE to Cache Updates

The recommended approach for caching updates is to use a client dataset (*TBDEClientDataSet*) or to connect the BDE-dataset to a client dataset using a dataset provider. The advantages of using a client dataset are discussed in Using a client dataset to cache updates (see page 1731).

For simple cases, however, you may choose to use the BDE to cache updates instead. BDE-enabled datasets and *TDatabase* components provide built-in properties, methods, and events for handling cached updates. Most of these correspond directly to the properties, methods, and events that you use with client datasets and dataset providers when using a client dataset to cache updates. The following table lists these properties, events, and methods and the corresponding properties, methods and events on *TBDEClientDataSet*:

Properties, methods, and events for cached updates

On BDE-enabled Datasets (or TDatabase)	On TBDEClientDataSet	Purpose
CachedUpdates	Not needed for client datasets, which always cache updates.	Determines whether cached updates are in effect for the dataset.
UpdateObject	Use a *BeforeUpdateRecord* event handler, or, if using *TClientDataSet*, use the *UpdateObject* property on the BDE-enabled source dataset.	Specifies the update object for updating read-only datasets.
UpdatesPending	ChangeCount	Indicates whether the local cache contains updated records that need to be applied to the database.
UpdateRecordTypes	StatusFilter	Indicates the kind of updated records to make visible when applying cached updates.
UpdateStatus	UpdateStatus	Indicates if a record is unchanged, modified, inserted, or deleted.
OnUpdateError	OnReconcileError	An event for handling update errors on a record-by-record basis.
OnUpdateRecord	BeforeUpdateRecord	An event for processing updates on a record-by-record basis.
ApplyUpdates (database)	ApplyUpdates	Applies records in the local cache to the database.
CancelUpdates	CancelUpdates	Removes all pending updates from the local cache without applying them.
CommitUpdates	Reconcile	Clears the update cache following successful application of updates.
FetchAll	GetNextPacket (and PacketRecords)	Copies database records to the local cache for editing and updating.
RevertRecord	RevertRecord	Undoes updates to the current record if updates are not yet applied.

For an overview of the cached update process, see Overview of using cached updates (see page 1723).

The following topics describe in more detail on how to use the BDE to cache updates:

- Enabling BDE-based Cached Updates (see page 1688).
- Applying BDE-based Cached Updates (see page 1691).
- Using Update Objects to Update a Dataset (see page 1692).

  Note: Even if you are using a client dataset to cache updates, you may want to read the section about update objects. You can use update objects in the *BeforeUpdateRecord* event handler of *TBDEClientDataSet* or *TDataSetProvider* to apply updates from stored procedures or multi-table queries.

The Data Dictionary (see page 1680)

3.2.3.7.9.6 Using the Update SQL Editor

To create the SQL statements for an update component

1. Using the **Object Inspector**, select the name of the update object from the drop-down list for the dataset's *UpdateObject* property. This step ensures that the Update SQL editor you invoke in the next step can determine suitable default values to use for SQL generation options.
2. Right-click the update object and select UpdateSQL Editor from the context menu. This displays the Update SQL editor. The editor creates SQL statements for the update object's *ModifySQL*, *InsertSQL*, and *DeleteSQL* properties based on the underlying data set and on the values you supply to it.

The Update SQL editor has two pages. The Options page is visible when you first invoke the editor. Use the Table Name combo box to select the table to update. When you specify a table name, the Key Fields and Update Fields list boxes are populated with available columns.

The Update Fields list box indicates which columns should be updated. When you first specify a table, all columns in the Update Fields list box are selected for inclusion. You can multi-select fields as desired.

The Key Fields list box is used to specify the columns to use as keys during the update. For Paradox, dBASE, and FoxPro the columns you specify here must correspond to an existing index, but this is not a requirement for remote SQL databases. Instead of setting Key Fields you can click the Primary Keys button to choose key fields for the update based on the table's primary index. Click Dataset Defaults to return the selection lists to the original state: all fields selected as keys and all selected for update.

Check the Quote Field Names check box if your server requires quotation marks around field names.

After you specify a table, select key columns, and select update columns, click Generate SQL to generate the preliminary SQL statements to associate with the update component's *ModifySQL*, *InsertSQL*, and *DeleteSQL* properties. In most cases you will want or need to fine tune the automatically generated SQL statements.

To view and modify the generated SQL statements, select the SQL page. If you have generated SQL statements, then when you select this page, the statement for the *ModifySQL* property is already displayed in the SQL Text memo box. You can edit the statement in the box as desired.

Warning: Keep in mind that generated SQL statements are starting points for creating update statements. You may need to modify these statements to make them execute correctly. For example, when working with data that contains NULL values, you need to modify the WHERE clause to read

```
WHERE field IS NULL
```

rather then using the generated field variable. Test each of the statements directly yourself before accepting them.

Use the Statement Type radio buttons to switch among generated SQL statements and edit them as desired.

To accept the statements and associate them with the update component's SQL properties, click OK.

3.2.3.7.9.7 Applying BDE-based Cached Updates

Applying updates is a two-phase process that should occur in the context of a database component's transaction so that your application can recover gracefully from errors. For information about transaction handling with database components, see Managing Transactions (see page 1498).

When applying updates under database transaction control, the following events take place:

1. A database transaction starts.
2. Cached updates are written to the database (phase 1). If you provide it, an *OnUpdateRecord* event is triggered once for each

record written to the database. If an error occurs when a record is applied to the database, the *OnUpdateError* event is triggered if you provide one.

3. The transaction is committed if writes are successful or rolled back if they are not,

Write Status	Transaction
Successful	Database changes are committed, ending the database transaction. Cached updates are committed, clearing the internal cache buffer (phase 2).
Unsuccessful	Database changes are rolled back, ending the database transaction. Cached updates are not committed, remaining intact in the internal cache.

For information about creating and using an *OnUpdateRecord* event handler, see Creating an OnUpdateRecord Event Handler. (see page 1693) For information about handling update errors that occur when applying cached updates, see Handling Cached Update errors (see page 1696).

Note: Applying cached updates is particularly tricky when you are working with multiple datasets linked in a master/detail relationship because the order in which you apply updates to each dataset is significant. Usually, you must update master tables before detail tables, except when handling deleted records, where this order must be reversed. Because of this difficulty, it is strongly recommended that you use client datasets when caching updates in a master/detail form. Client datasets automatically handle all ordering issues with master/detail relationships.

There are two ways to apply BDE-based updates:

- You can apply updates using a database component (see page 1687) by calling its ApplyUpdates method. This method is the simplest approach, because the database handles all details of managing a transaction for the update process and of clearing the dataset's cache when updating is complete.
- You can apply updates for a single dataset (see page 1695) by calling the dataset's ApplyUpdates and CommitUpdates methods. When applying updates at the dataset level you must explicitly code the transaction that wraps the update process as well as explicitly call *CommitUpdates* to commit updates from the cache.

  Warning: To apply updates from a stored procedure or an SQL query that does not return a live result set, you must use *TUpdateSQL* to specify how to perform updates. For updates to joins (queries involving two or more tables), you must provide one *TUpdateSQL* object for each table involved, and you must use the *OnUpdateRecord* event handler to invoke these objects to perform the updates. See Using update objects to update a dataset (see page 1692) for details.

Using the BDE to Cache Updates (see page 1689)

Using Update Objects to Update a Dataset (see page 1692)

Enabling BDE-based Cached Updates (see page 1688)

3.2.3.7.9.8 Using Update Objects to Update a Dataset

When the BDE-enabled dataset represents a stored procedure or a query that is not "live", it is not possible to apply updates directly from the dataset. Such datasets may also cause a problem when you use a client dataset to cache updates. Whether you are using the BDE or a client dataset to cache updates, you can handle these problem datasets by using an update object.

To update a dataset

1. If you are using a client dataset, use an external provider component with *TClientDataSet* rather than *TBDEClientDataSet*. This is so you can set the *UpdateObject* property of the BDE-enabled source dataset (step 3).
2. Add a TUpdateSQL component to the same data module as the BDE-enabled dataset.
3. Set the BDE-enabled dataset component's UpdateObject property to the *TUpdateSQL* component in the data module.

4. Specify the SQL statements (see page 1696) needed to perform updates using the update object's *ModifySQL*, *InsertSQL*, and *DeleteSQL* properties. You can use the Update SQL editor to help you compose these statements.
5. Close the dataset.
6. Set the dataset component's *CachedUpdates* property to *True* or link the dataset to the client dataset using a dataset provider.
7. Reopen the dataset.

Note: Sometimes, you need to use multiple update objects. For example, when updating a multi-table join or a stored procedure that represents data from multiple datasets, you must provide one *TUpdateSQL* object for each table you want to update. When using multiple update objects, you can't simply associate the update object with the dataset by setting the *UpdateObject* property. Instead, you must manually call the update object from an OnUpdateRecord event handler (when using the BDE to cache updates) or a BeforeUpdateRecord event handler (when using a client dataset).

The update object actually encapsulates three *TQuery* components. Each of these query components perform a single update task. One query component provides an SQL UPDATE statement for modifying existing records; a second query component provides an INSERT statement to add new records to a table; and a third component provides a DELETE statement to remove records from a table.

When you place an update component in a data module, you do not see the query components it encapsulates. They are created by the update component at runtime based on three update properties for which you supply SQL statements:

- ModifySQL specifies the UPDATE statement.
- InsertSQL specifies the INSERT statement.
- DeleteSQL specifies the DELETE statement.

At runtime, when the update component is used to apply updates, it:

1. Selects an SQL statement to execute based on whether the current record is modified, inserted, or deleted.
2. Provides parameter values to the SQL statement.
3. Prepares and executes the SQL statement to perform the specified update.

Indicating What Records Are Modified (see page 1717)

Overview of BDE Based Cached Updates (see page 1688)

3.2.3.7.9.9 Creating an OnUpdateRecord Event Handler

When a BDE-enabled dataset applies its cached updates, it iterates through the changes recorded in its cache, attempting to apply them to the corresponding records in the base table. As the update for each changed, deleted, or newly inserted record is about to be applied, the dataset component's *OnUpdateRecord* event fires.

Providing a handler for the *OnUpdateRecord* event allows you to perform actions just before the current record's update is actually applied. Such actions can include special data validation, updating other tables, special parameter substitution, or executing multiple update objects (see page 1692). A handler for the *OnUpdateRecord* event affords you greater control over the update process.

Here is the skeleton code for an *OnUpdateRecord* event handler:

```
procedure TForm1.DataSetUpdateRecord(DataSet: TDataSet;
 UpdateKind: TUpdateKind; var UpdateAction: TUpdateAction);
begin
  { perform updates here... }
end;
void __fastcall TForm1::DataSetUpdateRecord(TDataSet *DataSet,
  TUpdateKind UpdateKind, TUpdateAction &UpdateAction)
{
  // Perform updates here...
```

```
}
```

The *DataSet* parameter specifies the cached dataset with updates.

The *UpdateKind* parameter indicates the type of update that needs to be performed for the current record. Values for *UpdateKind* are *ukModify*, *ukInsert*, and *ukDelete*. If you are using an update object, you need to pass this parameter to the update object when applying the update. You may also need to inspect this parameter if your handler performs any special processing based on the kind of update.

The *UpdateAction* parameter indicates whether you applied the update. Values for *UpdateAction* are *uaFail* (the default), *uaAbort*, *uaSkip*, *uaRetry*, *uaApplied*. If your event handler successfully applies the update, change this parameter to *uaApplied* before exiting. If you decide not to update the current record, change the value to *uaSkip* to preserve unapplied changes in the cache. If you do not change the value for *UpdateAction*, the entire update operation for the dataset is aborted and an exception is raised. You can suppress the error message (raising a silent exception) by changing *UpdateAction* to *uaAbort*.

In addition to these parameters, you will typically want to make use of the *OldValue* and *NewValue* properties for the field component associated with the current record. *OldValue* gives the original field value that was fetched from the database. It can be useful in locating the database record to update. *NewValue* is the edited value in the update you are trying to apply.

Warning: An *OnUpdateRecord* event handler, like an *OnUpdateError* or *OnCalcFields* event handler, should never call any methods that change the current record in a dataset.

The following example illustrates how to use these parameters and properties. It uses a *TTable* component named *UpdateTable* to apply updates. In practice, it is easier to use an update object, but using a table illustrates the possibilities more clearly.

```
procedure TForm1.EmpAuditUpdateRecord(DataSet: TDataSet;
  UpdateKind: TUpdateKind; var UpdateAction: TUpdateAction);
begin
  if UpdateKind = ukInsert then
    UpdateTable.AppendRecord([DataSet.Fields[0].NewValue, DataSet.Fields[1].NewValue])
  else
    if UpdateTable.Locate('KeyField', VarToStr(DataSet.Fields[1].OldValue), []) then
      case UpdateKind of
        ukModify:
          begin
            UpdateTable.Edit;
            UpdateTable.Fields[1].AsString := VarToStr(DataSet.Fields[1].NewValue);
            UpdateTable.Post;
          end;
        ukInsert:
          begin
            UpdateTable.Insert;
            UpdateTable.Fields[1].AsString := VarToStr(DataSet.Fields[1].NewValue);
            UpdateTable.Post;
          end;
        ukDelete: UpdateTable.Delete;
      end;
        UpdateAction := uaApplied;
end;
void __fastcall TForm1::EmpAuditUpdateRecord(TDataSet *DataSet,
  TUpdateKind UpdateKind, TUpdateAction &UpdateAction)
{
  if (UpdateKind == ukInsert)
  {
    TVarRec values[2];
    for (int i = 0; i < 2; i++)
      values[i] = DataSet->Fields->Fields[i]->NewValue;
    UpdateTable->AppendRecord(values, 1);
  }
  else
  {
    TLocateOptions lo;
    lo.Clear();
    if (UpdateTable->Locate("KeyField", DataSet->Fields->Fields[0]->OldValue, lo))
```

```
        switch (UpdateKind)
        {
          case ukModify:
            UpdateTable->Edit();
            UpdateTable->Fields->Fields[1]->Value = DataSet->Fields->Fields[1]->Value;
            UpdateTable->Post();
            break;
          case ukDelete:
            UpdateTable->Delete();
            break;
        }
    }
    UpdateAction = uaApplied;
}
```

Applying Cached Updates Using a Database (see page 1687)

Applying Cached Updates with Dataset Component Methods (see page 1695)

Handling Cached Update Errors (see page 1696)

3.2.3.7.9.10 Applying Cached Updates with Dataset Component Methods

You can apply updates for individual BDE-enabled datasets directly using the dataset's ApplyUpdates and CommitUpdates methods. Each of these methods encapsulate one phase of the update process:

1. *ApplyUpdates* writes cached changes to a database (phase 1).
2. *CommitUpdates* clears the internal cache when the database write is successful (phase 2).

The following code illustrates how you apply updates within a transaction for the *CustomerQuery* dataset:

```
procedure TForm1.ApplyButtonClick(Sender: TObject)
begin
  Database1.StartTransaction;
  try
    if not (Database1.IsSQLBased) and not (Database1.TransIsolation = tiDirtyRead) then
      Database1.TransIsolation := tiDirtyRead;
    CustomerQuery.ApplyUpdates;                { try to write the updates to the database }
    Database1.Commit;                                    { on success, commit the changes }
  except
    Database1.Rollback;                                    { on failure, undo any changes }
    raise;                 { raise the exception again to prevent a call to CommitUpdates }
  end;
  CustomerQuery.CommitUpdates;                       { on success, clear the internal cache }
end;
void __fastcall TForm1::ApplyButtonClick(TObject *Sender)
{
  Database1->StartTransaction();
  try
  {
    if (!Database1->IsSQLBased && Database1->TransIsolation != tiDirtyRead)
      Database1->TransIsolation = tiDirtyRead;
    CustomerQuery->ApplyUpdates(); // try to write the updates to the database
    Database1->Commit(); // on success, commit the changes
  }
  catch (...)
  {
    Database1->Rollback(); // on failure, undo any changes
    throw; // throw the exception again to prevent a call to CommitUpdates
  }
  CustomerQuery->CommitUpdates(); // on success, clear the internal cache
}
```

If an exception is raised during the *ApplyUpdates* call, the database transaction is rolled back. Rolling back the transaction

ensures that the underlying database table is not changed. The raise statement inside the **try...except** block reraises the exception, thereby preventing the call to *CommitUpdates*. Because *CommitUpdates* is not called, the internal cache of updates is not cleared so that you can handle error conditions and possibly retry the update.

Handling Cached Update Errors (see page 1696)

3.2.3.7.9.11 Creating SQL Statements for Update Components

To update a record in an associated dataset, an update object uses one of three SQL statements. Each update object can only update a single table, so the object's update statements must each reference the same base table.

The three SQL statements delete, insert, and modify records cached for update. You must provide these statements as update object's *DeleteSQL*, *InsertSQL*, and *ModifySQL* properties. You can provide these values at design time or at runtime. For example, the following code specifies a value for the *DeleteSQL* property at runtime:

```
with UpdateSQL1.DeleteSQL do begin
  Clear;
  Add('DELETE FROM Inventory I');
  Add('WHERE (I.ItemNo = :OLD_ItemNo)');
end;
UpdateSQL->DeleteSQL->Clear();
UpdateSQL->DeleteSQL->Add("DELETE FROM Inventory I");
UpdateSQL->DeleteSQL->Add("WHERE (I.ItemNo = :OLD_ItemNo)");
```

At design time, you can use the Update SQL editor (see page 1691) to help you compose the SQL statements that apply updates.

Update objects provide automatic parameter binding (see page 1689) for parameters that reference the dataset's original and updated field values. Typically, therefore, you insert parameters with specially formatted names when you compose the SQL statements (see page 1687).

Using Multiple Update Objects (see page 1641)

Executing the SQL Statements (see page 1643)

3.2.3.7.9.12 Handling Cached Update Errors

The Borland Database Engine (BDE) specifically checks for user update conflicts and other conditions when attempting to apply updates, and reports any errors. The dataset component's OnUpdateError event enables you to catch and respond to errors. You should create a handler for this event if you use cached updates. If you do not, and an error occurs, the entire update operation fails.

Here is the skeleton code for an *OnUpdateError* event handler:

```
procedure TForm1.DataSetUpdateError(DataSet: TDataSet; E: EDatabaseError;
  UpdateKind: TUpdateKind; var UpdateAction: TUpdateAction);
begin
  { ... perform update error handling here ... }
end;
void __fastcall TForm1::DataSetUpdateError(TDataSet *DataSet,
